On-surface chemical self-assembly of graphene nanoribbons (GNRs) has opened the possibilities for producing complex graphene-based nanostructures with atomic precision [1]. Two- and multiterminal junctions in GNRs – essentially defects in these one-dimensional nanostructures – can be considered as elementary components of complex all-graphene nanoelectronic circuits [2]. We aim at establishing the design principles of such graphene-based nanoelectronic circuits by revealing the relations between the structure of GNRs junction and their electronic transport properties. The work is performed by means of first-principles and model Hamiltonian calculations combined with exhaustive high-throughput screening. We first focus on two-terminal GNR junctions with linear configurations being the simplest examples for which a sufficient body of experimental results is available (e.g. Refs. 3-7). Angled GNR junctions are more complex and are inevitable in the interconnects of nanoelectronic circuits. We systematically address the electronic transport properties of 60 and 120 degrees angled GNR junctions exploring ca. 400,000 distinct configurations, which allows us to formulate general guidelines into the engineering of transport properties of GNR circuits and identify a large number of junctions that have conductance close to the limit defined by the ballistic conductance of ideal GNR leads [8]. A user-friendly online application for modeling and calculation of the electronic transport properties of GNR junctions is presented [9]. Finally, we present a different, top-down view on the effect of the angled GNR junction configuration on the charge-carrier transport [10].

Reversible Polarity Control in 2D MoTe2 Field-Effect Transistors for Complementary Logic Gate Applications

Byoung-Soo Yu[1,2], Wonsik Kim[1], Jongtae Ahn[3], Soohyung Park[1] and Do Kyung Hwang[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]University of science and technology, Korea (the Republic of); [3]Changwon National University, Korea (the Republic of)

Precise control over polarity in field-effect transistors (FETs) plays a pivotal role in the design and construction of complementary metal–oxide–semiconductor (CMOS) logic circuits. In particular, achieving such precise polarity control in 2D semiconductors is crucial for the further development of advanced electronic applications beyond unit devices. This paper presents a systematic investigation on the reversible transition of carrier types in a 2D MoTe2 semiconductor under different annealing atmospheres. Photoemission spectroscopy and density functional theory (DFT) calculations demonstrate that annealing processes in vacuum and in ambient air induce a modification in the density of states, resulting in alterations in p-type or n-type characteristics. These reversible changes are attributed to the physisorption and elimination of oxygen on the surface of MoTe2. Furthermore, it is found that the device geometry affects the polarity of the transistor. By strategically manipulating both the annealing conditions and the geometric configuration, the n- and p-type unipolar characteristics of MoTe2 FETs are successfully modulated and ultimately demonstrating that the functionality of not only a complementary inverter with a high voltage gain of ≈20, but also more complex logic circuits of NAND and NOR gates.

8:45 AM EL03.13.03

Enhanced Photoresponse in Phosphotungstic Acid-Functionalized Black Phosphorus Transistors—Insights from Scanning Photocurrent Microscopy Hyeonseo Lee, Kyuhyun Kim, SeungHyun Oh and Junhong Na; Kangwon National University, Korea (the Republic of)

Black phosphorus (BP) is regarded as a promising 2D van der Waals material for optoelectronic applications due to its unique properties, such as a direct bandgap and high carrier mobility. However, BP rapidly oxidizes upon exposure to air, degrading its properties and reducing device performance. To prevent such oxidation-induced structural deformations, passivation layers like alumina have been applied, but they limit the photoresponse properties of BP. To address this issue, we aimed to improve the photoresponse properties of alumina-passivated BP transistors by functionalizing them with phosphotungstic acid (PTA).

Phosphotungstic acid ($H_3PW_{12}O_{40}$) belongs to the class of heteropoly acids with a Keggin-type structure, consisting of a central phosphate (PO_3^{3-}) ion surrounded by twelve tungsten atoms (W) coordinated with oxygen atoms, forming the complex anion $[PW_{12}O_{40}]^{3-}$. Due to its strong acidity and versatile solubility in water and many organic solvents, PTA is used in various applications, including as a staining agent in biology, in catalysis for organic synthesis, in the dye industry, and in corrosion inhibition.

By utilizing the high electron affinity of PTA, we confirmed the successful attachment of PTA to the BP surface using atomic force microscopy. Comparing the transfer characteristics of PTA-functionalized and non-functionalized BP transistors revealed that while both devices exhibited similar transfer characteristics, the functionalized devices demonstrated significantly enhanced photoresponse properties. Using scanning photocurrent microscopy (SPCM) under various bias conditions, we quantitatively analyzed the impact of PTA functionalization on the photoresponse of alumina-passivated BP transistors.

SPCM analysis provided a clear understanding of how PTA modifies the spatial photoresponse of BP transistors. Notably, the maximum photocurrent point was observed at the center of the BP channel when a 100mV drain-source voltage (V_{ds}) was applied. In contrast, the maximum photocurrent point in non-functionalized BP transistors occurred at the drain (or source) contact edge, indicating that the Schottky barrier-induced energy band bending is the dominant factor generating electron-hole pairs under light illumination. Additionally, PTA-functionalized BP transistors exhibited significantly higher photoresponsivity compared to non-functionalized devices, with the photocurrent increasing from 27nA to 285nA under a -100mV V_{ds}, representing an increase of over 10 times. This is attributed to PTA's high electron affinity, which facilitates efficient electron transfer from BP to PTA, leaving holes in the BP and suppressing electron-hole recombination. This mechanism results in higher photocurrent generation and a more uniform photocurrent distribution.

The combined effect of Al_2O_3 passivation, which preserves the intrinsic properties of BP and maintains high carrier mobility, and PTA functionalization significantly enhances the photoresponse of BP transistors. This study demonstrates that chemical functionalization with compounds like PTA can effectively improve the photoresponse of 2D van der Waals materials. These findings provide important insights for optimizing the performance of optoelectronic devices based on 2D van der Waals materials.

9:00 AM EL03.13.04

Contact Resistance on Magic Angle Graphene—A Path Towards Photodetectors Based on Superconducting Graphene Masahiro Ishigami[1], Swastik Ballav[1], David Castro[1], Michael S. Lodge[2], Robert Peale[2] and Ryuichi Tsuchikawa[1]; [1]University of Central Florida, United States; [2]Truventic LLC, United States

Magic angle graphene superconducts at below ~2 K and has received much attention due to its gate-tunable superconductivity. Gate-defined Josephson junctions based on magic angle graphene have high dynamic resistance at zero bias. As such, they can be used to produce sensitive and fast photodetectors with proper antennas. Contact resistance is critically important for these applications because appropriate impedance matching must be achieved throughout.

We have measured contact resistances on magic angle graphene as a function of contacting area, contacting metals and contacting methods (edge or top) as a function of twist angle from 0.9 to 1.5 degrees, temperature and gate voltage. This paper will discuss results and compare our observations to what has been reported in single layer graphene devices. This work was supported by U. S. Army OSD Phase II STTR contract W911NF23C0027 and by matching funds from the Florida High Technology Corridor (I-4) Program.

9:15 AM EL03.13.05

Low-Voltage Operation in 2D Aluminum Scandium Nitride FeFETs Chloe Leblanc[1], Yinuo Zhang[1], Hyunmin Cho[1], Seunguk Song[1], Chen Chen[2], Shalini Kumari[2], Joan M. Redwing[2], Roy H. Olsson[1] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]The Pennsylvania State University, United States

The continued evolution of Silicon-based CMOS technology has reached its physical limits with regards to energy consumption and density. This is an increasing concern for computations and algorithms that involve large amounts of data processing and multivariable optimization. The invention of new devices and architectures that emphasize low-power consumption is therefore needed. At the architecture level, access to memory and readout are the major bottlenecks of the traditional von Neumann computing architecture in commercial technology today. Ferroelectric-based non-volatile memories (NVM) could be an answer to this challenge. Ferroelectric materials share the ability to maintain a stable polar state in the absence of an electric field over long periods of time. This adjustable polarization can be used store, erase, and reprogram information in a non-volatile manner. Ferroelectric NVM enables in-memory computing applications, leading to vastly more energy efficient systems and architectures. But to be of interest in industrial applications, these ferroelectric devices must be highly scalable and operate at low switching voltages.

In this study, we demonstrated non-volatile ferroelectric field-effect transistors (FeFETs) based on Aluminum Scandium Nitride ($Al_{1-x}Sc_xN$) and two-dimensional van der Waals (2D vdW) semiconductor channels. In 2D vdW FeFETs, the remnant polarization of the ferroelectric material strongly controls the conductance of the atomically thick vdW semiconductor channel. $Al_{1-x}Sc_xN$ stands out for its numerous beneficial properties such as low dielectric loss, low deposition temperature compatible with modern CMOS production methods and high remnant polarization P_r (80–115 μC/cm^2). We showed operational FeFETs with channel lengths of 500, 250, 100 and 50 nm templated on 10 nm thick $Al_{0.68}Sc_{0.32}N$ and 5 nm thick $Al_{0.72}Sc_{0.28}N$ layers. We find that the voltage required to activate these devices is reduced to < 1V, while maintaining an ON/OFF ratio up to 10^6. Our devices are highly scalable, with channel lengths ranging from 500 nm to 50 nm. We found that the effect of charge trapping in the FeFETs was altered by ferroelectric film thickness and channel length. Our 2D channel of choice was monolayer MoS_2 and the underlying template for the $Al_{1-x}Sc_xN$ films was 〈111〉 Al. Measurements were performed in ambient, vacuum (<10^{-5} Torr) and cold (300 K to 150 K) environments to further characterize the effects of charge trapping on device behavior. Piezoelectric force microscopy scans were able to confirm that $Al_{1-x}Sc_xN$ switches uniformly between polar states below the entire channel area after a voltage pulse is applied to the FeFETs. These devices display a very low coercive field, which capacitor measurements also confirmed. Retention measurements further proved that the devices could maintain their polar state for at least 1000s. Finally, equivalent FeFET structures with p-type monolayer WSe_2 channels illustrated the behavior of the devices related to the choice of channel.

Monolithic 3D Integration of Multifunctional 2D Materials and Devices Saptarshi Das; The Pennsylvania State University, United States

In this presentation, I will delve into the exciting realm of monolithic 3D integration, where emerging 2D materials take center stage, empowering advanced memory, logic, and sensing devices. Notably, our recent breakthroughs have culminated in the successful demonstration of wafer-scale 2-tier and 3-tier 3D integration, utilizing MoS_2 and WSe_2 FETs as well as graphene as the building blocks. These achievements have paved the way for multifunctional circuits that hold immense promise for the future of electronics.

10:30 AM EL03.14.02

Single-Crystal 2D Materials-Based Next-Generation 3D CMOS Transistor Seunghwan Seo[1], Kiseok Kim[1], Junyoung Kwon[2], Doyoon Lee[1], Changhyun Kim[2], Jung-El Ryu[1], Jekyung Kim[1], Junmin Suh[1], June-Chul Shin[1], Hogeun Ahn[3], Minsu Seol[2], Jin-Hong Park[3], Sang Won Kim[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

CMOS scaling has provided a cost-effective development route for the electronics industry and enabled an unprecedented level of bit- and performance-density that have met consumers' demands for several decades. This non-stop scaling in CMOS technology has been driven by the introduction of innovative technologies. In recent CMOS technology, there have been advancements in both structural and material innovations. In terms of structural innovations, three-dimensional (3D) CMOS technology has recently emerged and been explored. 3D CMOS technology is based on the concept of 3D heterogeneous integration of CMOS devices; this approach enables to achieve to aggressive cell scaling to continue Moore's Law. Meanwhile, in terms of material innovations, two-dimensional (2D) materials have garnered significant attention as promising channel materials that can replace Si in electronic devices. This is because, it has been revealed that high carrier mobility can be maintained when the thickness of 2D materials is scaled even under 5 nm. In particular, the atomistic-level thickness of 2D materials enables extreme gate pitch scaling.

In this presentation, for the first time, we will present the development of single-crystal 2D materials-based high-performance 3D CMOS transistors, wherein CMOS transistors are 3D heterogeneously integrated. Firstly, we demonstrate that single-crystal 2D materials are instrumental in achieving high-performance CMOS transistors. Specifically, we grew single-crystal 2D MoS_2 and WSe_2 semiconductors, which were then employed as channel layers in 2D NMOS and PMOS transistors, respectively. We achieved 69.3 mA/mm and 84.1 mA/mm of on-current density from our NMOS and PMOS transistors, respectively, which are comparable to those obtained from CMOS transistors fabricated using as exfoliated 2D MoS_2 and WSe_2 flakes. Next, we integrate these devices vertically to realize a 3D heterogeneously integrated CMOS transistor. We initially fabricated the 2D PMOS transistor on the substrate, and subsequently, fabricated the 2D NMOS transistor on top of the previously fabricated device. Then, we successfully verified the high-performance operation of the underlaying 2D PMOS layer and the upper 2D NMOS layer in our 3D CMOS transistor, which mainly originated from the single crystallinity of 2D materials. Finally, we explored the applicability of our 3D CMOS transistors toward logic circuits by implementing inverter circuits. We expect that this result will be an important step toward achieving the ultimate performance- and bit-density in microprocessors.

10:45 AM EL03.14.03

Wafer Scale Evaluation and Device Fabrication of MoS_2 Film Grown by MOCVD Keisuke Atsumi[1], Shuhong Li[1], Kaito Kanahashi[1], Tomonori Nishimura[1], Vincent Tung[1], Yoshiki Sakuma[2] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]National Institute for Materials Science, Japan

The fabrication of wafer-scale FETs using CVD-grown MoS_2 has been the subject of intensive research for future integration. Although powder-source CVD, initially developed, has been extended to enable wafer-scale growth, its non-uniform powder source feeding prevents uniform growth on 300-mm wafers. Gas-source CVD, particularly MOCVD, offers a stable and switchable source supply, thereby yielding enhanced uniformity. MOCVD is anticipated to serve as an industrially compatible growth method. However, previous investigations of MoS_2 FET have suggested unsatisfying quality. Despite the importance of improving MOCVD film quality, the origin of degradation remains unrevealed. The objectives of this study are to evaluate the intrinsic quality of film MOCVD and to identify the factors influencing mobility degradation.
From the I_d-V_g curve, showing I_{on} of ~10^{-6} A and I_{on}/I_{off} ratio of ~10^7. To extract μ without the influence of contact resistance, Y-function method was employed and yielded an estimated value of ~40 cm^2/Vs. While this value is comparable to that reported by the other reports, it falls short of powder-source CVD standards. I_d-V_g characteristics at T = 20 - 300 K show that I_{on} decreased with decreasing T, and random teregraph noise (RTN) was observed within the temperature range of 20 - 100 K. μ was extracted by Y-function method at each temperature and it dropped with decreasing T, indicating the existence of thermally-activated trap sites in the band gap of MoS_2. In contrast to this result, μ of powder-source CVD increases with lowering T due to the suppression of phonon scattering. For mechanically exfoliated single grain MoS_2, the temperature dependence of μ has been reported to change from the thermally-activated behavior to the phonon limited behavior by healing sulfur vacancies. The critical mobility for this transition seems to locate around 50 cm^2/Vs at 300 K. For further investigation of the thermally-activated behavior, linear polarized second harmonic generation (SHG) mapping will be effective. In the MoS_2 channel region, distinct black dots could be identified in the SHG mapping. However, no scratches and residues corresponding to black dots are discernible from the AFM image. There are two interpretations about SHG polarization dependencies of black dots. (i) Low quality grains and/or grain boundaries may exhibit black dots. (ii) Grain rotation may result in black dots. Although it is crucial to separate these two scenarios by polarization-dependent SHG measurements, this study suggests that SHG mapping is a convincing tool for detecting the origin of degradation.

11:00 AM EL03.14.04

All Transition Metal Dichalcogenides Based Wafer Scale 1T1R Array via Crystallinity Engineering Hyunbin Choi, Hyunho Seok, Sihoon Son, Dongho Lee, Geonwook Kim, Seowoo Son, Geumbeom Lee, Wookhee Jeon and Taesung Kim; Sungkyunkwan University, Korea (the Republic of)

Recent research has increasingly focused on addressing the bottleneck issues inherent in conventional von Neumann computer architectures by using memristors array that emulate artificial neural networks. Among various memristor materials, such as oxide-based materials, organic materials, and 2D materials, Transition Metal Dichalcogenides (TMDs) have garnered significant attention due to their physical stability, versatile electrical properties facilitated by modifiable material characteristics, confined perform in atomic scale and low-power operation. However, in array structures for integrated systems, there are persistent challenges with multilevel implementation due to various electrical issues such as sneak currents and crosstalk. To resolve the issues, structures such as 1T1R (Transistor and memristor) and 1S1R (Selector and memristor) have been proposed. Nevertheless, the channel materials differences between data access devices and memristors are potentially causing processing issues and undesirable chemical interactions between the channel materials. In this study, we experimentally demonstrate the successful integration of high-crystallinity TMDs layers for transistor channels and low-crystallinity TMDs layers for memristor operation on a single wafer, which achieved through two distinct synthesis methods, forming a densely packed on array structure that function reliably.

11:15 AM EL03.14.05
Towards 200mm 2D Materials Transfer—Wafer Scale Characterizations During 2D Materials Transfer Onto Temporary Substrate Paul Brunet, Thibaut Meyer, Emmanuel Rolland, Benjamin Dey, Stephane Cadot, Camille Pinchart, Frank Fournel and Lucie Le Van Jodin; Université Grenoble Alpes, CEA-Leti, France

Microelectronics companies always go further in the more Moore and more than Moore law trying to achieve smaller and smaller devices. However, at low dimensions, the mobility in silicon is drastically hampered. To overcome the limits of the silicon at low dimension, 2D materials are seen as a good candidate as their mobility is not affected by size.[1] This explains why 2D materials and more specifically TMDs are emerging in all industrial roadmap as the silicon successor. However, a considerable challenge needs to be taken into account as good crystalline quality 2D material's growth is reached only at a high temperature (900°C - 1100°C). This value is not compatible with BEOL (< 400°C) integration and up to now a critical transfer step is mandatory, to bring the 2D from its growth substrate to the final substrate.
During this step, all the intrinsic properties have to be preserved for integration into 2D material-based devices [2]. The transfer process can be split into two steps.
The 2D separation from its growth substrate and then bonding or fishing on the appropriate substrate. There is no easy solution involving a direct transfer from the growth substrate to final substrate, and, all the time, the use of temporary substrate is required. The latter can be, polymer,[3] thermal release tape [4] or glass substrate [5], [6]. The main difficulty remains to collect it on the temporary substrate without generating cracks, folds or any other damages. Once the material on the temporary substrate, another transfer from the temporary substrate to the final substrate is needed. Finally, all additional layers or handle used for the transfer are removed.
A lot of effort was made on 2D material characterization of MoS_2 grown by Atomic Layer Deposition (ALD) process.[7] As most of the time, characterizations are performed on a small area, and the data are not fully representative of the overall quality of the transferred 2D layer across the whole surface. Thus, a comprehensive wafer-scale characterization is essential to monitor the quality and uniformity of the transferred 2D material. Automation and statistics across the whole wafer acquired with several characterization tools, such as Raman spectroscopy, photoluminescence (PL), Atomic Force Microscopy (AFM), Wavelength Dispersive X-ray Fluorescence (WDXRF), scanning electron microscopy (SEM) were used to get growth information i.e. the thickness of the 2D, defects, homogeneity.

In this presentation, we detailed the first step, consisting of the 200 mm transfer of 2D material from the growth substrate to a temporary substrate. Our method is based on direct bonding. The main advantage relies on the possibility to avoid any additional layer to be deposited on top of the 2D. This prevents any contamination and the 2D material is directly transferred from one wafer to another, preventing wrinkles or cracks generation. We show here that thanks to a 200 mm wafer scale characterization we are able to optimize the MoS2 growth such as the quality of the transfer.

11:30 AM EL03.14.06

On-Chip Synthesis of Quasi Two-dimensional Semimetals from Multi-Layer Chalcogenides Jun Cai[1], Huairuo Zhang[2], Albert Davydov[2], Zhihong Chen[1] and Joerg Appenzeller[1]; [1]Purdue University, United States; [2]National Institute of Standards and Technology, United States

Two-dimensional (2D) materials are pivotal for exploring quantum phenomena and advancing next-generation electronics. Commonly used methods for preparing 2D materials include bottom-up approaches like vapor-phase deposition, which transport precursors onto substrates for reaction, and top-down methods such as mechanical exfoliation to obtain atomically thin layers from bulk materials. Alternatively, thin crystalline, non-layered materials are often grown epitaxially, which is not substrate agnostic. Achieving substrate-independent synthesis of non-layered quasi-2D materials remains challenging despite these established methods.

In this work, we report a templated and versatile on-chip synthesis approach for the formation of quasi-2D non-layered crystalline Kagome semimetals. This method involves a controlled transformation of a series of nanometer-thin layered vdW semiconducting chalcogenides (e.g. InSe) through reaction with the diffused metal atoms within the materials. We present the growth kinetics of this approach through a comprehensive set of experiments, varying the temperature and the chalcogenide flake thickness. Additionally, we analyze the transport properties of the quasi-2D Kagome semimetals, which exhibit two types of carriers and a low resistivity of ~ 45 μΩ cm at room temperature. Finally, we provide a pathway to construct high-performance 2D field-effect transistors (FETs) using our novel synthesis technique by creating a semimetal/semiconductor/semimetal heterostructure with intimate contacts, which offers not only improved DC performance but also mitigated parasitic capacitances for better AC performance.

11:45 AM EL03.14.07

The Effect of 2D Nanosheet Size on the Performance of Printed Devices Anthony Dawson[1], Vincent Renard[1,2] and Jonathan Coleman[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Université de Nantes, France

Printed networks of materials such as few layer MoS2 nanosheets enable the production of low-cost but poorer performance devices. Printed networks are arrays of nanoparticles deposited across a large area, with nanoparticles contacting one another at junctions. The poor performance of nanosheet networks is due to low nanosheet network mobility of about 0.1 cm2/Vs, this is in part due to inter-nanosheet junctions.

To improve network mobility of printed networks, we must better understand these junctions. To achieve this, size-controlled networks have been developed by tuning nanosheet dimensions and characterising their electrical performance. Tuning of nanosheet aspect ratio from 500 to 100 has been achieved for the first-time using Sonication Induced Scission.

Using this size selection technique, devices of a range of nanosheet sizes are developed, and their electrical properties characterised, revealing new insights into charge transport in these nanosheet networks.

What's Needed to Make 2D Semiconductors Useful for Electronics? Eric Pop; Stanford University, United States

I will present my perspective of how two-dimensional (2D) semiconductors could be used in electronics. For example, they could be used in applications where their ultrathin nature provides distinct advantages, such as flexible electronics [1], light-weight solar cells [2], or nanoscale transistors [3]. They may not be useful where conventional materials work sufficiently well, like transistor channels thicker than a few nanometers. I will focus on 2D materials for 3D heterogeneous integration of electronics, which has major advantages for energy-efficient computing [4]. Here, 2D materials could be monolayer transistors with low leakage (due to larger band gaps than silicon), used to access high-density memory [5]. Some encouraging results from our group [6-9] and others [10] have shown monolayer transistors with good performance, which cannot be reached with sub-nanometer thin conventional semiconductors, and the 2D performance can be boosted by strain [9,11]. I will also describe some unconventional applications, using 2D materials as thermal insulators [12], heat spreaders [13], and thermal switches [14]. Combined, these studies reveal fundamental limits and some applications of 2D materials, which take advantage of their unique properties.

2D-Material Based p-Type Vertical FETs Realized by Using Metallic TMDs as an Electrical Contact Park Hyokwang, Hoseong Shin and Won Jong Yoo; Sungkyunkwan University, Korea (the Republic of)

2D-material based p-type semiconductors, which are inevitable components of CMOS technology, have been bottlenecked in realizing their desired performances despite researchers' extensive studies on electrical contacts formed by using traditional metals. In this regard, developing advanced-structured devices, including vertical Field-Effect-Transistors (FETs), has predominantly progressed for n-type semiconductors. Here, we demonstrate van-der-Waals metallic contacts utilizing atomically thin 2D metals of TaS_2, $NbSe_2$, and NbS_2 having high work functions in the range of 4.8 to 5.9 eV which are favorable for forming p-type ohmic contact to WSe_2 while suppressing Fermi-level-pinning induced mainly due to the direct deposition process. We found that $NbSe_2$-contacted WSe_2 semiconductor devices show a reliably high on-current of ~10^4 A/μm with p-type ohmic contact properties. Moreover, we demonstrate the fabrication of p-type vertical FETs realized by using 2D metals with a high on-off ratio of ~10^5. We, further, demonstrate a vertical pseudo-CMOS based on 2D metals which can significantly reduce channel length of FETs.

2:15 PM EL03.15.03

Demonstration of Self-Aligned Edge Contact for High-Performance WS_2 2D Field-Effect Transistors Seokjin Ko, Dongryul Lee, Jehwan Park and Jihyun Kim; Seoul National University, Korea (the Republic of)

The conventional Si-based semiconductor architectures face scale-down limitations due to the performance degradation caused by short-channel effects. Two-dimensional (2D) transition metal dichalcogenides (TMDs) have become prominent candidates to replace Si owing to their excellent electrical properties at sub-nanometer thickness emanating from their atomically thin layered structures and dangling bond-free surfaces. Tungsten disulfide (WS_2), one of the members of TMDs, exhibits thickness-dependent bandgap (multilayer: 1.3 eV, monolayer: 2.1 eV) and electron mobility of ~234 cm^2/Vs, making it a great alternative as an n-type channel material in 2D field-effect transistors (FETs). However, the full potential of the WS_2 is restrained by the charge transport degradation and high contact resistance caused by the formation of a Schottky barrier (SB) in the metal–TMD junctions. Edge contacts have emerged as a promising method to fabricate TMD-based FETs with low contact resistance and controllable polarity without the need for extrinsic chemical doping or additional processing steps during the formation of the contact metal. Contrary to the Fermi-level pinning at specific energy levels of gap states at the metal–TMD interfaces in surface contacts, the absence of a van der Waals gap state in the edge contacts reduces the overall barrier width and enhances charge injection. This work introduces a self-aligned edge contact (SAEC) process for WS_2 FETs. This SAEC process enables the fabrication of edge contact WS_2 FETs without additional lithography which is required to define the channel in conventional edge contact methods. The SAEC process utilizes hexagonal boron nitride (hBN) layers transferred onto the top-gate metal as an etch mask to define the edge contact region where the hBN layers become the gate sidewall spacer after dry-etching. The SAEC process combines the advantages of previous edge contact methods with the self-aligned processes commonly used in the current Si technology, resulting in 2D devices with excellent electrical properties, such as a high on/off current ratio and enhanced field-effect mobility (μ_{FE}).

In this work, WS_2 and hBN nanolayers were sequentially mechanically exfoliated and dry-transferred onto a Si/SiO_2 substrate to form a WS_2/hBN stack. The top-gate section was patterned using electron beam lithography (EBL), before depositing Ti/Au (20/80 nm) top-gate electrode. In the first reactive ion etching (RIE), the WS_2/hBN stack with the top-gate electrode was etched with an SF_6/Ar gas mixture to partially etch the hBN nanolayer. Then, another exfoliated hBN nanolayer was dry-transferred onto the top-gate electrode to cover the whole gate metal and the adjacent parts of the WS_2 channel. The second RIE was performed using the same gas mixture to form the hBN gate spacers and expose the edges of the WS_2 channel by completely etching away the periphery of the WS_2 and hBN nanolayers. Ti/Au (30/30 nm) source/drain electrodes were defined via EBL and were deposited at the edge contact boundaries.

The formation of steep edges in the WS_2 channel via RIE and the subsequent formation of edge contact after contact metal deposition were confirmed through atomic force microscopy and cross-sectional transmission electron microscopy, respectively. Our SAEC WS_2 FET showed a high on/off current ratio of ~10^7 and μ_{FE} of 97.37 cm^2/Vs. The self-aligned formation of edge contacts led to the formation of metallized WS_2 layers induced by a strong orbital overlap between WS_2 and the metal atoms, which eliminated the barrier derived from the van der Waals gap and resulted in the lowering of the SB. This unique metal–TMD interface enabled effective layer-by-layer carrier injection into the WS_2 conduction band. The SAEC process can unleash the full potential of 2D TMDs by effectively removing the SB at the metal-semiconductor interface, while preserving their intrinsic properties.

Temperature-Dependent Electrical Transport Property Characterization of 2D MoS_2 Channel FETs Grown Using Salt-Based Precursors Andrew M. Jones[1], Rashmi Jha[1], Vamshi K. Gogi[1], Greg Muha[1], Sujoy Ghosh[2], Sumner B. Harris[2] and Kai Xiao[2]; [1]University of Cincinnati, United States; [2]Oak Ridge National Laboratory, United States

2D Transition Metal Dichalcogenides (TMDs) materials have been the focus of recent development for channel materials in scaled sub 10-nm Gate All Around (GAA) Complementary Metal Oxide Semiconductor (CMOS) Field Effect Transistors (FET)[1]. MoS_2 TMDs are one of the major candidates for this application [2]. Salt-assisted growth techniques of MoS_2 have been recently reported which can promote lateral growth at atmospheric pressure and relatively low-temperatures during Chemical Vapor Deposition (CVD) sulfurization process. The initial performance of these MoS_2 FETs has been reported, though much work needs to be done to understand the temperature-dependent response of this material in FET devices. In this work, we report our analysis on salt-based precursor driven CVD grown MoS_2 channel FETs at various temperatures. MoS_2 material was grown using Ammonium Molybdate salt precursor subsequently sulfurized using CVD at 700°C. After the growth of MoS_2 crystals, they were transferred onto a p-Si substrate with 300nm of SiO_2 on top used as a gate dielectric. The crystals produced by this salt-based precursor driven CVD growth method were approximately 50 microns in length which allowed us to fabricate devices of channel lengths ranging from 0.5μm to 5μm using e-beam lithography. Cr/Au was used as source/drain contacts. When measured at ambient temperature and pressure, the threshold voltage (V_{Th}), ranged from -35V to -25V depending on the length of the channel. The best case drain current (I_{DS}) was 11.5μA, or 1.2μA/μm when normalized by channel width. After establishing the room temperature FET operation, these devices were tested at various temperatures ranging from 200K-400K. Our results show that at lower temperatures (200K-275K), V_{Th} decreases slightly and remains constant. As the temperature is increased above room temperature (325K-400K), the value of V_{Th} grows exponentially until at 400K, the gate loses control on the channel entirely. In addition to temperature influencing the V_{Th}, the data also shows a strong correlation between temperature and carrier mobility. As temperature increases, the carrier mobility decreases drastically. This trend holds until 400K, at which point the devices cease to display transistor-like characteristics. Interestingly, the gate leakage current was still low at 400K, indicating excessive generation of carriers at 400K that can possibly convert the channel mostly towards semi-metallic. These observations will be benchmarked against observations made on 2D films grown using non-salt-based techniques to understand the role of salt-precursors.

Scalable Two-Dimensional α-In_2Se_3 Thin Films and Ferroelectric Memory Array Lei Xu, Zhenhua Wu and Xiaotian Zhang; Shanghai Jiao Tong University, China

Non-volatile memories based on ferroelectric materials are one of the most competitive next-generation memories due to their low power consumption, fast read and write speed, non-volatility, and compatibility with CMOS manufacturing processes. However, the high-density integration of ferroelectric memories is tightly blocked by the depolarization-field caused by critical dimension effect of conventional ferroelectric thin films. Meanwhile, the emerging 2D Van der Waals (vdW) ferroelectric materials with robust ferroelectricity in ultrathin scale offer the great potential in the miniaturization of the device and screen the depolarization field in ultrathin form to bypass the limitations of conventional ferroelectric materials. Wherein, α-In_2Se_3 is recognized as one of the most promising 2D ferroelectrics due to its stable layered structure at room temperature, high Curie temperature (>200 °C) and special dipole-locked in-plane (IP) and out-of-plane (OOP) ferroelectricity at the monolayer limit. However, the coexistence of multiple phases during the growth of In_2Se_3thin films remains as a challenge to growing uniform and pure α phase In_2Se_3 in large area. In addition, there have been few studies thus

far aimed at investigating the epitaxial growth properties of α-In_2Se_3 films and there is still lack of array demonstration of ferroelectric device based on as-grown 2D α-In_2Se_3 films.
Herein, we demonstrate a controllable synthesis of centimeter-scale α-In_2Se_3 from monolayer to multilayer films by adjusting the thickness of the boundary layer over the substrate in a chemical vapor deposition (CVD) process. Raman spectroscopy, transmission electron microscopy (TEM) and second harmonic generation (SHG) were carried out to identify the uniform alpha phase across the whole film. The α-In_2Se_3 triangular domains grow epitaxially on mica surface with mainly two orientations and epitaxial relationship over large area is further confirmed by in-plane XRD. In the meantime, piezoresponse force microscopy (PFM) measurements demonstrate the robust ferroelectricity and good stability of the polarization of as-grown α-In_2Se_3 films at room temperature. In addition, we demonstrate the transportmechanism for ferroelectric resistive switching, endurance and retention characteristics by constructing a crossbar ferroelectric semiconductor junction (FSJ) array based on α-In_2Se_3 continuous films for next-generation memory.

Observations on Transport in Contacts to 2D Semiconductors Using Diverse Contact Structures Aaron D. Franklin; Duke University, United States

Most semiconducting nanomaterials would be perfect for use in nanoscale transistors if only the transport between metal contacts and the atomic-scale crystal could be mastered. Over the years, we (speaking both personally for my lab and collectively for the field) have cleaned, damaged, preserved, gapped, removed, and doped the 2D semiconductor beneath the source/drain top contacts – so, where does that leave us? While I won't pretend to have a definitive answer to this question, I will offer a few observations based on work from my group. We have explored the impact of intentional damage to MoS_2 and WS_2 immediately prior to contact metal deposition, finding a benefit for few-layer films with a few seconds of ion beam exposure [1]. With further ion beam bombardment, we explored clean edge contacts to various 2D semiconductors that showed superb and consistent scalability, but at a notable cost to contact resistance [2] – a tradeoff that would have to be carefully managed. Finally, we discovered an intriguing asymmetry in the scaling of top contacts to MoS_2 that suggests greater scalability of the drain-side [3] – perhaps an asymmetry worth embracing for future 2D transistor technologies. There is so much more to understand and improve in the metal-2D contact interface; these observations will hopefully provide some insights for moving forward.

Hybrid van der Waals Integration through Hydrogel-Mediated Laser Printing Donghyup Kim and Jiwoong Park; The University of Chicago, United States

Van der Waals integration for 2D heterostructures is a generalized strategy for assembling various materials into tailored heterostructures without lattice and processing limitations. An effective and reliable transfer medium and method are crucial for successful van der Waals integration. The liquid medium has been widely used for a wet-transfer method, which is a facile and clean transfer but is usually accompanied by poor transfer quality and stability. Here, we report that a structured liquid, such as hydrogel, can be used as an effective transfer medium for the reliable transfer of 2D materials and beyond. The hydrogel-assisted transfer enables cleaner transfers with spatially homogeneous internal strain distribution and exceptional transfer stability. Furthermore, the hydrogel serves as an ideal medium for layer-by-layer laser printing due to its super-fast release rate and transparent nature for the laser beam. We demonstrated that hydrogel-mediated laser printing can be applied to stack various materials beyond 2D materials and realize hybrid van der Waals integration for device fabrication.

Two-Dimensional MoS_2 Based Field Effect Transistors as Gas Nano-Sensors Filippo Giubileo[1], Sebastiano De Stefano[2], Loredana Viscardi[2,1], Kimberly Intonti[2,1], Enver Faella[3], Aniello Pelella[2], Arun Kumar[2], Ofelia Durante[2,1], Maurizio Passacantando[3,1] and Antonio Di Bartolomeo[2,1]; [1]CNR-SPIN, Italy; [2]Università degli Studi di Salerno, Italy; [3]Università degli Studi dell'Aquila, Italy

Nowadays, sensor technology is very important in our society to monitor the environment, detecting toxic gases relevant to healthcare, environmental pollution, and air quality. Some mature gas sensing technologies include semiconductor-based, electrochemical, photoionization, and infrared adsorption. The main figures of merit to identify the best technology for broad applications are sensitivity, selectivity, cost, and compactness. Recent advancements in the field of gas nano-sensors are mostly focused on sensitivity performance, while selectivity remains the main weakness for the development of innovative sensors. The most promising solution for the next generation sensors with enhanced selectivity is the exploitation of 2D materials as gas sensing elements, having high surface area to volume ratio and mechanical flexibility. We use molybdenum disulfide (MoS_2) as conducting channels in back-gated field effect transistors. The gate terminal in FET provides an extra knob for controlling the carrier mobilities, which helps to achieve a higher sensitivity compared to other devices. In particular, we investigated the effect of pressure, electric stress, gas type on the electrical characteristic of the transistor. The electrical conductivity shows a clear response to the presence of different gas molecules. The presence of defects and point vacancies in the MoS_2 crystal structure facilitates the adsorption of gas molecules, which strongly affect the transistor's electrical characteristics. We systematically investigate how different gases modify the transistor behaviour and the correlation with the adsorption energy onto the MoS_2 surface. Finally, we consider the possibility of using the electrical noise generated in gas sensor as a useful signal for improving the sensor's selectivity, the microscopic, random fluctuation phenomena in physical systems being rich sources of information. Our results can pave the way to realize environmental gas nano-sensors, for air pollution monitoring, with enhanced selectivity through fluctuation spectroscopy, in which 2D materials are exploited as the conductive channels in nanometric back-gated FET. This activity is performed within the framework of the project PRIN 2022 PNRR, 2DEGAS "Development of two-dimensional environmental gas nano-sensors with enhanced selectivity through fluctuation spectroscopy".

Electrical Double Layer Force Enabled CMOS-compatible Transfer of van der Waals Materials Sheldon Zheng, Jiangtao Wang, Tianyi Zhang, Jiadi Zhu, Tong Dang, Ang-Yu Lu, Tilo H. Yang, Peng Wu, Xinyuan Zhang, Kenan Zhang, Kyung Yeol Ma, Zhien Wang, Vladimir Bulovic, Tomas Palacios and Jing Kong; Massachusetts Institute of

Technology, United States

The integration and stacking of van der Waals (vdW) materials to target substrates or circuits is critical to their applications in high-end electronics, optics, moiré electronics, *etc*. Since high quality vdW materials are often grown with harsh conditions, the transfer of these vdW materials to target substrates is one of the key steps in the integration. However, the step of detaching nanomaterials from the growth substrate typically requires the use of either chemical etchants, electrochemical bubbling, or metal-assisted mechanical strain, which often leaves residue or introduces contamination, making the process CMOS-incompatible, low-yield and the quality of the vdW materials degraded. Furthermore, the substrate cannot be used again, adding significant cost to the manufacturing process (especially for single crystalline substrates). In this work, we present an electrical double layer (EDL) force enabled transfer method (termed as EFT, EDL Force Transfer) that is CMOS-compatible, with minimal damage to the vdW layer, widely applicable to different types of substrates and materials, and cost-effective. With the formation of the EDL, the vdW material is immediately repelled from the substrate by the strong EDL repulsion force. This method is suitable for various vdW materials (e.g., carbon nanotube, MoS_2, h-BN, etc.) and substrates (e.g., oxide, nitride, etc.). The as-transferred vdW materials show ultra-high nanoscale cleanliness, along with minimized wrinkles, cracks, metal contaminations and other transfer-induced defects. The MoS_2 transistors fabricated with this transfer method show higher ON current and reduced threshold voltage variation than devices made via chemical etching transfer. This EFT approach offers a facile and manufacturing-viable solution for vdW material integration, which will significantly advance the future development of atomically thin electronics.

Stack Control of Bi/Pt Bilayer Electrodes for Enhanced *P*-Type Operation in WSe_2 FETs Ryuichi Nakajima[1], Tomonori Nishimura[1], Kaito Kanahashi[1], Keiji Ueno[2], Yasumitsu Miyata[3] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]Saitama University, Japan; [3]Tokyo Metropolitan University, Japan

2D materials are promising for future integrated circuit due to the tolerance for short channel effect. However, Fermi level pinning (FLP) represents a critical issue in 2D systems, particularly for *p*-type FET operation. To suppress FLP, Bi has been addressed because of its low melting point and large vapor pressure, facilitating defect-free deposition that counters defect-induced gap states (DIGS). Moreover, its small density of states helps avoid the formation of metal-induced gap states (MIGS). Indeed, high-performance *n*-type MoS_2 FET have been achieved using Bi contacts. However, the work function (WF) of Bi is inadequate for the *p*-type operation.

Here, we propose a novel strategy involving surface segregation in Bi/Pt bilayer electrodes for WSe_2 FETs, where Pt has the highest WF among practical metals and the defect formation during Pt deposition could be suppressed by first Bi layer. By annealing the bilayer electrodes, Bi will be segregated on Pt surface due to large difference of adsorption energy, resulting in the direct Pt contact with WSe_2 [J. Vac. Sci. Technol. A Vacuum, Surfaces, Films **19**, 1432 (2001)]. In this study, *p*-type operation of WSe_2 FETs was investigated by controlling the electrode structure.

The segregation of Bi/Pt was first investigated by X-ray photoelectron spectroscopy and X-ray diffraction. It was demonstrated that superior segregation occurs after annealing below 300°C, while reactions started above 400°C. Subsequently, 4L-WSe_2 FET with 10-nm Bi/30-nm Pt electrodes was fabricated and Id-Vg measurement was carried out at RT before/after annealing at 300°C. Strong *n*-type characteristics were observed initially due to the low WF of Bi, while I_d-V_g transfer curve changed from *n*-type to *p*-type after annealing. This method holds promise for facilitating *p*-type operation in 2D FETs and warrants further discussion on FLP.

Highly Permeable and Selective Crumpled Graphene Oxide Membranes for Hydrogen Separation Pengxiang Zhang, Qian Wang, Maksim Trubianov, Yixin Zhang, Mo Lin, Musen Chen, Konstantin S. Novoselov and Daria V. Andreeva; National University of Singapore, Singapore

Two-dimensional (2D) materials-based membranes especially graphene oxide (GO) membranes have been proven to be the promising materials for the gas separation application due to their easy operation, energy-saving and high efficiency. The intrinsic in-plane defects, consisting of the nanopores in flakes and grain boundaries, and plane-to-plane interlayer spacing provide the lamellar GO membranes with molecules transport pathway, which determine the permeability and selectivity of the membrane. The dense lamellar structure and tortuous permeation path endow the lamellar GO membrane with high selectivity but hinder the gas molecules passing through, which limits the application of GO membranes in industrial fields. Herein, inspired by the enhanced gas exchange of crumpled alveolus in human body, a novel crumpled structure of GO membranes was introduced and fabricated facilely by using the heat-induced shrink polymer. The crumpled features endowed the membranes with much larger gas-accessible area and therefore higher H_2 permeability about 2.1×10^4 Barrer with decent H_2/CO_2 selectivity around 90, which surpassed the state-of-the-art membranes. The intrinsic selective lamellar layers and loose disordered flake alignments constituted the anisotropic multidomain structure which guaranteed high permeability with excellent selectivity. The fabricated crumpled GO membranes were also tested in severe environments and exhibited good thermal-stability and humidity-stability. The accessibility for mass-production and long-term stability made the crumpled GO membranes become potential in industrial exploitation.

EL03.16.02

Clean Transfer of MoS_2 by Eutectogels Prepared via *In Situ* Photopolymerization Iván García, Mario Flores, Saúl Carrasco, Andres De Luna Bugallo and Josue Mota-Morales; Universidad Nacional Autónoma de México, Mexico

Two-dimensional materials and their van der Waals heterostructures have demonstrated enormous potential for advancing technological innovations in electronics, optoelectronics, catalysis, and energy storage. The methods used to synthesize these heterostructures play a crucial role in determining their final applications. In this context, atmospheric pressure chemical vapor deposition (APCVD) has been widely used to synthesize MoS_2 monolayers with tunable optoelectronic properties. However, the growth temperatures of these materials can exceed 700°C, which is incompatible with standard complementary metal oxide semiconductor (CMOS) microfabrication processes. One of the alternatives to this problem is to "transfer" these 2D materials after growth by placing them on substrates that are compatible with these processes without compromising the crystalline quality and uniformity of the 2D material.

Currently, transfer methods are limited and have drawbacks such as introducing defects into the material structure or surface contamination. In addition, the methods are complex and in some cases require the use of sophisticated equipment. To overcome these drawbacks and to minimize residues and structural damage generated during the process, the use of polymers, such as cellulose acetate or PDMS, as support elements for the crystals during their transfer has been reported.

On the other hand, deep eutectic solvents (DES) immobilized into non-aqueous gels, called eutectogels, have emerged as a sustainable alternative to flexible materials with tunable mechanical, thermal and adhesion properties. To achieve the clean transfer of MoS_2 crystals, this study proposes the use of eutectogels obtained from monomer-containing DES (DESm) to asiste in the 2D crystal transfer. By photopolymerizing DESm on MoS_2 crystals in situ, the crystals are transferred to target substrates.
The results obtained by Raman and photoluminescence spectroscopy show that it is possible to transfer MoS_2 crystals without structural damage or impurities introduced during the transfer process.

EL03.16.03

Tunable-Bandgap Transition Metal Dichalcogenides Enabled by Strain Engineering Jun Wang; The Hong Kong University of Science and Technology, China

Strain engineering offers a tool for tuning of the electronic and optoelectronic properties of two-dimensional (2D) materials. In this study, we demonstrate a direct strain engineering method to tune the bandgaps of transition metal dichalcogenides using selenium substitution to synthesize highly strained $MoSe_2$ film. We observe that during the annealing step, the synthesized $MoSe_2$ demonstrates a high and homogeneous in-plane tensile strain (4.9%), due to the lattice mismatch with the template materials, higher than method of bending substrates (~2%) or wrinkling. The strain is therefore tuned by adjusting the substitution temperature, which modulate the $MoSe_2$ bandgap upto ~0.47 eV, concurrently with an enhanced Hall mobility to 797 cm^2/Vs, comparable with the high record (~240 cm^2/Vs) from WS_2 samples. Consequently, the responsivity of the device is significantly improved from 0.15 to 0.77 mA/W for high-strain $MoSe_2$ photodetector under near-infrared (1060 nm) illumination. This controllable chalcogen substitution method provides a new strategy for fabricating 2D van der Waals materials with controllable and uniform strain, which has great significance for enhancing the performance of optoelectronic devices.

EL03.16.04

Layer-by-Layer Assembly of Porous 2D Metal-Oxide Architectures by Nanofabrication Tiago Elias Abi-Ramia Silva and Andreas Güntner; ETH Zürich, Switzerland

Metal oxides (MOxs) commonly exhibit semiconductor behavior and chemoresistance, which enables their use as gas sensors. In our research, we have demonstrated the flexibility and adaptability of the layer-by-layer assembly of chemoresistive and catalytic filtering films. This method creates a highly integrated system[1] for the exclusive detection of critical gases. Among the various synthesis methods available, flame spray pyrolysis (FSP) is particularly interesting, as it can produce nanocrystals (NCs) and deposit them as highly porous thin films.[2] Here, we interface up to three layers of different metal oxides with closely controlled thicknesses onto Al2O3 substrates with interdigitated electrodes. We will show the strong effect of layer thickness and electronic coupling on the sensitivity and selectivity of chemoresistive sensors when detecting volatile organic compounds. This compact solution provides a flexible platform that can be tailored to a diverse range of analytes, empowering researchers to customize their gas sensing applications. Its high degree of integration also allows for its exploration of low-power, distributed solutions, broadening the applicability of MOx NCs in gas sensing.

Transport Phenomena in Artificial Graphene Polytypes Yoav Sharaby, Nirmal Roy and Youngki Yeo; Tel Aviv University, Israel

The stacking order (polytypes) of graphene multi-layers in mechanically exfoliated flakes is naturally dictated by energetically favorable considerations, a polytype with the higher symmetry is found more in comparison to one which has lower symmetry.
As a case study tetra-layer graphene is known to have three distinguishable polytypes, Bernal, Rhombohedral, and an intermediate polytype namely Polar. ABAB, ABCA, and ABCB stacking accordingly. While Bernal and Rhombohedral are considered stable the polar state is found much less in mechanically exfoliated graphene. Furthermore, during device fabrication the initial polytype may change to another, a more stable one, preventing the study of transport properties in unique polytypes.
In this study, by careful design of the heterostructure stacking of vdW materials, artificial polytypes are made and stabilized. Allowing the study of more than a single polytype in a single device. Such capabilities allow a broader understanding of the transport properties in a single multi-layer graphene switchable device.

EL03.16.06

Unraveling Defects Introduced on the Basal Plane of MoS_2 Monolayers by Hydrogen Peroxide for Hydrogen Evolution Reaction Leonardo H. Hasimoto[1,2,3], Murilo Santhiago[1,2], Cláudia de Lourenço[1,4], Ana B. de Araujo[1,4], Jefferson Bettini[1], Tarcisio M. Perfecto[1] and Edson R. Leite[1]; [1]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [2]Federal University of ABC, Brazil; [3]Colorado State University, United States; [4]University of Campinas, Brazil

Hydrogen as a fuel is promising for a more sustainable economy once it possesses high energy density and is considered a clean energy source. A prospective route for green hydrogen production is the electrochemical water splitting powered by renewable electricity. However, the best catalysts are currently based on noble metals such as platinum, which are expensive and scarce. Aiming for economically feasible alternatives, MoS_2 has been studied for such applications due to its high abundance and low cost.[1] As well-known for MoS_2, the catalytic activity relates to edge sites while the basal plane is predominantly inert to such a process. Thus, different works have proposed different defect engineering routes to generate defects on the basal plane of MoS_2 and create catalytic sites. The introduction of such defects plays an essential role in tuning the electrocatalytic activity on the basal plane of MoS_2 monolayers towards HER. Solution-based defect-engineering routes are scalable,[2] can effectively activate porous electrodes,[1] and do not require high-cost equipment to generate defects on MoS_2.[3,4] Among the different possibilities hydrogen peroxide (H_2O_2) is a mild, metal-free, and carbon-free, oxidant that can activate the basal plane to drive HER. It is reported that depending on the experimental conditions, H_2O_2 might lead to the formation of edge-like defects and vacancies on the basal plane.[5] In this work, we demonstrate for the first time the insertion of defects on monolayer MoS_2 and study the impact of such defects on the HER activity. In a first approach, we prepared ultra-large supported and free-standing monolayers on gold surfaces to evaluate chemical changes that occurred only in the basal plane. Raman, photoluminescence, and X-ray photoelectron spectroscopies results confirmed the alterations on the surface of MoS_2 after the treatment with H_2O_2. HR-TEM was employed to provide in-depth information regarding the changes in the structure of MoS_2. Remarkably, we tracked the same area with nanoscale resolution before and after H_2O_2 treatment to comprehend the impact of H_2O_2 in free-standing monolayers. Our results reveal that there is lack of structural coherence on the basal plane at high exposure times. The electrocatalytic activity of the monolayers was measured without introducing unintentional defects related to microfabrication processes.[6] The obtained results revealed a cathodic shift of the overpotential required to drive HER, achieving 372 mV at 10 mA cm^{-2}. Thus, our work provides new fundamental basis for the chemical transformations of MoS_2 monolayers.

EL03.16.07

Strain Tuning of Localized Neutral and Charged Excitons in a Monolayer Semiconductor Qiaohui Zhou[1], Ali Soleymani[1], Fei Wang[1], Kenji Watanabe[2], Takashi Taniguchi[2], Jiang Wei[1] and Xin Lu[1]; [1]Tulane University, United States; [2]National Institute for Materials Science, Japan

One promising path for the development of optoelectronic devices is the integration of two-dimensional (2D) materials with functional substrates. Transition metal dichalcogenides, such as tungsten diselenide (WSe_2), have attracted considerable interests due to their strong light-matter interaction. In this work, we show the strain tuning of localized neutral and charged excitons in a monolayer WSe_2 by using the inverse piezoelectric effect from a single crystal piezoelectric substrate. An out-of-plane electric field applied to the piezoelectric substrate, depending on the direction, can generate either tensile or compressive strain.
We used the commercially available (001) orientated piezoelectric substrate, $(PbMg_{0.33}Nb_{0.67})_{1-x}$: $(PbTiO_3)_x$; x = 0.29-0.32 (PMNT-PT), for this study. After pre-patterning of electrodes by using electron beam lithography, we transferred the monolayer WSe_2 on the substrate, followed by boron nitride (BN) and graphite layers to form a top-gated field effect transistor. We noticed that previous reports on strain tuning mainly focused on neutral excitons [1,2]. To the best of our knowledge, independent strain manipulation and electric control have not been realized in the layered materials. While the localized charged excitons, which can be optically initialized as quantum emitters, could provide more possibilities for applications in optoelectronics and quantum information sciences.
We carried out the measurements in a closed cycle cryostat with a base temperature of ~3.6 K. We first characterized the localized neutral excitons, which generally exhibit negligible hysteresis and a maximum energy shift of ~4.5 meV in the range of -200 to +200 V. The localized charged excitons, on the other hand, show a much larger hysteresis. Particularly, the difference for both sweeping directions at 0 V reaches more than 2 meV. We furthermore measured the polarization and observed a hysteresis loop as well. Such hysteresis in polarization and energy are absent in the neutral excitons. We thus hypothesized that the extra charge in the localized charged exciton couples to the ferroelectric dipole moment in the substrate. Although being known as piezoelectric, the PMN-PT substrate is actually a relaxor ferroelectric with weak ferroelectricity.
Our results demonstrate that 2D materials can be combined with functional ferroelectric substrates to produce highly tunable optoelectronic devices. The capacity to manipulate localized excitons in WSe_2 dynamically creates

new opportunities for novel optoelectronic devices.

Fabricating Vertically-Aligned Monolayer Graphene Helices for Chiral Metamaterial Development Zihao Lin, Carol Mikhael, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota Twin Cities, United States

Graphene has been heavily investigated as one of the chiral metamaterials because it demonstrates a strong response in the THz range, which is useful for detecting and analyzing low concentrations of chemical and biological materials. However, graphene's structure is achiral, making it unsuitable as a chiral material for analyzing chiral molecules. Moreover, its extremely thin thickness results in weak light interaction. To achieve strong interaction between incident light and chiral molecules, the graphene surface should be aligned parallel to the incident light. This means that the graphene should be vertically-aligned on the substrate when the incident light is vertically illuminated from the substrate. To satisfy the requirements, in this work, a dual-component self-assembly method that utilizes stress gradient induced by ultraviolet (UV) light is developed. Graphene, together with a thin SU-8 photoresist, are both self-twisted and curved vertically, forming vertically-aligned graphene helices. This assembly process enables the creation of graphene helices with helix heights up to 4 mm and an aspect ratio (height/width) of 2700.This height is equivalent to 4 million times the height of monolayer graphene. Raman measurement and SEM secondary electron test were performed to prove the pristine graphene property on the entire surface of the helix. Furthermore, to explore the chiral properties of the 3D graphene helix, simulations were performed, with the results distinctly emphasizing its unique chiral characteristics. It is believed that this work is the first time to realize graphene self-twist to a vertically-aligned monolayer graphene helix as a chiral sensor. The developed new fabrication technique can be further applied to other 2D materials like MXene, hBN and MoS_2.

EL03.16.09

High Anisotropy in Proton Conductivity of Pore-Free Graphene Oxide Membrane Tatsuki Tsugawa, Kazuto Hatakeyama, Michio Koinuma and Shintaro Ida; Kumamoto University, Japan

In this study, we demonstrate that the proton conductivity of pore-free graphene oxide laminate membranes differs by a factor of 100,000 between the out-of-plane and in-plane directions. This remarkable anisotropy suggests that the directional dependence of proton transport in two-dimensional (2D) materials is significantly influenced by the presence or absence of nanopores, highlighting important potential applications for 2D materials. Graphene oxide (GO) is a 2D material composed of carbon and oxygen with a thickness of approximately 1 nm. The presence of the oxygen functional groups on the GO sheet surface makes it dispersible in various solvents, easy to composite and exhibiting many properties, making it a material that can be used in a wide range of applications. In fact, expected to be a superior proton conductor due to its exceptionally high proton conductivity based on nanoscale carbon-defects with various oxygen functional groups. However, in addition to the oxygen functional groups, the presence of many carbon-defects (pores) on the GO sheet surface cause the complexity of the proton conductivity mechanism and the low reproducibility. The formation of the pores in the GO surface is caused by the breakdown of the C=C bonds and breaks the C-C bonds in the graphene backbone during the oxidation process, which introduces COOH and C=O groups. In other words, the introduction of oxygen functional groups in the plane while maintaining the C-C bond will theoretically get in a pore-free GO (Pf-GO). The oxygen functional groups that achieve these results are C-O-C (epoxy group) and C-OH (hydroxy group). It has been reported that the oxygen functional groups of Brodie's method Graphite Oxide with Fuming HNO_3 or $KClO_3$ exist almost as epoxy groups and such GO are considered pore-free. However, the graphite oxide prepared by the Brodie's method was known to be difficult to exfoliate into water. Our previous study, monolayer GO nanosheets were successfully obtained with high efficiency using weakly basic solvents with ammonia, and its detailed structure has been revealed. Pf-GO are expected to exhibit unique properties as graphene-like materials, different from conventional graphene oxide.

STEM observations showed that no pores were observed from Pf-GO. In contrast, many pores were observed in STEM images of conventional GO nanosheets. In general, pores are generated in GO nanosheets prepared by the Hummers method. Thus, the structure of the Pf-GO studied in the present work totally differs substantially in terms of pores when compared with a conventional GO nanosheets. The reasons why Pf-GO membranes exhibit much higher proton barrier properties than conventional GO membranes can then be explained as follows. In general, the out-of-plane proton conductivity is lower than the in-plane proton conductivity because the protons between layers have to move to the next layer via pores or sheet boundaries. The higher resistance in the out-of-plane direction is therefore due to the proton pathways being much longer than those in the in-plane direction. Therefore, our results that the out-of-plane proton conductivity of Pf-GO is much lower that of a conventional GO, whereas the in-plane conductivity of Pf-GO is almost identical to that, suggest that Pf-GO contains substantially fewer or no pores on its surface. On the other hand, the in-plane proton conductivity is almost identical. This is due to the abundant oxygen functional groups, as in conventional graphene oxide, and to the interlayer spreading. These results warrant further investigation, including studies of the influence of pores in applications such as proton insulators and separation membranes based on 2D materials. The Pf-GO developed in the present study is expected to be used not only to enhance proton-impermeable property but also as a barrier thin-film material with high mechanical strength and compatibility with complex shapes.

EL03.16.10

Achieving Room-Temperature Thermal Rectification with a Suspended Asymmetric Graphene Channel Patterned with Electron Beam Lithography

Mohammad Razzakul Islam[1], Afsal Kareekunnan[1] and Mizuta Hiroshi[1,2]; [1]Japan Advanced Institute of Science and Technology, Japan; [2]University of Southampton, United Kingdom

Thermal rectification, the ability to control heat flow directionally, is a key phenomenon in the development of advanced thermal management systems. This study explores thermal rectification in graphene-based devices, focusing on the thermal transport properties of asymmetric suspended graphene nanostructures. Previously, sub-10 nm periodic nanopore phononic crystal structures were patterned on one-half of the suspended graphene ribbons using helium ion beam milling (HIBM). The results revealed significant thermal rectification ratios at temperatures below 250 K, with improvements linked to nanopore size and pitch adjustments [1]. However, the rectification effect diminished at room temperature, attributed to insufficient asymmetry-induced differences in heat flow between the forward and reverse directions.

To address this limitation and achieve thermal rectification at room temperature, we introduced a novel approach involving the fabrication of periodic parallel nanoribbons on one side of the suspended graphene ribbon using electron beam lithography (EBL) followed by reactive ion etching. This approach yielded a thermal rectification ratio of approximately 45% at room temperature. The success of EBL over HIBM lies in its ability to introduce structural irregularities and point defects near the nanoribbon edges, acting as phonon scattering centers and manipulating phonon dynamics to enhance thermal rectification [2].

While HIBM is advantageous for precise nanostructure patterning without introducing atomic defects, EBL's cost-effectiveness and capability to manipulate phonon transport dynamics make it the preferred technique for achieving room-temperature thermal rectification in graphene. This study advances the understanding of thermal rectification mechanisms in graphene and highlights the critical role of fabrication techniques in optimizing device performance.

Benchmark Investigation of SCC-DFTB Against Standard Dft to Model Electronic and Phononc Properties in Two-Dimensional MOFs for Thermoelectric Applications Masoumeh Mahmoudi Gahrouei and Laura de Sousa Oliveira; University of Wyoming, United States

Metal–organic frameworks (MOFs) are two or three-dimensional ultrahigh porosity materials that consist of metal nodes connected by organic linkers. MOFs have the potential to be used as thermoelectric materials. Thermoelectric materials use temperature differences to generate electrical energy. The main motivation for this project is to further our knowledge of thermoelectric properties in MOFs and find which available self-consistent-charge density functional tight-binding (SCC-DFTB) method can best predict (at least trends in) the electronic, phononic and therefore thermoelectric properties of MOFs at a lower computational cost than standard density functional theory (DFT). To this end, we compared SCC-DFTB/3ob and SCC-DFTB/mio, GFN1-xTB and GFN2-xTB against PBE and hybrid DFT (HSE06) for Zn3C6O6, Zn-NH-MOF, Ni3(HITP)2 and Cd3C6O6 2D MOFs for the monolayer and stacked AA, serrated and AB structures. In this talk, we present these findings as well as additional modeling insights gleaned from this work. The latter includes teasing apart the relative importance of correctly predicting band shape compared to band gap in estimating thermoelectric performance. Among the MOFs modeled, Zn3C6O6, Zn-NH-MOF and Cd3C6O6 are predicted to have a higher power factor than Ni3(HITP)2 (one of the highest performing synthesized thermoelectric MOFs), and that thermal transport is substantially lower for Zn-NH-MOF, leading to the highest ZT among the group.

Substitutional Fe Doping of WSe_2 Monolayers and Their Topological Hall Effect at Room-Temperature Mengqi Fang[1], Siwei Chen[1], Chunli Tang[2], Zitao Tang[1], Wencan Jin[2] and Eui-Hyeok Yang[1]; [1]Stevens Institute of Technology, United States; [2]Auburn University, United States

The topological Hall effect (THE) is a significant transport property in magnetic materials, arising from spin texture irregularities. It has been widely studied in various magnetic systems[1, 2]. For example, skymions have been observed in chiral magnets such as Mn3Sn [3] and Mn3Ga [4], as well as in SrRuO3/SrTiO3 [5]and Pt/Tm3Fe5O12[6] heterostructures. Skyrmions are unique spin textures with potential applications in high-speed, low-energy consumption logic and memory devices [7]. Their formation is typically driven by the Dzyaloshinskii-Moriya interaction (DMI), a chiral exchange interaction encouraged by broken inversion symmetry [8]. This study presents the temperature-dependent ferromagnetic order in chemical vapor deposition (CVD)-grown Fe-doped WSe2 (Fe:WSe2) monolayers. Vibrating Sample Magnetometer (VSM) measurements reveal distinct magnetic hysteresis, affirming the ferromagnetic nature of Fe:WSe2, with sustained magnetic properties up to room temperature. Furthermore, distinct from the intrinsic anomalous Hall effect (AHE) in a ferromagnet, we find the transverse Hall resistivity of Fe:WSe2 displays two additional dip/peak features, consistent with the contribution of THE. The topological Hall effect is attributed to the magnetic skyrmions that emerge from the DMI at the Fe:WSe2 and Pt interface. THE in Fe:WSe2 monolayers highlight the potential for manipulating magnetic textures.

The robustness of THE persistent up to room temperatures suggests the existence of stable induced skyrmion-like features. Complex spin textures from Fe doping, which are crucial for THE, are less affected by the thinness or interface irregularities that can weaken AHE. This research enhances our grasp of both ferromagnetism and the interplay between topological and anomalous Hall effects in 2D vdW magnetic systems, paving the way for creating scalable and integrated heterostructures into spintronic and non-volatile memory applications.

Oxygen-Edge Enriched Borophene for High-Performance Gas Sensor at Room-Temperature Juan Casanova-Chafer and Carla Bittencourt; Université de Mons, Belgium

The growing demand for real-time environmental monitoring, driven by the Internet of Things (IoT), underscores the need for gas sensors that combine affordability, durability, and low power consumption with high sensitivity. In this study, we present a novel and green synthesis of oxygen-edge enriched borophene, a 2D nanomaterial with a unique lattice structure of boron atoms, tailored for use in miniaturized gas sensors. The synthesis was achieved through a sustainable sonochemical method using benign solvents, ensuring both environmental compatibility and cost-effectiveness.
Extensive characterization of the borophene layers was conducted, with transmission electron microscopy (TEM) revealing a highly crystalline structure and an average lateral size of ~120 nm, offering an exceptional surface-area-to-volume ratio that enhances gas sensing performance. To further understand the role of oxygen in the sensing mechanism, we employed X-ray photoelectron spectroscopy (XPS) and photoluminescence (PL) to investigate the chemical bonds and oxidation states. Synchrotron-based X-ray absorption spectroscopy (XAS) provided crucial insights into the electronic properties and confirmed the pivotal contribution of oxygen in optimizing sensor functionality.
The borophene-based sensor demonstrated remarkable sensitivity to nitrogen dioxide at room temperature, effectively detecting concentrations of a few parts per billion (ppb). This performance represents a significant advancement in gas sensor technology, offering a practical and efficient solution for IoT applications in environmental monitoring.

EL03.16.14

Precision 2D Material Transfer Via a 3D Printed Curved Application Tool Carly Grossman[1,2]; [1]Harvard University, United States; [2]Tufts University, United States

Two-dimensional (2D) materials are composed of atomically thin layers of covalently bonded atoms. These layers, weakly held together by van der Waals forces, can be easily separated through mechanical exfoliation methods, enabling the isolated manipulation of each layer and the realization of new electronic properties. To fully harness the potential of 2D materials, precise and reliable transfer of these layers is essential. We employed a dry transfer technique which uses a stamp to precisely place the 2D material onto the substrate[1].

Several polymers are commonly used as stamps in dry transfer methods, including polydimethylsiloxane (PDMS), poly(methyl methacrylate) (PMMA)-coated PDMS, and the polypropylene carbonate (PPC)-coated PDMS that we use [2-4]. PPC, in particular, is advantageous because at room temperature, PPC exhibits strong adhesion, allowing for the secure pick-up of thin 2D materials, while at elevated temperatures, its adhesion significantly decreases, enabling a clean and controlled release of the material onto the target substrate [4].

We have developed a 3D printed device designed to improve the control over this process. The device holds the PPC-coated PDMS in a dome-shaped configuration, allowing for more controlled and gentle application of the 2D material onto the substrate. This is particularly effective when working with fragile substrates, such as thin (5-50 nm) membrane silicon nitride chips for transmission electron microscopy, since the design reduces the contact area of the PPC-coated PDMS with the substrate, minimizing unnecessary contact. This also prevents the transfer of unwanted flakes, making for a cleaner overall transfer process. By using this device, we can leverage the precise transfer application method to effectively and efficiently prepare samples of 2D materials.

Anisotropic Gold Nanorod Decorated n-$Mo_{0.5}W_{0.5}S_2$/p-Si Heterojunction Broadband Photodetector using Surface Plasmon Resonance Effect Deepak K. Sahu, Shreyasi Das and Samit K. Ray; IIT Kharagpur, India

Transition metal dichalcogenides (TMD) are van der Waals semiconducting two-dimensional materials with a layered structure. These consist of a transition metal (M) and a chalcogen (X) in chemical formula MX_2 and have an atomic-scale thickness of the order of a few nanometers. TMDs have an adjustable bandgap, significant excitonic binding energy, and exhibit strong spin-orbit coupling & light-matter interaction. However, binary TMDs contain deep-level defect states (DLDS), mainly contributed by sulfur vacancies that strongly limit their optoelectronic applications. Ternary TMD (MXY or $M_1M_2X_2$) is an expansion of these binary TMDs; it exhibits great thermodynamic stability with suppressed DLDS and larger bandgap tunability through simple composition manipulation. In this study, we synthesized a TMD alloy **$Mo_xW_{1-x}S_2$** by altering its composition using a low-cost hydrothermal process followed by liquid phase exfoliation to extract nanosheets and then investigated the structural, vibrational, and optical features that were dependent on the alloy composition. The origin of three characteristic Raman modes and the appearance of (002) peak in X-ray diffraction spectra are strong evidence of 2H-phase semiconducting alloy **$Mo_{0.5}W_{0.5}S_2$** formation. The bandgap values of such alloys were found in between the parent compounds (MoS_2 and WS_2). Gold nanorods (AuNR) of tunable aspect ratio were synthesized by a one-pot seedless wet chemical synthesis method. Further, we developed a vertical heterojunction 1D/2D/3D type

Au/AuNR/$Mo_{0.5}W_{0.5}S_2$-*p* Si/Al photodetector, which was found to exhibit a high rectification ratio of 535 and high light-to-dark switching ratio of the order of nearly ~2×10^3. The as-fabricated photodetector has a wider spectral response from 300 nm to 1100 nm, contributed by the absorbance of AuNR, **$Mo_{0.5}W_{0.5}S_2$**, and Si. Since the formation energy of sulfur vacancy surrounded by tungsten atom, i.e., $V_{S\text{-}W} < V_{S\text{-}Mo}$. Hence, the effect of $V_{S\text{-}W}$ dominates and acts as shallow-level traps in the forbidden gap of **$Mo_{0.5}W_{0.5}S_2$** and donates electrons to the conduction band (CB), thereby increasing the free carrier density, which ultimately participates in photocurrent generation. Hence, the photocurrent of the as-fabricated photodetector made up of **$Mo_{0.5}W_{0.5}S_2$** is higher than that of their binary counterparts. To further enhance the photodetection ability, gold nanorods were decorated on **$Mo_{0.5}W_{0.5}S_2$** nanosheets, and **AuNR-$Mo_{0.5}W_{0.5}S_2$ composite-*p* Si** visible to near-infrared photodetector was fabricated through metal nanoparticle-assisted surface plasmon resonance. Here, also the plasmons of AuNR decay through Landau damping and release hot electrons to the CB of alloy **$Mo_{0.5}W_{0.5}S_2$.** Moreover, the formation of built-in potential between 2D alloy and 3D Si is not only able to separate photogenerated charge carriers efficiently but also promising for facile integration with existing CMOS technology. Hence, the large-scale & cost-effective solution-processed synthesis method of alloys coupled with the synergistic effects of suppressed DLDS, Si heterojunction, and SPR effect together promise prospects for industrial-scale production of high-performance photodetectors for commercial use.

Twist-Angle Dependent Properties of Bilayer MoS_2 Agnieszka Kuc; Helmholtz-Zentrum Dresden-Rossendorf, Germany

Angeli and MacDonald reported a superlattice-imposed Dirac band in twisted bilayer molybdenum disulphide (tBL MoS_2) for small twist angles towards the R^M_h (parallel) stacking. Using a hierarchical set of theoretical methods, we show that the superlattices differ for twist angles with respect to metastable R^M_h (0°) and lowest-energy H^h_h (60°) configurations. When approaching R^M_h stacking, identical domains with opposite spatial orientation emerge. They form a honeycomb superlattice, yielding Dirac bands and a lateral spin texture distribution with opposite-spin-occupied K and K' valleys. Small twist angles towards the H^h_h configuration (60°) generate H^h_h and H^X_h stacking domains of different relative energies and, hence, different spatial extensions. This imposes a symmetry break in the moiré cell, which opens a gap between the two top-valence bands, which become flat already for relatively small moiré cells. The superlattices impose electronic superstructures resembling graphene and hexagonal boron nitride into trivial semiconductor MoS_2.
Changes in the twist angle not only affect electronic properties of the material, but also affect the interactions with intercalated species. Here, we show that the hydrogen atom diffusion coefficient strongly changes when twist angle changes from H^h_h to R^M_h stackings, up to one order of magnitude. This can be utilized when designing materials for directional transport of hydrogen or novel fuel cells.

Two-Dimensional Materials Engineering Using Twist-Control Emanuel Tutuc; The University of Texas at Austin, United States

Recent years have witnessed the emergence of a new class of moiré materials, where energy bands are designed and experimentally realized by controlling the relative twist angle of consituent layers. We review here experimental techniques used in realizing moiré materials with exmaples from graphene and transistion metal dichalcogenide heterostructures.

9:30 AM EL03.17.03

Probing van der Waals Potentials in Twisted hBN Moiré Superlattices Stefano Chiodini[1], James Kerfoot[2], Giacomo Venturi[1], Sandro Mignuzzi[2], Eugene Alexeev[2], Barbara Rosa[2], Seth Ariel Tongay[3], Takashi Taniguchi[4], Kenji Watanabe[4], Andrea C. Ferrari[2] and Antonio Ambrosio[1]; [1]Fondazione Istituto Italiano di Tecnologia, Italy; [2]University of Cambridge, United Kingdom; [3]Arizona State University, United States; [4]National Institute for Materials Science, Japan

When a twist angle is applied between two layered materials (LMs), the moiré superlattice spatially modulates the registry of the layers and the sample functional properties. Several works have recently explored the optical, [1] electric, [2] and electro-mechanical [3] moiré-dependent properties of such twisted LMs, but no direct visualization and quantification of van der Waals (vdW) interactions has been presented, so far. Here, we show the application of tapping mode AFM phase imaging to probe the stacking-dependent vdW potential in twisted hBN moiré superlattices. [4] This technique is non-invasive, compatible with every environment and no sample perturbation is required. Additionally, we will discuss some recent result on the (electro-) mechanical properties of t-hBN moiré patterns. [5]

Moiré-Induced Dirac Cones Replicas and Minigaps Opening in Graphene/hBN Superlattices Olivia Pulci[1], Simone Brozzesi[1], Maurizia Palummo[1] and Alberto Zobelli[2]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]Université Paris-Saclay, CNRS, France

Moiré pattern is a novel and extensive structure that emerges from the interference of multiple periodic templates. In condensed-matter physics, moiré patterns, also known as moiré superlattices, can be created by stacking two or more two-dimensional (2D) layered materials with a small twist angle and/or a slight lattice mismatch. The presence of moiré pattern results in the formation of a long range moiré potential, which interacts with the electrons of the system and affects the dispersion of the energy levels. In recent years, moiré superlattices have garnered significant attention due to their remarkable manifestation of previously unexplored phenomena and unique functionalities [1], like strongly correlated phases [2] and subsequent observation of superconductivity and topological states [3], and exotic excitonic states [4] arising from the interaction between excitons and moiré potential. The aim of this study is to demonstrate that the existence of a moiré pattern in a graphene/hBN heterostructure has a substantial influence on the energy levels dispersion of the system. In particular, we show that this influence goes beyond the coupling between the planes and the rehybridization of levels that can be expected in van der Waals heterostructures, but significantly affects the energy levels dispersion of graphene within an energy range inside the hBN gap, where only contributions from C atoms are expected to be present. By means of DFT calculation based on a localized basis set approach, this study demonstrates that the presence of the long range moiré potential results in the formation of six replicas [5] of the graphene Dirac cones around the K-K’ point of the 1BZ of graphene, which are separated by a reciprocal space superlattice vector G m from the main cone. The intersection between the main cone and its replicas result in the opening of minigaps in the energy levels of graphene, without the direct interplay of the interaction with the hBN states. The relative positions of these minigaps is dependent on the moiré reconstruction of the system and can be tailored by tuning the rotation angle between the layers.

This confirms how incredibly fascinating these systems are, not only for the physics that can be observed but also for their potential in the field of engineering and applications in next-generation optical devices.

Thermal Transport in Metal-Organic Frameworks—A Molecular Dynamics Approach Riccardo Dettori, Claudio Melis, Francesco Siddi and Luciano Colombo; Università degli Studi di Cagliari, Italy

Thermal transport properties in metal-organic frameworks (MOFs) are critical for their applications in areas such as gas storage, separation, and catalysis. In this work, we adopt a combination of classical molecular dynamics (MD) simulations, lattice dynamics calculations, and ab initio simulations to investigate thermal transport in MOFs. We use Density Functional Theory (DFT) and lattice dynamics calculations to characterize the material from first principles. Then, we adopt the recently developed Chebyshev Interaction Model for Efficient Simulation (ChIMES)[1,2], a linearly parametrized machine-learned force field that, leveraging the Chebyshev polynomials of the first kind, allows us to obtain a complete description of the total energy and the forces in the system starting from ab initio calculations. This approach gives the possibility of obtaining an interaction model for model potential MD simulations using a relatively small set of data compared to other machine learning-based approaches. We perform equilibrium and non-equilibrium MD simulations on extended structures, providing a comprehensive analysis of thermal conductivity in MOFs, and highlighting the influence of structural characteristics, defect presence, and material composition. Our findings demonstrate the potential of ChIMES in advancing the simulation capabilities for complex materials like MOFs and offer valuable insights for the design of MOFs with tailored thermal properties.

Tilt-Engineered Molecular-Scale Selector for Enhanced Learning in Artificial Neural Networks Jung Sun Eo[1], Jaeho Shin[2], Takkyeong Jeon[1], Jigon Jang[3] and Gunuk Wang[1]; [1]Korea University, Korea (the Republic of); [2]Rice University, United States; [3]Kwangwoon University, Korea (the Republic of)

There have been studies of understanding and controlling the charge transport through molecular junction wince it gives fundamental grounds that helps to gain a novel idea to realize numerous potential molecular functional devices. [1,2] There are some key factors considered in molecular charge transport, such as molecular barrier which is directly related to molecular orbital levels, coupling strength, asymmetric factor, and molecular configuration and conformation. Much research has been reported to obtain deeper insights of such key factors under certain controlled conductions with the effect of the external stimuli applied on the molecular junction such as light irradiation [3], electrochemical gating [4], electrical field [5], and mechanical stress such by tip loading force [6]. Molecular heterojunction with two-dimensional (2D) semiconductor provides various key factors for the charge transport through the heterojunction; however, the effect of molecular tilt configuration on the molecular heterojunction have never been studied. Here, we present the effect of molecular tilt configuration on the molecule/mono-layer (1_L) 2D semiconductor heterojunction by tip loading force with conductive atomic force microscopy (C-AFM) technique. With various tip loading force (1-30 nN), the molecular tilt configuration affects differently for the three different interfaces in Au/molecule/1_L-2D semiconductor/Au heterojunction that the transition voltage spectroscopy (TVS), which is a conventional tool to analyze charge transport through molecular junction, rectification ratio (*RR*), and pattern recognition accuracy is simulated with MNIST data images. Molecule/2D semiconductor heterojunction system has been reported as molecular diode (with *RR*) and rectifying selector and it is a novel platform owning so much various potential in, that understanding the charge transport by the effect of external stress on the heterojunction will help developing such future molecular scale selector implementation for the crossbar array architecture.

11:00 AM EL03.18.03
Fabrication of Chemiresistive Gas Sensors from Triphenylene-Based MOFs for Greenhouse Gas Monitoring
Ignasi Fort Grandas[1,1,1], Yuzelfy Mendoza Gamero[1,1,1], Mauricio Moreno Sereno[1,1], Daniel Sainz[1,1], Paolo Pellegrino[1,1], Anton Vidal Ferran[1,1,2] and Albert Romano-Rodriguez[1,1]; [1]Universitat de Barcelona, Spain; [2]Catalan Institution for Research and Advanced Studies, Spain

Current monitoring systems of Greenhouse Gases (GHGs) are bulky and energetically expensive, thus being restricted to a few fixed locations. However, the need arises to develop gas sensing devices that could be placed in large numbers and many locations. For instance, by introducing gas sensors in autonomous data collection and transmission systems, data on specific target gas levels would be acquired, allowing the development of more precise climate change models via the Internet of things (IoT). To fulfil that purpose, the sensing devices must be designed to fit the following criteria: miniaturized, cost-effective, energy efficient and selective. Within the wide arrange of sensor types, room temperature chemiresistive devices stand out due to their low-energy consumption and miniaturized characteristics.

Metal-organic Frameworks (MOFs) show great promise as active materials for gas sensing devices. Their

nanostructured, high surface area and high-porosity nature make them a fitting choice for gas related applications, and a subfamily of the MOFs present room-temperature conductivity values ideal for chemiresistive studies. There are various types of conductive MOFs depending on their conduction mechanisms. In this work, we focus on 2D MOFs with extended conjugation and though-plane conduction mechanisms. Our work ranges from triphenylene derivative MOFs, such as 2,3,6,7,10,11-hexahydroxytriphenylene (HHTP) and 2,3,6,7,10,11-hexaaminotriphenylene (HITP) MOFs, to new MOFs based on highly-conjugated ligands containing N heterocycles and imine groups. We synthesized highly crystalline layers of the beforementioned 2D MOFs, aiming to improve their conductive and gas sensing properties and also carrying out a comprehensive study of their crystallographic structures to elucidate the conduction and gas sensing mechanisms. The conductive MOFs are deposited onto interdigitated electrodes (IDE) to fabricate the gas sensing devices. We compare IDEs of different designs, as well as the ligand and metal of choice of each MOF that yield the most suitable chemiresistive responses for the GHGs sensing devices.

In this presentation, we will present and discuss the findings regarding the full characterization of the crystallinity and morphology of the 2D MOFs and the deposited layers, bringing new insights on the underlying conduction and gas sensing mechanisms. We will also present the gas sensing performance of these chemiresistive devices towards the most relevant GHG, namely CO_2, CH_4 and N_2O.

11:15 AM EL03.18.04

Charge Transfer Exciton at Hybrid Organic-2d Inorganic Heterointerface Yuchen Kan[1], Parag Deotare[1,2] and Zhengyang Lyu[2]; [1]University of Michigan, United States; [2]University of Michigan–Ann Arbor, United States

The low dimensionality and van der Waals nature of organics and transition metal dichalcogenides (TMDs), provides a unique opportunity to combine two disparate excitonic systems without elemental diffusion. Such hybrid interfaces can be engineered to demonstrate photophysical properties that do not normally coexist in the individual material systems.

In this work, we use advanced optical spectroscopy to investigate hybrid type-II heterointerface formed between monolayer tungsten disulfide (WS_2) and Tris(4-(5-phenylthiophen-2-yl)phenyl)amine (TPTPA) dispersed in a crystalline rubrene matrix. We study the hybrid charge transfer excitons (HCTEs) formed between TPTPA and WS_2 and find that the TPTPA molecules, embedded in orthorhombic rubrene crystalline structure are aligned with specific orientations. Furthermore, the dipole orientation of TPTPA molecules rotates with the rubrene single crystal domain. Such orientation control enables us to systematically study the HCTE dynamics and we find that the formation efficiency is dependent on the twist angle between the monolayer and TPTPA orientation. Finally, circular dichroism measurements reveal that HCTEs preserve the valley (K an K') pseudospin information of the WS_2 monolayer in spite of the charge transfer process at the interface. The results provide new insights into the charge transfer dynamics at hybrid interfaces that can directly influence future applications in energy conversion, sensing and on-chip data communication and processsing.

Van der Waals Heterostructures and Superlattices—Boundless Opportunities at Bondless Boundaries
Xiangfeng Duan; University of California, Los Angeles, United States

The rise of two-dimensional atomic crystals (2DACs) and van der Waals heterostructures (vdWHs) has catalyzed a bonding-free strategy for constructing heterostructures beyond the limits of traditional epitaxial approaches. In this talk, I will start with a brief overview of the early exploration of van der Waals (vdW) interactions for the heterogeneous integration of highly disparate materials with pristine electronic interfaces. I will then focus on our recent efforts in synthesizing and investigating a rich family of vdW superlattices (vdWSLs) consisting of alternating crystalline atomic layers and self-assembled molecular interlayers of customizable chemical compositions and structural motifs. I discuss how we may use the molecular interlayers to tailor the electronic and optical properties of various 2DACs, and particularly highlight a unique class of chiral molecular intercalation superlattices exhibiting robust chiral-induced spin selectivity and elusive chiral superconductivity. With versatile molecular design and modular assembly strategies, 2D-molecular vdWSLs offer unprecedented flexibility for weaving distinct building constituents into artificial solids with customizable chemical modulation, structural topology, and artificial potential landscapes in 3D space. This opens boundless opportunities to tailor the electronic, optical, and quantum properties, thus defining a rich material platform for diverse emerging technologies.

2:00 PM EL03.19.02
Scaling Up the 2D Epitaxy from 2-Inch to 300 mm Sapphire Substrates Apostolia Manasi[1], Sergej Pasko[1], Henry Medina Silva[2], Emre Yengel[1], Jan Mischke[1], Simonas Krotkus[1], Pierre Morin[2], Alexander Henning[1] and Salim El Kazzi[1]; [1]Aixtron, Germany; [2]imec, Belgium

Molybdenum Disuflide (MoS_2) and Tungsten Diselenide (WSe_2) are respectively the most promising n-type and p-type two dimensional (2D) semiconductors considered for future transistor scaling. Much of the research is hence ongoing to produce single crystal 2D films on large area wafers. The most common approach is the 2D epitaxial growth on sapphire substrates which are commercially available up to 200 and 300 mm wafer size. Sapphire are however known to exhibit an inhomogeous surface if care is not taken on their miscut orientation but also their surface preparation [1, 2]. One can thus deduce that his inhomegenity becomes more important for the 200/300 mm sapphire wafers compared to the 2 inch ones.
In this vein, we investigate here the MOCVD growth of MoS_2 and WSe_2 on both 2 inch and 200/300 mm sapphire substrates. We start by sheding the light on the challenges that are faced when 200/300 mm substartes are used and the difference with their 2 inch counterpart. We then focus on the impact of surface preparation and growth conditions on the quality of grown MoS_2 and WSe_2 films. We explain how the growth learning on 2 inch allows to upscale the growth on 200/300 mm substrates and how 300 single crystal 2D film can be obtained.

Design Rule of Multi-Dimensional Ternary Materials Jong-Young Kim[1], Wooyoung Shim[2] and Sung Kyoon Ko[1,2]; [1]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Earlier, many physicists and chemists systematically described the crystal structure in chemical spaces of binary system using only information such as chemical elements and stoichiometry. Still, researchers use heuristic limits, chemical intuition, or rules of thumb to estimate the likelihood to estimate probable structure in more general and complex system such as ternary chemical space. In this work, for the realization of new *unknown* III-V(III: Al,In,Ga; V:P,As,Sb)-based ternary compounds, we attempted to derive additional insights from computational screening by examining the similarities between 1) high-throughput(HT) screening and 2) classical frameworks for crystal structure classification. For the HT screening, we have predicted the structural framework (cation-eutaxy) of *unknown* ternary *A-B-X* (*A*=alkaline, alkaline earth, *B*=transition metal, main group, *X*=O,S,Se,Te,N,P,As,Sb,Bi) compounds via algorithmic methodology using 'structure prototypes' consisting of metadata such as space group, stoichiometry, and # of sites. As a comparison, we propose a generalized description of the dimensionality of ternary *A-B-X* by competition among metallic, covalent, and ionic character of *A-X*/*B-X* bonding. The general description is an extension of van Arkel-Ketelaar diagram, describing ionic/covalent/metallic bonding characteristics of binary *AB* compounds using average configuration energy(CE) and difference in CE of *A*/*B* constituents, to ternary composition. Interestingly, 575 *unknown* suggested compounds acquired from our HT screening are found to be well-consistent with the classification of known cation-eutaxy compounds by our extended van Arkel-Ketelaar diagram. This result evidences that our algorithmic classification (HT screening) provides an effective descriptor for the dimension of the *B-X* network in *A-B-X* ternary chemical space. Our approach guides the discovery of *unknown* van der Waals materials with unique properties. We also demonstrated memristive devices for gate-tunable synaptic and logic functions using van der Waals crystals of prospective III-V semiconductors,[1] which is promising for neuromorphic and in-memory computing.

Self-Flux Synthesis of Transition Metal Dichalcogenides—Impact of Thermal Cycling and Refinement Procedures on Point Defect Density and Crystal Size

Luke Holtzman[1], Kaikui Xu[2], Katherine Lee[1], Madisen Holbrook[1], Matthew R. Rosenberger[2], James Hone[1] and Katayun Barmak[1]; [1]Columbia University, United States; [2]University of Notre Dame, United States

Two-dimensional transition metal dichalcogenides (TMDs) have generated great interest due to their unique optoelectronic properties and applications in moiré physics through complex heterostructures. Yet, many of these desired properties are limited by the presence of point defects in TMDs, highlighting the need for TMDs as close to crystallographic perfection as possible. To date, TMDs synthesized with a two-step self-flux method have been shown to contain point defect densities more than an order of magnitude lower than those made by any other synthesis method, leading to maximized Hall carrier mobilities and photoluminescent trion quantum yields [1-3]. However, a single thermal cycle of the two-step flux synthesis takes over 1 month due to long dwells at elevated temperatures and slow cooling rates, restricting high throughput synthesis of large TMD bulk crystals using the two-step flux method. Recent work has shown increase in size of flux $MoSe_2$ crystals of >30% by using multiple thermal cycles, raising exfoliation and fabrication yields during electronic device and heterostructure fabrication.

In this work, we investigate the crystal growth mechanism and point defect density evolution of WSe_2 and $MoSe_2$ during a flux thermal cycle using optical imaging and conductive atomic force microscopy. Ampules containing WSe_2 and $MoSe_2$ are quenched at varying points during the thermal cycle to determine the effects of dwell length and cooling temperature on final crystal size and point defect density. We determine high-quality TMD crystals are formed with only a multi-day high-temperature dwell and rapid quench in water, decreasing total synthesis time by 75% and enabling the use of quick, additional thermal cycles. The fully-formed crystals are then refined by putting them back through a thermal cycle with fresh selenium precursor at an elevated chalcogen-to-TMD molar ratio, and the effects on point defect density and crystal size are investigated with each additional cycle. The refining process' influence on electronic and optoelectronic properties are explored through transport and photoluminescent studies. Use of these growth optimizations greatly decrease the total time required for low point-defect flux TMDs with diameters approaching a centimeter, which increase exfoliation yield and monolayer size, enabling increased applications in transistor arrays or terahertz spectroscopy studies.

Machine-Learning-Assisted Cooling Control for MoS_2 Chemical Vapor Deposition Xingjian Hu, Dhamelyz Silva Quinones, Chi Jiang, Alexander Hool and Haozhe Wang; Duke University, United States

Chemical vapor deposition (CVD) is a prominent technique for synthesizing high-quality, large-area monolayer MoS_2. Cooling is a crucial post-growth stage in most MoS_2 CVD systems. Despite its significant influence on the material's crystallinity, morphology, and properties, it has garnered limited attention in CVD research.
In our study, we explored the effects of cooling on CVD MoS_2 by incorporating cooling processes both during and after growth. We employed machine-learning-assisted feature identification to rapidly distinguish MoS_2 flakes with varying layers and morphologies in optical microscopy. Additionally, we utilized RAMAN and photoluminescence (PL) spectroscopy to identify layers and crystallinity, scanning electron microscopy (SEM) to examine surface morphology and structures with high solutions, and atomic force microscopy (AFM) to measure the thickness of MoS_2 flakes. Our results demonstrated that we successfully obtained monolayer MoS_2 flakes with diverse hierarchical structures by adjusting the cooling rates. This research endeavors to provide more comprehensive insights into the growth mechanisms of CVD MoS_2.

3:30 PM EL03.20.01

Impact of CVD Growth Promoters in the Band Alignment of Single Phase 2D MoS_2 and $MoTe_2$ Layers on SiO_2/Si Alessio Lamperti[1], Pinaka Pani Tummala[1,2], Alessandro Cataldo[1], Sara Ghomi[1], Christian Martella[1], Alessandro Molle[1] and Valeri Afanas'ev[2,3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]KU Leuven, Belgium; [3]imec, Belgium

In view of an integration of 2-dimensional (2D) transition metal dichalcogenides (TMDs) in microelectronics processes and devices, growth methodologies and strategies for a direct integration on top of Si wafers are highly demanding and needed. Among the growth methods, chemical vapor deposition (CVD) based approaches are considered the most promising way to satisfy the requirement for the controlled, uniform growth of 2D TMDs over large areas at the wafer scale. To target such conditions, the use of organic or inorganic molecules, known as growth promoters, has been successfully implemented in several CVD growth processes; the use of perylenes, such as PTAS, or inorganic salts, such as KCl or NaOH, spread in solid form or mixed and delivered in liquid solutions inside the CVD reactor together with the Mo and S precursors has been attained and reported [1, 2, 3, 4]. Despite the wide consideration for the integration of TMDs in microelectronics platforms, minimal consideration has been given to address the band alignment of such 2D layers on SiO_2/Si substrates, the natural choice to be considered for the direct integration of 2D TMDs in CMOS fabrication process. Motivated by this gap, in this study, we studied the band alignment of two TMDs, namely, MoS_2, probably the TMD at the best maturity stage in terms of growth control over large areas, and 1T' or 2H-phase $MoTe_2$, possibly the most promising for resistive switching, neuromorphic and optoelectronics applications [5]. In particular, our study focuses on the impact of the growth promoters on the band alignment at the interface between the TMDs layers and the substrate.
Here, we make use of internal photoemission (IPE) and x-ray photoelectron (XPS) spectroscopies to measure and calculate the band alignment. For MoS_2, we found values spanning from 4.2 eV, when using PTAS or NaOH, down to 3.9 eV for KCl to compare with 3.6 eV in MoS_2 with no promoters [6]; for CVD-grown $MoTe_2$, we extracted a 3.9 eV value for 1T'-phase moving to 4.2 eV for 2H-$MoTe_2$, with a shift of 0.4 eV consistent with the value observed in single phase exfoliated layers.

Defect Engineering of Ultra-large MoS_2 Monolayers by Electron Beam Lithography Toward the Hydrogen Evolution Reaction Ana B. de Araujo[1], Cláudia de Lourenço[1], Leonardo H. Hasimoto[1,2], Alisson R. Cadore[1], Edson R. Leite[1] and Murilo Santhiago[1,2]; [1]Brazilian Nanotechnology National Laboratory, Brazil; [2]UFABC, Brazil

The search for clean, renewable, and environmentally friendly hydrogen sources has made water an excellent feedstock candidate to produce hydrogen. Green H_2 production from water occurs by a system known as water splitting, however, a major challenge for this process is its unfavorable energy demand in bare electrodes, requiring a catalyst. Among the most studied materials in recent years, transition metal dichalcogenides (TMDs) stand out for their high performance in the hydrogen evolution reaction (HER). Among the TMDs, MoS_2 has shown promising catalytic properties with excellent stability and non-toxicity [1]. The catalytic sites of MoS_2 monolayers towards hydrogen evolution are well known to be vacancies and edge-like defects. However, it is still very challenging to control the position, size, and defective areas on the basal plane of MoS_2 monolayers by most of the defect-engineering routes [2]. In this work, the fabrication of defective arrays with resolution of approximately 250 nm on high aspect ratio MoS_2 monolayers using nanolithography is reported for the first time. By adjusting the size and distance of the patterns, it is possible to establish a quantitative relationship between the number of defects, i.e. edges created in the basal plane, and their electrocatalytic performance. The electrocatalytic activity of the arrays toward the hydrogen evolution reaction (HER) was measured by fabricating microelectrodes using a recently reported method that preserves the catalytic sites [2,3]. This catalyst showed outstanding activity, with an onset overpotential of 437 mV. Characterization analysis by Raman spectroscopy, AFM, KPFM, SEM and EDS revealed that the exposed regions underwent effective corrosion, resulting in ultra-large defect arrays on the basal plane.

Optical and Magnetic Properties of Fe-Infused 2D-MoS_2 Yujia Wang[1,1], Nurul Azam[1,1], Jeff Rable[1,1], Syed Shahed[1,1], Zachariah B. Hennighausen[2], Jing Kong[2], John P. Ferrier[1,1], Matthew Matzelle[1,1], Bernardo Barbiellini[3,1,1], Barun Ghosh[1,1], Arun Bansil[1,1] and Swastik Kar[1,1,1]; [1]Northeastern University, United States; [2]Massachusetts Institute of Technology, United States; [3]LUT University, Finland

Doping of two-dimensional (2D) transition metal dichalcogenides (TMDs) with magnetic impurities has generated significant interest for their potential applications as room temperature dilute magnetic semiconductors. In particular, iron-doped 2D-MoS_2 is interesting, as it has been reported to demonstrate diamagnetic, ferromagnetic, and paramagnetic behaviors. A key focus has been to understand whether their observed properties originate purely from the infused Fe atoms, or from defect/defect complexes in these systems. We present our results from simultaneous investigations of the structural, optical, and magnetic properties of mono- and multilayer 2D-Fe@MoS_2. Samples were synthesized by a chemical vapor deposition (CVD) system that allows controlled introduction of Fe atoms into the 2D structure of MoS_2. Aberration corrected high resolution scanning transmission electron microscopy (STEM), high-angle annular dark-field imaging (HAADF), and atomic force microscopy (AFM) were used to characterize the structure of these 2D materials from atoms-scale to nano- and micro-scales. Confocal Raman and photoluminescence (PL) mapping were employed to investigate the impact of Fe-infusion on the in-plane and out-of-plane vibrational modes, and the dynamics of the A-exciton and A-trion populations and their binding energies. Magnetic properties of these materials were investigated using magnetic force microscopy (MFM) and scanning nitrogen-vacancy center microscopy (SNVM). These experimental results suggest that while Fe infusion in our system led to sizable modification in the Raman and PL behavior, and MFM measurements appear to show phase-sensitive responses, no clear indication of ferromagnetic ordering could be found. We will discuss the nature of magnetism in Fe-doped MoS_2 based on our experimental observations and parallel theoretical modeling.

4:15 PM EL03.20.04
Very-Thin Dopant Layer on MoS_2 Monolayer to Get Degeneracy/Heavily Doped Situation Puneet Jain, Shotaro Yotsuya, Kosuke Nagashio and Daisuke Kiriya; The University of Tokyo, Japan

Transition metal dichalcogenides (TMDCs) are an emerging class of materials with versatile and unique electrical, optical, physical, chemical, and mechanical properties. They have a general formula of MX_2, where M is a transition metal atom (like Mo, W, etc.), and X is a chalcogen atom (like S, Se, or Te). Examples of TMDCs, are molybdenum disulfide (MoS_2), molybdenum diselenide ($MoSe_2$), tungsten disulfide (WS_2), and tungsten diselenide (WSe_2), etc. Because of its robustness like high mobility, excellent gate controllability, high on/off current ratio, ultra-low stand-by current, and good stability, etc., MoS_2 is the widely studied material in the family of TMDCs. MoS_2 monolayer behaves as a semiconductor with a direct electronic bandgap of 2.4 eV. It has potential applications in nanoelectronics, optoelectronics, and flexible electronics, etc.

Doping is a very significant approach to manipulate electronic and photonic characteristics of various 2D materials for advanced applications in neuromorphic hardware, logical circuits, and optoelectronic devices, because by doping, we can improve the device performance by controlling the carrier concentration. Moreover, in electronic devices, the doping technique can improve the on-state current by reducing the effective barrier and contact resistance height at the metal/TMD junction, as contact resistance is a major issue in 2D materials.

In the present work, at first, we fabricated a thin-film transistor (TFT) with MoS_2 ML as channel (with channel length of 5 μm), and Bi as source/drain. This TFT was then doped with an asymmetrical molecule (this molecule has a lone pair of electrons, which helps to dope MoS_2 ML. Doping has been done only in the channel region). It has been found that after doping, degeneracy is obtained. The doping was also confirmed from Raman and PL spectroscopy, which clearly shows red-shift in A_{1g} and A peaks, respectively.

The doping was then extended from a single device to an array of devices, where all the devices have MoS_2 ML as channel, and Bi as source/drain. This array was fabricated using photolithography, with channel width and length varied from 5 to 50 μm. The array was then again doped with the same asymmetrical molecule (discussed above) to understand the doping mechanism, i.e., how doping is done, when the channel length and width changes. Is the doping same or not, in all the devices. It has been found that for the array, doping is not uniform. In other words, doping depends more on channel width as compared to channel length, i.e., doping is more dominant on the devices that have 50 μm channel width and less dominant on the devices with 5 μm channel width. This may be due to the SF_6 etching, which is used to etch the ML. Apart from SF_6 etching, substrate wettability may also be a reason. This is also confirmed from the AFM studies, that doping on 50 μm channel width is more like a thin-film, while on 5 μm channel width is more like particle type.

Details will be discussed in the meeting.

Minimizing Defects in Wafer-Scale WSe_2 Monolayers Lin-Yun Huang, Haoming Liu, Li Lain-Jong and Yi Wan; The University of Hong Kong, China

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have attracted great attention as they prospect of continuing Moore's law. Recent advancements in wafer-scale single crystal 2D TMD growth and device technologies have demonstrated their scalable potential and excellent electronic performance, approaching the projection made by the International Roadmap for Devices and Systems (IRDS). However, while notable progress has been achieved with n-type characteristics in MoS_2, the performance of p-type WSe_2 remains suboptimal, primarily due to the lack of efficient bottom-up synthesis methods for high-quality WSe_2 monolayers.
To address this gap, we have developed a hydroxide vapor phase deposition (OHVPD) approach for synthesizing high-quality p-type monolayer WSe_2. By introducing moisture into the epitaxial process, tungsten hydroxide acts as an immediate that provides a lower sulfurization energy pathway, facilitating the growth of WSe_2 with significantly reduced point defect density. Combining this with C-plane sapphire substrates having single exposed

surfaces, we have achieved 2-inch single-crystal WSe_2 with low defect density.
Moreover, our systematic study of the effect of the H_2 to H_2O ratio on the quality of WSe_2 provides insight into the fundamental mechanisms at play. Scanning tunneling microscopy (STM) characterization reveals that OHVPD-WSe_2 exhibits a total defect density of 7.8×10^{11} cm^{-2}, an order of magnitude lower than that of conventionally grown CVD-WSe_2. Optical characterizations, including cryogenic photoluminescence (PL), show negligible defect emission, confirming its intrinsic properties. Field-effect transistor (FET) devices based on our OHVPD-WSe2 display typical p-type characteristics, with a peak mobility of 110 $cm^2V^{-1}s^{-1}$ and an average mobility of 87 $cm^2V^{-1}s^{-1}$.

Monday Morning, December 2, 2024
Sheraton, Second Floor, Republic B

10:30 AM *EL04.01.01
Materials Optimization and Physics Discovery via Automated Scanning Probe Microscopy of Combinatorial Libraries Sergei V. Kalinin[1,2] and Richard Liu[1]; [1]The University of Tennessee, Knoxville, United States; [2]Pacific Northwest National Laboratory, United States

For over three decades, scanning probe microscopy (SPM) has been a pivotal method for exploring material structures and functionalities at nanometer and often atomic scales in various environments, including ambient, liquid, and vacuum. Historically, SPM applications have predominantly been downstream, with images serving as illustrations or sources of fundamental physical knowledge. However, the rapidly growing developments in rapid materials synthesis via self-driving labs and established applications such as combinatorial spread libraries are poised to change this paradigm. Rapid synthesis demands matching capabilities to probe materials on small scales and with speed, characteristics inherent to SPM. However, many SPM methods are not intrinsically quantitative, and all require constant monitoring and optimization by human operator.

In this presentation, I will illustrate the development of fully automated SPMs for probing combinatorial libraries of functional materials including photovoltage in hybrid perovskites, ferroelectricity in classical ferroelectrics, and topography in multicomponent alloys. I discuss the optimization of the full SPM discovery cycle, and introduce the machine learning methods necessary for the exploration of ternary and higher-dimensional systems. These include automated optimization of classical topographic imaging, Kelvin Probe Microscopy, and Piezoresponse Force Microscopy. I will further illustrate existing ML strategies for automated exploration of combinatorial libraries via automated large stage and probing structure-property relationships within the image. The corresponding software libraries are fully open. Finally, I will overview the coming challenges in the field. Overall, SPM will play a crucial role in closing the loop from materials prediction and synthesis to characterization.

11:00 AM EL04.01.02

Rapid and Noise-Resilient Mapping of Photogenerated Carrier Lifetime in Halide Perovskite Thin Films

Guillaume Vidon[1], Gabriele Scrivanti[2], Nao Harada[3], Etienne Soret[1], Emilie Chouzenoux[2], Jean-Christoph Pesquet[2], Jean-François Guillemoles[1] and Stefania Cacovich[1]; [1]Centre National de la Recherche Scientifique, France; [2]Université Paris-Saclay, France; [3]Institut Photovoltaïque d'Île-de-France, France

Halide perovskite materials hold significant potential for solar energy and optoelectronics. However, to enhance their efficiency and stability, it is crucial to address challenges related to lateral inhomogeneity. Photoluminescence imaging techniques are commonly used to measure their opto-electronic and transport properties[1], but achieving high precision requires longer acquisition times. Extended light exposure, due to the high reactivity of perovskites, can significantly alter these layers, compromising the quality of the data.

We propose a method to extract high-quality lifetime images from quickly acquired, noisy time-resolved photoluminescence images[2]. Our approach employs concepts from constrained reconstruction, incorporating the Huber loss function and a specific form of Total Variation Regularisation. This method effectively mitigates local signal-to-noise ratio (SNR) limitations, allowing access to greater detail and features in the results. Through simulations and experiments, we show that our method outperforms traditional pointwise techniques. Additionally, the analysis can be extended to determine the surface recombination rate. The determination of these key parameters can offer valuable insights into the advancement and optimization of halide perovskite materials. Indeed, the mitigation of bulk and interfacial recombination stands as a central focus within the solar cell community. Finally, we identify optimal acceleration and optimization parameters tailored for decay time imaging of perovskite materials, offering new insights for accelerated experiments crucial in degradation process characterization. Importantly, this methodology has broader applications: it can be extended to other beam-sensitive materials, various imaging characterisation techniques, and more complex physical models for time-resolved decays.

11:15 AM EL04.01.03
The Quest for Interoperable Perovskite Solar Cell Data—Challenges and Opportunities T. Jesper Jacobsson; Linköping University, Sweden

The recent development of halide perovskite solar cells has been impressive, both in terms of increased performance and in the number of published papers. The sheer number of papers does, however, make it increasingly difficult to get a good overview of the field. It is also difficult to truly take advantage of all device data generated when it is inconsistently formatted and scattered over thousands of papers. During the last few years, I have been working with different strategies for how we can collect past, precent, and future perovskite data in a way that makes it useful beyond its appearance in initial publications. Among those efforts we find the Perovskite Database, which contains formatted device data for over 45000 perovskite devices, and a system for unambiguous communication of perovskite compositions. In this talk, I will demonstrate those initiatives as well as present a few stories showcasing insights enabled by this type of interoperable data. Specific examples will include a quantitative discussion about a discrepancy between short circuit currents extracted from JV and EQE measurements, a reflection about herd behavior in experimental design, and an analysis about to which extent a high device efficiency is needed to write a paper that attracts lots of citations.

11:30 AM EL04.01.04
Strain Regulation Attenuates Natural Operation Decay of Perovskite Solar Cells Tiankai Zhang[1,2] and Feng Gao[1]; [1]Linköping University, Sweden; [2]Southeast University, China

Perovskite solar cells (pero-SCs) have undergone a rapid development in the last decade. However, there is still a lack of systematic studies to investigate whether the empirical rules used in silicon solar cells working lifetime assessment can be applied to pero-SCs. It is commonly believed that pero-SCs show enhanced stability under day/night cycling due to the reported self-healing effect in the dark. In our research, it is discovered that the degradation of highly efficient $FAPbI_3$ pero-SCs is in fact much faster under natural day/night cycling mode, questioning the widely accepted approach to estimate the pero-SCs' operational lifetime based on continuous mode testing. We reveal the key factor to be the lattice strain during the operation, an effect that gradually relaxes under the continuous illumination mode but cycles synchronously under the cycling mode. The periodic lattice strain under the cycling mode results in deep trap accumulation and chemical degradation during operation, decreasing the ion migration potential and hence the device lifetime. We introduce phenylselenenyl chloride (Ph-Se-Cl) to regulate the perovskite lattice strain during day/night cycling, which achieved the certified efficiency of 26.3% and a 10-time improved T_{80} lifetime under the cycling mode after the modification.

11:45 AM EL04.01.05
Bayesian Optimization and Prediction of the Durability of Wide Bandgap Perovskite Thin Films Under Light and Heat Stressors Deniz N. Cakan, Eric Oberholtz, Ken Kaushal, Sean P. Dunfield and David Fenning; University of California, San Diego, United States

Wide-bandgap perovskites are top contenders for tandem solar cells, but they suffer from instability when exposed to the necessary operational conditionals of elevated temperature and light. Here, Bayesian optimization (BO) of wide bandgap perovskite compositions is used to optimize the light and heat stability of perovskite films in the triple halide Cs-FA perovskite design space. To improve experimental power, we leverage robotic automation of perovskite thin film deposition and processing, which provides highly reproducible methods for robust comparisons across the composition space. We demonstrate that the BO framework also requires just 40% of the samples needed to extract the same learnings as a conventional grid search method.

From the large body of stability data, we develop a regression model that offers a robust prediction of perovskite stability under light and heat based on the composition and easily measurable film-level optical properties. The model predicts the amount of phase degradation after 700 hours of 1-sun, 85°C illumination with a mean absolute error of 0.5% across the full Cs-FA triple halide space. Furthermore, it links quick and straightforward optical measurements conducted in less than 5 minutes to the 100s of hours long, resource-intensive light and heat tests of ISOS-L-2.

Overall, integration of (1) reproducible automated processing, (2) experiments leveraging Bayesian optimization to learn faster, and (3) machine-learning to predict perovskite stability from early optoelectronic characterization together holds promise to accelerate the development of durable perovskite materials and devices.

Heteroepitaxial Metal Halide Perovskites via Pulsed Laser Deposition

Monica Morales-Masis; University of Twente, Netherlands

Epitaxial and heteroepitaxial growth of metal halide perovskites (MHP) offers a unique platform for better understanding of the correlation between materials' properties and processing, as well as enable studies of polymorph stabilization and substrate-induced strain control.
Pulsed laser deposition (PLD), a physical vapor deposition technique, is a dry, single-source vapor-phase technique with unique properties to deposit metal halide perovskites on various substrates [1-5]. Here we discuss the use of PLD for the epitaxial growth of $CH_3NH_3PbI_3$ on KCl single crystal substrates and verified the stabilization of the cubic polymorph of $CH_3NH_3PbI_3$ with techniques such as reciprocal space maps, polar figures and EBSD [5]. Photoluminescence measurements confirm that the films have a bandgap of 1.64 to 1.66 eV corresponding to the cubic phase. Beyond $CH_3NH_3PbI_3$, we will discuss the cases of heteroepitaxy of $CsSnI_3$ and $CsPbI_3$, both having also a close lattice match with KCl substrates. The critical role of the PLD growth parameters to achieve epitaxy of either the hybrid or inorganic perovskites will be described.
Finally, and moving beyond 3D perovskites, the growth of highly oriented structures of $(PEA)_2PbI_4$ with PLD atop MHPs heteroepitaxial layers is demonstrated. X-ray diffraction, grazing incidence wide angle scattering, time-resolved PL and conductivity measurements and atomic force microscopy are furthermore employed to gain understanding of the structure, texture, morphology and carrier transport of the 2D/3D heteroepitaxial layers. This work demonstrates the benefits of vapor-based growth for 2D metal halide perovskites via PLD and paves the way for heterostructure and device integration.

The Emergence of Porous Hybrid Metal Halide Semiconductors Ioannis Spanopoulos; University of South Florida, United States

Hybrid halide perovskite semiconductors have proven to be prominent candidates for many optoelectronics applications, spanning from solar cells and LEDs to photodetection and lasing. They exhibit a unique combination of fine-tunable traits that cannot be met by any other class of semiconductors, deriving directly from their hybrid nature. Finding a way to generate porosity in this class of materials would allow them to be utilized in currently unexplored applications such as sensing, photonic crystals, integrated waveguides, and solid-state batteries. We recently developed a general strategy for generating porosity to hybrid metal halide materials using molecular cages serving as structure-directing agents and counter-cations. [1][2] The reaction of the [2.2.2] cryptand (DHS) linker with Pb(II) in acidic media gave rise to the first porous 2D metal halide semiconductor with formula $(DHS)_2Pb_5Br_{14}$. The corresponding material is stable in water for over a year, while gas and vapor sorption studies revealed that it can selectively and reversibly adsorb H_2O and D_2O at room temperature (RT). Solid-state NMR measurements and DFT calculations verified the incorporation of H_2O and D_2O in the organic linker cavities, and shed light on their molecular configuration. In addition to porosity, the material exhibits broad light emission centered at 617 nm with a full width at half-maximum (FWHM) of 284 nm (0.96 eV). The recorded water stability is unparalleled for hybrid metal halide and perovskite materials, while the generation of porosity opens up new pathways toward unexplored applications (e.g. solid-state batteries) for this class of hybrid semiconductors. This work sets the foundation for a new family of versatile hybrid semiconductors, namely porous metal halide semiconductors (PMHS), solving current stability material deficiencies, whereby means of molecular and crystal engineering, the path towards commercialization is open.

2:15 PM EL04.02.03

Improved Control of Perovskite Thin Film Fabrication via Optical *In Situ* Spectroscopy and Reactive Spin Coating Simon Biberger, Maximilian Spies, Konstantin Schötz, Frank-Julian Kahle, Nico Leupold, Ralf Moos, Helen Grüninger, Fabian Panzer and Anna Kohler; Universität Bayreuth, Germany

Efficient solar cells require a high-quality halide perovskite (HP) film, which is typically achieved through a solution-based solvent engineering spin coating approach. Here, HP crystallization is induced by applying an antisolvent (AS) to the precursor solution film on the spinning substrate after a specific spinning time. The process involves various controllable and uncontrollable parameters that need to be considered. As a result, fabrication recipes (such as spin speed or timing of AS dispensing) are usually developed empirically and vary between labs. Additionally, factors like changes in the atmosphere that are hard to control can introduce substantial variations between and even within batches of devices.

In this work we developed a closed-loop feedback system based on our multimodal optical In-Situ spin coater system in combination with a real-time analysis of the optical spectra during spin coating. We optically monitor the solvent layer thickness as the parameter of interest during the spin coating process. When the target level is reached, the HP crystallization is autonomously induced by dispensing the AS via a syringe pump. This method compensates for the effects of uncontrolled parameters, like variation in solvent evaporation rate due to atmospheric changes, thus leading to reproducible film quality for different perovskite compositions.[1]

Thus, the reactive spin coating approach will open up future possibilities to simplify the transfer of recipes from one laboratory to the next by removing the influence of external effects, such as atmosphere or the human factor, on the layer formation as the processing is only based on system-internal parameters. Additionally, the reactive approach is not limited to the solvent layer thickness as the parameter of interest. Any optically accessible property of the solvent film, such as precursor state composition, can be a potential parameter for the reactive approach. Eventually, our approach also represents a valuable contribution for an in general improved process control in the solution processing of halide perovskite thin films, making it relevant for their successful upscaling and commercialization in optoelectronic devices in the future.

2:30 PM EL04.02.04

Room Temperature Processed Tin Perovskites Jessica H. Persaud and Faiz Mandani; Rice University, United States

Perovskites have become attractive semiconductors in photovoltaic devices due to their unique optoelectronic properties; however, with lead-based perovskite approaching the theoretical device limit, all-perovskite tandems have become increasingly of interest but are limited due to the limitations of tin-based perovskites. Sn-based perovskites have emerged due to their similar band structure, bandgap tunability, and higher Schockley- Queisser limit. Despite this potential, they currently lag in terms of stability and efficiency compared to their lead-based counterparts, primarily due to high defect densities from rapid thin-film formation and Sn vacancies caused by oxidation. While Sn oxidation is detrimental to device performance and stability, controlled crystallization is hypothesized to reduce uncoordinated Sn(II) and enhance overall device performance and stability.

Researchers have extensively employed additive, cation, and solvent engineering to control the crystallization of Sn-based perovskites, though understanding of the process remains limited. We aimed to deepen our understanding of the crystallization of Sn-based perovskites and how it differs from Pb-based perovskites. Utilizing additive engineering, we are able to preferentially orient a $FASnI_3$ film along the [001] and [010] planes, indicative of more controlled crystal growth. While having preferential growth is consistent in using many ammonium-based additives, we are able to grow $FASnI_3$ thin films completely at room temperature, minimizing the amount of added energy into the system to oxidize Sn(II), as elevated temperatures are known to increasing oxidize Sn(II). Upon exposure to ambient conditions, x-ray photoelectron spectroscopy (XPS) measurements have shown increased stability of the engineered $FASnI_3$ with significantly less Sn(IV) content compared to pure $FASnI_3$ and 10.48% power conversion efficiency when implemented into a p-i-n solar device.

2:45 PM EL04.02.05

Deposition of 2D $Cs_3Bi_2Br_3I_6$ Perovskites—Thermal Evaporation vs Spin Coating Charles Chen[1,2], Robert Palgrave[1] and Xizu Wang[2]; [1]University College London, United Kingdom; [2]Institute of Materials Research and Engineering, Singapore

Halide perovskites have gained significant attention in the scientific community due to their remarkable potential in photovoltaic applications. These materials are known for their exceptional properties, including high absorption coefficients, defect tolerance, long diffusion lengths, and long carrier lifetimes, which contribute to the high efficiencies observed in solar cells. However, conventional halide perovskites face significant challenges such as instability when exposed to air, humidity, or heat, and the toxicity associated with their lead content.

Efforts to develop non-toxic, lead-free alternatives have primarily focused on tin-based systems, with relatively less research dedicated to bismuth and antimony-based systems. In this work, we present for the first time the co-evaporation of cesium bromide (CsBr) and bismuth iodide (BiI_3) to form the mixed halide perovskite system $Cs_3Bi_2Br_3I_6$ (CBBI). CBBI is of great interest, since it possesses the 2D phase and similar band gap energies as its pure-iodide derivative $Cs_3Bi_2I_9$ (CBI), which mainly crystallizes in the 0D phase. The higher dimensionality is beneficial for charge carrier properties. Our deposition method is compared to the more conventional spin-coating technique.

For the thermally evaporated films, an ex-situ method using atomic force microscopy (AFM) analysis of the precursor films was employed to determine and adjust the evaporation rate of the precursors, ensuring an accurate stoichiometric ratio satisfying the Cs:Br ratio. Thermally evaporated films were characterized and compared to spin-coated films using a variety of techniques, including X-ray diffraction (XRD), scanning electron microscopy (SEM), Raman spectroscopy, and ultraviolet-visible (UV-vis) spectroscopy. XRD and Raman spectroscopy confirmed the successful deposition of the thermally evaporated films. XRD data indicated that these films do not possess a large degree of preferential orientation, whereas Raman data suggested that the 2D phase is the main structure present, with some 0D phase also detected. SEM and UV-vis data revealed morphological and optical differences between the two types of films.

Furthermore, we constructed solar cells based on a planar architecture. Incorporating compact TiO_2 (c-TiO_2) as the electron transport layer and spiro-OMeTAD as the hole transport layer, we observed highest efficiencies when solution-processed CBBI was deposited on mesoporus TiO_2. For the thermally evaporated CBBI films, we find that phenyl-C61-butyric acid methyl ester (PCBM) between c-TiO_2 and the active layer is more suitable. Moreover, for the thermally evaporated CBBI films, the inclusion of a thin 7.5 nm layer of MoO_x between the hole transport layer and the Au electrode led to increased device efficiency. The thermally evaporated films deposited on different surfaces exhibited significantly larger grain sizes, indicating thermal evaporation to be a more attractive method for photovoltaic applications.

The field of thermal evaporation of lead-free perovskite-inspired systems has been notably underexplored. Our work addresses this gap by presenting comprehensive results from the thermal evaporation of these systems.

Exciton-Polaron Interactions in Metal-Halide Perovskite Quantum Dots Patanjali Kambhampati[1], Oleg Prezhdo[2] and Maksym V. Kovalenko[3]; [1]McGill University, Canada; [2]University of Southern California, United States; [3]ETH Zürich, Switzerland

Metal-halide perovskites have been under intense investigation for their remarkable performance in energy conversion materials based upon their novel properties. In particular, a key aspect is their ionic lattice which features glassy anharmonicity giving rise to dynamic disorder. In this fluctuating potential energy landscape, the polaron becomes more important than the phonon. Coupling to phonons is important in covalent semiconductors in terms of the way in which the electronic system interacts with the lattice bath. Coupling to polarons becomes more important in perovskites and the observation of polaron formation and the impact of polaron formation upon optical properties is a key area of research.

The way in which the excitons couple to the lattice can be revealed by ultrafast electronic spectroscopies. We apply a suite of three ultrafast spectroscopies to probe the response of CsPbBr3 metal-halide perovskite quantum dots, spanning weakly to strongly confined. We exploit the state-of-the-art in electronic spectroscopies including time-resolved photoluminescence (t-PL) with 3 ps resolution, transient absorption (TA) with 100 fs resolution, and Coherent Multi-Dimensional Spectroscopy (CMDS) with 10 fs resolution to probe the hierarchy of dynamical processes that govern the function of these materials.

These experiments most dramatically reveal new physics of coherence in these materials in terms of exciton-lattice interactions. The t-PL experiments reveal a giant oscillator strength effect at low temperatures which we assign to spatial decoherence effects induced by lattice structural dynamics as revealed by ab initio molecular dynamics (AIMD) simulations. The CMDS experiments on the other hand reveal a coherence in time that is surprisingly long lived at 300 K. The excitonic coherence is long lived relative to exciton dephasing times and population lifetimes. The excitonic splitting observed reveals lineshape dynamics that reflect both coupling to phonons and polarons. The polaron formation dynamics reveals liquid-like behavior as the system undergoes spectral diffusion. The TA experiments reveal a breaking of phonon bottlenecks via Auger processes following the quantum dynamics of exciton-polaron coupling.
This suite of three world leading ultrafast electronic spectroscopies provides deep insights into the exciton-lattice interactions that arise in the dynamically disordered potential energy landscape of metal-halide perovskite quantum dots.

3:45 PM EL04.03.02

Realization of 2-2 Elpasolites Using Atomic Resolution STEM and Degradation Assisted XRD Pritish Mishra[1,1], Mengyuan Zhang[1], Andy Paul Chen[1], Yeng Ming Lam[1] and Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Agency for Science, Technology and Research, Singapore

In the previous decade, a lot of research has been done in the area of halide perovskite materials which has led them to be used in all different types of photonic applications. The low dimension crystals of this structure have also shown a lot of promise in quantum photonic devices. We synthesized perovskite Quantum Dots of composition Cs_2PbSnI_6 for photonic applications in Near Infra-red emission range. The atomic arrangement of B site cations in this composition dictated if the crystal structure formed was a double perovskite (elpasolite) or not. All the elpasolites reported in literature have different oxidation states of the two cations at the B site (+1, +3) for example in $Cs_2AgBiBr_6$, where Ag is +1 and Bi is +3. But in our case, both the B site cations, Pb and Sn, are in +2 state. This increased the chances of having a disordered crystal structure where the B site cations do not follow any order. To verify the crystal structure a few different characterization methods were used, such as X-Ray

Diffraction (XRD) or Selected Area Electron Diffraction (SAED) in Transmission Electron Microscope (TEM). But the active perovskite phase, the black phase, was only metastable at room temperature, any action of air, moisture, electron beam and solvent can lead to phase transition to inactive (yellow) phase. Also, the low signal to noise ratio in XRD and EDX led to inconclusive results in nanocrystals as small intensity peaks were not seen. Furthermore, the crystals formed were seen to be cubic in TEM and were always found to land on one of the facets. Since the crystal structure is also cubic, this led to presence of only (100) and (110) reflections and their multiples in both XRD and SAED patterns. The use of solvent also triggered coagulation of nanoparticles and formation of nanowires. Further the use of solvent also led to carbon contamination under electron beam. Due to a combined issue of all the degradation mechanisms, all the measurements were done in air-free conditions. The crystal structures of all possible arrangement of B site cations for both black and yellow phases were simulated using DFT. These structures were then used for Le-Bail refinement and refined with Rietveld refinement. These refined crystal structures were then used for matching with SAED ring pattern of ensemble of quantum dots. XRD was carried out in both air-free and ambient conditions to identify the peaks of interest, which indicated the possibility of ordered structure. Also, atomic resolution STEM images of multiple orientations of the crystals were carried out using high tiltilng holder to confirm the ordered double perovskite crystal structure. The resulting methodology for distinction between ordered and disordered structures can be extended to many more material systems. The possibility of 2-2 elpasolites mentioned in this work would help in understanding the structure and properties of wide range of materials under the umbrella of Perovskites.

4:00 PM EL04.03.03

An Updated Approach to Quantify Mobile Ions in Perovskite Solar Cells Based on Capacitance Transients

Moritz C. Schmidt[1], Biruk A. Seid[2], Felix Lang[2] and Bruno Ehrler[1,3]; [1]AMOLF, Netherlands; [2]University of Potsdam, Germany; [3]University of Groningen, Netherlands

Even though the efficiency of perovskite solar cells has increased significantly in recent years, their long-term stability is still poor, hindering commercial applications. One of the main reasons for this poor stability is mobile ionic carriers, which can migrate within the perovskite crystal lattice and accumulate at the adjacent charge transport layers, reducing the extraction efficiency of electronic carriers. To compare strategies to mitigate ion migration, reliable ways of quantifying the density, mobility, and activation energy of mobile ions are necessary. Here, we propose an updated way of characterizing mobile ions based on capacitance transients. In capacitance transients, we generally measure the modulation of the electronic capacitance due to mobile ions drifting through the perovskite. In our updated approach, we first approximate the time-dependent ionic carrier, electronic carrier, and potential distribution within a perovskite solar cell after applying a voltage pulse. Subsequently, we calculate the capacitance from these distributions using a small-signal approximation of the drift-diffusion equations, resulting in capacitance transients. By fitting capacitance transients generated from drift-diffusion simulations, we show that an accurate extraction of the density, mobility, and activation energy of mobile ions within the perovskite is possible. Lastly, we apply the proposed model to measured capacitance transients of p-i-n perovskite solar cells and approximate their ion density, ionic mobility, and activation energy.

4:15 PM EL04.03.04

Scanning Photocurrent Microscopy for Comparing Single Crystals of 3D and Multidimensional 2D-3D Hybrid Lead Bromide Perovskites Fernando Ramiro Manzano, Elena Segura-Sanchis, Rocío G. García-Abola, Roberto Fenollosa and Pedro Atienzar; Instituto de Tecnología Química, Spain

We studied single crystals of 3D and multidimensional 2D-3D hybrid perovskites using Scanning Photocurrent Microscopy. This technique enables the comparison of different crystals by extracting radial cross-sections of the photocurrent decay. The results revealed that the 3D samples' effective decay length is significantly larger, by two

orders of magnitude, than that of the multidimensional perovskite.
Scanning Photocurrent Microscopy is a valuable technique that enables faithfully extracting the diffusion length (L_d) through a single experiment. It consists of a spatial scan of a focused laser source accompanied by the collection of the generated photocurrent. The diffusion length is obtained from an exponential decay fitted to the acquired data. In order to perform this analysis, the sample should meet some requirements: to show an effective 1D geometry, where the L_d is much larger than its cross-section, or a 2D planar sample where the electrode is an infinite line. However, it has been demonstrated that an exponential decay could define the L_d in discrete 2D samples under the assumption that the sample's thickness is less than the diffusion length. Therefore, the electrodes could be constrained by certain boundaries, thus defining a specific length or area.
Our goal is to employ this technique but with modifications for extracting radial photocurrent decays. It consists of employing a combination of a single point (tip electronic probe) and a surface (back-contact electrode) as electrodes. In fact, each extracted profile is geometrically defined by maintaining the same initial probe position while varying the sample edge limit. This allows for studying the photocurrent decay length as a function of the border distance. By defining an effective photocurrent length at the point where the response intersects with a factor of e^{-1}, we can plot this length relative to the border distance. This allows for comparing different lead bromide perovskites, in particular 2D-3D multidimensional samples with respect to a pure 3D ones. For profiles corresponding to long distances to the collection tip electrode, the 2D-3D multidimensional samples are characterized by a single exponential and the 3D samples show a marked two exponential response. Both the single (2D-3D samples) and first exponential (3D samples) show similar micrometric effective decay lengths. However, the second exponential, that corresponds to the 3D samples, show two orders of magnitude larger response.

Progress in Perovskite Solar Cell Performance and Reliability—Insights at the Interfaces Edward H. Sargent; Northwestern University, United States

Perovskite photovoltaics that combine performance and stability have seen much progress; yet continued efforts to deepen durability science - physical understanding of degradation pathways, and the overcoming of such processes - are urgently needed. I will update on progress and talk about future work.

9:00 AM EL04.04.02
Towards Sustainable Photovoltaics—The Impact of Substituting ITO with AZO on Perovskite Solar Cells
Kassio P. Zanoni, Joost W. Reinders and Henk J. Bolink; Instituto de Ciencia Molecular, Spain

This oral presentation will underscore the potential of aluminum-doped zinc oxide (AZO) layers (deposited by pulsed laser deposition) as a substitute for indium tin oxide (ITO) in high-performing, stable, state-of-the-art perovskite solar cells (PSCs). The presentation will highlight the relevance of advanced synthesis and processing techniques, detailed characterization methods, and interfacial engineering in developing sustainable transparent conductive oxide (TCO) alternatives.

AZO presents several advantages over ITO, including cost-effectiveness, higher abundance, thermal resilience, and lower toxicity. Despite these benefits, its application in PSCs remains underexplored. This work demonstrates the enhancement of AZO properties such as transparency, conductivity, and stability, with a focus on low-energy deposition methods compatible with organic materials. Utilizing PLD, we successfully produced AZO films with optimized morphological, electrical, and optical characteristics. These films were evaluated in perovskite solar cells across three different device architectures: superstrate, substrate, and semitransparent/bifacial configurations, all fabricated using scalable vacuum-processed techniques. A significant correlation between PLD chamber pressure and solar cell efficiency was identified, with AZO-based cells achieving power conversion efficiencies and stabilities comparable to the archetypal TCO, ITO. By improving charge carrier dynamics and addressing degradation processes, this presentation aims to contribute to the broader adoption of hybrid perovskite technologies in more-sustainable photovoltaic applications.

9:15 AM EL04.04.03

Reducing UV-Driven Degradation of p-i-n Perovskite Solar Cells Using Strong-Bonding Hole Transport Layers

Chengbin Fei[1], Anastasia Kuvayskaya[2], Xiaoqiang Shi[1], Mengru Wang[1], David Fenning[3], Yanfa Yan[4], Matthew C. Beard[5], Laura T. Schelhas[5], Alan Sellinger[2,5] and Jinsong Huang[1]; [1]University of North Carolina, United States; [2]Colorado School of Mines, United States; [3]University of California, San Diego, United States; [4]The University of Toledo, United States; [5]National Renewable Energy Laboratory, United States

Promising durability and efficiency have been demonstrated for perovskite solar cells in indoor testing(1), but outdoor durability to date has been inadequate for commercialization, and the underlying mechanisms for degradation are not clear. Here we report degradation mechanisms of p-i-n structured perovskite solar cells under unfiltered sunlight in comparison with widely used light emitting diodes. The weak chemical bonding between perovskites and polymer hole transport materials (HTMs) and transparent conducting oxides (TCOs) are found to dominate the accelerated A-site cation migration and thus the degradation of perovskite solar cells under sunlight with strong ultraviolet components(2), instead of the direct degradation of HTMs. An aromatic phosphonic acid, [2-(9-ethyl-9H-carbazol-3-yl)ethyl]phosphonic acid (EtCz3EPA), synthesized as part of this work enhances the bonding at the perovskite/HTM/TCO region with phosphonic acid group bonded to TCOs and nitrogen group interacting with lead in perovskites. A hybrid HTM of EtCz3EPA with strong hole extraction polymers retained high efficiency and improved the UV stability of perovskite devices. The champion perovskite minimodule with the hybrid HTM, independently measured by Perovskite PV Accelerator for Commercializing Technologies (PACT) center, has retained operational efficiency over 16% after 29 weeks of outdoor testing.

The Effect of Sequential Spin-Coating Perovskite Deposition on the Self-Assembled Monolayer of Inverted Perovskite Solar Cells Sua Park, Lee Donghyeon, Shinhyun Kim and Min-cheol Kim; Pusan National University, Korea (the Republic of)

Organic-inorganic halide-based perovskite solar cells (PSCs) are gaining attraction in the energy technology field due to their rapid development. Nevertheless, addressing issues such as cost reduction or maximizing performance and stability by improvements of fabrication processes and materials is necessary for commercialization. Therefore, researchers have been focusing on improving the performance and stability of the inverted structure of PSCs, suitable for low-temperature processes and tandem solar cells, particularly by using self-assembled monolayers (SAMs) as the hole transport layer (HTL). In the meantime, the fabrication process suitable for roll-to-roll processing is necessary for large-area production. A sequential spin-coating process depositing the PbI_2 first, followed by the deposition of organic halide to form a perovskite film is suitable for roll-to-roll processing since it does not require additional anti-solvent treatment or vacuum flashing process. However, the sequential spin-coating deposition process has the disadvantage that a polar solvent is applied continuously, which can affect the underlying SAMs-based HTL. Previous studies have shown that strong polar solvents can cause desorption of SAMs due to the easy detachment of anchoring between the SAMs and substrate. In addition, detached molecules by strong polar solvents can randomly redeposit in the bottom layer during perovskite crystallization, blocking carriers to the bottom electrode. Therefore, the more detached molecules are desorbed from the surface, the higher the leakage current and the lower the power conversion efficiency (PCE). As a result, the sequential spin-coating deposition process on SAMs can be very unfavorable. In this study, we aimed to investigate the compositional changes at the interface of HTL and perovskite films using a sequential spin-coating deposition process and to identify the differences between sequential spin-coating deposition and one-step spin-coating processes. Finally, we can propose a solution to improve the application of SAMs to perovskite fabricated by sequential spin-coating.

9:45 AM EL04.04.05
Interface Defect Elimination with Modified ALD Layer ELT in p-i-n Perovskite Solar Cells Chittaranjan Das[1,2], Mayank Kedia[1], Thi Hue Nguyen[1] and Michael Saliba[1,2]; [1]Universität Stuttgart, Germany; [2]jülich forschungszentrum, Germany

Metal halide perovskite solar cells exhibit remarkable efficiencies (26.1% for single junctions and 33.9% for tandem cells)[1]. However, commercialization faces hurdles related to intrinsic perovskite film instability, interfacial chemical reactions, and contact layer detachment, leading to overall performance decline. Notably, in tandem cells with a p-i-n configuration top cell, delamination of the electron transport layer (ETL) from the perovskite absorber significantly reduces device performance [2]. Researchers have addressed instability issues through ultra-thin, low-temperature processed atomic layer deposition (ALD) of Al_2O_3, effectively controlling perovskite layer instability and interfacial chemical reactions [2, 3]. However, achieving robust mechanical stability at the interface remains a challenge. While groups have explored ALD SnO_2 on perovskite in p-i-n cells [4,5], high-temperature processing of metal oxides like SnO_2 and TiO_2 often alters perovskite surface chemistry, hindering device efficiency [6]. Consequently, ALD SnO_2 necessitates an interlayer (C_{60} or PCBM), introducing a risk of entire ETL stack delamination.
To circumvent the temperature and chemical reaction induced surface chemistry changes in perovskite, we implemented a modified ALD approach for ETL deposition directly onto the perovskite, aiming to minimize processing-induced interfacial defects. This approach yielded significantly improved device performance (11% efficiency) compared to the standard direct ALD method (6-7% efficiency).
Hard X-ray photoelectron spectroscopy (HAXPES) revealed that standard ALD ETL deposition triggers Pb-O bond formation and perovskite surface degradation through nitrogen dissociation and halide migration due to processing temperature. Conversely, our modified ALD ETL deposition minimized perovskite surface degradation and halide migration, interestingly preventing Pb-O formation. The superior performance observed in p-i-n cells using our modified approach stems from a smoother and more intact interface between the perovskite and ETL. Furthermore, solar cells fabricated with the modified ALD process exhibited enhanced shelf-life stability compared to those using standard ALD. While the performance and stability of p-i-n cells with our ALD ETL approach fall short of C60/ETL combinations, it offers a promising avenue for further development of direct ETL deposition in p-i-n cells for tandem cell applications.

Engineering Metal Halide Perovskites for High-Performance Light-Emitting Diodes and Field-Effect Transistors Ni Zhao, Aqiang Liu, Zhiwen Zhou and Zheng Zhang; The Chinese University of Hong Kong, Hong Kong

Metal halide perovskites are emerging as a revolutionary class of semiconductors due to their unique combination of outstanding optical and electronic properties and their versatility in low-temperature synthesis and substrate compatibility. In this talk I will focus on the development and optimization of perovskite-based light-emitting diodes (PeLEDs) and transistors. For PeLEDs, a vapor-based acetate methylamine (FAAc) treatment has been introduced to address the challenges associated with halide vacancy defects in blue-emitting PeLEDs. The innovative approach mitigates solvent-induced damage during the typical post-deposition process, ensuring a controlled and uniform incorporation of halide ions into the perovskite lattice. The study reveals the superior performance of F-PEAX treatment over conventional organic salts, resulting in blue-emitting PeLEDs with peak external quantum efficiencies (EQEs) of 19.28%, 11.55%, and 7.28% at emission peaks of 483 nm, 474 nm, and 465 nm, respectively. These devices also exhibit narrow full-width at half-maximum (FWHM) electroluminescence, making them ideal for high-definition display applications. Additionally, I will discuss the advancements in tin halide perovskite (THP) transistors. Our development of a one-step vapor-processing method for phase-pure CsSnI3 thin films overcomes the limitations of traditional solution-processed THPs. This method achieves wafer-size uniform films with high crystallinity and low defect density, enabling the fabrication of high-performance transistors with field-effect hole mobility exceeding 30 $cm^2V^{-1}s^{-1}$, on/off current ratios over 10^8, and excellent operational stability. These findings demonstrate the potential of $CsSnI_3$ transistors for scalable and cost-effective production, paving the way for their integration into complementary circuits alongside n-type oxide-based transistors.

11:00 AM EL04.05.02
Solution-Grown Perovskite Single Crystalline Radiovoltaic Cells with 10% Power Conversion Efficiency

Kostiantyn Sakhatskyi[1,2], Anastasiia Sakhatska[1,2], Bekir Turedi[1,2], Gebhard Matt[1,2], Vitalii Bartosh[1,2], Frank Krumeich[1,2], Federico A. Geser[3], Alberto Stabilini[3], Malgorzata M. Kasprzak[3], Charlie McMonagle[4], Dmitry Chernyshov[4], Sergii Yakunin[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Paul Scherrer Institute, Switzerland; [4]European Synchrotron Radiation Facility, France

Nuclear batteries present an appealing energy source characterized by an exceptionally long operational lifespan and a remarkable energy density, finding prominent application for equipment requiring sustained, autonomous operation over protracted durations, encompassing spacecraft, cardiac pacemakers, subaqueous systems and automated scientific stations. Except of radiation safety issues, primary constraint hindering the extensive adoption of nuclear batteries is attributed to the limited efficiency and intricate fabrication processes of energy-conversion materials. Most widespread nuclear batteries are radioisotope thermoelectric generators which exhibit an energy conversion efficiency of merely 5%. In the quest for augmented efficiency, research endeavors have shifted towards direct conversion of gamma and beta radiation through radiovoltaic cells, where the best efficiency is so far achieved with costly and non-scalable diamond battery technology. In this study, we address the issue of efficiency, reporting 10% power conversion efficiency for the direct conversion of high-energy photons up to 20 keV with solution-grown methylamonium-formamidinium lead iodide ($MAFAPbI_3$) perovskite single-crystal radiovoltaic cells. Our experimental investigation determined the electron-hole pair creation energy for $MAFAPbI_3$ single crystals to be 5.05 eV, substantiating that the short-circuit current closely approaches the theoretical upper limit, as defined by the Klein model. Additionally, the devices exhibited a high open-circuit voltage of 600 mV even under low irradiation power density conditions of 69 nW mm^{-2} . Furthermore, the perovskite radiovoltaic cells demonstrated remarkable stability, maintaining their performance for a continuous 24-hour X-ray irradiation at a power density of 100 nW mm^{-2} . These findings underscore the promising potential of highly efficient and low-cost perovskite-based nuclear batteries.

11:15 AM EL04.05.03

Hybridization of Delta $FAPbI_3$ and Atomic-Layer-Deposited SnO_2 Enhances Artificial Synaptic Behavior

Sang-Uk Lee and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Resistive switching characteristics can be extended to artificial synapse for neuromorphic computing. Organic-inorganic hybrid halide perovskites are emerging materials for nonvolatile resistive switching memory devices. 1-dimensional hexagonal $FAPbI_3$ (δ-$FAPbI_3$) was found to demonstrate resistive switching behavior. However, δ-$FAPbI_3$ cannot be used for artificial synapse due to the absence of analog switching characteristics. Here, we report a bilayer memristor hybridizing δ-$FAPbI_3$ with atomic-layer-deposited (ALD) SnO_2 for artificial synapse. The activation energy required for vacancy migration was increased from 0.42 eV for δ-$FAPbI_3$ to 0.53 eV after introduction of ALD-SnO_2, associated with the Schottky barrier at the heterojunction structure, which led to an analog switching behavior at applied voltage. Consequently, this significantly reduced the current level in the high resistance state by restricting the orientation of migration channels. Artificial synaptic characteristics were confirmed by linear potentiation/depression, long-term potentiation (LTP), long-term depression (LTD) and spike-timing-dependent plasticity. The non-linearity in LTP and LTD was considerably reduced from 12.26 to 0.60 and from -8.79 to -3.47, respectively. Moreover, the δ-$FAPbI_3$/ALD-SnO_2 bilayer system achieved a recognition rate of up to 94.04% based on the modified National Institute of Standards and Technology database using deep neural networks. This study highlights the critical role of the interface layers, such as ALD-SnO_2, in controlling ion migration and modifying resistive switching behavior.

11:30 AM EL04.05.04

Clarify the Cathode Degradation in Organic Lead Halide Perovskite Light-Emitting Diodes

Thi-Hoai Do[1], Yu-

Fan Yin[1], Hsin-Yu Lin[1] and Tzung-Fang Guo[1,2]; [1]National Cheng Kung University, Taiwan; [2]Research Center for Critical Issues, Academia Sinica, Guiren Dist., Taiwan

Despite achieving over 30% efficiency in 2023, perovskite light-emitting diodes (PeLEDs) suffer from inherently poor stability during storage, causing significant degradation and short operation lifetimes, severely compromising their viability for practical applications. Consequently, it is imperative to block all intrinsic degradation pathways, necessitating urgent and thorough investigation. In our work, we discovered that even when storing the CH3NH3PbBr3 devices inside a nitrogen-filled glove box with trace amounts of oxygen and moisture levels below 1.0 ppm, there is still a time-dependent formation of non-emissive electroluminescence (EL) patterns in the active areas. By varying hole transport layers, perovskite components from 3D to quasi-2D, and diverse cathode configurations, we demonstrated that these non-emissive EL patterns are linked to the degradation of the metal cathode. Trace moisture, temperature fluctuations, or ion migration initiate a chemical reaction with CH3NH3PbBr3 perovskite, leading to degradation products that compromise the metal cathode, thus posing a challenge to the stability and lifespan of the devices. Remarkably, we found that employing a conductive metal oxide, such as Indium-Zinc-Oxide (IZO), in combination with a polyethyleneimine ethoxylated (PEIE) buffer as the cathode structure (PEIE/IZO), or using PEIE combined with Ag as the cathode (PEIE/Ag) instead of Al, effectively prevents cathode degradation. PeLEDs with Al cathodes exhibited non-emissive EL patterns within just 4 hours of storage in the nitrogen-filled glove box. In contrast, PeLEDs with the PEIE/IZO or PEIE/Ag cathode structures showed no dark patterns in the active areas even after 14 days of storage. Our findings reveal that cathode degradation is a crucial factor limiting the performance and lifespan of PeLEDs. Addressing this issue requires the development of suitable electrode buffers incorporating metal or conductive metal oxide-based cathode configurations. This study effectively resolves a major bottleneck in perovskite light-emitting diodes under unbiased conditions, facilitating the advancement of stable perovskite optoelectronics.

11:45 AM EL04.05.05
A Perovskite Tetrachromatic Sensor for Imaging Beyond the Visible Spectrum in Harsh Conditions Xiao Qiu and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

A tetrachromatic light sensor can detect light in four independent color channels and extend its detection range beyond the visible spectrum. However, current tetrachromatic sensors face challenges, such as the inability to work reliably under harsh temperatures. In this work, we present a fully integrated tandem tetrachromatic perovskite imaging system. Four layers of all-inorganic perovskites in the device serve as ultraviolet, blue, green, and red light detectors and can discriminate spectral and non-spectral colors. The tandem image sensor comprises four 32×32 color-selective pixel arrays. The non-encapsulated device is tested to function from 150 K to 500 K under atmospheric pressure and vacuum environments and can remain functional down to 16 K. The fabrication process and device structure are scalable, with the potential to be used for tetrachromatic imaging under harsh environmental conditions for diverse applications, such as extravehicular detection, autonomous driving, quality control in the industry, and so on.

SESSION EL04.06/QT01.05: Joint Session: *Quo Vadis* Halide Perovskites?

Sheraton, Second Floor, Republic B

1:30 PM *EL04.06/QT01.05.01

Improving Reverse Bias Stability and Ion Migration in Perovskite Solar Cells David S. Ginger; University of Washington, United States

Ion migration and reverse bias stability are recognized as potential barriers to commercial photovoltaic applications of halide perovskite semiconductors. In this talk we will discuss our work on scalable interface passivation layers, quantification of their reductions in interfacial defect densities, and will show how they are able to suppress halide vacancy migration both under illumination and under voltage bias. Next, we study how device architecture engineering can have a significant impact on the reverse bias behavior of perovskite solar cells. Surprisingly, while past research has emphasized the role hole tunneling from across the electron transport layer on reverse bias instabilities, we show that by using a thicker conjugated polymer hole transport layer, and a more electrochemically stable back electrode, we can realize average breakdown voltages exceeding -15 V, comparable to those of silicon cells, demonstrating cells that can survive reverse bias under partial shading for hours at a time.

2:00 PM *EL04.06/QT01.05.02

Probing Interfacial Defects and Stability Challenges in Metal Halide Perovskites Laura Herz; University of Oxford, United Kingdom

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies of single-junction devices now exceeding 26%. However, highly defective interfaces with charge extraction layers, the low hurdle for ionic migration, and the structural flexibility of the perovskite structure still pose both opportunities and challenges to their commercialization in light-harvesting applications. Combinatorial characterization approaches are vital for probing and analysing such instabilities.

We discuss the use of combinatorial techniques[1-3] to probe the effect of halide segregation in mixed iodide-bromide lead perovskites with desirable electronic band gaps near 1.8eV attractive for tandem photovoltaic cells. We report recent insights from in-situ photoluminescence and X-ray diffraction techniques, and further demonstrate a temperature-dependent reversal of halide segregation at temperatures above ambient that may prove highly beneficial for solar cells under operating conditions[3] and is attributed to the trade-off between the temperature activation of segregation, for example through enhanced ionic migration, and its inhibition by entropic factors.

In addition, we demonstrate the vital role of absorption spectroscopy in determining the suitability of processing techniques for $FAPbI_3$ films, which have recently been shown to exhibit a peculiar effect of “intrinsic quantum confinement” (QC)[4,5] We reveal that such QC features are clearly detrimental to photovoltaic operation.[6] A meta-analysis of literature reports, covering 244 articles and 825 photovoltaic devices incorporating $FAPbI_3$ films reveals that PCEs rarely exceed a 20% threshold when such absorption features are present.[6] We discuss how such effects can be mitigated through different approaches to $FAPbI_3$ film growth.

We further demonstrate a combined modelling and experimental approach[7] towards exploring the origins of energy-level alignment at the interface between wide-bandgap mixed-halide perovskites and charge-extraction layers, which still causes significant losses in solar-cell performance, focusing on $FA_{0.83}Cs_{0.17}Pb(I_{1-x}Br_x)_3$ with bromide content x ranging from 0 to 1, and poly[bis(4-phenyl)(2,4,6-trimethylphenyl)amine| (PTAA). Through a combination of time-resolved photoluminescence spectroscopy and numerical modeling of charge-carrier dynamics[7] we reveal that open-circuit voltage losses associated with a rising energy-level misalignment derive from increasing accumulation of holes in the HOMO of PTAA, which then subsequently recombine non-radiatively across the interface via interfacial defects. These findings highlight the urgent need for tailored charge-extraction materials exhibiting improved energy-level alignment with wide-bandgap mixed-halide perovskites.

2:30 PM *EL04.06/QT01.05.03
Light Emission from Single Perovskite Quantum Dots Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lead halide perovskite nanocrystals are of broad interest as classical light sources (LED/LCD displays) and as quantum light sources (quantum sensing and imaging, quantum communication, optical quantum computing). Studies at the single-particle level unravel the pure photophysics of these novel quantum dots. Most of the rather exceptional properties are related to the peculiar exciton fine-structure of band-edge states, with emission through bright triplet excitons at low temperatures. Perovskite QDs exhibit giant oscillator strength phenomena and single-photon emission, making them the fastest single-photon colloidal QD emitters [1]. The nondegenerate bright triplet excitons, with millielectronvolts-scale splitting, exhibit predominantly linear polarization, as anticipated theoretically accounting for the crystal field, exchange interaction, and shape anisotropy. However, one also sees a non-negligible degree of circular polarization even without external magnetic fields by investigating the four Stokes parameters of the exciton fine-structure in individual $CsPbBr_3$ QDs through Stokes polarimetric measurements [2]. A degree of circular polarization up to ~38% is determined, which could not be detected by using the conventional polarimetric technique. The ultimate goal of quantum optics is to achieve exquisite control of light-matter interaction at the single-quanta level. Chiral photons are particularly advantageous because they carry background-free binary data, and the spin-controlled light propagation direction promises powerful nonreciprocal quantum devices. We also present the generation of strongly chiral emission in single perovskite QDs by placing them near chiral plasmonic particles, boosting the degree of circular polarization by an order of magnitude. The chirality transfer occurs through the interaction of the local chiral plasmonic field with the photonic states of the perovskite NCs. The handedness anisotropy of both excitation and emission showed an order of magnitude increase at the presence of chiral field, which was accompanied by a 3-4-fold acceleration of the radiative decay rate.

3:30 PM *EL04.06/QT01.05.04
Chiral Induced Spin Selectivity in Lead-Halide Hybrid Semiconductors and Semiconductor Interfaces
Matthew C. Beard; National Renewable Energy Laboratory, United States

Understanding and the interconversion between spin and charge current under chirality induced spin selectivity (CISS) is critical in leverage chiral semiconductors for developing room-temperature control over spin, charge and light. To achieve their full application potential, an understanding of spin-relaxation in these systems are needed. We discuss spin-selective excitation of excitons in chiral 2D lead iodide perovskite (n = 1) single crystals using time- and polarization-resolved broad-band circular dichroism. Exciton spin relaxation times are studied at room temperature. We also studied the spin-dynamics using THz emission spectroscopy and report on the circular photogalvanic and inverse CISS effect. Controlling spin accumulation in semiconductor structures at room temperature is an essential component of the next generation of energy efficient optoelectronic technologies. I will discuss our recent results showing CISS enabled spin accumulation in III-V semiconductor optoelectronic structures.

Optoelectronic Impact of Exciton Fine Structure and Exciton-Phonon Interactions in 2D Perovskites Michal Baranowski; Wroclaw University of Science and Technology, Poland

An exciton, a quasi-particle consisting of an electron and a hole bound by Coulomb interaction, represents the lowest electronic excitation in a perfect semiconductor. The exchange interaction, which couples the spins of the electron and hole, affects excitonic states, leading to fine structure splitting. This interaction lifts the degeneracy of states with different angular momenta, separating the bright and dark exciton states. The energy separation and ordering of exciton states can significantly impact the optoelectronic properties of materials.
The emerging field of two-dimensional organic-inorganic halide perovskites (2DP) offers a novel platform to explore exciton fine structure splitting (FSS) and its potential applications. In these materials, quantum and dielectric confinement enhance the Coulomb interaction, resulting in a much larger FSS compared to conventional low-dimensional systems. The splitting of excitonic states in 2DP can reach tens of meV, which is orders of magnitude greater than in epitaxial structures or nanocrystals. This large splitting, combined with the excellent optical properties of 2DP and the ease of engineering their band structure and quantum confinement, makes them an ideal system for studying exciton FSS physics.
Here, I present our recent findings, revealing a complete spectrum of excitonic states within its fine structure. Furthermore, I demonstrate that the excitonic properties of 2D perovskites are significantly influenced by carrier-lattice interactions, resulting in a complex interplay between exciton fine structure and phonons that profoundly affects their optical response. I will focus on the phonon bottleneck effect between bright and dark exciton states. Despite the substantial splitting between these states, which can reach tens of meV, 2D perovskites exhibit surprisingly intense photoluminescence emission even at cryogenic temperatures, indicating a non-Boltzmann distribution of excitons. However, the reason for this high bright-state occupation has remained unclear. Using magneto-optical spectroscopy, I will show that the exciton population is characterized by a higher temperature than the crystal lattice. To explain this observation, we employed detailed microscopic and material-specific many-particle theory to investigate the formation, relaxation, and decay dynamics of excitons. Our modelling

reveals that the energy mismatch between the exciton fine structure and phonons leads to a pronounced phonon bottleneck effect, highlighting the importance of exciton fine structure and carrier-phonon interaction in the optical response of metal halide perovskites.

Quantum Exciton Transport in Perovskite Nanocrystal Superlattices Libai Huang; Purdue University, United States

At the most fundamental level, transport of energy carriers in solid-state materials is determined by their wavefunctions and their interactions with the environment. While quantum transport theory has predicted distinct transport regimes resulting from the intricate interplay between coherent wave-like and incoherent particle-like mechanisms, these predictions are awaiting experimental verification. This study demonstrates unambiguous signatures of quantum transport in perovskite nanocrystal (NC) superlattices by directly imaging exciton propagation with high spatial and temporal resolutions over 7-298 K. At 7 K, coherent propagation of the excitons dominates, with transient ballistic motion within a coherence length that extends up to 40 NC sites. The interference of the wave-like motion leads to Anderson Localization in the long-time limit. As temperature increases, a peak in the long-time diffusion constant is observed at a temperature where static disorder and dephasing are balanced, which substantiates direct evidence for environment-assisted quantum transport (ENAQT). We established a strong correlation between theoretical predictions and experimental measurements using a stochastic Anderson localization model. These results provide a fundamental understanding of quantum transport that interpolated coherent and incoherent limits in disordered systems and highlight perovskite NCs as promising building blocks for quantum materials.

EL04.08.01

Trade-Off Effect of Hydrogen-Bonded Dopant-Free Hole Transport Materials on Performance of Inverted Perovskite Solar Cells Maning Liu; Lund University, Sweden

The involvement of functional groups in design of dopant-free small-molecule hole-transport materials (HTMs) such as halogen bonding[1] and hydrogen bonding[2] for fabrication of high-performance halide perovskite solar cells (HPSCs), has recently become an effective strategy to replace currently commercialized high-cost Spiro-

OMeTAD and PTAA. Hydrogen bonding (HB), can primarily enhance the stability of molecular structures within the system by strongly attracting the nearby molecules, while facilitating the formation of so-called H-aggregates.[3] These H-aggregates can arrange the molecules in long-range ordered structures, which are in turn supposed to improve the charge mobility. Moreover, HB-containing HTMs can also tailor the interfacial properties of the perovskite layer by passivating the perovskite/HTM interface, which is beneficial for interfacial hole transfer and protection of perovskite layer.

Petrus et al.[4] and Kaneko et al.[5] successively integrated hydrogen-bonded groups into the cores of corresponding amide units, thereby promoting interfacial charge separation and resulting in elevated performance of inverted HPSCs, with power conversion efficiencies (PCEs) up to 20.3%. In our recent work, we observed that the HB-induced formation of interlayers in a long-range ordered orientation, leading to significant enhancements both in the device performance and operational stability.[6] To date, all reported HB-containing HTMs have exhibited obviously improved performance compared to their reference HTMs generally without HB. However, an intriguing research question arises: do HB-induced H-aggregates universally confer positive effects on the design of new dopant-free small-molecule HTMs, particularly in fabrication of inverted MHPSCs, considering the critical role of HTMs as the growth template of perovskite bulk crystals? Thus, a comprehensive understanding of HB-induced H-aggregates of small-molecule HTMs and their influence on the performance of inverted HPSCs still remains highly desirable.

In this work, we investigate the trade-off effect of HB-induced H-aggregates within the triphenylamine (TPA)-based small molecule HTMs as well as at the perovskite and HTM interface. Our DFT calculations demonstrate that an excessive H-aggregate, namely face aggregate, can be formed upon either unilateral (O2) or bilateral (O3) HB units at the core parts of the molecule skeleton, which significantly reduces the hole mobility compared to the case (O1) without any HB units. Although we observed a positive role of HB-functionalized perovskite surface in promoting the interfacial hole extraction, the overall performance of this type of inverted devices is dominated by the charge transfer ability within the HTMs. Thus, the inverted HPSCs built based on the HB-free O1 HTMs with a highest PCE of 21.44% outperform the other two cases (O2 and O3 HTMs) that contain HB units in the molecular structure. On the other hand, the passivation of these HB units on the perovskite surface is indeed favorable for enhancing the device stability, which benefits from tailoring the interfacial properties upon the formation of N-Pb and H-I bonding. Although HB-induced H-aggregation could improve the charge mobility, the adverse accumulation between TPA units must be avoided. To mitigate this issue, introducing flexible units such as vinyl between H-aggregation units and TPA units is highly recommended. The observed trade-off effect of HB-containing HTMs in this work can pave the way for future rational design of functional small molecule HTMs, for simultaneously efficient and stable inverted devices.

Enhancing Efficiency and Stability of Tin Halide Perovskite Light-Emitting Diodes via Engineered Alkali/Multivalent Metal Salts

Seonkwon Kim, InCheol Kwak, Soo Young Cho, Seonmi Eom, Yonghyun A. Kwon, Seung Yeon Ki and Jihyeon You; Yonsei University, Korea (the Republic of)

Sn-based perovskite light-emitting diodes (PeLEDs) have emerged as promising alternatives to Pb-based PeLEDs with their rapid increase in performance owing to the various research studies on inhibiting Sn oxidation. However, the absence of defect passivation strategies for Sn-based perovskite LEDs necessitates further research in this field. We performed systematic studies to investigate the design rules for defect passivation agents for Sn-based perovskites by incorporating alkali/multivalent metal salts with various cations and anions. From the computational and experimental analyses, sodium trifluoromethanesulfonate (NaTFMS) was found to be the most effective passivation agent for PEA_2SnI_4 films among the explored candidate agents owing to favorable reaction energetics to passivate iodide Frenkel defects. Consequently, the incorporation of NaTFMS facilitates the formation of uniform films with relatively large crystals and reduced Sn^{4+}. The NaTFMS-containing PEA_2SnI_4 PeLEDs demonstrate an improved luminance of 138.9 cd/m^2 and external quantum efficiency (EQE) of 0.39% with an improved half-lifetime of more than threefold. This work provides important insight into the design of defect passivation agents for Sn-based perovskites.

EL04.08.03

Optimization of the Aerosol-Assisted Solvent Treatment on Perovskite Film on Flexible Substrate Using Strain Engineering Yuan Zhang and Joe Briscoe; Queen Mary University of London, United Kingdom

Aerosol-Assisted Solvent Treatment (AAST) is an effective post-treatment method designed to improve the grain size of perovskite films, thereby reducing grain boundaries (GBs) and improving the performance of solar cells.[1,2]
The process involves placing the perovskite film on a heated graphite block inside a cylindrical quartz reactor. A solvent aerosol of N,N-dimethylformamide (DMF), generated by a piezoelectric mister, is introduced into the reactor with the assistance of nitrogen gas. This leads to the vaporization of DMF on the surface of the perovskite film, initiating a mass transformation between grains. Smaller grains, due to their higher surface energy, are gradually dissolved, and the material is then added to larger grains, facilitating their growth. This process aligns with the Ostwald ripening model, resulting in a significant increase in grain size after just 5 minutes of AAST. Consequently, the Power Conversion Efficiency (PCE) of the device is enhanced from 18.7% to 20.0%, alongside an improvement in device stability.
However, during the application of AAST on perovskite films deposited on flexible substrates, a red shift in Photoluminescence (PL) was observed. Combined with X-Ray Diffraction (XRD) analysis, this phenomenon was attributed to the in-plane compressive stress within the grain boundary of perovskite. To address this issue, the process was adapted by simply bending the perovskite film during AAST, effectively reducing the aforementioned stress. This modification maintained the balance of strain engineering, offering a nuanced approach to optimizing the treatment process for flexible substrates.

EL04.08.04

Optimization of Air-Processed Perovskite Solar Cells Through Dual Incorporation of Chlorine Precursors and Potassium Thiocyanate Ahmed A. Bensekhria[1], Ivy M. Asuo[1], Ibrahima Ka[2], Riad Nechache[2] and Federico Rosei[1]; [1]Institut National de la Recherche Scientifique, Canada; [2]WattByWatt Inc., Canada

Perovskite solar cells (PSCs) have become the focus of intense research due to their rapidly increasing power conversion efficiency (PCE), recently reaching 25.7%. Despite their impressive optoelectronic properties, most high-efficiency devices reported so far were fabricated using spin-coating in controlled environments such as glove boxes. To enable large-scale production, it's urgent to develop new strategies that facilitate the fabrication in ambient air while improving stability.
Halide mixing is an effective method to achieve diverse structures and properties in perovskite materials. Compared to CszFA1−zPbX3 (X = Cl, Br, I), CszFA1−zPbX3-yIy (X = Cl, Br) exhibits significant differences in crystallinity and optoelectronic properties. Inspired by these findings, various cationic chlorides such as CsCl, FACl, MACl, RbCl, and PbCl2 have been investigated to improve the stability of PSCs by modifying surface

morphology and enhancing thermal stability. However, the coexistence of mixed perovskite with the photoinactive FAPbI3 phase can induce ion trapping and complicate performance reproduction, thus hindering scaling-up efforts.

In this work, we investigated the effect of incorporating different cationic chlorides on the photovoltaic performance of PSCs using a vacuum-based pre-crystallization procedure. We modified the morphology and charge transport properties of a mixed-cation perovskite precursor. The perovskite active layer and the complete PSC fabrication were performed under ambient air conditions, thereby, simplifying the process and reducing costs. Our findings demonstrate that the stability and efficiency of air-processed PSCs are significantly affected by Cl bonding in the cationic chloride precursor. Incorporating simultaneously, moderate amounts of CsCl and KSCN in the precursor inks promotes the formation of smooth, compact films with larger grain sizes. Combining these two precursors resulted in efficient planar PSCs with a high PCE of 18.1%. Additionally, the moisture stability of the PSCs significantly improved, retaining over 80% of the initial efficiency after exposure to ambient humidity (25-60% relative humidity) for 520 hours.

These remarkable performances of our air-processed PSCs are mainly attributed to the advanced selection of precursors and a scalable deposition process, resulting in high structural quality with compact morphology and large grain sizes and better inherent stability of the halide perovskite. This work successfully enhances the performance and stability of air-processed perovskite solar cells through the synergistic incorporation of chlorine precursors and potassium thiocyanate. Using slot die as a large-scale deposition method, solar cells with an active layer between 0.025 cm2 and 1 cm2 fabricated using the developed recipe have exhibited efficiencies between 18.1 and 14.4 %, thereby demonstrating the scalability of this approach. We have thus contributed to the field by providing a viable pathway for the large-scale production of stable and efficient PSCs, addressing key challenges in commercializing this promising technology.

EL04.08.05

Improving Quality of Vapor-Processed Perovskite Thin Film via Methylamine Post-Treatment Chaiwarut Santiwipharat, Ujjwal Das, Kevin Dobson and William Shafarman; University of Delaware, United States

While the development of methylammonium lead iodide ($MAPbI_3$) perovskite in solar harvesting research has matured for solution-based fabrication methods, the growth of high-quality material from vapor processes continues to be difficult due to the challenges of vapor chemistry control. Methylamine (MA) vapor post-deposition treatments are approaches to improve the quality of $MAPbI_3$ perovskites that are compatible with vapor-processed films. Exposure to MA vapor causes a collapse of the $MAPbI_3$ crystal structure, becoming a transparent liquid phase in MA ambient, recrystallizing back to the perovskite structure on the removal of MA gas. The treatment improves film morphology and crystallinity, producing highly oriented, large-grain perovskite films. In this work, characterization of the liquefaction and recrystallization processes during MA post-treatments of vapor-grown $MAPbI_3$ perovskite films is performed. The impacts of major treatment factors, including substrate temperature, MA partial pressure, and MA exhaust flow are identified. Enhancement of material electronic properties through defect healing following treatment is confirmed from steady-state and time-resolved photoluminescence spectroscopy. Solar cells from the films treated at optimal conditions showed increased open circuit voltage to over 1 V and fill factor up to 70%. Statistical data on solar cell performance is provided as additional evidence to support the conclusion. The result of this study is a useful pathway for the fabrication of high-quality $MAPbI_3$ films from all-vapor process manufacturing.

EL04.08.06

Structural and Optoelectronic Investigations of Smallest Organic Spacers Based 2D Ruddlesden-Popper and Dion-Jacobson Perovskites Abhishek Yadav and Shahab Ahmad; Indian Institute of Technology Jodhpur, India

In recent years, 2D metal halide perovskites (MHPs) emerged as organic-inorganic solution processable semiconductors attributed to their enhanced structural stability and unique optoelectronic properties compared to 3D MHPs [1,2]. The 2D MHPs are mainly classified into two phases named Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) perovskites, which depend on the incorporated organic spacer type and its arrangement [2]. To investigate how the incorporated organic spacer type can affect the fundamental properties and which is better for optoelectronics. In this work, we incorporated the smallest and analogous organic spacers 'ethylammonium' (EA) and 'ethylenediammonium' (EDA) in $MAPbI_3$ to form analogous RP-EA and DJ-EDA perovskites (n=1-4), respectively and investigated their structural, morphological, dielectric, and optoelectronic properties [3]. In addition, the effective high-frequency dielectric constants (ε_{eff}) of RP-EA and DJ-EDA are estimated and correlated with their optical properties, which showed that higher ε_{eff} mismatch from bulk counterparts ($MAPbI_3$) is responsible for sharp exciton absorbance behaviour observed in the DJ-EDA perovskite thin films. Furthermore, the DJ-EDA perovskite-based photodetectors revealed improved stability and a higher photoresponsivity of ~1.00 mA/W (n=4). They retained 97.67% (n=2) of the initial photocurrent after 50 cycles under 1 Sun illumination in the ambient atmosphere conditions owing to their van der Waals gap-free structure. On the other hand, the RP-EA perovskite photodetectors showed fast response times, which is attributed to better band alignment and in-plane crystal morphology. This work provides the fundamental understanding of structural and photophysical properties of the smallest carbon chain organic spacers-based RP and DJ perovskites, which can further their development for several other optoelectronic applications.

EL04.08.07

Fabrication of 2D, Quasi-2D and 3D Tin Iodide Perovskite Thin Films Using Aqueous Precursor Inks and Evaluation of Their Optical Properties and Stability Koji Yokoyama, Haruki Horikawa, Sunghyun Kwon, Shun Yokoyama and Hideyuki Takahashi; Tohoku University, Japan

Metal halide perovskites are promising photoactive materials for photovoltaic cells. One of their advantages is that their optical properties and operational stability can be controlled by their composition and structural dimensions. While lead iodide perovskites have attracted considerable research interest, their tin counterparts are also gaining attention due to their low toxicity and desirable optical bandgap. However, tin iodide perovskites are vulnerable to oxygen and moisture, leading to oxidation and decomposition even in ambient environments. Additionally, tin sources are insoluble in water. Therefore, inert environments and anhydrous organic solvents are required to synthesize tin iodide perovskites. The ambient aqueous-phase synthesis of tin iodide perovskites can be achieved by using appropriate reductants to suppress oxidative decomposition and chelating agents to form soluble tin-chelate complexes. We previously reported that 3D methylammonium tin iodide perovskite ($MASnI_3$) crystals can be stably synthesized from ambient aqueous solutions using ascorbic acid (AA) as both a reductant and chelating agent. In this study, we extend this approach to the synthesis of 2D ($(PEA)_2SnI_4$; PEA: phenylethylammonium) and quasi-2D ($(PEA)_2(MA)_{n-1}Sn_nI_{3n+1}$; n=3–5) tin iodide perovskite crystals, and further to the fabrication of these thin films.

Stannous iodide/chloride and AA were added to the precursor aqueous solutions as the tin source and reductant/chelating agent. MAI was then added as the organic cation source for 3D perovskites, PEAI for 2D perovskites, and both MAI and PEAI for quasi-2D perovskites. These aqueous solutions were stirred and heated before being spin-coated onto glass substrates or glass substrates with TiO_2 layers, followed by annealing in ambient air to form thin films. For comparison, anhydrous organic solvent-based precursor solutions were prepared and spin-coated to form thin films. The resulting thin films were characterized using scanning electron microscopy (SEM), X-ray diffractometry (XRD), ultraviolet-visible-near infrared (UV-Vis-NIR) absorption spectroscopy, and photoluminescence (PL) spectroscopy. The ambient stability of each thin film was evaluated by comparing the XRD, absorbance, and PL spectra immediately after preparation and after exposure to ambient air for a certain period. The tin sources were completely dissolved in aqueous solutions with AA, indicating that AA served as a chelating agent and formed soluble Sn-AA complexes. When the prepared precursor solutions were spin-coated onto the substrates, they rapidly turned blackish, indicating the formation of perovskite thin films. In the SEM images of the thin films, plate-like, accordion-like, and cubic structures were observed, which are characteristic structures of 2D, quasi-2D, and 3D perovskites, respectively. The XRD profiles also supported these respective structural dimensions. The optical bandgaps of 2D, quasi-2D, and 3D perovskite thin films were determined to be 1.9, 1.3–1.5, and 1.2 eV, respectively, from the UV-Vis-NIR and PL analyses, clearly indicating that the optical properties were successfully tuned by the structural dimensions. The 2D perovskite thin films retained high PL intensity even after exposure to ambient air, indicating their extraordinary stability. Furthermore, for all dimensions of perovskite thin films, those prepared from aqueous precursor solutions containing AA exhibited higher stability than those obtained from anhydrous organic solvent-based precursor solutions. This suggests that AA not only stabilizes the valence states of tin species in the precursor solutions but also remains in the resulting thin films, protecting them from oxidative decomposition. In summary, an unprecedented approach using AA as a multifunctional additive—reductant, chelating agent, and surface protector—successfully prepared highly stable 2D, quasi-2D, and 3D tin iodide perovskite thin films from aqueous precursor solutions.

EL04.08.08

Development of Gradient Composition Lead Halide Perovskite Single Crystals for Scintillation Rock D. Huebner[1,2], Kunal Datta[1], Carlo Andrea Riccardo Perini[1], Brent Wagner[2], Zhitao Kang[2] and Juan-Pablo Correa-Baena[1]; [1]Georgia Institute of Technology, United States; [2]Georgia Tech Research Institute, United States

In recent years, the demand for fast, high-quality radiographic imaging and sensing technology has been steadily increasing across diverse fields such as medical diagnostics, security, and research applications, including Time-of-Flight Positron Emission Tomography (TOFPET). However, current radiographic imaging technology relies on expensive and environmentally sensitive single crystal scintillators grown from melts in high temperature furnaces. Metal halide perovskites (MHPs) are an emerging class of semiconductors that offer promising alternatives to current scintillator materials due to their ease of fabrication, low cost, and desirable optoelectronic properties. However, self-absorption, or reabsorption of emissions from within the crystal, is a key issue facing MHP single crystal scintillators due to the increased fraction of nonradiative recombination. This work approaches the problem of self-absorption by utilizing the unique property of compositional flexibility in MHPs to create a halide gradient heterojunction within a perovskite single crystal. This gradient is achieved using inverse temperature crystallization, an already accepted solution-based growth method for MHPs, to create a heterojunction between CH_3NH_3(MA)$PbBr_3$ and CH_3NH_3(MA)$PbCl_3$. We propose that the gradient in composition causes a gradient in band structure, allowing emissions to pass through the bulk of the crystal without being reabsorbed, as well as enabling carriers funneling from higher to lower band gaps. These factors lead to enhanced efficiencies compared to bulk single crystal scintillators.

EL04.08.09

Halide Perovskite Devices (*n-i-p*) in Vacuum Dependent Study—What Can Go Wrong? Sudeshna Ghosh[1], Akash Nayak[1], Debasmita Pariari[2], Dipankar Das Sarma[2] and Shaibal K. Sarkar[1]; [1]Indian Institute of Technology Bombay, India; [2]Indian Institute of Science, India

Organic-inorganic halide Perovskite devices, with high specific power, low processing cost, flexibility, and high tolerance to defects, make it a suitable candidate for the space applications, however with a caveat. In the domain of space-based applications, solar cells encounter a myriad of environmental stressors, including vacuum conditions, exposure to atomic oxygen, elevated levels of high-energy radiation (X-rays and gamma rays), as well as charged particle radiation (comprising high-energy electrons and protons), plasma exposure, extreme temperature fluctuations, and cyclic thermal conditions term, among others. Consequently, enduring stability over extended durations emerges as a paramount consideration within such a context. Through this presentation, I elucidate the fundamental scientific impediments faced by perovskite photovoltaic devices employing the n-i-p architecture and incorporating triple cation /$FAPbI_3$ compositions within high vacuum environments, i.e. 10^{-5} Torr. Our investigation discerns two intertwined challenges: (a) constraints in charge transport and (b) variations in optoelectronic attributes upon transitioning these devices from ambient conditions to high vacuum settings. Notably, our study underscores the significant influence of experimental parameters within specific high vacuum conditions on these observed phenomena. We explicate the adverse consequences of 2D-perovskite passivation on device performance compared to its unaltered state, stemming from degradation induced by vacuum conditions. Furthermore, we delineate how ALD-Al_2O_3 passivation presents itself as a viable option for maintaining continuous functionality under such challenging environmental circumstances over 300 hours retaining 94 % of its initial value.

EL04.08.10

Low-Dimensional Hybrid Lead-Free Azetidinium Metal Halides Young Un Jin[1], Bernd Marler[2], Andrei N. Salak[3], Marianela E. Castillo[1], Niels J. Benson[1] and Doru C. Lupascu[1]; [1]Universität Duisburg-Essen, Germany; [2]Ruhr-Universität Bochum, Germany; [3]Universidade de Aveiro, Portugal

In the past decade, hybrid halide perovskites have attracted attention in optoelectronics and photovoltaics due to their large absorption coefficient, appropriate bandgap, and decent electronic properties.[1,2] However, the Pb-content in the crystal structure and instability issues have raised questions for industrialization of these materials. The synthesis of alternate lead-free hybrid halides is of high interest in the field. Inorganic metal halide, $Cs_2AgBiBr_6$ has been found to be one of the good alternatives, where the material does not include Pb, and is more stable than Pb-containing halides.[3] Nevertheless, its wide and indirect bandgap does not yield a high power conversion efficiency in photovoltaics. As a hybrid structure of lead-free halides, $(MA/FA)SnI_3$ or $(MA)_3Bi_2I_9$ have been considered noteworthy. $(MA/FA)SnI_3$ has a proper bandgap, but poor stability under moisture. The Sn^{2+} easily oxidizes to Sn^{4+}.[4] $(MA)_3Bi_2I_9$, is not considered to be an ideal light absorber in photovoltaics due to its large bandgap and low dimensionality, but its structural and optical property induce interest in luminescent perovskite research.[5]
According to this background, we have synthesized several new lead-free azetidinium metal halides and investigated their fundamental material properties: $[(CH_2)_3NH_2]_2AgBiBr_6$, $[(CH_2)_3NH_2]_3Bi_2I_9$, $[(CH_2)_3NH_2]_3Bi_2Br_9$, $[(CH_2)_3NH_2]_3Bi_2Cl_9$, $[(CH_2)_3NH_2]_3Sb_2I_9$, $[(CH_2)_3NH_2]_3Sb_2Br_9$, and $[(CH_2)_3NH_2]_3Sb_2Cl_9$. Azetidinium, $[(CH_2)_3NH_2]^+$ is one of the potential organic molecular cations for the A-site in hybrid halide perovskites since it has a similar effective radius as methylammonium and formamidnium.[6] In spite of that, Azetidinium has been rarely studied in hybrid halide perovskites. Our materials have a low-dimensional perovskite-like structure from 0D to 2D where the replacement on the B-site is based on Ag^+/Bi^{3+}, Bi^{3+}, and Sb^{3+}. All materials have shown good stability in moisture. We found an excitonic band state. This is promising in tandem photovoltaics and luminescent perovskites. To understand the molecular dynamics of azetidinium in the crystal lattice, we used synchrotron X-ray diffraction

measurements at low temperatures. We believe that our study contributes on an expanded understanding of halide perovskite materials for future research.

Metastable Oxygen-Induced Light-Enhanced Doping in Mixed Sn-Pb Halide Perovskites

Jasmeen Nespoli, Matthijs Mugge, Snigdha Lal, Bahiya Ibrahim, Bart Boshuizen, Valentina M. Caselli, Arjan J. Houtepen, Lars J. Bannenberg and Tom J. Savenije; Delft University of Technology, Netherlands

Mixed Sn-Pb perovskites are promising solar cells materials for single- and multi-junction solar cells thanks to the possibility of tuning the bandgap energy down to 1.2-1.3 eV. However, tin-containing perovskites are adversely affected by multiple factors leading to doping. In this work, we investigated metastable oxygen-induced doping in $ASn_xPb_{1-x}I_3$ (where A is methylammonium or a mixture of formamidinium and cesium) by means of microwave conductivity, structural and optical characterization techniques. We observe that longer oxygen exposure times lead to progressively higher dark conductivities ranging from <~1 to ~40 S/m, which slowly decay back to their original levels over days when the layers were stored under N_2. Allegedly, oxygen acts as an electron acceptor, leading to tin oxidation from Sn^{2+} to Sn^{4+} and creation of free holes which effectively p-dope the perovskite. Additionally, the metastable oxygen-induced doping is enhanced by exposing the perovskite simultaneously to oxygen and light. Presumably, on illumination electrons are excited to the conduction band of perovskite and the reaction with oxygen is substantially favored in comparison to valence band electrons, explaining the enhanced conversion rate by light. Next, we show that doping not only leads to a reduction in the photoconductivity signal but also induces long-term effects even after loss of doping, which is thought to derive from consecutive oxidation reactions leading to the formation of defect states. In addition to that, we revealed that short-term exposure to oxygen immediately impairs the charge carrier dynamics of the perovskite, while structural and optical changes are only noticeable upon long-term exposure to oxygen and light. Indeed, on prolonged exposure the perovskite crystal structure deteriorates due to a build-up of SnO_x species and loss of iodide due to the release of I_2 near the surface. We emphasize that, although the exposure to oxygen is relatively short, this is sufficient to cause immediate and enormous changes in the charge carrier dynamics. Basically, we state that the defect density arising from short-term exposure to oxygen immediately impairs the solar cell opto-electronic properties, while perovskite structural and optical properties degradation only emerges upon accumulation of oxidation products. We believe that the exposure to oxygen of mixed Sn-Pb perovskites solar cells during production and operation should be strictly prevented to improve their performance and lifetime. Moreover, understanding the oxygen-induced degradation processes is of fundamental importance to select the best materials, device architectures and encapsulation, and appropriate fabrication conditions.

Imidazolium Ionic Liquids for the Defect Passivation of Blade-Coated NiO_x/Perovskite Interface

Rojita Panta,

Sashil Chapagain, Peter Armstrong, Thad Druffel and Craig A. Grapperhaus; University of Louisville, United States

Solar cells are the future of meeting global energy demand. Currently, silicon solar cells dominate the market, but their expensive cost and complex manufacturability limit their suitability. Therefore, there is a need for less expensive, simple, and easily synthesized alternatives such as perovskite solar cells. They are highly efficient and solution-processable. However, it consists of some defects at the interface and bulk of perovskite which lowers its performance as well as stability. Thus, defect passivation of perovskite is the efficacious way to further improve its power conversion efficiency (PCE) and durability. In this work, four different anions paired with the same imidazolium cation in ionic liquids were used to improve the interface of $NiO_x/MAPbI_3$ interface. Based on preliminary studies, 1-butyl-3-methyl imidazolium ($BMIM^+$) cation and four different anions, Br^-, BF_4^-, PF_6^-, and Gly^- (glycinate) were selected to impede the redox reaction between $NiO_x/MAPbI_3$ interface. Among them, glycinate anion shows the best performance which is due to its coordinating ability to the adjacent layers and its high conductivity. This approach led to increased efficiency from 11.2% to 14.2% PCE and the champion device maintained 84.3% of its initial PCE after 500 h under continuous light illumination at 35 °C in a glovebox.

Ambient Synthesis of Low-Defect Formanmidinium-Based Perovskite Solar Cells with Bromine-Enhanced Structural Stability Muntae Hwang, Il-Wook Cho, Jaewon Oh, Hyunbok Lee and Mee-Yi Ryu; Kangwon National University, Korea (the Republic of)

Using mixed cations and halides is a useful strategy for synthesizing high-efficiency organic-inorganic metal halide perovskite solar cell because it improves the stability of the perovskite structure. Adding cesium (Cs) cations instead of formamidinium [$CH(NH_2)_2^+$, FA] cations in $FAPbI_3$ addresses the phase transition issue of $FAPbI_3$ under room temperature, resulting in increased power conversion efficiency (PCE) of solar cell. In $CsFAPbI_3$ synthesized under ambient conditions, substituting high concentration of Cs instead of FA is important because FA is decomposed into sym-triazine and ammonia in the presence of moisture. Additionally, an increase in Cs concentration leads to lower free energy of mixing in $CsFAPbI_3$, thereby enhancing structural stability. However, when synthesizing $CsFAPbI_3$ with high concentration of Cs under ambient conditions, phase separation with δ-$CsPbI_3$ occurs due to moisture, leading to a decrease in PCE.
In this study, we present a method to suppress δ-$CsPbI_3$ formation in $Cs_{0.22}FA_{0.78}PbI_3$ by incorporating lead bromide ($PbBr_2$) into the perovskite precursor. The substitution of bromine (Br) directly forms Br-enriched perovskite phase instead of intermediate phase, leading to homogeneous grain growth, thereby suppressing δ-$CsPbI_3$ and reducing grain boundaries. Moreover, the properties of perovskites with varying concentrations of Br were analyzed. As the concentration of Br increased, there was a preference grain growth for the (110) plane direction over the (100) plane direction of perovskite phase, leading to decrease thickness of perovskite. Additionally, the light soaking effect, which indicates a separation between Br and iodine (I) during illumination, increased with higher Br concentrations. The highest PCE of 15.56% was observed in the perovskite solar cell with a 10% of Br concentration, attributed to the longest carrier lifetime and strongest PL intensity, resulting in reduced non-radiative recombination between the perovskite layer and charge transport layer. This study demonstrates a promising approach for producing low-defect FA-based perovskite films under ambient conditions, potentially advancing the commercial viability of perovskite-based solar cells.

EL04.08.14

Naphthalene Diimide-Modified SnO_2 Enabling Low Temperature Processing for Efficient ITO-Free Flexible Perovskite Solar Cells Il-Wook Cho[1,2], Ga Yeon Kim[2], Sangcho Kim[2], Yu-Jun Lee[2], Jaewon Oh[1], Muntae Hwang[1], Mee-Yi Ryu[1], Jinho Lee[3], Soo-Young Jang[2], Kwanghee Lee[2] and Hongkyu Kang[2]; [1]Kangwon National University, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of); [3]Incheon National

University, Korea (the Republic of)

A low-cost and indium-tin-oxide (ITO)-free electrode-based flexible perovskite solar cell (PSC) that can be fabricated by roll-to-roll processing shall developed for successful commercialization. High processing temperatures present a challenge for the PSC fabrication on flexible substrates. The most efficient planar n-i-p PSC structure, which utilize a metal oxide as an electron transport layer (ETL), necessitate high annealing temperature. In addition, the device performance deteriorates owing to the migration of halogen ions, which causes the oxidation of the metal electrodes. These drawbacks conflict with the development of highly efficient flexible PSCs fabricated on ITO-free transparent electrodes. Therefore, the development of ETL that can be processed at low temperature is one of the biggest challenges.
In this work, we demonstrated an innovative method of forming high-quality ETL at low temperature for highly efficient flexible PSC. By simply adding a (sulfobetaine-*N*,*N*-dimethylamino)propyl naphthalene diimide (NDI-B) into the tin dioxide (SnO_2), we obtained high quality and good coverage of SnO_2 film in spite of low temperature annealing. NDI-B plays a crucial role in ETL/perovskite interface; NDI-B suppresses the interfacial nonradiative recombination between ETL and perovskite by passivating defect centers and modulating the work function difference between ETL and perovskite. Consequently, we have successfully fabricated a low temperature processed flexible PSC and obtained the highest PCE of 17.48 %.

EL04.08.15

Reversible Oxidative p-Doping in 2D Tin-Based Halide Perovskite Transistors Jaeyong Woo[1], Yeeun Kim[1], Young-Kwang Jung[2], Heebeom Ahn[1], Inha Kim[1], Youjin Reo[3], Hyungbin Lim[1], Changjun Lee[1], Jonghoon Lee[1], Yongjin Kim[1], Hyeonmin Choi[1], Jeongjae Lee[1], Samuel D. Stranks[2], Henning Sirringhaus[2], Yong-Young Noh[3], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom; [3]Pohang University of Science and Technology, Korea (the Republic of)

Tin-based halide perovskites exhibit excellent electrical properties, making them promising semiconducting materials for various optical and electrical devices. Despite significant advances, their susceptibility to environmental factors such as oxygen and moisture often limits reliable device operation [1]. Two-dimensional tin-based perovskites show better stability than their three-dimensional counterparts while maintaining good electrical properties [2], but they are still not entirely stable. Therefore, understanding atmospheric effects and the underlying mechanism is crucial for developing stable and reliable tin-based perovskite devices. However, the intricate mechanisms are yet to be fully elucidated.
In this study, we investigated the effects of ambient air exposure on phenethylammonium tin iodide ($(PEA)_2SnI_4$) perovskite field effect transistors (FETs) [3]. Upon exposure to ambient air for minutes, we observed a significant p-shift (+15.8 V in the threshold voltage) and enhanced p-type conduction. Remarkably, successively exposing $(PEA)_2SnI_4$ FETs to vacuum conditions displays a gradual recovery of the electrical properties to their pristine states. The X-ray photoelectron spectroscopy and X-ray diffraction studies revealed negligible degradation, such as Sn^{2+}-to-Sn^{4+} oxidation or perovskite decomposition, under successive air and vacuum conditions. Additional electrical measurements identified oxygen in ambient air as the primary agent driving this reversible doping phenomenon.
To identify the mechanism of reversible p-doping, we did a theoretical study using density functional theory. We found that oxygen molecules occupying interstitial sites within the perovskite lattice can act as electron acceptors which induce p-doping without causing degradation. Both experimental and theoretical results support that reversible p-doping phenomena occur when exposing the perovskites to ambient air for several minutes. Our findings will advance the understanding of environmental effects on tin-based perovskites, offering insights for improving the reliability and stability of perovskite devices.

Photoelectrochemical Perovskite-BiVO$_4$ Tandem Devices for Solar Fuel Synthesis

Virgil Andrei; University of Cambridge, United Kingdom

Metal halide perovskites have emerged as promising alternatives to commonly employed light absorbers for solar fuel synthesis, enabling unassisted photoelectrochemical (PEC) water splitting[1,2] and CO$_2$ reduction to syngas.[3,4] While the bare perovskite light absorber is rapidly degraded by moisture, recent developments in the device structure have led to substantial advances in the device stability. Here, we give an overview of the latest progress in perovskite PEC devices, introducing design principles to improve their performance and reliability. For this purpose, we will discuss the role of charge selective layers in increasing the device photocurrent and photovoltage, by fine-tuning the band alignment and enabling efficient charge separation. A further beneficial effect of hydrophobicity is revealed by comparing devices with different hole transport layers (HTLs).[1,2] On the manufacturing side, we will provide new insights into how appropriate encapsulation techniques can extend the device lifetime to a few days under operation in aqueous media.[2,3] To this end, we replace low melting alloys with graphite epoxy paste as a conductive, hydrophobic and low-cost encapsulant.[2,5] These design principles are successfully applied to an underexplored BiOI light absorber, increasing the photocathode stability towards hydrogen evolution from minutes to months.[6] Finally, we take a glance at the next steps required for scalable solar fuels production, showcasing our latest progress in terms of device manufacturing. A suitable choice of materials can decrease the device cost tenfold and expand the device functionality, resulting in flexible, floating artificial leaves.[4] Those materials are compatible with large-scale, automated fabrication processes, which present the most potential towards future real-world applications.[7,8] Similar PEC systems approaching a m^2 size can take advantage of the modularity of artificial leaves,[9] whereas thermoelectric generators can further bolster water splitting by utilizing waste heat to provide an additional Seebeck voltage.[10,11]

Unraveling Charge Transport and Passivation Effects in Perovskite Solar Cells with Different Modifications

for Enhanced Performance and Stability Apoorva Singh[1,2] and Praveen C Ramamurthy[1]; [1]Indian Institute of Science Bangalore, India; [2]University of Massachusetts Amherst, United States

Perovskite solar cells, which have emerged in the last decade, have garnered significant interest and growth due to their exceptional properties such as high absorption coefficients, efficient charge carrier mobilities, solution processibility, low cost, and compatibility with roll-to-roll industrial processing. Despite the excitement and potential surrounding this rapidly advancing photovoltaic technology, challenges remain in comprehending the fundamentals of charge carrier transport, material composition, and film growth dynamics. Additionally, degradation and instability continue to be major obstacles to commercialization.
Firstly, the presented studies explore intriguing results from modifications made to the solar cell devices' electron transfer layer (SnO2) vices using chlorinated alkali salts (Li, Na, and K) in the classical perovskite structure CH3NH3PbI3Firstly the studies explore intriguing results from modifications made to the solar cell devices' electron transfer layer (SnO_2) vices using chlorinated alkali salts (Li, Na, and K) in the classical perovskite structure $CH_3NH_3PbI_3$. Secondly, wide-bandgap compositions, including $CH_3NH_3PbBr_3$ and the mixed iodide-bromide system ($CH_3NH_3PbI_{3x}Br_{3(1-x)}$), were examined as photoactive layers to evaluate their potential in tandem solar cells. A significant portion of the research focuses on tracking the degradation profiles of these devices at different load conditions, such as continuous illumination and maximum power point tracking. Performance and stability experiments utilize advanced and novel spectroscopic techniques. Lastly, a few unusual degradation pathways in perovskite solar cells and observations made by incorporating piezoceramic material into the photovoltaic architecture, resembling the memory effect, are briefly introduced. The insights gained may help address some of the critical challenges in the field.

EL04.08.18

Tertiary Amine Oxides as Perovskite Nanocrystal Ligands and Components of Polymeric Nanocomposites Grace Leone and Todd Emrick; University of Massachusetts Amherst, United States

As a class of semiconductor nanocrystals that exhibits high photoluminescence quantum yield (PLQY) at tunable wavelengths, perovskite nanocrystals (PNCs) are attractive candidates for optoelectronic and light emitting devices. However, attempts to optimize PNC integration into optoelectronic and light emitting devices suffer from PNC instability and loss of PL over time. Here, we describe the impact of organic and polymeric N-oxides when used in post-synthetic processing of PNCs, whereby a significant increase in quantum yield is observed in solution, and stable PL emission is obtained in polymeric nanocomposites. Specifically, when using aliphatic N-oxides in post-synthetic ligand exchange with $CsPbBr_3$ PNCs in solution, a substantial boost in PNC brightness was observed (~40% or more PLQY increase), followed by an alteration of the perovskite chemistry. However, when N-oxide substituents were positioned pendent to a poly(n-butyl methacrylate) backbone, the optically clear flexible nanocomposite films obtained had bright PL emission and maintained optical clarity, PL emission, and nanocrystal structure for months. Tertiary amine oxides are currently being investigated as small molecule aliphatic and polymeric ligands for lead-free perovskite nanocrystals, particularly $Cs_3Cu_2I_5$. In preliminary experiments, amine oxides have demonstrated an ability to bind to Cu-based NCs and improve dispersion. X-ray diffraction proved useful for characterizing the PNC crystal structure before and after ligand exchange, while electron microscopy (EM) and small-angle x-ray scattering (SAXS) measurements of the PNC-polymer nanocomposites are used to evaluate the ability of the polymeric N-oxide platform to cleanly disperse PNCs in flexible polymer films.

EL04.08.19

***n*- and *p*-Type Dopants for Halide Perovskites** John L. Lyons, Michael W. Swift, Brendon Jones, Michael Stewart, Barbara Marcheschi, John Murphy, Kyle Sendgikoski, Todd H. Brintlinger and Sarah Brittman; U.S. Naval Research

Laboratory, United States

The halide perovskites, such as cesium tin bromide ($CsSnBr_3$) and methylammonium lead iodide (MAPI), are high-performing light emitters, with applications in lighting, displays, and photovoltaics. All of these applications would benefit from better control over the perovskites' electrical conductivity. However, it has proven difficult to achieve high p-type carrier concentrations in these materials, and reliable n-type-doping strategies have not been developed. In this work, possible dopants are first evaluated in the halide perovskites using first-principles calculations based on a hybrid functional with spin-orbit coupling. This approach not only leads to accurate predictions for band structure and band offsets, but also provides a better description of dopant properties. We assess whether dopant impurities (such as Ag, Na, and Cu for acceptors, and Bi, Sc, and Y for donors) can act as shallow dopants on the proper substitutional site, and whether other configurations of these impurities might lead to compensation of potential electrical conductivity. Among the p-type dopants considered, sodium and silver are identified as the most promising acceptors for achieving p-type conductivity, and optimum chemical potential conditions for these dopants are identified [1]. Turning to donor doping, we find that common n-type dopants such as Bi are deep defects [2]. We demonstrate the validity of our first-principles calculations by comparing with optical measurements of Bi-doped $CsPbBr_3$ crystals. Bi donors are found to give rise to characteristic near-infrared luminescence, in good agreement with theoretical predictions. While Bi is a deep donor in the halide perovskites, yttrium and scandium are identified as promising donor dopants that are capable of yielding n-type conductivity in a variety of halide perovskite systems [2].

Direct Upcycling of Lead Halide Perovskite Solids by Using Supramolecules for Second Harmonic Generation

Qian Wang and Lina Quan; Virginia Tech, United States

Extensive research has been conducted on organic-inorganic lead halide perovskites, exploring their significant potential for applications such as photovoltaics, LEDs, and detectors. However, the major issue of lead toxicity has drawn considerable attention, requiring an urgent solution for the efficient, sustainable upcycling of halide perovskite precursors. In this study, we will introduce a novel family of supramolecular metal halide materials by extracting the primary precursor components of halide perovskites—lead halide and organic amines—into a solid-state crystalline system through the self-assembly of supramolecular structures. Remarkably, we observed nonlinear optical activities in the upcycled single-crystalline self-assembled structures, which can directly produce circularly polarized second harmonic generation (CP-SHG) through linearly polarized infrared light excitation, exhibiting a high polarization efficiency at room temperature. These findings suggest promising applications in the fields of nonlinear optics and photonics. Additionally, annealing the recycled compound at high temperatures convert the supramolecular metal halides back into parent perovskite phase, which demonstrate restored light absorption, and narrow photoluminescence. The supramolecular material's dual functionality and thermal robustness make it suitable for high-efficiency solar cells, LEDs, and high-temperature sensors, thereby enhancing our understanding of phase transitions in hybrid materials and facilitating the development of advanced multifunctional optical and electronic devices.

Self-Clocking True Random Number Generator with Enhanced Stochasticity in Polymer-Blended Perovskite

Minz Lee[1,2], Dante D. Ahn[1,2] and Yusin Pak[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Random numbers play a critical role in many areas, including lotteries, simulations, and cryptographic applications. As the Internet of Things (IoT) and optical computing continue to grow, the need for robust encryption methods to ensure the security of personal data has become paramount. Currently, software-based algorithms predominantly use deterministic random numbers due to their cost-effectiveness and ease of use. However, the vulnerability of these systems to powerful supercomputers necessitates the search for more secure alternatives. The rise of artificial intelligence technologies has brought hardware-based random number generators into the spotlight, with true random number generators (TRNGs) using photonic sources emerging as promising alternatives.

TRNGs, relying on shot, thermal, and electronic noise sources, are often sensitive to environmental changes and require intricate comparator circuits for constant threshold adjustment. Optical phase noise, while less affected by environmental variations, demands sophisticated laser and optical control equipment. Despite these challenges, TRNGs that utilize photon entropy sources offer intriguing possibilities through the duality of light and particles, providing a system for maximum uncertainty. This study introduces a novel approach: a hybrid (anionic polymer and perovskite) photodetector-based TRNG designed to maximize stochastic and random photogeneration. The system is comprised of four components: a light-emitting diode (LED), a photodiode, an amplifier, and a JK flip-flop, representing a notably simplified circuit configuration. Utilizing a simple circuit with a JK flip-flop, this system achieves remarkable miniaturization, generating 10,000 bits per second without succumbing to resets or time delays. The stochastic voltage fluctuations observed, particularly at frequencies of 10 kHz or higher when light interacts with the polymer-blended MAPbI3, hold significant promise for cryptographic applications. This study shows that through the use of natural light coupled with the employment of advanced optoelectronic materials, the fabrication of an ultra-compact TRNG chip, necessitating merely two components, is feasible.

To verify the randomness of the generated binary sequences, we conducted the NIST random number test, which encompasses 15 distinct statistical tests applied to 10^6 numbers. This evaluation compared the performance of the newly developed hybrid (anionic polymer and perovskite) photodetector-based TRNG against two reference systems: a commercial silicon photodiode-based random number generator and a bare perovskite TRNG. The random numbers produced by the Si photodiode TRNG passed a mere 3 out of the 15 tests. In comparison, the bare perovskite TRNG passed 9 tests, with 6 failures predominantly linked to the length of sequences with repeated numbers and the frequency of recurring patterns. Notably, the polymer-blended perovskite TRNG surpassed all 15 tests with an average pass rate above 97%, solidifying the generated number sequence as nearly unpredictable and devoid of discernible correlation. The results substantiate the superior quality and dependability of the random numbers generated by the polymer-blended perovskite TRNG.

Future research will explore practical applications of the TRNG in real-world scenarios, focusing on integrating this technology into existing computing and IoT frameworks. Continued efforts in miniaturization, circuit optimization, and energy efficiency exploration will further enhance the adoption of this novel TRNG paradigm. This breakthrough approach contributes to the development of more secure and reliable computing and Internet of Things technologies, ensuring enhanced protection of personal and sensitive data in the digital age.

Revealing Intermediate PbI_2-DMF Solvated Crystallites via UV-VIS *In Situ* Spectroscopy on Perovskite

Precursor Solution Maximilian Spies[1], Simon Biberger[1], Fabian M. Eller[2], Eva Herzig[2] and Anna Kohler[1]; [1]Universität Bayreuth, Germany; [2]University of Bayreuth, Germany

We investigated the precursor solution for the fabrication of lead iodide perovskite thin films via UV-VIS absorption spectroscopy during the spin coating process (in situ). The optical absorption spectra of the precursor solution at concentrations suitable for thin film fabrication are difficult to measure and evaluate. However, we use thin film techniques to monitor the changes in absorption spectra of the precursor solution at concentrations relevant for device fabrication. The iodoplumbate complexes that are present in the precursor solution absorb light in the UV range, providing insights into the precursor chemistry. Since the iodoplumbate complexes are very sensitive to their environment and can alter their coordination considerably when changing parameters like the solvent or concentration, we conducted an optical in situ study during the critical phase before the nucleation. We observe the emergence of PbI_2-DMF solvated (PDS) crystallites during spin coating. These PDS crystallites mainly form from PbI_3^- complexes and act as a predecessor for subsequent crystalline perovskite phases. The amount of PDS phase is closely connected to the concentration of the precursor solution film, which we estimate using white light interference.

EL04.08.23

A Novel Dopant Strategy to Realise Ambient-Processed Hole Transport Layer for Stable Perovskite Solar Cells Shivam Nauriyal[1], Rajat Sharma[1], Shubham Gupta[2], Brijesh Patel[2], Pabitra K Nayak[2] and Shaibal K. Sarkar[1]; [1]Indian Institute of Technology Bombay, India; [2]Tata Institute of Fundamental Research Hyderabad, India

Organic-inorganic halide perovskite photovoltaics have emerged prominently in PV technology, achieving a certified efficiency milestone of 26.1%, approaching the Shockley-Queisser limit. However, stability remains the foremost obstacle to their commercialization, notably within the widely utilized n-i-p architecture of metal halide-based perovskite solar cells (PSCs), where instability manifests primarily at the perovskite/hole transport layer interface. In the context of the n-i-p architecture, spiro-OMeOTAD is commonly employed as the hole transport material, frequently coupled with the additive duo of Li-TFSI and tBp. However, the durability of perovskite solar cells over the long term is compromised due to Li^+ intercalation in the absorber layer under operational conditions, in addition to its intrinsic hygroscopic properties, which exacerbate external degradation. This study presents a novel organic dopant for the small-molecule hole transport layer processed under ambient conditions, significantly enhancing the doping efficiency and thermal stability of the PSCs.
In contrast to Li-TFSI-doped spiro-OMeOTAD, this dopant obviates the need for overnight aging to improve conductivity while maintaining >23% efficiency. Our subsequent investigation, utilizing diverse characterization techniques, reveals enhanced photoluminescence quantum yield (PLQY) and electroluminescence, indicating a substantial reduction in non-radiative recombination centers in perovskite/spiro-OMeTAD:dopant interface relative to perovskite/spiro-OMeTAD:Li-TFSI. Furthermore, the increased size of the dopant cation restricts its mobility, thereby contributing to enhanced stability compared to conventional Li-TFSI. This superiority is evident in stability studies where spiro-OMeTAD:dopant based PSCs maintained over 90% stability for more than 500 hours of maximum power point tracking under 1-sun in ambient conditions. Moreover, these devices showed minimal change during thermal cycling for 50 cycles (~ 100 hours) from 85°C to -30°C, whereas those doped with Li-TFSI experienced significant degradation. Finally, we show a much-improved performance under damp heat conditions (85% RH and 85°C) for spiro-OMeTAD:dopant based PSCs.

EL04.08.24

Nature of Exciton-Lattice Coupling and the Role of Organic Cation Substitution in Two-Dimensional Derivatives of Metal Halide Perovskites Katherine A. Koch[1], Martin Gomez-Dominguez[2], Esteban Rojas-Gatjens[2], Ramesh Dhakal[1], Burak K. Ucer[1], Stephen M. Winter[1], Juan-Pablo Correa-Baena[2] and Ajay Ram S. Kandada[1]; [1]Wake

Forest University, United States; [2]Georgia Institute of Technology, United States

A critical element of the photo-physics of metal halide perovskites (MHP) and their derivatives stems from the strong electron–phonon coupling arising from their ionic character and from the convoluted dynamics of the hybrid organic–inorganic lattice. Here, we investigate the nature and consequences of such strong lattice interactions on the exciton dynamics in prototypical two-dimensional Ruddlesden-Popper metal halides (RPMH), which are the 2D derivatives of MHPs. We have previously experimentally identified that the primary excitations in these material systems are exciton-polarons[1], where the polaronic coupling is intrinsically built into the exciton wavefunction and fundamentally drives the thermalization, recombination and dephasing dynamics[2,3]. In an attempt to underpin the role of the organic cation in these polaronic interactions, we perform a comprehensive study on a halogenated phenylethylammonium lead iodide perovskite [$(X\text{-}PEA)_2PbI_4$] to compare with our previous studies on phenylethylammonium lead iodide perovskites [$(PEA)_2PbI_4$]. The choice of the library of the cation ensures minimum reorganization of the lattice and enables us to explore unambiguously the changes governed primarily by the organic-inorganic framework. Analysis of the low-temperature linear optical spectra suggests negligible disruption in the electronic structure due to the substitution. Resonance Raman spectra obtained through impulsive vibrational spectroscopy however indicate significant change in the phonon characteristics. We observe that the lowest energy optical phonon mode shows a systematic blue shift upon substitution. We further analyze this through density functional theory calculations and identify the changes in the degrees of freedom within the inorganic metal halide layer induced by the chemical modification of the organic layer. Importantly, despite the changes in the phonon structure, exciton-phonon scattering, which is mediated by a relatively wide distribution of phonon modes in the 2-10 meV energy range remains largely intact. We also present a detailed analysis of coherent nonlinear spectral lineshapes measured via two-dimensional spectroscopy[4] and comment on the modifications in the many-body excitonic interactions induced by the organic cation substitution.

Phase Transitions in 2D Halide Perovskites Using Machine Learned Potentials Erik Fransson, Julia Wiktor and Paul Erhart; Chalmers University of Technology, Sweden

Hybrid halide perovskites are a promising class of materials for various applications, including high-efficiency solar cells, lasers, and light-emitting diodes. One of the drawbacks of these bulk 3D materials is that they often exhibit relatively low stability. So-called two-dimensional (2D) halide perovskites, composed of a small number of perovskite layers stacked on top of each other and separated by organic cations that act as spacers, have been shown to exhibit much improved stability compared to their 3D counterparts.

Here, we demonstrate that the dimensionality of 2D halide perovskites and the choice of organic linker molecules can have a strong impact on phase transitions in these materials. This is investigated through large-scale molecular dynamics simulations using machine-learned potentials. We focus on the prototypical combination of the linker molecule phenethylammonium (PEA) with the perovskite methylammonium lead halide (MAPI), but also consider the organic linker molecules butylammonium (BA) and phenylmethylammonium (PMA). Phase transitions from a high-temperature phase without octahedral tilting to a lower temperature structure with a global out-of-phase octahedral tilting pattern are found. These phase transitions can be directly observed via thermodynamic and structural parameters such as heat capacities and octahedral tilt angles. We analyze the phase transition temperatures and characteristics with varying numbers of perovskite layers to understand how the transition properties change as a function of the system's dimensionality. For a larger number of perovskite layers, the 3D bulk MAPI phase transition temperature is recovered, whereas, for only a few perovskite layers, the phase transition temperature shifts up by about 50 K. Additionally, we observe surface effects, such as the surface layers (closest to the organic linker) exhibiting stronger octahedral tilting and undergoing phase transitions at higher temperatures (about 100 K) compared to the interior bulk layers.

Design of Substituent in Tertiary Phosphine Oxide for Surface Defect Passivation in Perovskite Solar Cell

Sun-Ho Lee, Seong Chan Cho, Sang Uck Lee and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Organic-inorganic hybrid halide perovskites receive significant attention since the report of a 9.7%-efficient and 500-h-stable solid-state perovskite solar cell (PSC) in 2012. Owing to their intriguing optoelectronic characteristics and simple solution processability, power conversion efficiency (PCE) of PSCs swiftly increased from 9.7% to 26.1% in a decade. However, solution process and ionic nature of the perovskite might generate defects on the surface and grain boundary, which can affect device efficiency and stability. Interfacial engineering was proposed as one of effective methods to passivate defects. Here, we report effect of substituent in tertiary phosphine oxide (PO) passivating materials on photovoltaic performance and stability of PSCs, where the studied substituents were alkyl group with different chain length (triethylphosphine oxide (TEPO), tributylphosphine oxide (TBPO), trihexylphosphine oxide (THPO)) and cyclohexyl, phenyl, and hexterocyclic groups (tricyclohexylphosphine oxide (TCPO), triphenylphosphine oxide (TPPO) and TMPPO). From the current-voltage measurements together with theoretical calculation, TMPPO was found to be most effective substituent. Density functional theory (DFT) calculation revealed that TMPPO interacts with perovskite surface via binding of both oxygens in P=O and morpholine (oxygen in cyclohexyl group) with undercoordinated Pb on the perovskite surface. X-ray photoelectron spectroscopy showed that the Pb 4f peak shifted to lower binding energy, which confirmed the interaction via electron donating from TMPPO to the undercoordinated Pb^{2+} ions. Photoluminescence, space-charge limited current and electrochemical impedance spectroscopy were studied to understand the defect passivation. The recombination by surface traps was found to be substantially reduced by TMPPO, which eventually improved the power conversion efficiency from 21.78% to 23.72% mainly due to the improved open-circuit voltage. Moreover, operational stability was improved by the TMPPO post-treatment and bare perovskite film maintained its alpha phase over 1000 hours under light at ambient condition.

EL04.08.27

Perovskite Qauntum Dot Surface Stabilization Using Nonpolar Solvent Dispersible Lewis-Base Ligand for Efficient and Stable Solar Cells

Sanghun Han[1], Jongmin Choi[1] and Younghoon Kim[2]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Kookmin University, Korea (the Republic of)

Thick and conductive perovskite quantum dot (PQD) solids for thin film solar cells can be fabricated via facile ligand exchange process. However, the conventional ligand exchange process that using ionic short-chain ligands and polar solvent inevitably deteriorate the PQDs surface, causing the surface trap sites such as uncoordinated

Pb^{2+} sites. Thus, there is a limitation to boosting the performance of PQD solar cells using conventional ligand exchange process. Herein, we introduced novel surface stabilization strategy that can enhance the photovoltaic performance and operational stability of PQD solar cells using nonpolar solvent dispersible short-chain Lewis-base ligand. It is demonstrated that the triphenylphosphine oxide ligand can efficiently cover the uncoordinated Pb^{2+} sites via Lewis-base interaction and nonpolar solvent octane can preserve the surface components without additional desorption of surface ligands and ions. As a result, the surface stabilized PQD solar cells provide an enhanced power conversion efficiency of 15.4% together with durable device operational stability.

EL04.08.28

Machine Learning Quantification of Grain Characteristics for Perovskite Solar Cells Yalan Zhang and Yuanyuan Alvin Zhou; The Hong Kong University of Science and Technology, Hong Kong

Microstructures including grains, grain boundary grooves, and surface fluctuations prevalent in metal halide perovskite (MHP) films and can substantially impact the electronic properties, photovoltaic performance, and stability of solar cells. To surpass the Shockley-Queisser limits of perovskite solar cells (PSCs) and unlock the full potential of MHPs, it is essential to characterize and modify these microstructures. However, the measurement and statistical interpretation are still challenging due to their huge quantities. Here, we developed a machine-learning-based toolkit for extracting and quantifying microstructural characteristics of MHP from atomic force microscope, enabling a reliable statistical analysis. A convolutional neural network with U-Net structure was trained for grain region extraction, and multiple kinds of methodology were produced for quantifying the microstructural characteristics including grain surface area, grain boundary groove angles, groove width, grain surface depression and bulge. Based on this toolkit, we then expanded the study from localized measurement to their statistical distribution over the whole film, and reveal their correlation with the perovskite solar cells performance. This work not only interpret the relationship between microstructure-property-performance of perovskite solar cells, but also reveal potential modification direction for MHP and PSCs.

EL04.08.29

Exploring the Physics and Chemistry on the Perovskite Solar Cells Fabricated by Scalable Slot-Die Coating Process in Ambient Air Damian Glowienka[1], Shih-Han Huang[2,3], Pei-Huan Lee[2], Feng-Yu Tsai[2] and Wei-Fang Su[2,3]; [1]Gdansk University of Technology, Poland; [2]National Taiwan University, Taiwan; [3]Ming-Chi University of Technology, Taiwan

Perovskite solar cells (PSCs) are rapidly advancing technologies, consistently improving in terms of power conversion efficiency (PCE) and stability. However, the reproducibility of PCE across PSC devices has often been overlooked. Utilizing the scalable slot-die coating technique, PCEs ranging from 10.21% to 17.05% have been recorded, but a notable spatial distribution of performance across a 4x4 cm substrate has been observed. This variability in efficiency predominantly stems from electrical losses.

To gain a deeper understanding of these losses, our study employed advanced loss analysis techniques, including numerical simulations, to investigate the underlying mechanisms. Our findings suggest that a significant portion of the efficiency reduction can be attributed to an increase in bulk defect density, which directly correlates with the quality of the perovskite layer and influences the recombination process. Additionally, substantial charge carrier transportation losses at the HTL/perovskite interface were identified, linked to the Fermi level pinning mechanism prevalent in low-efficiency devices.

This research has culminated in the development of a chemical passivation strategy that improved the PCE from 13.81% to 18.07%, enhancing reproducibility across batches of devices. These results underscore the importance of broadening our focus beyond individual 'champion' devices to encompass all devices across different batches. Such an approach is critical for improving the reliability of the device fabrication process and achieving reproducible results in perovskite solar cell production.

EL04.08.30

Development and Fabrication of High Efficiency and Stability of Semitransparent Perovskite Solar Cells for 4-Terminal Perovskite/Silicon Tandem Solar Cells

Satish Bykkam[1], Katarzyna Grochowska[2], Katarzyna Siuzdak[2], Seweryn Szultka[1], Stanislaw Czapp[1] and Damian Glowienka[1]; [1]Gdansk University of Technology, Poland; [2]Polish Academy of Sciences, Poland

Semitransparent perovskite solar cells (PSCs) have emerged as a cutting-edge technology, bridging the gap between energy harvesting and architectural integration. Recent advancements have elevated the certified power conversion efficiency (PCE) of semitransparent PSCs to 21.68% [1]. However, for the inverted architecture, the highest recorded efficiency up to our knowledge has not crossed the limit of 18%. The crucial benefit of using inverted perovskite architecture is that it has shown superior environmental and thermal stability which is a key factor in the future application [2]. However, to use the full potential of the semitransparent solar cells, the multi-junction (tandem) could be fabricated from different band gap semiconductors.

The current research work, development, and fabrication of the semitransparent PSCs with three compositions of commercially available SnO_2 nanoparticle materials working as a buffer layer. PSCs has been also modified by changing the top metal electrode with the transparent conductive oxide (TCO) contact in order to improve the average visible transmittance (AVT) in PSCs in order to utilize part of light by c-Si solar cells. We achieve this by using three different material compositions, indium zinc oxide (In_2O_3: Zn, IZO), tungsten-doped indium oxide (In_2O_3: W, IWO) and tin-doped indium oxide (In_2O_3:Sn, ITO) as a thin film with a thickness in the range from 100 nm to 300 nm. In the following work we present the results of 4T perovskite/silicon devices improvement of efficiency and stability in order to pass the reliability tests including light soaking (ISOS-L) (>1,000 h), damp-heat (ISOS-D) (65°C /65 RH%, > 1,000 h) and outdoor stability (ISOS-O) (>4000 h).

8:00 AM *EL04.09.01
Optical Control of Symmetry Breaking in Metal Halide Perovskites Lina Quan; Virginia Tech, United States

Optical control of polarization in light, spin, and structure in solids provides a noninvasive way to drive the multifunctionality of materials. However, designing such responsive materials often requires high-energy photons or extremely low-energy photons coupled to the lattice phonon modes in traditional solid-state materials, such as oxide perovskites. Soft lattice halide perovskites are emerging as semiconducting solid-state materials that revolutionize state-of-the-art materials chemistry, physics, and optoelectronics.
In this talk, I will present our recent work on controlling polarization in light, spin, and structures in halide perovskites. I will begin with our recent observations of controlling and probing hidden polar states in copper halide perovskites by directly exciting the Jahn-Teller active copper halide lattice. This approach allows us to drive the polar domains, potentially advancing the ferroic applications of these materials.

8:30 AM EL04.09.02
Unraveling the Exciton Fine Structure of Strongly Confined 1D and 2D Halide Perovskite Nanocrystals Anna Abfalterer, Michael Seilbeck, Andreas Singldinger, Nina A. Henke and Alexander S. Urban; Ludwig-Maximilians-Universität München, Germany

Recently, single photon emission was demonstrated for the first time in standard 3D lead halide perovskite (LHP) nanocrystals (NCs).[1–3] For quantum-confined LHP nanostructures, such as 2D nanoplatelets (NPLs) and 1D nanowires (NWs), however, such single emitter studies have hitherto remained scarce,[4] possibly due to generally lower photoluminescence quantum yields and increased instability in these structures compared to the 3D NCs[5].
This limits the full exploration of LHPs with different dimensionalities as single photon emitters. Consequently, critical structure-property relationships cannot be unraveled.
By treating our low-dimensional LHP NCs post-synthetically with a novel ligand, the optical properties of our 2D $CsPbBr_3$ NPLs and 1D $CsPbBr_3$ NWs are enhanced substantially. We observe an up to 2.5- and 7-fold enhancement of the photoluminescence quantum yield for the three-monolayer thick NPLs and NWs, respectively, in comparison to the untreated NPLs and NWs prepared with standard oleylamine and oleic acid ligands. Strikingly, we observe that the post-synthetic ligand treatment makes these highly confined NCs stable enough to enable deterministic single NC spectroscopy and measurement of their exciton fine structure for the first time.
Consequently, with our results, we widen the available knowledge on the energetic structure of different-dimensional LHP NCs and pave the way to uncover crucial structure-optical property relationships to ultimately enable next-generation LHP quantum communication technologies.

8:45 AM EL04.09.03

Cathodoluminescence and Electron Backscatter Diffraction to Correlate Optical and Structural Properties of Halide Perovskite Thin Films at the Nanoscale Imme Schuringa[1], Saskia Fiedler[1], Albert Polman[1] and Bruno Ehrler[1,2]; [1]AMOLF, Netherlands; [2]University of Groningen (RUG), Netherlands

Metal halide perovskites form a very exciting material class for various opto-electronic applications. These materials form multi-crystalline films of exceptionally high quality by methods as simple as spin-coating. The soft and ionic nature of the polycrystalline perovskite films leads to highly complex material properties that can vary over time and from grain to grain. To include perovskites in commercial applications, we need to understand their optoelectronic and structural characteristics on the scale of single grains (e.g. nanometers). Cathodoluminescence (CL) microscopy has been used successfully in the past to study grain-to-grain variation in luminescence efficiency and has shown that surface traps not only dominate carrier trapping, but also are distributed unevenly amongst various grains.[1] We want to connect the optical properties to the structure of the film to find the origin of this optical heterogeneity. To this day, only few studies have correlated opto-electronic properties to structure at the nanoscale.[2,3] We combine nanoscale characterization of optical and structural properties by measuring cathodoluminescence and electron backscatter diffraction analysis on the same location in perovskite thin films. Electron backscatter diffraction is an electron microscopy technique that gives information on the local grain orientation, grain boundaries and strain.[2,4] For the first time, we combine these electron microscopy-based techniques on $CsPbBr_3$ thin films to make a quantitative correlation between luminescence intensity and grain orientation. In these evaporated thin films we find that the CL intensity and spectral shape is not correlated to the orientation of a grain, but that CL intensity is significantly decreased at the grain boundaries. We use simulations and time-resolved CL to disentangle the influence of morphology from enhanced non-radiative recombination. We showcase a new method that creates a direct link between optical and structural properties of many grains at the same time. By locating the origin of processes such as electronic carrier trapping or halide segregation, we hope to further the understanding of perovskites at the nanoscale, and inform the efforts towards more effective film passivation.

9:00 AM EL04.09.04
Wavelength Dependent Light-Induced Degradation of Perovskite Solar Cells Shinhyun Kim, Sua Park, Lee Donghyeon and Min-cheol Kim; Pusan National University, Korea (the Republic of)

Recently, perovskite solar cells (PSCs) are about to be commercialized due to their high power conversion efficiency and ease of fabrication. However, despite their high efficiency and excellent properties, there remain many challenges in the commercialization of perovskite solar cells primarily due to the low intrinsic stability of perovskite materials. Therefore, research on stability requires a lot of attention, with major factors undermining the stability of PSCs including moisture and oxygen, light, electrical bias, heat, and mechanical degradation.

Among the origin of perovskite degradation, elucidating the mechanism of light-induced degradation is critical since it is inevitable to irradiate the light to operate PSCs. Previous studies suggest that the interaction between trapped charge carriers and surrounding gas-phase molecules (oxygen and moisture) contributes to the degradation of the perovskite materials, and hole carriers are more particularly detrimental to this degradation process. In PSC, these charge carriers are generated by the broad wavelength solar irradiation. If perovskite materials degrade more significantly within specific wavelengths, blocking those wavelengths could enhance the long-term stability of PSCs.

Existing studies have suggested the degree of degradation of PSCs by wavelength with the identical intensity of the light irradiated through photodiodes or using band-pass filters from the same light source. In these studies, though the intensity of the irradiated light was identical, the number of generated charge carriers was not assured to be equal. Therefore, it was not clearly distinguished whether the difference in the degree of degradation was due to the wavelength of the light or the number of charge carriers.

Therefore, this study aims to evaluate the degree of degradation by wavelength (red = 610–800 nm, green = 500–590 nm, and blue = 300–500 nm) using band-pass filters while unifying the number of charge carriers generated in PSCs without maintaining the intensity of the irradiated light, adjusting the light intensity according to the number of charge carriers in an inert environment.

9:15 AM EL04.09.05
Unraveling the Origin of Mid-Gap Photoemission in Lead Halide Perovskites E Laine Wong[1], Yang Zhou[1], Isabella Poli[1], Jacques Hawecker[2], Michael Man[2], Keshav M. Dani[2] and Annamaria Petrozza[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Okinawa Institute of Science and Technology, Japan

Despite being solution-processed, the defect tolerant property of perovskites has allowed them to compete in the same league as silicon solar cells in terms of power conversion efficiency. However, even though often touted as one of its main strengths, proper identification and management of its many defects are crucial to the achievement of highly performant and stable photovoltaic devices. Among the various techniques used to investigate the presence of defects in perovskites, ultraviolet photoelectron spectroscopy and microscopy provides the most direct method to probe the presence, spatial distributions, and trapping dynamics of hole traps in perovskite thin films. These traps are often characterized by the presence of occupied mid-gap states in the photoemission spectra of perovskites that stretches from the valence band up to the Fermi level. Thus far, these mid-gap states have been attributed to a combination of defects such as PbI_2 defects, grain boundary defects, and polytype defects. Here, we investigate the diffraction patterns and photoemission spectra of a variety of perovskite thin films using spectroscopic low energy and photoemission electron microscope. By changing the stoichiometry of the perovskite films, we observe a positive correlation between the presence of excess PbI_2 and the photoemission intensity of these mid-gap states. In contrast, these mid-gap photoemission is strangely absent in Sn-based perovskites. Using microprobe low energy electron diffraction, we found that the presence of PbI_2 diffraction has a negative correlation with the presence of the mid-gap photoemission. Instead, upon laser irradiation, the disappearance of the PbI_2 diffraction coincides with the rise of the mid-gap photoemission. Based on these measurements, we thus reach a conclusion that the origin of these mid-gap photoemission spectra is in fact the spectra of metallic Pb, a decomposition by-product of PbI_2. The absence of these mid-gap photoemission in Sn-based perovskites is thus due to the propensity of Sn^{2+} to form various Sn^{4+} compounds such as SnI_4 and SnO_2 rather than decompose to metallic Sn.

9:30 AM EL04.09.06
Unveiling Trapping Mechanisms in Tin-Halide Perovskites Sidestepping Dopant-Mediated Recombination

Antonella Treglia[1], Giuseppe Maria Paternò[2], Isabella Poli[1] and Annamaria Petrozza[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Tin halide perovskites (THPs) are promising low-bandgap materials for photovoltaic and light-emitting applications[1-2]. In lead-based perovskites, iodine chemistry plays a major role in forming deep hole traps. However, in THPs, tin chemistry dominates[3], with tin vacancies acting as shallow defects and influencing intrinsic doping, while tin interstitials, iodine vacancies, and surface Sn(IV) serve as deep electron traps[4.]
Due to the intrinsic doping density, carrier trapping processes are overshadowed by the fast and efficient radiative recombination of photogenerated carriers with dopant holes[5,6]. As a result, even though trapping occurs, its impact on recombination dynamics might be indistinguishable from the rapid pseudo-monomolecular recombination with dopant carriers. Therefore, solely examining fast dynamics does not provide a comprehensive understanding of trap states' effects. Variations in carrier lifetime and radiative efficiency cannot be unambiguously attributed to changes in trap or doping density. This poses a significant challenge in thin-film optimization, as the effects of compositional engineering cannot be directly assessed.
To directly investigate processes unaffected by doping and dopant-mediated recombination, we use Transient Absorption Spectroscopy to study sub-bandgap and band-edge transitions over time scales from ultrafast (fs) to slow (µs). This approach clarifies the distinct roles of doping- and trap-mediated processes in determining optoelectronic properties.
The dynamics of sub-bandgap trap states at early times reveal two distinct processes: a slow component lasting longer than 1 nanosecond and a fast population of shallow traps lasting tens of picoseconds. The latter repopulates the band-edges and is particularly significant as it may impact the apparent carrier cooling. Contrarily, in time scales of microseconds, we detect long-lived trap states. By separately modulating doping and defect density with additives and intentional air exposure, we identify the spectral features and dynamics of Sn(IV) and tin interstitial (Sn_i) trap states. These findings are supported by simulations of photoexcited carrier dynamics, which replicate the decay of the transient absorption spectroscopy signal to explain the experimental data.

Broadband Luminescence in Zero-Dimensional Lead-Free Hybrid Copper Halides Yanyan Li[1,2], Ali Azmy[3], Ioannis Spanopoulos[3] and Peijun Guo[1,2]; [1]Yale University, United States; [2]Energy Sciences Institute, United States; [3]University of South Florida, United States

Lead halide perovskites have received significant attention in solid-state lighting (SSL) due to their high photoluminescence quantum yields, tunable emissions, and ease of solution processing. However, the presence of lead in these materials raises substantial environmental and health concerns. Environmentally friendly copper halides, which exhibit broadband emissions from self-trapped excitons (STEs), are emerging as promising alternatives for energy downconverting phosphors in multifunctional light-emitting applications. In this study, we successfully synthesized three new lead-free organic-inorganic hybrid copper halides: $(HA)_2CuI_3$ ($HA^+ = C_6H_{13}NH_3^+$, n-hexylammonium cation) and $(OA)_4CuX_5$ (X = Br, I; $OA^+ = C_8H_{17}NH_3^+$, n-octylammonium cation). $(HA)_2CuI_3$ crystallizes in the monoclinic space group *C2/c*, featuring 0D CuI_4 dimers, while $(OA)_4CuX_5$ (X = Br, I) crystallizes in the triclinic space group *P*, possessing 0D CuX_4 clusters. These different emission centers lead to distinct optical properties for the materials. Under 257 nm excitation, $(OA)_4CuBr_5$ and $(HA)_2CuI_3$ emit broad yellow light with PL peaks at 587 and 573 nm, respectively. Notably, OA_4CuI_5 exhibits white-light emission with two PL peaks at 493 and 616 nm, CIE chromaticity coordinates of (0.38, 0.38), and a high CRI value of 91. Time-resolved PL (TRPL) measurements reveal that their lifetimes extend into the microsecond range. Additionally, we observed that the two excitonic states in $(OA)_4CuI_5$ have different lifetimes, which we attribute to free excitons and STEs, respectively. Given their broad emission spectra, large Stokes shifts, and long lifetimes, their emissions likely originate from STEs. This work stimulates the exploration of single materials with white-light emissions for potential applications in lighting and display technologies.

How Ion Migration Dictates Perovskite Solar Cell Performance and Stability Prashant Kamat and Gabor Szabo; University of Notre Dame, United States

The thermodynamic and redox properties of halide perovskites provide a strong driving force for hole trapping and oxidation of iodide species. In particular this becomes a factor when the perovskite solar cell is operated under open circuit conditions. The accumulated holes participate in the oxidation of iodide and expulsion of I_2. The mobility of halides and their susceptibility to hole-induced oxidation play a crucial role in determining the long-term stability of metal halide perovskite solar cells. Although passivation of 3D perovskites using 2D perovskites has been reported widely, the instability of the 2D/3D interface during long term solar cell operation is apprent. The cation migration under light and heat significantly alters the 2D/3D interface, thus affecting the solar cell performance. In-situ spectroscopic measurements of halide ion and cation migration, and their effect on solar cell performance will be discussed.

Exploring Charge Transfer Dynamics in Perovskite Solar Cells Using First-Principles Methods Adriana Pecoraro, Francesca Fasulo, Michele Pavone and Ana B. Muñoz-Garcia; University of Naples Federico II, Italy

The potential of perovskite solar cells (PSCs) as a cost-effective, high-efficiency renewable energy source is largely hindered by their stability and performance issues.[1] The primary concerns originate from the interfaces between the perovskite and hole transport materials. In this study, we investigate these interface-related problems using cutting-edge first-principles calculations to offer a deeper understanding of charge transfer (CT) mechanisms and times in PSCs, particularly focusing on the role of perovskite chemical composition and the local interfacial environment.[2] Our study provides a detailed analysis of the interfaces between the spiro-MeOTAD hole transport material and two perovskite formulations: methylammonium lead iodide (MAPI) and the triple cation layered halide perovskite (LHP). We identify key chemical factors that promote favorable binding and enhance CT at these interfaces. We find that electronic interactions play a critical role in interface stability. By examining the coupling matrix elements and partial density of states, we identify specific LHP states acting as CT channels and observe a correlation between the best couplings and the localization of molecular orbitals toward the LHP surface.
Our analysis offers a novel atomic-scale perspective for a comprehensive rationalization of charge transfer mechanisms and times for some of the most representative systems of current state-of-the-art PSCs, paving the route to further investigation on the effects of dopants, defects, or buffer interlayers on key processes such as interfacial charge transfer.

Ultrafast Curing of R2R Processed Combustion Synthesized Tin Oxide Thin Films on ITO/PET Substrates by Photonic Annealing for Flexible Perovskite Solar Cells Nisha Sarda and Shaibal K. Sarkar; Indian Institute of Technology Bombay, India

The fabrication of hybrid halide perovskite devices on polymeric substrates is limited due to the relatively high-temperature processability of the metal-oxide layers. The *nip* architecture of perovskite solar cells is fabricated by using bilayer tin oxide as electron transport layer comprising of a compact and a colloidal particles dispersion thin film. Compact layer is used as perfect hole blocking layer formed from chloride precursors with high temperature processability and colloidal layer is nanoparticles of tin oxide to reduce the hysteresis with comparatively lower temperature requirements.

The motivation behind this work lies in reducing the process temperature to a limit where polymer substrates do not deform, by combustion synthesis route and radiative thermal treatment called photonic curing to deposit SnO_2 thin films on ITO coated PET substrates with uncompromised optical and electronic properties. Processing temperature of the chloride precursor is reduced by incorporating an oxidizer and mixture of fuels to undergo a combustion process at the time of annealing/photonic curing of compact layer. The exothermic process eventually reduces the overall annealing temperature of the films. Hence, this can be used for polymer substrates without their deformation.

The flexible devices with this process have achieved 24.3% power conversion efficiency (PCE). The coating of this compact layer has been done via R2R coating as well. The PCE of R2R coated flexible devices has reached 23.7% by thermal annealing and 23% by photonic curing. The devices show upto 70% of its initial performance after 9000 bending cycles with 10 mm bending radius, ~ 5000 hours of shelf life stability and good operational stability. The technology is promising for upscaling of flexible perovskite photovoltaics by significantly increasing the fabrication speed of the most time-consuming layer.

11:30 AM EL04.10.04

Impact of Non-Uniform Interfacial Ionic Accumulation on Perovskite Solar Cells Performance Degradation Studied via *In Situ* Impedance Spectroscopy Coupled with ISOS Stability Tests Juan Pablo Medina Flechas[1,2], Dounya Barrit[1], Carlos Chaparro[1], Paul Lin[1], Marion Provost[2], Estelle Cariou[2], Thomas Guillemot[2], Karim Medjoubi[2], Jorge Posada[3], Osbel Almora[4], Camille Bainier[1], Pilar Lopez Varo[2] and Philip Schulz[2]; [1]TotalEnergies OneTech, France; [2]Institut Photovoltaïque d'Ile-de-France, France; [3]EDF R&D, IPVF, France; [4]Universitat Rovira i Virgili, Spain

Adapted characterization methodologies to correlate key degradation mechanisms in full devices under operation with the variation in opto-electric properties are required for improving the long-term performance stability of perovskite solar cells (PSC). Particularly, complex dynamics of slow ionic redistribution at the perovskite (PK)/transport layers (TLs) interfaces, intrinsic to the PK layer physico-chemical stability and mediated by photo-thermal and voltage bias conditions, can impede the efficient charge extraction and trigger different types of hysteresis on current-voltage curves (I-V)[1] and metastability[2].

Impedance spectroscopy (IS) is a frequency-dependent technique increasingly used in PSC for the identification of multiple electro-chemical processes occurring at different timescales and operation modes. In this work, PSC accelerated degradation is studied by coupling in-situ IS with ISOS protocols[3]: ISOS-LC-1 light/dark (6h/18h) cycling and ISOS-L-1 light-soaking; both at 1 sun equivalent illumination and open circuit (Voc) load. During PSC degradation, the in-situ IS response is modelled using equivalent electric circuits (EC) composed of resistive (R), capacitive (C) and/or inductive (L) elements. A physical interpretation of the EC elements evolution is addressed in hand with drift-diffusion (DD) simulations[4] and with the use of additional ex-situ opto-electrical characterization techniques: I-V curves, suns-Voc, external-quantum efficiency (EQE), electroluminescence (EL) and photoluminescence (PL). Single junction cells and series-interconnected double junction modules of small area (< 0.64 cm^2) are characterized, with NiOx/SAMs/CsFAMAPb$(I_xBr_{1-x})_3$/C_{60}/SnO_2 inverted structures (bottom emission) deposited over glass-FTO substrates and with opaque (gold) or semitransparent (ITO) top-contacts.

Combining I-V and IS measurements with DD simulations proposes that specific hallmarks on the IS are correlated to: (i) the formation of interfacial energetic barriers when increasing voltage bias on initially fresh devices with gold contacts and in all the architectures after ISOS-LC-1 degradation; and (ii) to a rise in mobile ions concentration for aged devices, with higher capacitive polarization at low frequencies due to charge accumulation at the PK/TLs interfaces. Simultaneously, the coupling of IS with EL points out that the redistribution of high ionic concentrations occurs via non-uniform aggregates formation at PK/TLs interfaces when approaching flat band condition, acting as “locally rectifying” Schottky barriers. As a result, marked inductive components appear on the IS response in dark and turn more prominent at high injection levels, whilst they are partially masked with the increase of photogenerated carriers upon illumination.

A reversibility in the aggregates formation was observed after prolonged light-soaking under ISOS-L-1, mainly through the homogenization of EL and hyperspectral-PL emission along with a reduction of the IS hallmarks linked to interfacial energetic barriers. Thus, for this case study it is identified a relation between ionic aggregates formation (photo-thermal and voltage bias dependent) and the evolution of local barriers for charge injection/extraction. This can be juxtaposed with I-Vcurves fill factor reduction and s-shape transitions observed after the dark relaxation periods of ISOS-LC-1, and with performance metastability during the posterior recovery under sustained ISOS-L-1 light soaking. Lastly, the dependence of the coupled analysis on the PK bulk vs interfaces quality of charge extraction (EQE), and the influence of shunts recombination and transport losses (IS vs suns-Voc) are evaluated.

Understanding the Influence of Microstructure on Dominant Ionic Transport Pathways in Lead Halide Perovskites Connor Davel, Rock D. Huebner, Jack Lawton, Carlo Andrea Riccardo Perini, Juan-Pablo Correa-Baena and Nazanin Bassiri-Gharb; Georgia Institute of Technology, United States

Ionic Migration is a leading cause of early device failure in Lead Halide Perovskite (LHP) photovoltaics. Existing studies have proven that phase orientation, light, and voltage correlate strongly with ionic diffusion through the crystalline lattice and transformations into photo-inactive phases. However, the dominant modes of ionic migration at the microscale and their relation to microstructure and morphology are a continual source of debate and controversy in the field. In this work, non-destructive atomic force microscopy (AFM) techniques image the fine sub-grain and grain-boundary dependent ionic relaxation behavior to inform better solution processing strategies. We use electrochemical strain microscopy and conductive AFM to qualitatively identify ionic relaxation on the order of seconds in grains and grain boundaries through unsupervised machine learning analysis, decreasing bias when visualizing spatial relaxation behavior. Importantly, we find that by controlling the precursor chemistry via solvent composition, the microstructure and morphology of the film influence the bulk and grain boundary ionic diffusivity. Intensity-modulated photocurrent spectroscopy (IMPS) complements micro-scale insights and informs future device manufacturing protocols to minimize ionic transport at a fixed composition while maximizing carrier extraction. This multi-scale study gives further insight into how precursor chemistry and processing may be leveraged to improve device stability in addition to existing chemical passivation strategies.

High Efficiency and Stable Perovskite Solar Cells by Vacuum Evaporation Chenyi Yi; Tsinghua University, China

Perovskite solar cells have gained substantial attention due to their high photovoltaic performance and cost-effective production. However, challenges such as achieving high efficiency in large-area devices and ensuring adequate stability have limited their widespread commercialization. The conventional solution spin-coating technique used in research settings faces constraints including small active areas, uniformity issues, and the necessity of toxic solvents. In contrast, vacuum vapor deposition offers a solvent-free approach capable of large-scale, uniform perovskite film deposition, making it a viable option for industrial-scale production of perovskite solar cells. Nevertheless, the efficiency of perovskite cells fabricated using vacuum deposition has been substantially lower compared to solution-based methods, impeding its progress towards industrial application. Our team has innovated the process to surmount the low-efficiency challenge associated with vacuum deposition in perovskite solar cell fabrication, paving the way for the mass production of perovskite photovoltaic modules. This presentation will detail our team's advancements in enhancing the efficiency of large-area perovskite cells through vacuum evaporation, bolstering the stability of perovskite cells, and advancing high-efficiency flexible perovskite solar cells.

2:00 PM EL04.11.02

Enhancing Stability and Performance in Perovskite Solar Modules—Addressing Au/Perovskite Interface

Jiyeon Nam[1], Won-Kyu Lee[1], Da Seul Lee[2], Youngho Choe[1], Donghwan Kim[1], Hae-Seok Lee[1] and Yoonmook Kang[1]; [1]Korea University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

In the perovskite module, the upper and lower electrodes are interconnected via P2 scribes. This configuration results in direct contact between Au and the perovskite layer without the intervention of a hole transport layer (HTL), potentially promoting ion migration or chemical interactions between Au and the perovskite. Therefore, it is crucial to characterize and analyze this aspect to control degradation, particularly in regions with geometric freatures such as wrinkles where Au and perovskite contact may occur.

According to simulations conducted by W. Ming et al. the diffusion activation energy of Au interstitial ions within MAPbI3 is approximately 0.42 eV, which is relatively low. Interstitial defects do not inherently form deep levels but can readily become trapped within MA or Pb vacancies, thereby creating deep-level substitutional defects. While the occurrence of MA vacancies can vary, studies indicate the generation of volatile MA gas when the perovskite is irradiated with visible light under ambient conditions.

Considering these factors, it was anticipated that exposing perovskite cells and modules to light soaking under ambient conditions would lead to perovskite degradation, internal diffusion of Au, and potential trapping within MA vacancies, subsequently causing non-radiative recombination and impairing long-term stability.

To elucidate the degradation mechanism at the Au/perovskite interface, structural and chemical changes in cells and modules were measured pre- and post-light soaking. X-ray diffraction (XRD) was utilized to assess structural changes. Comparison of XRD peaks of perovskite before and after light soaking revealed the emergence of an intermediate phase (11.7°) and a PbI2 peak (26.3°) post-soaking. X-ray photoelectron spectroscopy (XPS) analysis of perovskite films without Au and Spiro-OMeTAD layers, post-removal, showed increased binding energy for Pb4f and I3d5 peaks after light soaking, indicating the formation of strongly bound PbI2. Additionally, fine Au peaks were detected on the perovskite surface, suggesting that light soaking induced perovskite decomposition, the creation of MA vacancies, and Au trapping at these sites, potentially acting as recombination centers and significantly affecting long-term stability.

In this study, not only were the pathways for Au diffusion into the perovskite matrix identified, but it was also confirmed that Au acts as a non-radiative recombination center upon diffusing into the perovskite. Electroluminescence (EL) was employed as a technique to observe recombination patterns within devices by applying bias, where radiative recombination emits light, resulting in brightness, while non-radiative recombination appears darker. By comparing EL images of modules before and after light soaking, it was observed that pre-soaking, there was a difference in EL intensity between wrinkled and non-wrinkled areas. However, post-

soaking, a significant decrease in EL intensity was noted at locations where wrinkles were present, as well as areas where Au and perovskite directly contacted near the P2 scribe. Furthermore, analysis of secondary ion mass spectrometry (SIMS) data revealed that post-light soaking, Au diffusion near the P2 region occurred significantly deeper in the depth direction compared to the reference point, indicating substantial Au diffusion and confirming the mobility of other ions.
In our follow-up research, we propose inserting a diffusion barrier between the top electrode and the perovskite to prevent ion migration. Candidate materials include metal oxides that prevent diffusion without degrading hole transport. Modules with the diffusion barrier are expected to maintain stability by preventing ion migration while retaining high efficiency

2:15 PM EL04.11.03

Lamination as an Alternative Manufacturing Pathway to Realize Stable Perovskite Solar Cells Md Aslam Uddin[1], Clare L. Lanaghan[1], Oluka Okia[1], Jack R. Palmer[2], David Fenning[2] and Neil P. Dasgupta[1]; [1]University of Michigan-Ann Arbor, United States; [2]University of California, San Diego, United States

Laminated perovskite solar cells (L-PSCs) have recently been shown to be a promising alternative to traditional layer-by-layer deposition processes. In this fabrication process, two transport layer-perovskite half-stacks are independently processed and laminated at the perovskite-perovskite interface through diffusion bonding. This process overcomes chemical and thermal stability limitations during cell fabrication by eliminating any deposition steps on top of the chemically and thermally sensitive perovskites. We have recently demonstrated L-PSCs with above 21% PCE, which is uniquely enabled by a combination of inorganic transport layers and SAM passivation at both ETL and HTL interfaces.[1]
Here, we demonstrate the lamination of MA-free $Cs_{0.1}FA_{0.9}PbI_3$ PSCs for the first time, avoiding the volatile and reactive nature of the MA^+ cation and instabilities from Br de-mixing. Laminated $Cs_{0.1}FA_{0.9}PbI_3$ PSCs incorporating *in situ* small-molecule passivants show a maximum efficiency of over 20.6% (average of 19.9 ± 0.6%). Additionally, lamination provides a pathway to improve stability compared to traditional fabrication processes because it results in the self-encapsulation of the perovskite layers between two substrates immediately upon finishing the device. We show that laminated devices retain 95% of their initial efficiency after 50 thermal cycles from -40° to 85 °C, while maintaining a mechanical toughness after TC50 that is greater than the pristine toughness reported for layer-by-layer cells of similar efficiency. We further demonstrated improved stability under 1-sun, 85°C test conditions. These results highlight the potential of both self-encapsulation and novel passivation strategies that are enabled by the lamination process toward durable, commercially-relevant perovskite solar cells.

Stability Analysis and *In Situ* Characterization of Perovskite Solar Cells Monica Lira-Cantu; Catalan Institute of Nanoscience and Nanotechnology, Spain

In the last few years, Perovskite solar cells have demonstrated an impressive power conversion efficiency enhancement, but also a boost in device stability. The latter is allowing us to be witness the first examples of PSC modules reaching commercialization. In this conference we will discuss about the implementation of stability analyses made to Perovskite Solar Cells fabricated at our laboratory in Barcelona (Spain): indoor, outdoor and in-situ characterization analysis have been carried out allowing for a global perspective on the different degradation mechanisms observed at different scenarios. Our results will include (a) the use of machine learning tools to corelate indoor (ISOS-L) and outdoor (ISOS-O) stability analysis; (b) the monitoring of strain observed to the halide perovskite during in-situ characterization under accelerated stability test under light and bias voltage and (c) the effect of additive engineering and transport layer modification on device lifetime.

Lattice Matching Using Spinel Oxides for Long Term Stability of Methylammonium-Free Lead Halide Perovskites Diana K. LaFollette, Carlo Andrea Riccardo Perini and Juan-Pablo Correa-Baena; Georgia Institute of Technology, United States

Perovskite solar cells still suffer from long term instability that can be linked to strain in the crystal structure induced during thermal annealing, causing defect formation, and ion migration. This work uses lattice matching to stabilize the cubic perovskite crystal structure and prevent secondary phase formation using a new family of materials: spinel oxides.

Spinel oxides are promising candidates for lattice matching and heteroepitaxial growth due to their wide range of tunable lattice parameters, ability to be grown in thin layers through techniques like physical layer deposition, and potential for good band alignment. This work shows the use of spinel oxides as a lattice matching layer to stabilize the cubic Cs-FA perovskite phase. This study increases key understanding of crystallization and degradation of lead halide perovskites and proposes a potential method for fabricating more efficient and stable perovskite solar cells. Grazing incidence XRD and grazing incidence wide angle X-ray scattering (GIWAXS) are used to structurally characterize the effects of the lattice templating layer on the crystal structure from the surface to the bulk. Cathodoluminescence SEM goes even further to spatially correlate the morphology of templated and non-templated films to their optical properties. This study shows the potential for spinel oxides to be used as a lattice matching layer to facilitate heteroepitaxial growth of lead halide perovskites and improve long term stability by stabilizing the crystal structure.

4:15 PM EL04.12.03

A Crystal Capping Layer for Formation of Black-Phase $FAPbI_3$ Perovskite in Humid Air Mingyang Wei; National University of Singapore, Singapore

Black-phase formamidinium lead iodide (α-$FAPbI_3$) perovskites are the desired phase for photovoltaic applications, but water can trigger formation of photoinactive impurity phases such as δ-$FAPbI_3$. We show that the classic solvent system for perovskite fabrication exacerbates this reproducibility challenge. The conventional coordinative solvent, dimethyl sulfoxide (DMSO), promoted δ-$FAPbI_3$ formation under high relative humidity (RH) conditions because of its hygroscopic nature. We introduced chlorine-containing organic molecules to form a capping layer that blocked moisture penetration while preserving DMSO-based complexes to regulate crystal growth. We report power conversion efficiencies of >24.5% for perovskite solar cells fabricated across an RH range of 20% to 60%, and 23.4% at 80% RH. The unencapsulated device retained 96% of its initial performance in air (with 40 to 60% RH) after 500-hour maximum power point operation.

4:30 PM EL04.12.04

Proton Radiation Tolerance of Wide-Bandgap Halide Perovskites for Advanced Space Photovoltaic Applications Hongjae Shim[1], Seongrok Seo[2] and Jae Sung Yun[3,1]; [1]University of New South Wales, Australia; [2]University of Oxford, United Kingdom; [3]University of Surrey, United Kingdom

The pursuit of efficient and resilient photovoltaic materials for space applications has led to the exploration of organic-inorganic halide perovskites, recognized for their excellent optoelectronic properties and potential radiation tolerance. This study specifically examines the proton irradiation effects on organic-inorganic mixed-halide perovskite thin films and their corresponding photovoltaic devices with a power conversion efficiency (PCE) of over 20%.
We subjected the perovskite thin films and photovoltaic devices to proton irradiation at an energy of 80 keV and a fluence of 2E14 protons/cm^2, simulating the extreme conditions encountered in space. Characterizations performed on the thin films included photoluminescence (PL) spectroscopy, X-ray diffraction (XRD), scanning electron microscopy (SEM), time-of-flight secondary ion mass spectrometry (Tof-SIMS) depth profiling, X-ray photoelectron spectroscopy (XPS) depth profiling, and time-of-flight elastic recoil detection analysis (Tof-ERDA) depth profiling. Additionally, current-voltage (I-V) measurements were conducted before and after proton irradiation to evaluate the photovoltaic performance.
Our results demonstrate that the perovskite photovoltaic devices not only endure the proton irradiation but also exhibit a recovery in performance post-irradiation. The in-depth characterization of the thin films provides insights into the mechanisms behind this recovery, highlighting the robustness and potential of wide-bandgap halide perovskites for space photovoltaic applications. This research contributes valuable knowledge towards the development of durable and high-performance solar cells for future space missions, emphasizing the importance of understanding and enhancing the radiation tolerance of advanced photovoltaic materials.

4:45 PM EL04.12.05

Assessing Perovskites' Stability Through Machine Learning Algorithms Abigail Hering[1], Mansha Dubey[1], Seyede Elahe H. Imeni[1], Meghna Srivastava[1], Yu An[2], Juan-Pablo Correa-Baena[2], Houman Homayoun[1] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]Georgia Institute of Technology, United States

Halide perovskites have high-performing yet variable optical properties, which is currently impeding their adoption in optoelectronic devices. The exact degradation mechanisms are not well understood due to the immense composition parameter space involved[12], and their dynamic, often confounding response to environmental stressors (such as humidity, temperature, oxygen, light, and bias).[3] To quantify the degradation of several different perovskite compositions, we use a custom-built, high throughput, *in situ* photoluminescence (PL) characterization to collect sufficient data to train a variety of machine learning (ML) models. We compare forecasts of PL of several $Cs_yFA_{1-y}Pb(Br_xI_{1-x})_3$ perovskites in response to relative humidity and temperature cycling with linear regression (LR), echo state network (ESN), and seasonal autoregressive integrated moving average with exogenous regressors

(SARIMAX)[4], and extreme gradient boosting (XGBoost)[5] algorithms. Overall, we find that these models enable predictions of PL figures of merit, such as peak location, area, intensity, and full-width half max (FWHM), with up to 98% accuracy when trained on 100 hours of data. Furthermore, we create a generalized model that can predict the PL behavior of ten compositions unseen during model training. The relative feature importance and correlations between environmental inputs and optical performance show that composition dominates sample degradation. The stable compositions, which in this family contain small percentages of cesium and bromine, respond more cyclically to environmental stressors, and they recover their optical properties after rest. The development of automized workflows for high- throughput data collection and ML analysis greatly accelerates energy materials discovery, as this model can be extended to encompass up to hundreds of perovskite compositions.[6]

5:00 PM *EL04.12.06

Revealing Light-Induced Changes in Mixed-Halide Perovskites Through Multimodal Microscopy Rebecca A. Belisle; Wellesley College, United States

Stability remains a key concern in the development of lead halide perovskites for optoelectronic devices. While perovskites are extremely defect tolerant, a key to their success as solution processed semiconductors, the presence of ionic defects that can readily move through the lattice at room temperature have been attributed to both reversable changes in behavior (i.e. current-voltage hysteresis), and irreversible device degradation (i.e. electrode corrosion). To add to this complexity, excited-state carriers have been observed to change the number of and nature of defects in materials, exacerbating instabilities under illumination and bias. To develop stable photovoltaics requires understanding and control of these effects. Here, we provide insight into photo-induced instabilities in mixed-halide perovskites. Using multimodal microscopy with complimentary X-ray diffraction we track changes in composition and optoelectronic property at the microscale in $MAPb(I_xBr_{1-x})_3$ perovskites. To understand the role of carrier-induced defects on heterogeneity we collect absorption and photoluminescence maps of encapsulated perovskite films before and after aging under one sun, allowing us to track local changes in optoelectronic property under illumination. With these measurements we observe that illumination drives both the well documented reversible halide-segregation process, and irreversible changes in the film structure, composition, and property. Over longer periods of time (>24 hours) we observe changes in structure and optical bandgap consistent with the selective expulsion of iodine from a mixed iodide-bromide perovskite composition. This is done without noticeable degradation of the perovskite, as the films are observed to have a higher bandgap, brighter luminescence, and more uniform luminescence after extended illumination. Overall, these advances improve our understanding of the complex photoinstabilities in mixed-halide perovskites, and the potential role tuning chemistry and microstructure can have on achieving long term stability.

A Robotics-Guided Approach to Tune the Emission of 2D Perovskites Through Organic Cation Alloying Jolene N. Keller, Zachary D. Coons and Connor G. Bischak; The University of Utah, United States

Tuning the optoelectronic properties of halide perovskite materials through alloying cations and halides has emerged as a powerful method to tailor these materials for specific applications, such as photovoltaics and LEDs. In two-dimensional perovskites, the organic spacer cation is typically considered as not impacting the electronic properties of the material. We show, however, that mixing different organic spacer cations tunes the emission of two-dimensional perovskites by controlling octahedral tilting of the inorganic layers. Using a homebuilt, high-throughput robotic system, we blend different organic cations and investigate their optical properties. Along with X-ray scattering and nanoscale imaging, we show that certain cation pairs mix and others phase separate. Our goal is to develop the materials design principles that dictate whether organic cations mix or demix when incorporated in a two-dimension perovskite, enabling new ways to tune the optical properties of these materials.

EL04.13.02

Optimization of Hole Transport Layer/Perovskite Interface for $MAPbI_3$ Solar Cells Fabricated on PET Substrates Bishal Bhandari, Justin C. Bonner, Cody R. Allen, Robert Piper and Julia W. Hsu; The University of Texas at Dallas, United States

Because high-quality films can be made from solution deposition and low-temperature processing, perovskite films can be fabricated on flexible substrates, enabling roll-to-roll (R2R) high-throughput manufacturing of perovskite solar cells (PSCs). To achieve high efficiency, transparent conducting electrodes (TCEs) used in flexible PSCs must be highly conductive, transparent, chemically inert, and smooth. However, the low working temperatures of plastic substrates restrict the processing parameters and lead to lower-quality TCE films. In this work, we fabricate flexible hybrid TCEs by combining flexographically printed silver metal bus lines with blade-coated silver nanowires and an overcoat of indium zinc oxide sol-gel film on polyethylene terephthalate (PET) substrates. With this approach, hybrid TCEs exhibit an average transmittance > 80%, sheet resistance < 10 Ω/sq, and surface roughness < 5 nm.[1] We fabricated perovskite solar cells (PSCs) with a *p-i-n* structure on hybrid TCEs and compared them to commercially available PET/indium tin oxide (ITO) and PET /insulator/metal/insulator substrates. Due to the thermal limitation of the plastic substrate, we utilized low-temperature solution-processable hole transport layers (HTLs) like poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) and nickel oxide nanoparticles for PSC fabrication. Using as received PEDOT:PSS as the HTL, PSCs on hybrid TCEs achieved an average PCE of 5.1%, while those on PET/ITO exhibited an average PCE of 2.5%. Lower device performance on both the TCEs was due to the acidic nature of PEDOT:PSS (pH = 1.7), which can etch metal oxide on the PET substrates and increase its surface roughness.[2] To mitigate such effects, we introduced a bilayer HTL by depositing a neutral PEDOT:PSS (pH = 7) layer on the PET/TCEs followed by the as-received PEDOT:PSS layer. This improved the average PCE of PSCs on hybrid TCEs to 10% and on PET/ITO to 3.9%. Further improvements were observed when MeO-2PACz, a self-assembled monolayer, was deposited on top of the PEDOT:PSS bilayer, enhancing the device performance to an average PCE of 11% on hybrid TCEs and 7.4% on PET/ITO. Additionally, to assess the scalability of PSCs made on hybrid TCEs, we fabricated 1 cm^2 large-area devices. We employed scanning electron microscope, X-ray diffraction, steady-state photoluminescence, time-resolved photoluminescence, surface photovoltage, and electrochemical impedance spectroscopy to study the structural properties of perovskite utilizing different HTLs on flexible TCEs and the impact of MeO-2PACz on charge transfer dynamics at the HTL/perovskite interface. In addition to providing better PSC performance, incorporating MeO-2PACz into the PEDOT:PSS bilayer can enhance their stability. We evaluated the shelf stability of PSCs fabricated on hybrid TCEs and PET/ITO stored in a nitrogen glovebox without encapsulation. PSCs fabricated on hybrid TCEs retained 50% of their initial average PCE over 1500 hours. While for PSCs fabricated on PET/ITO, the average PCE declined to 10% of its initial value in just over 200 hours. These findings aim to advance the development of high-performance, cost-effective, and stable flexible PSC technologies suitable for large-scale production.

EL04.13.03

Efficiency Improvement in Lead-Free Perovskite Solar Cells Using All-Inorganic Electron Transfer Layer (ETL) and Hole Transfer Layer (HTL) Byoung-Seong Jeong[1,2]; [1]Kyungpook National University, United States; [2]KNU Advanced Material Research Institute, Korea (the Republic of)

In this study, various factors such as individual layer thickness, acceptor density (NA), defect density, interface defect density, and the metal electrode work function affecting the efficiency of the lead-free perovskite solar cell (PSC) were investigated using the SCAPS-1D (Solar Cell Capacitance Simulator in 1 Dimension) simulation. The analyzed device had a structure of FTO/ZnO/$CsSnI_3$/NiO_x/Au. ZnO served as the electron transport layer (ETL), $CsSnI_3$ as the perovskite absorption layer (PAL), and NiO_x as the hole transport layer (HTL), all contributing to optimizing device performance.
Organic materials are highly affected by moisture and oxygen, whereas inorganic materials are less sensitive to these factors, thus simplifying the overall photovoltaic solar cell structure. The inorganic ETL materials selected in this study were chosen from those exhibiting n-type semiconductor characteristics, such as ZnO and TiO_2, known for their wide bandgap energy characteristics. Among them, ZnO, which is plentiful and non-toxic, offers a broad bandgap (Eg = 3.26 eV) and high electron mobility, ranking it among the most promising ETL materials. Materials such as NiO_x and Cu_2O, which exhibit p-type semiconductor characteristics, were chosen as inorganic HTL materials. Especially, NiO_x is noted for its excellent electron-blocking ability and chemical stability.

Tin-based perovskite materials were applied as the absorption layer. This Tin-based inorganic perovskite ($CsSnX_3$) offers advantages like a band gap near 1.4 eV and high mobility. Specifically, $CsSnI_3$ has a band gap ranging from 1.3 to 1.4 eV and demonstrates a high absorption coefficient of 10^4 cm^{-1} in the visible spectrum. Additionally, it boasts superior thermal stability with a melting point of 451°C, significantly higher than conventional perovskites such as $MASnI_3$ and $FASnI_3$, which melt at 200°C. For this device optimization, SCAPS-1D software was employed. To optimize the power conversion efficiency (PCE) of the device, the thickness of each layer (ETL, HTL, and PAL) was first considered. The optimal thicknesses were determined to be 20nm for the ETL (ZnO), 700nm for the PAL ($CsSnI_3$), and 10nm for the HTL (NiO_x), with Au as the metal electrode. Following the optimization of thickness, the ideal PAL acceptor density (NA) was determined to be 2×10^{19} cm^{-3} to achieve optimal PCE.
As a result of this optimization process, efficiency increased from 11% to maximum around 23%. These findings are expected to enhance the performance of eco-friendly, lead-free inorganic solar cells utilizing Sn-based perovskite as the PAL.

Full-Color Fiber Light-Emitting Diodes Based on Perovskite Quantum Wire Arrays Beitao Ren and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

Fiber light-emitting diode (Fi-LED), which can be used for wearable lighting and display devices, is one of the key components for fiber/textile electronics. However, there exists a number of impediments to overcome on device fabrication with fiber-like substrates, such as gravity and surface tension-induced non-uniform coating, low-quality crystallization, complex process for electrode deposition, etc., which culminate in uneven and inefficient light emission. Here, we uniformly grew all-inorganic perovskite quantum wire (PeQW) arrays by filling high-density alumina nanopores on the surface of aluminum (Al) fibers with a dip-coating process. The obtained PeQWs exhibit a prominent photoluminescence quantum yield (PLQY) of nearly 90% and a noticeable photoluminescence (PL) lifetime (T_{PL50}) of up to 1,500 hours under ambient condition. With a 2-step evaporation method to coat a surrounding transporting layer and semi-transparent electrode, we successfully fabricated full-color Fi-LEDs with emission peaks at 625 nm (red), 512 nm (green), and 490 nm (sky-blue), respectively. Intriguingly, additional polydimethylsiloxane packaging helps instill the mechanical bendability, stretchability, and waterproof feature of Fi-LEDs. The plasticity of Al fiber also allows the one-dimensional architecture Fi-LED to be shaped and constructed for two-dimensional or even three-dimensional architectures, opening up a new vista for novel lighting with unconventional formfactors.

Decoding the Broadband Emission of Two-Dimensional Pb-Sn Halide Perovskites Through High-Throughput Exploration Elham Foadian[1], Jonghee Yang[2], Yipeng Tang[1], Sumner B. Harris[3], Christopher M Rouleau[3], Syed Joy[4], Kenneth R. Graham[4], Benjamin J. Lawrie[3], Bin Hu[1] and Mahshid Ahmadi[1]; [1]The University of Tennessee, Knoxville, United States; [2]Yonsei University, Korea (the Republic of); [3]Oak Ridge National Laboratory, United States; [4]University of Kentucky, United States

Unlike single-component two-dimensional (2D) metal halide perovskites (MHPs) exhibiting sharp excitonic photoluminescence (PL), a broadband PL emerges in mixed Pb-Sn 2D lattices. Two physical models –self-trapped exciton and defect-induced Stokes-shift – have been proposed to explain this unconventional phenomenon. However, the explanations provide limited rationalizations without consideration of the formidable compositional space, and thus, the fundamental origin of broadband PL remains elusive. Herein, we established our high-throughput automated experimental workflow to systematically explore the broadband PL in mixed Pb-Sn 2D MHPs, employing PEA (Phenethylammonium) as a model cation known to work as a rigid organic spacer. Spectrally, the broadband PL becomes further broadened with rapid PEA_2PbI_4 phase segregation with increasing

Pb concentrations during early-stage crystallization. Counterintuitively, MHPs with high Pb concentrations exhibit prolonged PL lifetimes. Hyperspectral microscopy identifies substantial PEA_2PbI_4 phase segregation in those films, hypothesizing that the establishment of charge transfer excitons by the phase segregation upon crystallization at high-Pb compositions results in distinctive PL properties. Our results indicate that two independent mechanisms—defect-induced Stoke-shifts and the establishment of charge transfer excitons by phase segregation—coexist which significantly correlates with the Pb:Sn ratio, thereby simultaneously contributing to the broadband PL emission in 2D mixed Pb-Sn HPs. Our high-throughput approach allows us to reconcile the controversial prior models describing the origin of the broadband emission in 2D Pb-Sn MHPs, shedding light on how to comprehensively explore the fundamentals and functionalities of the complex materials systems.

EL04.13.06

Bulk Defect Passivation of $MAPbI_3$ Perovskite Films Using Benzyl Trimethyl Ammonium Tribromide Towards Improvement of Efficiency and Stability Bhabani Swain, Abdul Kareem K. Soopy, Hiba Shahulhameed, Afna Manaf and Adel Najar; United Arab Emirates University, United Arab Emirates

Solution-processed halide perovskites have a large variety of defects due to the low formation energy and fast growth process during spin coating process. Herein, we introduce benzyl trimethyl ammonium tribromide (BTMATB) in the precursor of perovskite solution to passivate uncoordinated defects in the bulk and at the grain boundary of perovskite film. The BTMATB introduced into perovskite precursor solution regulates the growth of the perovskite film, which effectively passivate the Pb^{2+} and X^- related defects in the bulk and grain boundary of $MAPbI_3$ perovskite films. In addition, the passivated films showed better morphologies and crystallinity compared to the pristine films. As a result, the BTMATB-treated planar perovskite solar cell device with a device architecture of ITO/SnO_2/$MAPbI_3$/Spiro-OMeTAD/Au achieves a power conversion efficiency (PCE) of 19.34 %, which is higher than the pristine device (PCE=17.14 %). Moreover, the hydrophobic benzyl chain improves the device stability by which the device retains 90% of PCE after 600 hr.

Breaking the Shockley-Queisser (SQ) Limit to Develop a Next Generation of Solar Cell Tuhin Ghosh and Jianbo Gao; Brock University, Canada

Abstract: To overcome the well-known Shockley-Queisser (SQ) limit, one novel approach is to utilize the hot carrier generation and collection mechanism, which can achieve more than 67 % power conversion efficiency. A hot carrier is the photogenerated carrier above band gap, due to its extra energy difference between incident photon energy and optical band gap.[i] One signature of the hot carrier photovoltaic (PV) technology is a higher open-circuit voltage (V_{OC}) than the band gap of solar absorbers.
However, hot carrier PV technology still suffers from the difficulty in collection of the ultra-short time scale hot carrier due to their rapid electron-phonon interaction. In the recent time, hybrid organic-inorganic based perovskite-based structure (e.g., $APbX_3$, where A = Cs, methylammonium (MA) or formamidinium (FA), X = (Cl, Br, I)) shows their capability in used as hot carrier solar cell due to their prolong carrier lifetime beyond 10s of picosecond or nanosecond, measured by the ultrafast pump-probe and time-resolved photoluminescence.[ii] However, all those characterizations not only investigated the perovskite thin films or solutions, rather than the solar cell working condition (i.e., *in-situ*), but also limited to the carrier diffusion mechanism, while the photocurrent obey the carrier drift understanding.
Here lies some urgency to characterize the photocurrent within *in-situ* based perovskite solar cell (PSC) using a novel ultrafast photovoltaic spectroscopy to directly collect the photocurrent, when the solar cell at work.[iii] For the first time, with a sub - 40ps time resolution, we discover a transient V_{OC} much larger than the band gap of the mixed cation (CsMAFA) perovskite solar cells with >20% efficiency. We further investigate the hot carrier drift

transport property, which depends on film thickness and temperature.

Eco-Friendly All-Layer Green Solvent Efficient Perovskite Solar Cells Min-cheol Kim[1], Byeong Jo Kim[2], Hyunseok Choi[1], Sua Park[1] and Gerrit Boschloo[2]; [1]Pusan National University, Korea (the Republic of); [2]Uppsala University, Sweden

Perovskite solar cells (PSCs) have made significant advancements, becoming great candidate for the next-generation photovoltaics. They offer notable power conversion efficiencies (PCEs) of up to 26.1%, high flexibility, and relatively low manufacturing costs. However, several key challenges prevent their widespread commercial adoption, including toxicity of the materials and chemicals used in their production. Most high-efficiency PSCs currently rely on the toxic solvent N,N-dimethylformamide (DMF), which is unsuitable for large-scale production. While many studies have addressed stability and scalability, less progress has been made in identifying non-toxic, green solvents for PSC production. This study aims to address this gap by identifying and utilizing green solvents for a more sustainable approach to PSC production.

This study focused on the utilization of gamma-valerolactone (GVL), a biodegradable and non-toxic polar aprotic solvent. The environmental friendliness and potential for dissolving perovskite precursors of GVL make it a promising candidate. However, GVL faces solubility challenges with critical components like lead iodide (PbI_2) and formamidinium iodide (FAI), which are necessary for high-efficiency perovskite films. This research investigates the use of methylammonium chloride (MACl) to enhance the solubility of FAI and PbI_2 in GVL-based solutions, facilitating the formation of high-quality perovskite films. Our results show that MACl not only resolves solubility issues but also significantly improves the morphology, optical, and electrical properties of the films. MACl promotes the formation of the α-phase in $FAPbI_3$, known for its superior photovoltaic performance over the δ-phase, which dominates without proper processing or additives.

We thoroughly characterized the impact of MACl on perovskite films using various analytical techniques, including Scanning Electron Microscopy (SEM) for morphology, X-Ray Diffraction (XRD) for phase composition, and photoluminescence (PL) and UV-visible spectroscopy for optical properties. Films with higher MACl concentrations exhibited larger grain sizes, reduced defect density at grain boundaries, and enhanced phase stability, all contributing to improved device performance. By leveraging the benefits of GVL and MACl, we developed an all-layer green solvent PSC fabrication process, achieving a PCE of 20.6%. When comparing the normalized performance by dividing the PCE by the green solvent index, the GVL-based all-layer green solvent PSC significantly outperformed other high-efficiency PSCs, highlighting the potential of GVL and MACl as viable alternatives for environmentally friendly PSC production.

In summary, this study introduces a sustainable PSC fabrication method that maintains high efficiency and stability. By addressing solubility challenges of GVL using MACl as an additive, we demonstrate the feasibility of producing high-performance, eco-friendly PSCs. This work advances green chemistry in photovoltaics and sets a foundation for future research aimed at reducing the environmental impact of PSC manufacturing.

EL04.13.09

Increased Below-Bandgap Absorption in $CsPbBr_3/Cs_4PbBr_6$ Through Post-Annealing and Regrowth

Naoki Noborio[1], Mitsuki Fukuda[1], Shuhei Ichikawa[1,2] and Kazunobu Kojima[1]; [1]Osaka University, Japan; [2]Research Center for UHVEM, Japan

Lead halide perovskites have attracted much attention for optical devices such as light-emitting diodes, solar cells, and photodetectors due to the high light-absorption coefficient and the tunable bandgaps by adjusting the halide ratios or changing the compositions. Among many kinds of lead halide perovskites, $CsPbBr_3$ has exhibited high external quantum efficiency (EQE) and remarkably narrow line-width of photoluminescence (PL). Similarly to other lead halide perovskites, however, the optical properties of $CsPbBr_3$ are also affected by the fragility against moisture, illumination, and heating, which limit further application in photonics and optoelectronics. To overcome the instability, $CsPbBr_3/Cs_4PbBr_6$ structures, where $CsPbBr_3$ nanocrystals embedded in Cs_4PbBr_6, have recently become a research hotspot. In addition, anti-Stokes light emission that occurs at higher energy than the excitation energy has been confirmed in the $CsPbBr_3/Cs_4PbBr_6$ composites, and it suggests a possibility to realize optical refrigeration[1]. Although anti-Stokes PL (AS-PL) is essential to achieve the optical refrigeration, the absorption coefficient decreases exponentially with energies below the bandgap energy. Assuming the EQE of the AS-PL is almost 100%, the optimal excitation energy for cooling is reported to be 2.33 eV[2], and increased light absorption at the excitation energy is critical to obtain large amount of AS-PL. In this study, we report on enhanced light absorption of $CsPbBr_3/Cs_4PbBr_6$ structures under below-bandgap excitation by increasing the crystal sizes and thermal annealing technique.

$CsPbBr_3/Cs_4PbBr_6$ crystals were grown by following procedures, CsBr powders and $PbBr_2$ powders (molar ratio 3:1) were dissolved in a fixed mixture of *N*, *N*-dimethylformamide (DMF) and aqueous solution of HBr (volume ratio 5:4) at 100°C. At first, the solution was cooled down to 50°C with 12 hours, and micro-sized crystals were precipitated at the bottom of a glass vial. To grow seed $CsPbBr_3/Cs_4PbBr_6$ crystals, we decreased the temperature of the solution to 40°C with the rate of 2.5°C per day, and subsequently cooled it to room temperature with the rate of 5°C per day. After the precipitated $CsPbBr_3/Cs_4PbBr_6$ crystals were dissolved in a mixture of DMF and HBr at 80°C to prepare a supersaturated solution, and a $CsPbBr_3/Cs_4PbBr_6$ seed crystal was placed at the bottom of the glass vial. The solution was then cooled to room temperature with a rate of 10°C per day. A large $CsPbBr_3/Cs_4PbBr_6$ crystal (0.725 g) with more than four times as heavy as the seed crystal (0.179 g) was successfully grown after the twice regrowth-process. AS-PLs were clearly observed in both seed and regrown crystals, and the PL spectra and the EQEs indicated that the regrown crystal maintained crystal quality same as the seed crystal. Furthermore, it was found that the light absorption under 2.33 eV excitation increased from 4.4% to 15.6% (around 4-fold) reflecting the sample sizes. In addition, the size of $CsPbBr_3$ nanocrystals embedded in Cs_4PbBr_6 can be controlled by proper annealing process[3], and it would improve the absorption coefficient and control the optoelectronic and photovoltaic properties. We conducted thermal annealing for the regrown $CsPbBr_3/Cs_4PbBr_6$ crystals at different annealing temperature (ranging from 125°C to 300°C) for a minute in ambient air atmosphere. The PL peaks after the annealing processes exhibited red-shifts as the annealing temperature increased. Consequently, the optimal annealing condition for the material was determined to be 200°C, where the light-absorption was enhanced maintaining high EQEs. We concluded that the regrowth technique and annealing treatment for $CsPbBr_3/Cs_4PbBr_6$ crystals were quite effective to achieve large amount of AS-PLs towards optical refrigeration.

Intrinsic Limits of Charge Carrier Mobilities in Halide Perovskites—From 3D to Layered Materials

Mikael Kepenekian[1], Bruno Cucco[1,2], Josh Leveillee[2], Viet-Anh Ha[2], Jacky Even[3], Feliciano Giustino[2] and George Volonakis[1]; [1]Université de Rennes, France; [2]The University of Texas at Austin, United States; [3]Institut National des Sciences Appliquées de Rennes, France

Layered halide perovskites hold great promises as potential alternatives to three-dimensional (3D) halide perovskites due to their improved stability and larger material phase space, allowing fine tuning of structural, electronic, and optical properties. However, their charge carrier mobilities are significantly smaller than those of 3D halide perovskites, which has a considerable impact on their application in optoelectronic devices. Here, we employ state-of-the-art *ab initio* approaches to unveil the electron-phonon mechanisms responsible for the diminished transport properties of layered halide perovskites. Starting from a prototypical halide perovskite, we model the case of n=1 and n=2 layered structures and compare their electronic and transport properties to the 3D reference.

The electronic and phononic properties are investigated within density functional theory (DFT) and density functional perturbation theory (DFPT), while transport properties are obtained via the *ab initio* Boltzmann transport equation. The vibrational modes contributing to charge carrier scattering are investigated and associated with polar-phonon scattering mechanisms arising from the long-range Fröhlich coupling and deformation-potential scattering processes. Our investigation reveals that the lower mobilities in layered systems primarily originate from the increased electronic density of states at the vicinity of the band edges, while the electron-phonon coupling strength remains similar. Such an increase is caused by the dimensionality reduction and the break in octahedra connectivity along the stacking direction. Our findings provide a fundamental understanding of the electron-phonon coupling mechanisms in layered perovskites and highlight the intrinsic limitations of the charge carrier transport in these materials.

EL04.13.11

Tin Perovskite with Various Modifications and Hole Transport Layers

Chun-Hsiao Kuan and Eric W. Diau; National Yang Ming Chiao Tung University, Taiwan

Tin-based perovskite solar cells (TPSCs) present a promising lead-free alternative to traditional lead-based PSCs for photovoltaic applications. By incorporating non-polar organic cations (IM+) into formamidine tin triiodide perovskite (FASnI3) in varying proportions and introducing Cs+ to create a triple cation structure, we discovered that the addition of sulfamic acid (SA) effectively reduces oxidized Sn4+ ions and suppresses the hysteresis phenomenon, achieving a 12.5% TPSC without hysteresis.
Enhancing performance and stability through a tandem TPSC configuration is an attractive pursuit. To achieve this, identifying a high-bandgap TPSC with a bandgap (Eg) of 1.8–2.0 eV is crucial to complement a low-bandgap TPSC with an Eg around 1.4 eV. In this study, we present the first quadruple-cation wide-bandgap TPSC with the perovskite structure FA0.55MA0.25Cs0.1PMA0.1SnBr2I, and an Eg of 1.93 eV, achieving a power conversion efficiency of 6.2%. Our findings indicate that PMA is essential in passivating the grain surface of perovskites and the interface between the perovskite and the hole-transport layer, leading to high performance and enhanced stability for the wide-bandgap TPSC with a quadruple-cation configuration.

Whats more, based on a new two-step method of tin perovskite using the concept of co solvents we introduced the co-cation method. Seven cations—methylammonium (MA), ethylammonium (EA), aziridinium (AZ), dimethylammonium (DMA), 2-hydroxyethylammonium (HEA), imidazolium (IM), and guanidinium (GA)—were used to co-crystallize with formamidinium (FA) to form co-cationic tin perovskite solar cells (TPSCs) via a two-step fabrication procedure. Time-of-flight secondary ion mass spectrometry results indicated that the pristine FA-based TPSC exhibited vacancies on both the perovskite surface and the perovskite/ PEDOT:PSS interface. Guanidinium (GA) effectively passivated these surface and interfacial vacancy defects, resulting in impressive device performance (PCE = 11.2%) and stability (>5000 hours) with negligible hysteresis.
While tin perovskites are promising as the leading candidates among lead-free perovskite options, their stability remains a significant challenge. The water absorption tendency of PEDOT:PSS makes it unsuitable as an HTL material. On the other hand, alternatives like polymer materials, despite their high hydrophobicity, often face difficulties with film formation. However, a two-step method involving PEAI pre-treatment offers a viable solution. In this method, SnI2 is prepared first, followed by a reaction with FAI in the second stage. This approach not only mitigates the rapid crystallization associated with perovskites but also, through PEAI pre-treatment, enables the development of a PTAA cell with an efficiency of 8.3%.
To further enhance the efficiency and stability of tin perovskite, a SAM structure with a thiophene π-extended conjugated unit (TQxD) was designed, which demonstrated the highest hole extraction rate and a conversion efficiency of 8.3%. This research is the first to apply a novel SAM structure in the lead-free perovskite field. Additionally, a new pyrrolopyrrolyl (PPr) polymer combined with thioalkylated/alkylated thiophene (SBT/BT) was developed. The polymer with thioalkylated tetradecyl (SBT-14) showed excellent performance and stability, achieving a power conversion efficiency (PCE) of 7.6% and long-term stability exceeding 6000 hours, a record for TPSC based on non-PEDOT:PSS. Furthermore, a series of new functionalized isothiophenes with triphenylamine (TPA) have been developed as hole transport materials (HTMs) for inverted tin-based perovskite solar cells (TPSCs). Among these, TPSCs prepared with 3-SBT-BT2D polymers exhibited the highest hole mobility and the slowest charge recombination, achieving the highest power conversion efficiency of 8.6% and maintaining 90% of their efficiency after 4000 hours. This represents the best efficiency reported so far for non-PEDOT:PSS TPSCs.

EL04.13.12

Temperature-Dependent Photophysics of Lead-Free Germanium Halide Perovskites Zachary VanOrman[1,2], Benjamin Savinson[1,3], Isaiah Gilley[4], Edward H. Sargent[4] and Sascha Feldmann[1,2]; [1]Harvard University, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]ETH Zürich, Switzerland; [4]Northwestern University, United States

Halide perovskites and their low-dimensional analogs feature excellent optoelectronic properties, resulting in efficient solar cells, detectors, and light-emitting applications. One hurdle toward widespread adoption and commercialization of halide perovskites remains their reliance on toxic lead. Substitution of Pb has been largely difficult, as geometric constraints can lead to the formation of non-perovskite structures, particularly when germanium is used.

Here, employing a recently reported organic scaffolding synthesis route[1] a series of high-purity 2D Ge perovskite single crystals with persistent octahedral structure were synthesized. We then investigated their temperature-dependent photophysical properties with that of their Pb-analogs.[2] In contrast to most existing studies to date focusing on room temperature response and limited by low luminescence yields, we find that the germanium-based material compares favorably to its Pb-analog at low temperatures, shedding light on the mechanism of temperature-dependent non-radiative decay channels for both Ge and Pb based 2D perovskites. Most notably, we report the lowest full-width-at-half-maximum photoluminescence peak reported for germanium halide perovskites to date. The insights into the photophysical mechanisms of these materials are a prerequisite to enable less toxic lead-free optoelectronic devices, where future design principles aimed at preventing non-radiative decay result in Ge-based perovskites with performance on par with or exceeding their Pb-based counterparts.

Improved Photogenerated Charge Carriers in $CsPbBr_3$ Perovskite Device Sandile Thubane, Mmantsae M. Diale and Nolwazi Nombona; University of Pretoria, South Africa

$CsPbBr_3$ perovskites have attracted attention in photovoltaic applications due to their long-term stability and broad absorption band. However, solar cell devices fabricated using this material have produced low power conversion efficiency (PCE) due to the large bandgap (2.3 eV) limiting its electrical conductivity. In this work, partial substitution of cations is done to alter the optical, structural, and electrical characteristics of $CsPbBr_3$ perovskite using a two-step solution-based deposition method. At low annealing temperatures, crystallization is observed as the Cs^+ cation is substituted with methylammonium iodide (MAI). Small grains and poor surface coverage are observed for the $CsPbBr_3$ perovskite. The partial substitution of Cs^+ to produce a double-cation perovskite facilitated an increase in grain size and pinhole-free morphology. Optical characteristics were improved as observed by the decrease in bandgap from 2.31 eV ($CsPbBr_3$) to 1.70 eV in the $MA_{0.6}Cs_{0.4}PbBr_3$ material. The small radius of Cs^+ in $MACsPbBr_3$ maintains a low effective radius in the perovskite material. It thus maintains the orthorhombic crystal structure of $CsPbBr_3$ as confirmed by X-ray diffraction. Space-charge-limited current measurements revealed an increase in electron mobility and low trap density in $FTO/TiO_2/MA_{0.6}Cs_{0.4}PbBr_3/Pd$ electron-only device as a result of pinhole-free morphology minimizing trap-assisted recombination, and improved surface coverage as compared to the pristine device. The double-cation electron-only device achieved a PCE of 5.2% while the pristine device achieved a PCE of 3.4%, maintaining 80% of their PCE for 48 and 58 hours, respectively. These findings offer a pathway to improve the electrical conductivity of $CsPbBr_3$-based perovskite material.

EL04.13.14

Efficient, Stable and Reproducible Inverted Planar Perovskite Solar Cells by Surface Modification of Dopant-Free Spiro-TTB Hole Transport Layer with PFN-P1 Interfacial Layer Tanwistha Chakrabarti[1], Sumon Das[1], Yen-Hung Lin[2] and Ajay Perumal[1]; [1]Indian Institute of Science Berhampur, India; [2]The Hong Kong University of Science and Technology, Hong Kong

Here, we report inverted (p-i-n) perovskite solar cells (PSCs) that employ an ultrathin layer of Poly(9,9-bis(3'-(N,N-dimethyl)-propyl-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene) known as PFN-P1 interfacial layer with small molecular dopant-free hole transport layer (HTL) namely (2,2',7,7'-Tetra(N,N-di-p-tolyl)amino-9,9-spirobifluorene) commonly known as Spiro-TTB. The surface modification of Spiro-TTB HTL with PFN-P1 interlayer results in improved wettability, larger grain size with higher crystallinity, reduced charge recombination, and improved energy level alignment, all of which lead to significantly improved device performance. The maximum power conversion efficiency (PCE) of 18.8% is demonstrated by optimized p-i-n perovskite solar cells using an ultrathin PFN-P1 layer over Spiro-TTB HTL and a mixed triple cation $Cs_{0.05}(FA_{0.83}MA_{0.17})_{0.95}Pb(I_{0.9}Br_{0.1})_3$ (CsMAFA) perovskite absorber layer. This is significantly higher than the maximum PCE of 15.2% for the Spiro-TTB only HTL device. Furthermore, the PSCs with PFN-P1 interfacial layer exhibit a higher open circuit voltage of approximately 1.1 V and a decreased hysteresis index (HI). Moreover, the addition of PFN-P1 layer between the HTL and the absorber layer protects the underneath Spiro-TTB from getting washed off by the DMF:DMSO mixed solvent used in perovskite precursor resulting in higher reproducibility. PFN-P1 modified PSCs exhibit smaller standard deviations (0.28, 0.18, and 0.01 respectively) for PCE, short-circuit current density (J_{SC}), and open-circuit voltage (V_{OC}) out of 20 devices, and the encapsulated devices retain 80% of their initial efficiencies after 500 hours of operation at 65 °C. This work offers an effective approach for fabricating reproducible inverted PSCs with high efficiency employing dopant-free thin HTLs.

EL04.13.15

High-Throughput Synthesis and Spectroscopy for Mapping Stability and Efficiency of Mixed Halide Sodium-Indium Double Perovskites

Yehonadav Bekenstein; Technion-Israel Institute of Technology, Israel

Lead-free double perovskites are promising for optoelectronic applications but suffer from low photoluminescence quantum yield (PLQY) due to forbidden transitions, indirect band-gaps, and energy traps. Emission mechanisms often involve the transfer of free excitons to self-trapped excitons. Exploring the role of dopant and B site alloying highlighted Sb-doped in $Cs_2NaInCl_6$ as a promising double perovskite candidate with notable PLQY. However, the role of anion compositions and possible mixtures under thermodynamic and kinetic constraints remains unclear. We used two halide mixing approaches: a direct synthesis with varying halide ratios (Cl, Br, I) and a high-throughput post-synthesis technique with an automated robotic system to explore a vast parameter space. We hypothesize that the stability of halide mixture phases could be extended to higher bromide and iodide concentrations compared to bulk counterparts. The high surface-to-volume ratio and the effect of passivating ligands can lead to kinetic trapping, in which more stable phases are inaccessible, similar to the ideas demonstrated for the silver-bismuth system. Automated experiments varied the temperature of the exchange reaction, aiming to understand the kinetic impact of temperature on halide exchange rates and the stability of halide-mixture phases. Our results showed that exchanging chloride for larger halides caused redshifts in excitation (~45 nm) and emission (~180 nm) wavelengths and increased lattice spacing. X-ray diffraction indicated halide-mixture phase stability up to 90% bromide content. When using only bromide as the X-site halide, the product (Cs_3InBr_6) was not a double perovskite but remained emissive and followed the redshift trend. The vision is that similar implementation of high throughput methodologies in future research will create comprehensive datasets to solve material stability and toxicity challenges.

EL04.13.16

Nanoconfined Metal Halide Perovskite Crystallization with Removable Polymer Scaffolds

Mia Klopfenstein and Stephanie Lee; New York University, United States

Nanoconfined crystallization, a method to control the formation of specific polymorphs and crystal orientations, typically involves creating nanoporous scaffolds prior to nanopore filling with target compounds. While nanoporous scaffolds are effective for manipulating crystallization across various materials, this method typically results in largely inaccessible, isolated nanocrystals within electrically insulating scaffolds. Typical crystal-scaffold composites for optoelectronics are thus limited in optoelectronic applications which require large active surface areas for photophysical processes. Here we reverse the order of fabricating crystal-scaffold composites by first electrospinning interconnected networks of metal halide perovskite MAPbI3 precursor nanofibers, then subsequently introducing a poly(methylmethacrylate) (PMMA) scaffold by spin coating from solution using an antisolvent for MAPbI3. Nanofibers were converted to semiconducting MAPbI3 by thermal annealing the fibers in the presence and absence of PMMA. Annealing electrospun fibers without the confining PMMA scaffold resulted in large MAPbI3 crystals protruding from the fiber surfaces. Thermal annealing in the presence of the PMMA scaffold resulted in suppressed MAPbI3 blooming from the fiber surfaces. For these fibers, small, densely packed MAPbI3

crystals within the fibers were visible via transmission electron microscopy. Near infrared photodetectors using a coplanar electrode geometry revealed a percolated charge transport network in MAPbI3 fiber-PMMA scaffold composites, with external quantum efficiencies as high as 79%, compared to 1.2% for photodetectors comprising of non-infiltrated MAPbI3 fibers. MAPbI3 fiber-PMMA scaffold composites also exhibited significantly improved stability in air, indicating this strategy to be promising for metal halide perovskite-based optoelectronics.

EL04.13.17

Studies on Non-Linear Optical Properties of Inorganic Lead Bromide Perovskite Nanocrystals Chandrima Goswami and Asha Bhardwaj; Indian Institute of Science, India

Cesium Lead Halide Perovskites are known for their alluring optoelectronic properties, such as high absorption coefficient, tuneable band gap in the visible region, long carrier diffusion lengths, and defect tolerance. Compared to their bulk counterparts, the Perovskite Nanocrystals (PNCs) show exceptionally high photoluminescence quantum yield (PLQY). The Perovskite Nanocrystals have facile solution processability as they do not require high temperatures for fabrication and are formed within seconds. Based on these properties, this class of materials is being extensively used in solar cells, light-emitting diodes, photodetectors, lasers, and so on. This incredible amalgamation of fascinating properties has only increased the quest to explore other properties of this material. In this aspect, there has been a significant amount of research to understand the non-linear optical properties of this class of materials. Perovskites are known to possess centrosymmetric crystal structures; hence, Second Harmonic Generation (SHG) is forbidden. However, the inversion symmetry may be broken by surface effects, and SHG has been observed in Organic Perovskites such as $MAPbI_3$(1). The generation of third harmonics (THG) is independent of crystal symmetry (2). The third-order non-linear responses from lead-based perovskites can find applications such as infrared to visible frequency conversion (3), (4), (5). In this work, we have synthesized Inorganic Cesium Lead Bromide Perovskite Nanocrystals using a conventional colloidal route. We have attempted to study the non-linear optical effects along with Material Characterization (X-ray Diffraction, Transmission Electron Microscopy) and Optical Characterization (Steady State Absorption and Photoluminescence). SHG and THG processes are studied on the prepared PNCs. The SHG generated signal is compared with standard quartz crystal, while the THG signal is compared with Si for benchmarking. Along with PLQY of 71.42%, the PNCs are observed to give strong SHG and THG signals.

Local A-Site Phase Segregation Leads to Cs-Rich Regions Showing Accelerated Photodegradation in Mixed-Cation Perovskite Semiconductor Films Zixu Huang[1], Fangyuan Jiang[1], Zhaoning Song[2], Kshitiz Dolia[2], Tao Zhu[2], Yanfa Yan[2] and David S. Ginger[1]; [1]University of Washington, United States; [2]The University of Toledo, United States

We use hyperspectral photoluminescence microscopy to study compositional heterogeneity and its influence on the stability of mixed-cation (formamindinium (FA) and cesium) lead halide perovskite solar cells of the composition $FA_{1-y}Cs_yPb(I_xBr_{1-x})_3$ at different concentrations of Cs. By correlating PL maps with time-of-flight secondary ion mass spectrometry (TOF-SIMS) imaging, we show that the redder regions of the film are associated with Cs-rich clusters. XRD and confocal Raman microscopy provide evidence for the presence of -phase $CsPbI_xBr_{3-x}$ clusters in these regions. Photo aging studies show that Cs-rich regions tend to undergo faster photoinduced PL degradation than the rest of the film. These observations highlight the importance of local heterogeneities and their influence on the stability of halide perovskite semiconductors being studied for solar cell applications.

EL04.13.19

Grain Engineering for Highly-Efficient Near-Infrared Perovskite Light-Emitting Diodes Sung-Doo Baek[1], Wenhao Shao[1], Weijie Feng[2], L J. Guo[2], Barry P. Rand[3] and Letian Dou[1]; [1]Purdue University, United States; [2]University of Michigan–Ann Arbor, United States; [3]Princeton University, United States

Metal halide perovskites have shown great potential for next-generation light-emitting diodes (LEDs). Notably, near-infrared (NIR) perovskite LEDs (PeLEDs) typically outperform their organic and quantum-dot counterparts. However, their performance still falls short of the high-performing but costly epitaxial III-V semiconductor devices, which generally exceed 30% in external quantum efficiency (EQE) with very high brightness. Enhancing the performance of PeLEDs requires a deeper understanding and control of grain growth and nanoscale morphology. In this study, we present a comprehensive grain engineering methodology that incorporates two complementary and synergistic approaches to improve outcoupling efficiency and promote defect passivation. Through a solvent engineering technique, we achieved exceptional control over perovskite grain size and spatial distribution, leading to a significant increase in light-outcoupling efficiency to approximately 40%. Additionally, by creating 2D/3D heterostructures with a conjugated cation, we observed reduced defect densities and faster radiative recombination rates.
As a result, the NIR PeLEDs demonstrated a peak EQE of 29.0% at a high current density of 183 mA/cm^2. An average EQE of 26.3% was obtained across 40 devices, with independent cross-validation across institutions. These devices also exhibited extremely high brightness, with a maximum radiance of 929 W/sr m^2. These findings indicate a promising future for PeLEDs as a low-cost, high-performance NIR light source for practical applications.

EL04.13.20

Ozone Gas-Sensing Based on Specular Reflectance Changes in Smoorth, Highly-Reflecting, PVP-Stabilized, All-Inorganic Perovskite Thin Films Samita Mishra, Jacob D. Wolfman and Yaakov R. Tischler; Bar-Ilan University, Israel

When gas molecules adsorb onto the surface of a semiconducting layer of the right bandgap and electrical/chemical properties, such films can provide state-of-the-art performance for detecting gases via changes in electrical conductivity or other optoelectronic properties. Recently, metal-halide perovskite materials, which have been extensively studied for applications in light-harvesting and light-emission, have drawn interest as sensing components due to their ability of exhibit reversable changes in electrical conductivity when exposed to gases like ozone, CH_4, H_2, and others [1]. Numerous studies have demonstrated the use of metal halide perovskites in detecting various air contaminants [2]. Despite this research, the instability and roughness of the films still inhibit the commercialization of perovskite-based sensors. Here, we report the fabrication of thin films of $CsPbI_xBr_{3-x}$ (x=3,2,1.5,1,0) perovskites for gas-sensing applications that are stable, homogenous, and smooth. To make such films, we used added polyvinylpyrrolidone (PVP) in the precursor solutions. The polymer helps to grow homogeneous films and it stabilizes the photoluminescent phase of $CsPbI_xBr_{3-x}$ in ambient conditions. We studied the effect of PVP on the structure and vibrational modes using Powder-XRD and Raman. We observed that the resultant films are optically smooth, and strongly reflect light. The as-fabricated thin film of the perovskites shows remarkable sensitivity to ozone. When exposed to ozone, the PVP-stablized perovskite films show a remarkable change in reflection, which is mostly reversable and definitely reusable, depending on the Bromide/Iodide ratio. Future gas sensing devices based on the bright phases of $CsPbI_xBr_{3-x}$ stabilized with PVP could be made easy and cost-effective with high sensitivity due to their straightforward fabrication procedure.

EL04.13.21

Non-Destructive Ligand Modification of Colloidal Perovskite Nanocrystals via Olefin Metathesis for Direct Optical Lithography Seongbeom Yeon[1], Yoseph Kim[2], Seongkyu Maeng[1], Jaeyeong Ha[1] and Himchan Cho[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Chungbuk National University, Korea (the Republic of)

Direct optical lithography is a process wherein precise patterns are formed by utilizing light to induce changes in the solubility of nanocrystals. To achieve effective incorporation of high-resolution pixels within displays, the application of lithography technology is essential, wherein direct optical techniques play a crucial role. Furthermore, direct optical lithography offers the advantage of reducing processing steps and enabling solution compatibility, large-area processing, and versatility with various materials. To enable direct optical lithography, photosensitive properties must be conferred via ligand exchange or the use of additives. However, such ligand modifications and subsequent patterning processes often compromise the optical and electrical properties of nanomaterials, especially in metal halide perovskite nanocrystals (PNCs) due to ionic characteristics. In this study, we address these issues by conducting ligand modification, endowing the ligands with light-sensitive attributes without damaging the pristine PNCs (PNC-P) surface. We achieve modified ligands with two anchoring sites through olefin metathesis reactions and systematically investigate the effects of the modified ligands on the optical properties, colloidal stability, and morphologies of PNCs with modified ligands (PNC-M). Furthermore, we attain high-resolution patterns by utilizing PNC-M possessing photosensitive property through ligand modification, which were not obtained in PNC-P. Our approach of non-destructive ligand modification via olefin metathesis provides a way for more effectively integrating various semiconducting materials into diverse optoelectronic devices.

EL04.13.22

In-Stability of 2D Capping Layers for Halide Perovskite Optoelectronics Carlo Andrea Riccardo Perini and Juan-Pablo Correa-Baena; Georgia Institute of Technology, United States

Surface treatments with bulky organic cations – too big to fit into a 3D perovskite lattice – have been instrumental for reducing non-radiative recombination, and therefore for increasing efficiencies, in metal halide perovskite films and devices. Bulky cation surface treatments are now included in most solar cell architectures with performances above 23%. In this contribution we study how changes in the surface heterogeneity, structure, chemistry, photoluminescence, and chemical composition of perovskite films treated with 2D capping layers affect performances and stability of complete devices, using techniques as grazing-incidence wide angle X-ray scattering, hyperspectral microscopy, and X-ray fluorescence, both in-situ and ex-situ. The role of bulky cation size, perovskite composition, halide counterion choice, and deposition route (solution vs. vapor) is discussed in correlation to the films' responses to stressors as light, heat, moisture, and oxygen. Our results reveal that bulky cations help prevent degradation of the perovskite films under exposure to moisture and oxygen, but that the

treated surfaces undergo continuous reconstruction under thermal stress and illumination, with impacts on device stability. We show that the structure of the bulky cation, as well as the choice of counterion, impact the dynamics of the interface reconstruction, enabling improved thermal stability of these interfaces. These results provide valuable insights to the community to help drive the design of capping layers to reduce surface reconstruction and increase the operational stability of perovskite optoelectronic devices.

EL04.13.23

Thermal Co-Evaporation of Lower-Dimensional Interlayers for Efficient Perovskite Solar Cells Kunal Datta[1], Sanggyun Kim[1], Ruipeng Li[2], Diana K. LaFollette[1], Carlo Andrea Riccardo Perini[1] and Juan-Pablo Correa-Baena[1]; [1]Georgia Institute of Technology, United States; [2]Brookhaven National Laboratory, United States

Ruddlesden-Popper (R-P) metal halide perovskite-derived interlayer structures have been successfully used in a variety of optoelectronic applications such as solar cells, photodetector and LEDs. Here , the n-value refers to the number of conjoined lead halide octahedral sheets between organic spacer cations. However, fast reactions during solution processing prevent accurate control on crystallization dynamics and limit the processing window to a narrow set of solution concentrations, spin conditions and annealing methods. This may result in uncontrolled reconstruction of the 3D/2D interface as well as poor control on layer thickness, which limits device performance and stability.
In this work, we first report the deposition of 2D (n = 1) Ruddlesden-Popper (PEA_2PbI_4 where PEA^+ is phenethylammonium) structures using solvent-free and industrially compatible thermal co-evaporation routes. Using synchrotron-based structural characterization, we characterize the structural properties of the 2D film and find them to be comparable to films deposited using solution-processing. Upon coating a 3D ($CsFAPbI_3$ where FA^+ is formamidinium) with the R-P layer, we use X-ray photoelectron spectroscopy, X-ray diffraction and hyperspectral photoluminescence imaging to show that the excess FA^+ on the surface of the 3D layer reacts with the R-P layer to form a quasi-2D (n = 2) phase. Once the FA^+ concentration depletes with increasing R-P thickness, the 2D phase (n = 1) forms. The development of this heterostructure has implications on charge-carrier dynamics with carrier lifetimes increasing in the presence of the n = 2 phase and decreasing thereafter as the n = 1 phase forms. Finally, the interfacial R-P layer is used in devices to demonstrate n-i-p solar cells with efficiency approaching 22%, showing a 2% absolute gain in performance from control devices with no interlayers. The gain in performance, shown to occur over a 40 nm R-P layer thickness window, occurs as a result of improvements in carrier transport across the perovskite/HTL interface, resulting in gains in the V_{oc} and FF. Taken together, we show a deposition pathway to achieve high efficiency solar cell devices prepared using R-P interlayers with a large thickness window developed using a scalable deposition method for the interlayer that can be translated to future commercial devices.

EL04.13.24

Unveiling Charge Carrier Recombination Dynamics in Tin-Lead (Sn-Pb) Perovskite Solar Cells—A Pathway to Enhanced Performance and Stability Abasi Abudulimu, Sheng Fu, Nadeesha Katakumbura, Nannan Sun, Steven Carter, Lei Chen, Manoj Rajakaruna, Jared Friedl, Tyler Brau, Zhaoning Song, Adam B. Phillips, Michael J. Heben, Yanfa Yan and Randy J. Ellingson; The University of Toledo, United States

Tin-lead (Sn-Pb) perovskite solar cells are at the forefront of photovoltaic research, offering an exciting balance of high efficiency and reduced environmental impact. Despite their promising attributes, the optimization of Sn-Pb perovskites has been hindered by inconsistent reports of carrier lifetimes, crucial for device performance. Our comprehensive study tackles these inconsistencies head-on by integrating state-of-the-art transient photovoltage (TPV) and transient photocurrent (TPC) techniques, along with time-resolved photoluminescence (TRPL) measurements under diverse operational conditions. Enhanced by rigorous simulation and analytical methods, our research provides novel insights:

1. **Elucidation of Trap-Assisted Recombination Mechanisms:** Dominant under low-light conditions, this finding is crucial for understanding device performance under real-world lighting.
2. **Quantification of the Radiative Recombination Coefficient:** Dominant at high illumination levels, it can influence the design of high-efficiency solar cells.
3. **Effective Carrier Lifetimes:** Specifically under standard 1 sun illumination, offering a realistic perspective on device operation.
4. **Correlation Between TPV and TRPL Data:** This establishes a robust methodological framework for predicting device performance.
5. **Validation and Reproduction of Open-Circuit Voltages:** confirms the accuracy of TPV-derived parameters, reinforcing the reliability of our measurements and data analysis.
6. **Impact of Device Degradation on Carrier Lifetime:** We identify the significant effects of device stability (during the measurement) on data integrity, underscoring the importance of robust testing environments.

Our findings not only clarify the previously reported discrepancies in carrier lifetime data but also provide a deeper understanding of the intrinsic carrier dynamics within Sn-Pb perovskites. By addressing both fundamental science and practical challenges, this work sets the stage for next-generation solar cells that combine enhanced performance with increased reliability, marking a significant stride toward sustainable energy solutions.

***In Situ* Multimodal Analysis of Metal Halide Perovskite Film Formation and Degradation** Huriye Ertay[1,2], Davide R. Ceratti[1,3], Tim Kodalle[4], Javid Hajhemeati[1], Celia Aider[1], Marion Provost[1], Carolin M. Sutter-Fella[4] and Philip Schulz[1]; [1]Institut Photovoltaïque d'Ile-de-France, France; [2]CNRS, UMR9006, France; [3]Chimie Paris Tech–École Nationale Supérieure de Chimie de Paris, France; [4]Lawrence Berkeley National Laboratory, United States

The recent developments in the metal halide perovskite solar cells (PSC) were able to achieve power conversion efficiencies comparable to silicon solar cells. This astounding performance was achieved due to advances in perovskite crystallisation, engineering both electron and hole transport layers as well as interface engineering to minimise losses. Despite achieving an impressive performance, PSC still face significant challenges for outdoor implementation due to limited reliability. Although there are many external factors at play such as humidity, temperature and even the prolonged sun exposure, the interfaces between the halide perovskite absorber layer and adjacent charge transport films play a big part in the inherent stability of the cell components.

Here, we studied the effect of external stressors such as the exposure to air and humidity on double cation, Cs0.3FA0.7Pb(Br0.2I0.8)3 and triple cation, Cs0.05(MA0.17FA0.83)0.95Pb(Br0.2I0.8)3 perovskites as well as perovskite crystallisation by in-situ Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) and photoluminescence (PL) spectroscopy measurements. We carried out GIWAXS measurements whilst depositing perovskite on different substrates to study perovskite crystallisation, where we were able to detect differences in perovskite crystallisation. Furthermore, to advance our understanding of degradation, we carried out real-time GIWAXS and concomitant PL measurements as the perovskite degrades under different conditions where it was possible to detect different perovskite crystal structures, present heterogeneously, diminish with time as the PbI2 concentration increased at the interface. We observed that different conditions triggered unique defect routes with different reaction kinetics. In air, we observed phase instabilities such as the breakdown of both double and triple cation perovskites into non-perovskite organic iodide species (CH3NH2I) as well as the delta phase of cesium iodide CsI. These phase instabilities were not present under 100% humidity without oxygen. Whilst the phase instabilities were present in air for both double cation and triple cation, we observed no intrinsic phase instabilities when 2D interlayer (4-FPEAI) was deposited on top of the perovskite. For 100% humidity, we observed partially reversible electron transfer from I- to Pb2+ leading to irreversible Pb0 formation for double and triple cation perovskite cells.

EL04.13.26

Charge Carrier Recombination Processes at Interfaces Between Perovskites and Hole-Transporting Self-Assembled Monolayers Christopher E. Petoukhoff, Luis Victor Torres Merino, Oleksandr Matiash, Carolina Villamil Franco, Pia Dally, Stefaan De Wolf and Frédéric Laquai; King Abdullah University of Science and Technology, Saudi Arabia

Solar cells formed from metal halide perovskites (MHPs) have reached remarkably high power conversion efficiencies over the past several years, with nearly 26% in single junction devices and over 34% in perovskite-Si tandems. To achieve high-efficiency tandem devices, stacking of MHPs with different bandgap energies is a necessity. Bandgap engineering in MHPs can be achieved by varying the stoichiometry of the components; for example, changing the halide ratio in $CsFAPb(Br_xI_{1-x})_3$ can continuously tune the bandgap across a wide range, from 1.6-2.2 eV. While this halide mixing is critical towards developing tandem devices, there is also a drawback: photo-induced phase segregation occurs within these materials, in which different halides separate into iodide-rich and bromide-rich perovskite phases, embedded within the remaining well-mixed phase.

Recently, surface modification of transparent conducting oxides with self-assembled monolayers (SAMs) have emerged as novel hole transport layers (HTLs) in MHP solar cells. The presence of SAMs has been shown to mitigate defect formation at metal oxide/MHP interfaces. Additionally, SAMs benefit from their ability to bond covalently to and tune the work function of transparent electrodes, their vanishingly low parasitic absorption, and their strong dipole moments. One SAM in particular, (2-(9H-carbazol-9-yl)ethyl)phosphonic acid (*i.e.*, 2PACz), and its derivatives have stood out as leading to the highest improvement in device efficiencies. While there have been numerous studies on the improved device performance when incorporating 2PACz-derivatives as HTLs, the interplay between charge extraction and recombination at SAM/MHP interfaces has not yet been fully explored.

In this work, using a combination of time-resolved and steady-state optical spectroscopies, we investigate hole extraction across SAM/MHP interfaces. We explore the use of 2PACz and its derivatives interfaced with MHPs of different bandgap energies. We reveal the competition between hole extraction and recombination through systematic transient absorption (TA) and time-resolved photoluminescence (PL) spectroscopic measurements. We demonstrate that certain SAMs can help suppress halide segregation, by monitoring the growth of the iodide-rich phase emission in steady-state PL measurements. Understanding the photophysical processes at SAM/MHP interfaces will help to facilitate more efficient MHP solar cells with greater phase stabilities.

EL04.13.27

Continuously Tunable Negative Pressure for Engineering Ideal Octahedral Rotations in $CsPbI_3$ Arkita Chakrabarti[1] and Aaron T. Fafarman[2]; [1]Arizona State University, United States; [2]Drexel University, United States

Despite the fascination it has held for theorists for decades, the phenomenon of triaxial tensile strain, or equivalently 'negative pressure,' has had few experimental demonstrations and those have been limited to a material-specific, chemically induced phase transition. In this work, the well-known phenomenon of strain induced by thermal-expansion-coefficient-mismatch between a thin film and its substrate is reimagined, replacing the canonical planar support with a three-dimensional, nano-confining scaffold in which we embed the material of interest. In this manner we demonstrate a general approach to exert a continuously tunable, triaxial, tensile strain, defying the Poisson ratio and achieving the exotic condition of 'negative pressure.' This approach is generalizable to any material with a low modulus and high thermal expansion coefficient, and we use it here to achieve negative pressure in perovskite-phase $CsPbI_3$ embedded within the cylindrical pores of anodic aluminum oxide (AAO) membranes. Thus, it is possible to continuously transform the perovskite structure towards higher symmetry, in contrast with the symmetry reducing action of any other mechanical perturbation. We use this effect to control the

octahedral rotation angle that is critical to the remarkable photovoltaic attributes of halide perovskites. Up to hundreds of megapascals of apparent negative pressure, the bandgap tunability is observed to follow the same quantitative trend observed for hydrostatic positive pressure, exploring the negative pressure region for the first time and demonstrating the dominance of bond stretching effects in comparison to the influence of average octahedral rotation angle on electronic structure. The possibility for novel dynamics under the reduced interatomic forces could have application to a variety of ferroic phenonomena, wherein at a fixed temperature, dipolar and external forces would have a greater relative influence on the equilibrium ordering, as desirable, for example, in photovoltaics and ferroelectric switching.

SESSION EL04.14: Defect Management and Characterization

Defects Management for Efficient NIR Perovskites LEDs Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Light-emitting diodes (LED) with different emission spectra are widely used in our daily life for a variety of applications. However, due to fundamental restrictions of light-emitting materials, the development of near-infrared LEDs (NIR-LEDs) is still modest. Recently, solution-processed tin-halide perovskites (THPs) have emerged as one of the most promising light-emitting materials for NIR-LED application. Electronic doping (p-type) is a unique property of THPs. To date, extensive efforts have been taken to reduce the p-doping concentration, with reference to their lead-based halide perovskites counterpart for a transition from a p-doped to an intrinsic semiconductor. This is mainly driven by the application of these materials in photovoltaic devices. However, in LED, where rather than charge extraction we want to maximize radiative charge recombination, carefully controlled p-doping becomes a favorable attribute of THPs for the successful creation of high-brightness devices. I will show how their electronic properties affect light emission efficiency, and I will present our efforts in material engineering to design and master the electronic properties of THP films in order to achieve bright and efficient LEDs.

Further improvements in perovskite solar cells (PSCs) require better control of ionic defects in the perovskite photoactive layer during the manufacturing stage and their usage. Here, we report a living passivation strategy using a hindered urea/thiocarbamate bond Lewis acid-base material (HUBLA), where dynamic covalent bonds with water and heat-activated characteristics can dynamically heal the perovskite to ensure device performance and stability. Upon exposure to moisture or heat, HUBLA generates new agents and further passivates defects in the perovskite. Not only are the defects during the fabrication passivated, but new defects that evolve during the usage and operation of the device are passivated as well.

We prove the dynamic passivation ability of HUBLA, both chemically through X-ray photoelectron spectroscopy (XPS) and physically through photoluminescence (PL) maps of aged and pristine perovskite thin films. We determined the threshold for the water-activated passivation to be at 20% relative humidity, and for the heat-activated passivation, it is ≥ 55 °C. This dynamic passivation significantly improves the robustness of the treated perovskite thin films. For instance, at 85 °C in ambient air (~30% relative humidity), the perovskite thin film with HUBLA developed 2/3 less PbI_2 than the control film.

In devices, this passivation strategy achieved high-performance devices with a power conversion efficiency (PCE) of 25.1%. HUBLA devices retained 94% of their initial PCE for approximately 1500 hours of aging at 85 °C in N_2 under 1 sun illumination. Further devices with HUBLA maintained 88% of their initial PCE after 1000 hours of aging at 85 °C and 30% relative humidity (RH) in air under 1 sun. (1)

Understanding the Structural Dynamics of 2D/3D Perovskite Interfaces Alan Kaplan, Marko R. Ivancevic, Quinn C. Burlingame and Yueh-Lin Loo; Princeton University, United States

The incorporation of 2D perovskite capping layers has become common practice in high-performance lead halide perovskite solar cells to passivate 3D perovskite surface defects. However, recent work has shown these 2D/3D interfaces to be highly dynamic, undergoing structural transformation when subjected to thermal stress or illumination. Here, we study the structural dynamics of a series of commonly used alkylammonium-based Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) phase 2D perovskites deposited on formamidinium lead iodide. By monitoring the grazing-incidence wide-angle x-ray scattering and photoluminescence of the 2D/3D perovskite heterostructures aged at 100°C or under 1 sun illumination, we observe that the 2D perovskite structures transform to progressively larger inorganic layer thickness (denoted by layer number n), eventually approaching a steady-state condition with only the 3D perovskite ($n=\infty$) remaining. This transformation slows by a factor of two when increasing the size of the RP-forming ligand from butylammonium to dodecylammonium. Furthermore, substituting the RP-forming dodecylammonium with DJ-forming 1,12-dodecanediammonium of similar size, decelerates the structural transformation by a factor of 10. These findings suggest that the use of DJ 2D perovskite capping layers could be a promising pathway to form stable 2D/3D heterostructures.

Understanding Dynamic Titled Domains in Halide Perovskites with Big-Box Refinements of X-Ray Total Scattering Data Kieran W. Orr[1,2] and Samuel D. Stranks[2]; [1]Stanford University, United States; [2]University of Cambridge, United Kingdom

While solar cell and light-emitting devices based on halide perovskite materials have become significantly more efficient over the past decade,[1] much of this progress has been the result of empirical fabrication optimisation, and the community's structural materials understanding lags behind in comparison. For example, off the back of recent single crystal diffraction[2,3,4] and computational[5,6] studies, the field is only just beginning to appreciate that there are transient nano-domains where the lead halide octahedra are mutually tilted embedded in a higher symmetry average perovskite structure. Such dynamic domains are important for the properties of halide perovskites,[2] and functional materials more generally, where structural disorder is often property determining.[7]

Here I present our current work characterising these tilted domains in mixed-component halide perovskites using X-ray total scattering in the form of powder pair distribution function (PDF) analysis. By designing an advanced big-box refinement protocol that simultaneously considers the Bragg scattering and PDF data, where atomic positions in a supercell are unconstrained by crystal symmetry but obey local chemical rules, we produce atomic configurations which show a snapshot in time of the atomic halide perovskite crystal structure. Analysis of these supercells reveals pancake-shaped nanodomains where octahedra are locally tilted to lower symmetry in addition to Pb displacement from octahedral centres. Crucially, we perform these analyses on samples that have mixed compositions (like the highest-performance formulations) to understand the effects of ion substitution at different crystallographic sites on the size, shape, and density of the tilted nanodomains. Importantly, our big-box refinement approach uncovers evidence for these local domains using powder PDF measurements which are i) easier and higher throughput than single crystal diffraction studies, and ii) amenable for use on the most technologically relevant samples using either powders from scraped films or native thin films[8] as they would be found in devices. Our results inform device makers on how to best tune their perovskite formulations to realise more efficient and stable optoelectronics, and our approach can be applied to a variety of other materials systems where structural disorder is a key factor for material performance.

Lead-Free Halide Double Perovskites—The Effects of Lanthanide Doping on Lattice Crystallinity and Related Photoluminescence Properties Simone Barbarossa[1], Salvatore Ferruggia Bonura[1], Valeria Demontis[2], Daniela Marongiu[2], Francesco Quochi[2], Michele Saba[2], Marco Cannas[1] and Simone Agnello[1]; [1]Università degli Studi di Palermo, Italy; [2]Università degli Studi di Cagliari, Italy

Over the past decade, considerable efforts have been directed towards enhancing the efficiency of solar cells and optoelectronic materials as part of the green transition. Within the latter, Perovskite materials have made an impact due to their attractive characteristics and promising potential.

Despite their impressive performance in lighting applications, such as achieving photoluminescence cutting quantum yields exceeding 100% in some cases[1], lead-halide materials still suffer from notable drawbacks including poor stability and lead toxicity[1]. As an alternative, an analogous class of materials, identified as double perovskites, has been introduced, which are characterized by the substitution of the Pb^{2+} ion of the octahedral structure with both M^+ and M^{3+}metal ions in equal proportions (e.g. $Cs_2AgInCl_6$)[2]. Indeed, double perovskites present remarkable thermal stabilities (up to 500°C) and attractive emission spectra spanning across the entire visible region[3], ideal for a wide range of lighting applications.
Introducing suitable additives through doping has shown promise in enhancing their performance, notably leading to a sharp increase in Photoluminescence Quantum Yield (PLQY). This enhancement is believed to stem from improved lattice crystallinity and the creation of new parity-allowed radiative recombination pathways[4].

Nevertheless, substantial further research is necessary to fully comprehend these materials.
In this context, the current study aims to address these knowledge gaps by investigating various co-doped compositions of $Cs_2Na_{1-x}[X_xY_yZ_{1-y}]Cl_6$ halide double perovskites, by incorporating various elements such as Ag, Er, Yb, and Bi. The research employs Raman spectroscopy and photoluminescence measurements to evidence how changes in composition and crystallinity due to dopant addition correlate with variations in photoluminescence characteristics and QYs.
In this regard, a comprehensive Raman analysis spanning from IR to UV, coupled with micro-luminescence, provides detailed insights into the structural attributes of these perovskites and their relationship to emission properties.
This approach aims to advance our understanding of the underlying mechanisms governing the emission behavior of these innovative materials.

This study was developed in the framework of the research activities carried out within the Project “Network 4 Energy Sustainable Transition—NEST”, Spoke 1., Project code PE0000021, funded under the National Recovery and Resilience Plan (NRRP), Mission 4, Component 2, Investment 1.3— Call for tender No. 1561 of 11.10.2022 of Ministero dell’Universita` e della Ricerca (MUR); funded by the European Union—NextGenerationEU.

Surface Chemistry of Tin Halide Perovskites and Its Effects on Optoelectronic Properties Antonella Treglia, Mirko Prato, Chun-Sheng Wu, E Laine Wong, Isabella Poli and Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Tin halide perovskites have recently garnered attention as low-bandgap materials for photovoltaic and light emitting applications.[1,2] They exhibit self-p doping, which significantly impacts the optoelectronic properties.[3,4] Additionally, the facile oxidation of Sn^{2+} to Sn^{4+} further enhances p-doping within the bulk and introduces non-radiative recombination centers on the surface.[5] Through a combination of photoemission optical spectroscopy and microscopy techniques, we investigate the chemical and optoelectronic heterogeneity, as well as the oxidation process, of tin perovskite processed without and with the addition of SnF_2.
We investigate the role of SnF_2 in determining the complex surface chemistry of tin halide perovskites. We show that oxygen is present on the surface of tin perovskite thin films even in the absence of exposure to ambient air. However, the presence of SnF_2 strongly affects the chemical nature of the found species. Specifically, fluorine acts as scavenger for Sn^{4+} species, effectively capturing available oxygen, which then preferentially binds to tin in the form of SnO_2 only when SnF_2 is added to the precursor solution. Conversely, without the additive, oxygen is mainly due to adventitious species. We thus highlight that the dominance of a single chemical state in the XPS Sn core level does not exclusively indicate Sn^{2+} species in the perovskite form but could also indicate the formation of superficial SnO_2. Through spatial mapping of both the local chemical environment with X-ray Photoemission Electron Microscopy (XPEEM) and photoluminescence mapping, we show that pristine films exhibit a higher accumulation of iodide at the grain boundaries. However, the addition of SnF_2 facilitates the preservation of the perovskite phase and reduces both chemical and optical heterogeneities.
Furthermore, we show that exposing the films to ambient air results in analogous surface degradation, regardless of the presence of the additive. We distinguish the process of bulk oxidation and the impact on the optoelectronic

properties: an initial increase in the doping density is observed, followed by the increase in long-lived deep defects.

Predicting Organic-Inorganic Halide Perovskite Photovoltaic Performance from Optical Properties of Constituent Films Ruiqi Zhang, Moungi G. Bawendi and Vladimir Bulovic; Massachusetts Institute of Technology, United States

The photovoltaic performance of organic-inorganic halide perovskite solar cells largely depends on the perovskite composition and fabrication process. Most laboratory-scale fabrication methods are not transferable to industrial scale technologies such as slot-die coating or roll-to-roll coating, etc. Hence, it is advantageous to predict solar cell performance before completing the device. Most of the prevalent perovskite solar cell physical models aim to interpret devices' interlayer recombination, band-bending, and charge injection, while the number of free parameters in these models require extensive measurements and fitting models that hinders their effectiveness as a prediction tool. Here, we present a machine learning (ML) method to take multiple measured device optical spectrums as input and directly predict the device JV curve output (Voc, Jsc and FF), thereby predicting the solar cell efficiency. These Blackbox models allow us to predict the performance of full devices with data that might contain many physical processes which could be too complex to predict accurately with a physics-based model. The model has achieved an averaged prediction percent error less than 5%. By analyzing the prediction weights of each parameter, we identify the optical transmission spectrum and photoluminescence spectral peak information are the most significant parameters that influence the algorithm results. This demonstrated work is the first work in the field to use ML to predict device photovoltaic properties solely from the optical properties of constituent materials and further establishes the potential of small-data-driven ML methods for guiding new designs of perovskite solar cell structures.

Why are Pb-Halide Perovskites so Resilient and How is Their Doping Affected by This? David Cahen; Weizmann Institute of Science, Israel

For progress in science, distinguishing ideas or suggestions from robust experimental/theoretical results, is critical. Such is the case for the widespread use of “defect tolerance” (DT) of Halide Perovskites (HaPs), which became a “fact” without direct experimental evidence, similar to their *bulk* doping. Both are critical to the exceptional optoelectronic properties of HaPs in solar cells, LEDs and detectors, and.... they are related. DT in semiconductors means that structural defects do not lead to (opto)electronically active effects. We found the first direct experimental evidence for DT in Pb-HaPs and will argue that the dynamic Coulombic screening in these intrinsically “soft” and polarizable materials underlies both (our earlier discovered) Self-Healing and their DT. *The low doping of HaPs results directly from their SH+DT.* In fact, doping them as done for Si or GaAs, does not work. Instead, the default explanation for nearly all reported Pb-HaP doping is via their surfaces and interfaces. While not unique (it works for other semiconductors), here the process dominates, because of their low bulk and relatively low surface defect densities. This understanding explains why, in the end, HaPs present a turbo-version of Kroemer’s “the interface is the device”.

The Dual Effect of Metal Halide Passivation on Perovskite Solar Cell Performance and Stability Josephine Surel, Pietro Caprioglio, Akash Dasgupta, Florine Rombach, Jin Yao and Henry Snaith; University of Oxford, United Kingdom

Wide band gap perovskite solar cells (PSCs) have shown notable improvements in performance in recent years; however, there are still significant open-circuit voltage (V_{oc}) losses to overcome, and stability poses a significant obstacle to commercialization. It is widely understood that non-radiative recombination between the perovskite and electron transport layer (ETL) is a primary source of V_{oc} losses, which can be largely mitigated through incorporating passivation materials at the interface.[1] However, the usefulness of passivation materials also depends on their effect on device stability, which is an area that requires further investigation. In this work, we present a study of the impact of vacuum deposited metal halide passivation (namely MgF_x)[2] on the performance and stability of wide band gap PSCs.

The primary focus of this work is understanding the dual effect of the MgF_x passivation through analysis of device performance and stability, as well as electronic properties, under ISOS-L-2 stress conditions.[3] PSCs with a 1.77 eV bandgap were passivated with a range of thicknesses of MgF_x. With the optimum thickness of 0.9 nm of MgF_x, devices exhibit up to a 50 mV improvement in V_{oc} and 1.5% absolute improvement in power conversion efficiency compared to unpassivated devices. This performance enhancement is countered by a negative impact on stability, however, dominated by a decrease in short-circuit current (J_{sc}). Under full-spectrum simulated sunlight at 85 °C and open-circuit in ambient air, a 50% reduction in J_{sc} was observed in 15 hrs for the passivated devices, compared to 100 hrs in the unpassivated devices.

We utilize variable rate J-V scanning to determine the extent to which this device performance loss can be ascribed to effects from mobile ions.[4] These measurements reveal that the accelerated performance degradation observed in devices passivated with MgF_x is largely due to enhanced impact of mobile ions, which impede current extraction, rather than significant material degradation. We performed analysis of charge collection quality to further investigate the mechanism of the J_{sc} degradation, as well as x-ray diffraction characterization to observe the extent of any material degradation at this interface. Additionally, we explore the alternative of CsF_x passivation to probe the impact of different metal ions introduced at the interface. This work reveals the significant role that small changes in architecture can play in device degradation under ISOS-L-S stress conditions and highlights the importance of careful selection of passivation materials to achieve both high performing and stable wide band gap PSCs.

Exploring Thermoelectric Properties of Cs2NaYbCl6 Double Halide Perovskite—A Comprehensive DFT Analysis Antonio Cappai, Luciano Colombo and Claudio Melis; Università degli Studi di Cagliari, Italy

Double halide perovskites have emerged as promising candidates in the field of thermoelectric materials, owing to their unique transport properties. Accurate prediction of these properties—such as thermal conductivity, electrical conductivity, and Seebeck coefficient—is essential for their practical applications. This is particularly critical for double halide perovskites like Cs2NaYbCl6, whose complex atomic structures lead to distinctive transport phenomena, including anomalous thermal transport and relatively low electron-phonon scattering rates.

In this study, we report and analyze the experimentally observed anomalous thermal transport behavior of Cs2NaYbCl6 perovskite at temperatures above room temperature. By calculating phonon dispersion relations and scattering rates up to the fourth order in lattice anharmonicity, we elucidate their temperature dependence. Our results show that specific phonon group velocities and lifetimes increase with temperature beyond 500 K. This behavior, driven by anharmonic effects, accounts for the observed rise in lattice thermal conductivity at high temperatures, which breaks the conventional phonon transport theories that consider only cubic anharmonicity. Our model quantitatively reproduces the experimental thermal conductivity data as a function of temperature, providing a robust framework for understanding these phenomena.

We also address the electrical transport properties critical to thermoelectric efficiency, namely electrical conductivity (σ) and the Seebeck coefficient. By means of full DFT calculations on wannierized electronic bands and solving the Boltzmann transport equation iteratively, we find that Cs2NaYbCl6 exhibits an intrinsically low rate of electron-phonon scattering events. This results in an electrical conductivity as high as ~2.0e5 1/(Ωm) at room temperature (300 K) and a relatively high Seebeck coefficient (~70 μV/K).

Combining these transport parameters, we estimate the figure of merit (ZT) for Cs2NaYbCl6 can reach values up to 1.2, representing the upper limit for this material under ideal conditions.

11:30 AM EL04.15.04

Nanoscale Heterogeneity in 2D Templating of $FAPbI_3$ Controls Structural and Optoelectronic Behavior in Durable Perovskite Solar Cells Connor Dolan[1], Andrew J. Torma[2], Aditya D. Mohite[2] and David Fenning[1]; [1]University of California, San Diego, United States; [2]Rice University, United States

Despite the outstanding optoelectronic properties of formamidinium lead iodide ($FAPbI_3$), the large size of the FA cation destabilizes the photoactive cubic phase in favor of a photoinactive hexagonal phase. In recent work[1], we demonstrated that 2D Ruddlesden-Popper perovskites with lattice parameters well-matched to cubic $FAPbI_3$ can template the growth of cubic $FAPbI_3$ with its inherent bandgap of 1.48eV for efficient and highly durable perovskite solar cells. Here, we investigate the origins of this templating and its impacts on structural and optoelectronic properties at the nanoscale. Using synchrotron nanoprobe x-ray diffraction (nano-XRD) and x-ray excited optical luminescence (XEOL), we demonstrate that the templating occurs locally and that significant heterogeneity in

crystallographic and optoelectronic structure remains at the nanoscale in these durable films.
We explore templating effects in 3 dimensions by performing nano-diffraction measurements of 2D-stabilized samples both in-plane (transmission geometry) and out-of-plane (reflection geometry). We find substantial heterogeneity in the local structure of 2D-stabilized $FAPbI_3$, with locally tetragonal (*I4/mcm*) and cubic (*Pm3m*) structures throughout the film, suggesting that templating occurs heterogeneously throughout the film. We find some preferential orientation of the templating effect in the out-of-plane direction. Templating also appears to be seeded around 2D clusters roughly 100-300nm in size. The local microstrain is significantly decreased in the tetragonal, templated regions relative to purely cubic regions, suggesting that the locally-templated growth may reduce structural defects. XEOL mapping reveals locally redshifted regions with bright luminescence intensity in 2D-stabilized $FAPbI_3$, indicating that the templating improves optoelectronic quality by reducing nonradiative defect centers. These results highlight the three-dimensional distribution of templating that occurs in $FAPbI_3$ crystallized using 2D perovskite templates and offer insights as to pathways for homogenizing templating to further reduce nonradiative defects and degradation.

11:45 AM EL04.15.05

Directing the Crystallization Pathway of Formamidinium Lead Iodide in Anti-Solvent Free Processes Paulo E. Marchezi[1], Jack R. Palmer[1], Tim Kodalle[2], Raphael Moral[2], Carolin M. Sutter-Fella[2] and David P. Fenning[1,1]; [1]University of California, San Diego, United States; [2]Lawrence Berkeley National Laboratory, United States

Understanding the nucleation, crystallization, and phase transition mechanisms in $FAPbI_3$ perovskite films is crucial for improving their stability and performance. Adding alkylammonium chlorides (RACl) to the perovskite ink, especially methylammonium chloride (MACl), is known to result in low-temperature crystallization, grain growth and preferential orientation of α-$FAPbI_3$ when perovskite thin films are deposited in anti-solvent based processes. [1–4] As efforts increase to scale perovskite deposition, antisolvent-free methods are of considerable interest but result in distinct solute-solvent and solvent-solvent interactions relative to processes that employ anti-solvents.[1,2,4] Here we show that inclusion of RACl additives wields significant influence over the crystallization dynamics and temperature-dependent phase stability of lead-halide perovskite films formed by anti-solvent-free processing by means of *in situ* grazing incidence wide-angle X-ray scattering. The *in situ* experiments reveal that the ionic radii and vapor pressure of the RACl conjugate base are critical factors affecting the crystallization mechanism, final film morphology, and optoelectronic properties of the perovskite films. Promising alternatives to MACl, where the MA has particularly detrimental reactivity, are identified. Overall, we provide a framework for future development of crystallization design using anti-solvent-free processes, focusing on the influence of the additive cations in the perovskite film formation mechanism.

"Yes, The Same Device Twice"—Toward Improved Reproducibility in Halide Perovskite Research Tonio Buonassisi; Massachusetts Institute of Technology, United States

Assuming reproducibility is essential for scientific progress (and manufacturing scale-up!), it is surprising how few studies make "reproducibility" a key focus area. This talk is a response to this status quo.

First, we give space to the discussion of "hidden" variables affecting reproducibility. Goetz and Vaynzof's seminal contribution [1] states: "it is clear that [halide perovskite] properties are incredibly sensitive to numerous factors, many of which remain unknown even after a decade of extensive research." Recent efforts in the field to elucidate, measure, and control these variables will be summarized, as well as spotlights of recent research occurring throughout the ADDEPT Center to make perovskites more reproducible [2].

Second, we give space to the concepts of "determinism" and "probability" in materials research. While indeed the underlying laws governing perovskite film formation and degradation appear to be deterministic, the outsized role of discrete events in stimulating phase transitions invites a probabilistic perspective. In this context, we discuss a growing body of evidence that suggests that process control through automation and end-to-end impurity management can reduce the probability of negative uncontrolled variables, thus enabling the reproducibility needed to perform high-quality science.

Third, we discuss practical challenges of managing some degree of irreproducibility when establishing a process-recipe baseline or conducting an optimization campaign. In one example of an efficiency-optimization campaign, moderate run-to-run variance prompted us to consider another approach to straight-up Bayesian optimization: establishing "trust regions" believed to contain the noise-free optimum, and performing Latin hypercube searches therein, dynamically adjusting as experimental conditions changed [3].

Discovering Novel Low-Bandgap Halide Perovskites for Solar Cells Using a Computational and Experimental Approach Anika Bhoopalam, Letian Dou, Seok Joo Yang and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States

To pass the theoretical maximum efficiency of single-junction solar cells, there have been numerous efforts in developing tandem solar cells, which allow for the absorption of a broader band of the sun's emission spectrum.

Halide perovskites are particularly of interest for tandem devices [1] because of their impressive electrical and optical properties as well as the sheer tunability of their bandgaps and defect behavior via composition and structure engineering. In this work, we use a combination of first principles simulations and rational experimental synthesis and characterization to discover some promising new low bandgap (< 1.1 eV) perovskites for use as bottom cells in tandem devices. Using previously established predictive machine learning models [2], we navigate the massive chemical space of ABX3 perovskite alloys considering various inorganic and organic species at different cation sites, to determine a few hundred compositions predicted to be stable and display narrow bandgaps. Next, we perform density functional theory (DFT) computations on selected candidates and calculate their bulk formation energy and decomposition energy using the PBEsol functional. In addition, we calculate their electronic band structures using the hybrid HSE06 functional [3]. Along with this approach, we consider a novel class of double layered perovskite materials with the general formula A4M(II)M2(III)X12 or A4M(IV)M2(II)X12, which are promising for achieving low bandgaps (as seen for Cs4Cu(II)Sb2(III)Cl12, for instance) [4,5]. As double perovskites incorporate multiple B site elements, they provide additional opportunities to find low-bandgap perovskites. Based on our calculations, we arrive at multiple promising ABX3 3D perovskite alloys and layered perovskite compositions, which are experimentally tested by spin-coating of thin films. From the film studies, Tauc plots, photoluminescence measurements, and thermal stability measurements (ex. thermogravimetric analysis) are carried out. These measurements help determine the experimental bandgap, thermal stability, and an indication of the defects in the films. In the end, multiple compounds are identified as promising candidates for further investigation and use in solar cells.

Data-Driven Discovery of Novel Halide Perovskites for Photovoltaics and Photocatalysis Maitreyo Biswas and Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States

ABX_3 halide perovskites (HaPs) have been a topic of immense interest over the last two decades by virtue of their diverse optoelectronic applications as well as easy tunability of their electronic properties [1]. HaPs possess a unique combination of attractive properties, showing high absorption coefficients, low carrier recombination rates, high carrier mobility, and a general tolerance to defect states and ion migration [2]. Hybrid organic-inorganic perovskites (HOIPs) are of particular interest, but their long-term stability and performance efficiency remain less than ideal, which motivates comprehensive studies of composition engineering to tailor multiple properties. Such efforts are hindered by the combinatorial nature of the HaP chemical space, given the myriad organic and inorganic cations that may occur at A/B sites, the prospects of cation or anion mixing, and the existence of numerous polymorphs and metastable phases. A computational screening approach that combines high-throughput density functional theory (DFT) and experimental data with machine learning (ML) provides a promising route for success.

In this work, we employed state-of-the-art regression techniques based on Regularized Greedy Forest (RGF) [3] to train composition-based predictive models for the perovskite decomposition energy, band gap, and photovoltaic (PV) efficiency, based on a multi-fidelity dataset of ~ 1300 compounds [3,4] comprising calculations from semi-local and hybrid DFT functionals as well as nearly 100 experimental data points. Inputs to the model include numerical vectors encoding the ABX_3 composition (automatically accounting for mixing at any site), elemental properties of the A, B, and X-site species (with weighted averages used to indicate mixing), and one-hot encoded vectors representing the perovskite phase and data fidelity. In order to extensively span the chemical space, we enumerated a dataset of 151,140 hypothetical HaPs [5] in different phases and used an ensemble of multi-fidelity predictions over 4000 individual models to obtain their properties at a high accuracy. Using these predictions, we performed screening for two applications: (a) suitable absorbers for single-junction solar cells, where low decomposition energy, band gap between 1 and 2 eV, and PV efficiency > 15% were used as the metrics [5], and (b) suitable candidates for photocatalytic water splitting, where the screening criteria were low decomposition energy, suitable band gap and edges (empirically calculated) that straddle the H_2O redox potentials, and high solar-to-hydrogen (STH) efficiency [6]. We performed in-depth DFT computations to validate the best predictions, most of which are mixed cation HOIPs, and arrived at a list of novel compositions with great promise for both applications. The simplicity and accuracy of our models facilitate their application to many different areas of interest, easy expansion to include other ionic species and properties, and ready coupling with targeted experiments to drive rational discovery.

Optically Transparent Lead Halide Perovskite Ceramics Michael C. Brennan, Christopher McCleese and Tod Grusenmeyer; Air Force Research Laboratory, United States

We utilize room-temperature uniaxial pressing at applied loads achievable with low-cost, laboratory-scale presses to fabricate freestanding $CH_3NH_3PbX_3$ (X^-=Br^-, Cl^-) polycrystalline ceramics with millimeter thicknesses and optical transparency up to ~70% in the infrared. As-fabricated perovskite ceramics can be produced with desirable form factors (i.e., size, shape, and thickness) and high quality surfaces without any post-processing (e.g., cutting or polishing). This method should be broadly applicable to a large swath of metal halide perovskites and not just the compositions shown here. In addition to fabrication, we analyze microstructure—optical property relationships through detailed experiments (e.g., transmission measurements, electron microscopy, X-ray tomography, optical profilometry, etc.) as well as modelling based on Mie theory. The optical, electrical, and mechanical properties of perovskite polycrystalline ceramics are benchmarked against single crystalline analogues through spectroscopic ellipsometry, Hall measurements, and nanoindentation. Finally, scintillation from a transparent $MAPbBr_3$ ceramic is demonstrated under λ-ray irradiation from a ^{137}Cs source. From a broader perspective, scalable methods to produce freestanding polycrystalline lead halide perovskites with comparable properties to their single crystal counterparts could enable key advancements in the commercial production of perovskite-based technologies (e.g., direct X-ray/g-ray detectors, scintillators, nonlinear optics).

Phase Behaviour and Dynamics of Organic Cations in Formamidinium Lead Iodide (FAPI) Using Machine-Learned Potentials Sangita Dutta, Erik Fransson, Tobias Hainer, Paul Erhart and Julia Wiktor; Chalmers University of Technology, Sweden

Hybrid halide perovskites have received tremendous attention due to their promising applications in photovoltaics and optoelectronics. Formamidinium lead iodide (FAPI) has emerged as one of the most interesting compounds, due to its tuneable stability. While it has already been extensively studied, there are remaining questions about its atomic structure, phase behaviour, and dynamics of FA cations, especially at low temperatures. In this context, molecular dynamics simulations can bring insights into the unanswered questions. However, due to the chemical complexity, it is not trivial to construct a model for atomistic simulations of perovskites. Recently, the promise of machine learning has been demonstrated in simulating finite-temperature dynamics of complex materials using completely atomistic approaches with accuracy comparable to first-principles simulations.

In the present study, we generate a machine-learned potential for FAPI using the GPUMD package [1] to study the phase behaviour and dynamics of FA molecules. We carry out MD simulations to understand the structural phase space of the material. Our machine-learned potential successfully captures all the phase transitions reported in the literature: the first phase transition from a cubic (Pm-3m) to a tetragonal (P4/mbm) phase occurs at 310K and a second transition occurs at 100K to a disordered phase [2,3]. The low-temperature phase is not easily identified as it exhibits some disorder and local variation[4]. We analyse the octahedral tilting and preferred FA orientations, which further sheds light on understanding the nature of the low-temperature phase of the material. Further, to understand the local symmetry we study the rotational dynamics of the FA molecules. The FA molecules rotate freely at high temperatures in the cubic and tetragonal phases on the timescale of picoseconds. However, at lower temperatures (around lower phase transition) the rotational dynamics of FAs deviate from an Arrhenius behaviour, leading to the discovery of a disordered glassy state.

Exploiting Metal-Halide Perovskites Thermal Evaporation for Device Customization and Quantum

Confinement Annalisa Bruno; Nanyang Technological University, Singapore

Metal-halide perovskites (MHP) have emerged as highly promising optoelectronic materials due to their exceptional properties and versatile fabrication methods [1-6]. These materials are crucial in applications ranging from solar cells to quantum emitters, harnessing quantum confinement to unlock unique device functionalities. Thermal evaporation represents a robust technique for depositing halide perovskite films, offering precise control over layer thickness, composition tuning, stress-free deposition, and surface modification capabilities. This method has revolutionized thin film production by enabling the creation of ultrathin perovskite layers, forming the basis for constructing multi-quantum well structures.

By manipulating growth parameters, thermal evaporation influences the optoelectronic properties of nanoscale thin films, leveraging quantum confinement effects to precisely control photoluminescence characteristics. This capability opens avenues for unconventional optoelectronic functionalities and novel perovskite applications [7-10].

Controlling Cs_2PbX_4 Nanostructure Formation via Solution Processing for Robust Cesium-Based Perovskite Solar Cells Gaukhar Nigmetova, Zhuldyz Yelzhanova, Gulzhan Zhumadil and Annie Ng; Nazarbayev University, Kazakhstan

This study investigates the incorporation of low-dimensional (LD) inorganic materials for interfacial engineering in perovskite solar cells (PSCs) through solution processing methods. While LD perovskite nanostructures have shown promise for enhancing device performance in cesium-based PSCs, the underlying growth mechanisms remain underexplored. The work demonstrates how controlling the solvent evaporation dynamics during solution processing modulates the nanomorphology of Cs_2PbX_4. An evolution of Cs_2PbX_4 nanostructure growth is observed on $CsPbI_2Br$ thin films. Nanostructures grown from $CsPbI_2Br$ are shown to introduce a beneficial passivation effect, improving the interface quality with the hole transport layer (HTL). Systematic characterization reveals that carefully engineered LD nanostructure morphologies strongly impact the optoelectronic properties of PSCs. Optimized $CsPbI_2Br$/Cs2PbX_4 heterostructures enhance the power conversion efficiency by an average of 25.5% compared to devices without interfacial engineering. Under long-term photovoltaic aging and post-irradiation testing simulating low Earth orbit conditions, the optimized devices maintain over 87.5% of their initial efficiency, demonstrating improved stability. The findings provide new insights into controlling the morphology of inorganic LD nanomaterials through solution processing parameters. The promising stability results highlight the potential of this approach for robust PSC performance in harsh operating environments.

Ferroelastic Engineering of Vapor-Grown Perovskite Heterostructures Betty Shamaev, Noam Veber and

Up-to-date as of November 14, 2024

Yehonadav Bekenstein; Technion–Israel Institute of Technology, Israel

Engineering halide Perovskite heterostructures and interfaces are of great interest. Vapor phase growth of perovskite crystals on substrates may result in frustrated, strained material interfaces. We show that such strain accumulation triggers structural changes driven by ferroelasticity, resulting in crystallographic twin domains. I will introduce a novel approach to ferroelastic engineering in vapor-grown perovskite heterostructures, shedding light on the twin domain structures and their influence on electro-optical properties. Structural characterization and optical analysis correlate the perovskite ferroelastic effect with alternating luminescence patterns and facet stability.
I will show the emergence of alternating crystallographic twin domains, exhibiting unique orientations and domain boundaries, specifically alternating between (110) and (002) orientations, with a (112) domain boundary. These domains, predominantly formed during the cooling process, demonstrate extended stability, attributed to the appearance of mainly lower surface energy facets. We observe distinctive crystal surface tilts between neighboring domains, indicating significant strain-induced structural transformations. All the above structural alternation has a direct and impactful effect on the observable optoelectronic properties of these materials.
I will show striking differences in reflectivity and photoluminescence intensity between neighboring domains, with some facets being more emissive. Similar enhancements also appear in direct electronic measurements via AFM. The difference in electro-optical properties is generated by different facet terminations, with a significantly higher surface energy of the $PbBr_2$ facet. This is also reflected in the aging of such samples where defect concentration marks the variations between neighboring domains. The vision is that this new understanding could lead to ferroelastic engineering of enhanced stability of perovskite heterostructures and devices.

Colloidal Nanocrystals of Monomethylhydrazinium Lead Bromide—A 2.5D Perovskite Viktoriia Morad[1], Taehee Kim[1], Sebastian Sabisch[1], Simon C. Boehme[1], Nadine Schrenker[2], Sara Bals[2], Gabriele Raino[1] and Maksym V. Kovalenko[1]; [1]ETH Zürich, Switzerland; [2]Universiteit Antwerpen, Belgium

The field of functional inorganic materials for optoelectronics has witnessed in the past decades a rapid development of metal halide perovskites with ABX_3 formula, where B = Pb, Sn, X = Cl, Br, I and A is a small cation, either inorganic (Cs^+) or organic (methylammonium, MA^+ or formamidinium, FA^+). Every constituent of the perovskite lattice has been scrutinized and numerous organic cations came into consideration for A site position. The rule for retaining a three-dimensional (3D) perovskite lattice in good approximation is summarized by the concept of Goldsmith tolerance factor, limiting the size of A cation to not much larger than 260 pm.[1] At the edge of the 3D perovskite stability window are a couple of non-trivial organic cations, *e.g.* monomethylhydrazinium (MMH^+, 263 pm), azetidinium (AZT^+, 250 pm) and aziridinium (AZR^+, 227 pm).[3-5] While AZR^+ still allows for a cubic perovskite lattice, AZT^+ and MMH^+ introduce lattice distortions, resulting in the retention of 3D structural connectivity with the adoption of symmetry lower than cubic. Among other organic cations, MMH^+ especially stands out with its lone electron pair, readily coordinating to metals. Recently discovered bulk $MMHPbBr_3$ features two MMH^+ cations in coordination environment of one Pb atom together with distorted octahedral environment of Br atoms.6 The other crystallographically inequivalent Pb atom resides in a conventional octahedral perovskite environment. Both $PbBr_6$ octahedron types retain corner-sharing and assemble into a typical perovskite ABX_3 structure, albeit with lowered monoclinic noncentrosymmetric space group, and alternating layers of distorted and undistorted $PbBr_6$ octahedrons layers. The unique $MMHPbBr_3$ structure cannot be immediately categorized as one of two classical structural types, a 3D perovskite or a layered 2D perovskite with n=1. The degree of wavefunction hybridization between the distorted and undistorted layers would define where $MMHPbBr_3$ falls. Using density functional theory (DFT), we reveal the unique 2.5D structure of $MMHPbBr_3$ where the electron-wavefunction has three-dimensional confinement and hole-wavefunction is confined within an undistorted perovskite layer. Herein, we for the first time obtain $MMHPbBr_3$ in the form of colloidal nanocrystals (NCs), revealing the unique excitonic nature of this material. We characterize the synthesized NCs structurally and report the emission properties at the ensemble and single dot levels.

Innovative Approaches to the Manufacture of Tin Dioxide-Doped Titanium Dioxide for Efficient Perovskite-Based Solar Cells Wisly Fidel[1], Jacques Botsoa[1], Conchi Ania[1], Ibrahim Bel-Hadj[2], Gérald Ferblantier[2], Barthélemey Aspe[3] and Esidor Ntsoenzok[1]; [1]Université d'Orléans, France; [2]Université de Strasbourg, France; [3]CNRS-Université d'Orléans, France

Renowned for their excellent optoelectronic properties, halogenated perovskite materials are making unprecedented advances in the photovoltaics field. This emerging photovoltaic (PV) cell technology, which exploits many different materials and coating technologies, holds the promise of low-cost, lightweight and flexible solar power generation [1]. Composed of an absorber layer sandwiched between an electron transport layer (ETL) and a hole transport layer (HTL), the electron carrier is among the various factors influencing the performance of perovskite photovoltaics. Leading ETLs materials, such as titanium dioxide (TiO_2) and tin dioxide (SnO_2) have emerged as high-performance in perovskites solar devices [2]. However, to further enhance the performance of the ETL, we need further improvement in their electrical and optical properties. To achieve the required performance, TiO_2, and SnO_2 materials are generally doped. Another very promising material is SnO_2-doped TiO_2, but its use has yet to be optimized. In this study, we report the fabrication of thin films using PVD magnetron sputtering and pulsed laser deposition (PLD) techniques. We determined the optimal compositions for SnO_2-doped TiO_2 and TiO_2-doped SnO_2 and obtained efficient ETLs with a very good crystalline atomic arrangement. In the case of sputtering technique, the thin films were deposited on fluorine doped tin oxide (FTO) and silicon substrates with temperature ranging from 250 to 450°C in a reactive ($Ar+O_2$) mixture using pure titanium and tin targets. For PLD, depositions were carried out using targets of TiO_2 containing 5, 10, and 15% of SnO_2 at substrate temperature of 500°C on FTO and silicon using the third harmonic (λ = 355 nm) of Nd:YAG nanosecond laser. Thus, the effect of tin dopant and titanium dopant on the surface morphology, microstructural, optical, and electrical properties of these ETL thin films were systematically investigated by using various range of measurements such as scanning electron microscopy (SEM), X-ray diffraction (XRD), Ultraviolet–visible-near infrared (UV–Vis–NIR) spectroscopy, Raman spectroscopy, Rutherford backscattering spectroscopy (RBS), Nuclear Reaction Analysis (NRA), Hall Effect and four points probe measurements. For PLD technique, it is observed that a 15% ratio of tin oxide is efficient for improving both, the optical and electrical properties of titanium oxide. In the case of the sputtering technique, it has been observed that, depending on the deposition conditions (temperature, oxygen flow rate), pure TiO_2 exhibits a resistivity lower than 10 mΩ.cm with visible range transmittance that can be adjusted according to the oxygen flow rate. These performances have been further improved by doping TiO_2 with tin. Our study provides novel insights into the improving both the optical and electrical properties of two promising ETL materials (SnO_2 doped TiO_2 and TiO_2 doped SnO_2) using two reproducible fabrication methods suitable for industrial development.

Correlating Structural Phase Transitions and Optoelectronic Properties in Two-Dimensional Perovskites
Perry Martin and Connor G. Bischak; The University of Utah, United States

Ruddlesden-Popper (RP) metal halide perovskites have emerged as a promising class of optoelectronic materials. Due to their two-dimensional (2D) structure of alternating layers of organic cations and metal halide octahedra, these materials can undergo structural phase transitions near room temperature that drastically affect their optical properties. And yet, the connection between the structural dynamics of these materials and their optoelectronic properties have not been extensively studied. As such, this work aims to correlate changes in optoelectronic properties to subtle structural changes in the 2D perovskite lattice using photoluminescence (PL) spectroscopy and temperature-dependent grazing incidence wide angle X-ray scattering (GIWAXS), respectively. Additionally, we visualize the dynamics of 2D perovskite phase transitions using PL microscopy and find that the phase transition dynamics depend on the identity of the organic cation.

EL04.18.02
Additive-Free Oxidized Spiro-MeOTAD Hole Transport Layer Significantly Improves Thermal Solar Cell Stability
Matthias J. Grotevent, Yongli Lu, Tara Sverko, Meng-Chen Shih, Shaun Tan, Hua Zhu, Tong Dang, Jeremiah Mwaura, Richard Swartwout, Finn Beiglboeck, Linda Kothe, Vladimir Bulovic and Moungi G. Bawendi; Massachusetts Institute of Technology, United States

Achieving thermal stability of perovskite solar cells is a significant challenge. While *pin*-perovskite devices demonstrate high power conversion efficiency and thermal stability, they face issues with the C60 electron transport layer, hindering commercialization. Therefore, it is advisable not to limit perovskite solar cell research to one device architecture. The *nip*-perovskite solar cell architecture, which typically uses Spiro-MeOTAD with additives as a hole transport layer, shows promising power conversion efficiencies. However, the device's stability at elevated temperatures is a concern. It is generally believed that additives necessary for enhancing electrical

conductivity and optimizing energy level alignment cause reduced stability—suggesting that Spiro-MeOTAD-based hole transporting layers are inherently unstable. This study presents a reliable noble metal-free synthesis of Spiro-MeOTAD(TFSI)$_4$, which is used as the oxidizing agent. Without the need for additives, the stability of the Spiro-MeOTAD-based hole transporting layers improves significantly, offering a potential solution to the stability issue in perovskite solar cells.
The electrical conductivity is essentially developed with the first 1% of oxidation. Further oxidation shifts the energy levels away from the vacuum level, allowing tuning of the energy level alignment without additives—contradicting the current understanding of this system. Without additives, devices demonstrate efficiencies up to 24.2%. The thermal stability of the *nip*-perovskite solar cell strongly depends on the perovskite composition, demonstrating stable devices at elevated temperatures up to 85 °C under one sun over 1400 hours of continuous illumination with a power conversion efficiency of around 6% (with an unoptimized perovskite layer). Notably, the intrinsic thermal stability of the hole transport layer is demonstrated. At the same time, degradation may be activated from perovskite degradation and ion diffusion, which may be further suppressed by compositional engineering and adequate ion barrier layers.

EL04.18.03

Deciphering the Difference Between Molecular Cation and 2D Perovskite Surface Passivation in Perovskite Solar Cells Sam Teale[1,2], Matteo Degani[3], Edward H. Sargent[2] and Giulia Grancini[3]; [1]University of Oxford, United Kingdom; [2]University of Toronto, Canada; [3]Università degli Studi di Pavia, Italy

The deposition of large ammonium cations onto perovskite surfaces to passivate defects and reduce contact recombination has enabled exceptional efficiency/stability in perovskite solar cells. These ammonium cations can either assemble as a thin molecular layer at the perovskite surface or induce the formation of a low-dimensional - usually two-dimensional (2D) - perovskite capping layer on top of the three-dimensional (3D) perovskite. The formation of these two different structures is often overlooked by researchers although they impact differently on device operation. In this presentation we carefully distinguish between the two passivation types and discuss the impact of these two techniques on world record device performance. Using first-hand experimental data combined with a meta-analysis derived from hundreds of research articles, we provide a set of conditions required to form 2D perovskite atop of 3D. We then exam the electronic properties of the two structures and demonstrate that 2D perovskite forms a blocking layer for electron transport within a solar cell stack. We discuss the mechanisms by which 2D perovskite passivation and molecular passivation can improve photovoltaic efficiency and stability, and we summarise the knowledge gaps needed to be addressed to better understand and optimize ammonium cation-based passivation strategies.

EL04.18.04

Vapor Deposition of Yb-doped $CsPbCl_3$ via Evaporation of $YbCl_3$ and Mechanosynthesized $CsPbCl_3$ Seda Sarp, Iver J. Cleveland, Pulkita Jain, Yukun Liu, Minh N. Tran and Eray S. Aydil; New York University, United States

A potential alternative to silicon-perovskite tandem solar cells for surpassing the Shockley-Quessier Limit is high-efficiency downconversion of blue and UV photons to near-infrared by a single quantum cutting layer deposited beneath the glass on the silicon solar cell. Yb-doped $CsPbCl_3$ has attracted significant attention as a quantum-cutting material because of $CsPbCl_3$'s high absorption coefficient and near-infrared (1.25 eV) photoluminescence quantum yields (PLQY) approaching 200%.[1-5] However, most of these results have been obtained with nanocrystal dispersions suffering from sub-bandgap absorption and scattering, and it has been difficult to scale up. Therefore, a large-scale, proven scalable deposition method such as vapor deposition is desired for integration into solar panel manufacturing. The development of vapor deposition for the deposition of Yb-doped $CsPbCl_3$ is at its nascent stages, and surpassing 100% PLQY and achieving uniform emission has presented substantial challenges, with only one yet-to-be-reproduced report of 183% PLQY via a single source evaporation from Yb-doped $CsPb(Cl_{1-x}Br_x)_3$.[6] Here, we present the mechanosynthesis of $CsPbCl_3$ powders via ball milling of CsCl and $PbCl_3$ and $CsPbCl_3$ co-evaporation onto glass substrates with $YbCl_3$ to synthesize thin films of Yb-doped $CsPbCl_3$. Film thickness (typically 180-210 nm) and stoichiometry were controlled via the evaporation fluxes of the precursors using quartz crystal microbalances. PLQY is sensitive to the mechanosynthesis parameters through the phase purity of the starting powder. We obtain phase pure $CsPbCl_3$ under mechanosynthesis conditions that favor maintenance of high temperatures during ball milling and after annealing at 400°C. We investigated various synthesis parameters, such as Yb concentration, and post-deposition annealing conditions, such as the time, temperature, and environment, such as annealing in air versus in a nitrogen-filled glovebox. $CsPbCl_3$ evaporates congruently in the 450-480°C range and forms $CsPbCl_3$ films. Yb can be incorporated via coevaporation yielding films with PLQY ranging from 0% to greater than 50%. PLQY is sensitive to temperature, and its temperature dependence varies with the annealing environment. PLQY peaks at around 300°C for air-annealed films, decreasing precipitously thereafter, with XRD showing impurity phases at 400°C. In contrast, PLQY from films annealed in the nitrogen-filled glovebox remains high at 400°C.

Origin of Persisting Photoresponse of One-Year Aged Two-Dimensional Lead Halide Perovskites Stored in Air Under Dark Conditions Marie Krecmarova[1], Andrés F. Gualdrón-Reyes[2], Jesús Rodríguez-Romero[2], Iván Mora-Seró[2], Juan P. Martínez-Pastor[1] and Juan F. Sanchez[1]; [1]Universidad de Valencia, Spain; [2]Universitat Jaume I, Spain

Two-dimensional halide perovskites are promising for advanced photonic, optoelectronic and photovoltaic applications. However, their long-term stability is still a critical factor limiting their implementation into further commercial applications [1,2]. Here, we present an environmental stability analysis of $BA_2(MA)_{n-1}Pb_nI_{3n+1}$ ($BA=C_4H_{12}N^+$, $MA=CH_6N^+$) two-dimensional perovskites with the lowest quantum well thicknesses of n=1 and n=2, after one year of aging under ambient humidity, oxygen content, and light conditions. We observed that both crystal phases (n=1, 2) degraded similarly, resulting in the removal of organic components and crystal decomposition into PbI_2, Pb oxides and Pb hydroxides. However, we have found a significant difference between their aging under ambient light and dark conditions, affecting their degraded morphology and photoactivity. Both crystal phases exposed to ambient light aged into a morphology characteristic by the formation of several pinholes and voids, accompanied by photoluminescence degradation. Samples stored under dark conditions surprisingly preserved photoluminescence activity, which morphologically aged into microrod structures. We conclude that the observed loss of photoactivity of 2D perovskites aged under ambient light is attributed to photo-accelerated degradation processes causing faster crystal surface photo-oxidation accompanied with a creation of multiple I vacancies and hydration of the inner crystal. The retainment of photoactivity in 2D perovskites aged under dark conditions is attributed to slower surface oxidation processes into Pb salts, as confirmed by X-ray photoemission spectroscopy. The formed surface layer even allow for a layer-by-layer degradation and act as a protection barrier against further additional loss of I atoms and the consequent hydration of the inner part of samples. We demonstrate that light is the most critical external factor accelerating 2D perovskite degradation processes in ambient air and thus affecting their long-term stability. We conclude in this work that perovskite material structural engineering, together with their surface passivation or encapsulation strategical techniques applied are essential steps for their further application into long-term stable commercial devices.

Surface Engineering of Tin Oxide Nanoparticles by pH Modulation Facilitates Homogeneous Film Formation for Efficient Perovskite Solar Modules Chae-Eun Seo[1], Hyun-Sung Yun[2] and You-Hyun Seo[2]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Producing clean energy in a sustainable manner is a critical global imperative. Solar energy provides notable potential due to its unlimited supply, high power density, and environmental benefits, distinguishing it from other energy sources. Although Si-based solar cells dominate the market, the development of alternative solar cell materials continues due to high processing costs and limited application areas. Perovskite solar cells (PSCs) exhibit outstanding photovoltaic properties, including high light absorption coefficients in the visible spectrum, low exciton binding energy, and long carrier diffusion lengths. When integrated with solution-based technologies that offer low production costs, PSCs have achieved an efficiency exceeding 26.1% within just 15 years, establishing them as one of the most promising candidates for replacing Si-based solar cells. To commercialize PSCs, various research efforts are being directed towards bifacial and flexible devices, tandem cells, and other areas. In all these fields of research, large-area fabrication emerges as a crucial factor. However, there are significant efficiency variations between small-scale cells and large-scale modules. Therefore, research on perovskite solar modules (PSMs) is necessary to improve efficiency and stability. Achieving high-efficiency PSMs necessitates uniform film deposition to minimize performance losses typically seen with PSCs. Defects such as microscopic pinholes may not pose significant issues at the cell level but can critically affect performance and durability at the module scale. In addition to improving the quality of perovskite films, the formation of homogeneous and defect-controlled charge transport layers is an essential component for achieving high-performance PSMs. Tin oxide (SnO_2) films generally used as the electron transport layer (ETL) in solution-processed PSCs introduce numerous microscopic defects at the ETL/perovskite interface.
Herein, we describe a simple approach to forming a homogeneous film and reducing hydroxyl groups on SnO_2 film surface by adding nitric acid (HNO_3) to SnO_2 dispersion. The surface of SnO_2 nanoparticles (NPs) initially exists as oxide ions (O^-) under basic conditions at high pH. Modulating the pH of the SnO_2 NP colloidal dispersion with a small amount of HNO_3 induces hydroxyl groups on the surface of the NPs. The induced hydroxyl groups on the surface of the SnO_2 NPs lead to the formation of oxo groups (Sn-O-Sn) between NPs by condensation reaction. The formation of oxo groups on SnO_2 NP surfaces reduces surface oxide ions. These oxide ions generate hydroxyl groups on the SnO_2 film surface after the annealing process at ambient conditions. By modulating the pH, the reduced oxide ions consequently minimize the hydroxyl groups on the SnO_2 film, which act as electronic defects. By surface engineering of SnO_2 NPs, high performance has been achieved: 23.7% efficiency for a unit cell, 20.3% efficiency for a 24.5 cm^2 minimodule, and 19.0% efficiency for a 214.7 cm^2 submodule. These efficiencies are averages from results obtained by reverse/forward scans. In outdoor tests, the target PSM generated 16.5% higher

cumulative electricity over a month compared to a control PSM. Furthermore, under damp heat conditions (85°C and 85% RH), the target PSM maintained 80% of its initial efficiency over 1080 hours. These results demonstrate the significance of the proposed surface engineering strategy in the chemical modification and uniformity of the ETL in large-scale PSMs. [1] In future studies, we will aim to apply this strategy for homogeneous ETL at low temperatures into roll-to-roll process. This approach is expected to accelerate the commercialization of all-printing PSMs.

Humidity-Induced Phase Transition Stages in $FAPbI_3$ Revealed by Ultralow-Dose 4D-STEM Byeongjun Gil[1,2], Yeoun-Woo Jang[3], Yimei Zhu[2], Myung-Geun Han[2] and Miyoung Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Brookhaven National Laboratory, United States; [3]Rice University, United States

Metal halide perovskites, particularly formamidinium lead triiodide ($FAPbI_3$), are promising for solar cells due to their thermal stability and near-optimal bandgap. However, a significant challenge with $FAPbI_3$ films is their tendency to transition from the desirable α-phase to a photoinactive δ-phase at room temperature [1]. This transition is believed to involve several intermediate stages, including hidden polytypes, and identifying them is crucial for improving the stability of the material system [2]. However, tracking these stages at the single-grain level is difficult due to the sensitivity of the materials to electron beams and mechanical tips [3].

To address this challenge, we established ultralow-dose four-dimensional scanning transmission electron microscopy with nano-beam diffraction (4D STEM-NBD) using direct detection electron detectors (DDEC). This approach maximizes the signal-to-noise ratio for tracking phase changes in FAPbI3 at the nanoscale under humidity exposure.

We first determined a critical electron dose of approximately 30-50 e/Å2, below which the electron beam does not induce changes in the diffraction pattern. For the 4D STEM-NBD measurements, we significantly reduced the electron dose to less than 2 e/Å2 per scan, substantially lower than the critical electron dose, while still maintaining identifiable diffraction signals. We confirmed that the pristine diffraction patterns were preserved even after 10 subsequent scans, enabling us to track sequential phase changes through multiple scans of the same area.

Using the established 4D STEM-NBD technique, we investigated the degradation processes of $FAPbI_3$ under controlled conditions. The sample was exposed to 60% relative humidity outside the microscope and systematically analyzed at the same spot every hour. We observed that the phase transitions proceeded sequentially from 3C to 6H, 4H, and 2H, ultimately leading to amorphization initiating from the grain boundary. The 3C phase refers to the cubic α-$FAPbI_3$, and the 6H, 4H, and 2H phases are different polymorphs of the δ-$FAPbI_3$ [2]. The two distinct lattice orientation relations were observed in the 3C to 6H transition, while a single coherent orientation was observed in transition in between δ -phases (6H-4H-2H). The transition rate of 3C-6H was significantly faster than that of the 4H-2H transition, implying that the transitions between polytypes of the δ-phase are the rate-determining steps, possibly due to differences in the atomic displacement steps involved. The exact roles of previously suggested approaches to suppress the α-δ transition, including compositional and additive engineering, on each stage remain unclear. Nevertheless, these findings shed light on the hidden mechanisms of the α-δ phase transition and provide insights into developing effective strategies to suppress this transition.

Enhancing Stability and Efficiency of CsPbI3 Perovskite Solar Cells via 3-(Aminomethyl)piperidinium Pretreatment

Sohyun Kang, Seungmin Lee and Jun Hong Noh; Korea University, Korea (the Republic of)

The inorganic perovskite cesium lead triiodide (CsPbI3) has a bandgap of 1.73 eV, making it suitable for the top cell in perovskite tandem solar cells. Additionally, the single halide composition of inorganic perovskite offers advantages in halide segregation and thermal stability compared to light-harvesting layers with mixed halides. However, achieving high performance in CsPbI3 perovskite solar cells (PSCs) remains challenging, as their efficiency is still lower than that of halide-mixed PSCs. This is primarily due to severe energy losses caused by various defects, such as vacancies and anti-site defects, occurring on the surface and grain boundaries. A common approach to managing these defects in the light absorber layer is to utilize 2D perovskites, but the high crystallization temperature of CsPbI3 prevents introduction of organic spacer. Here, we propose a pretreatment with 3-(aminomethyl)piperidinium (3AMP) before depositing the CsPbI3 film. The 3AMP molecule is predicted to be effective in controlling defects in CsPbI3-based PSCs, because of thermal stability compared to common 2D perovskite organic spacers such as butylammonium. By introducing thermally stable 3AMP, we observed changes in the crystallographic and interfacial properties, resulting in an improved power conversion efficiency of over 21% and an open-circuit voltage of 1.21 V. Additionally, devices treated with 3AMP showed improved stability compared to control devices.

EL04.18.09

16% Efficient Lead-Free Perovskite Solar Cells Achieved by Defect Passivation and Energy Level Adjustment

Yuedong Shi, Zihao Zhu and Qixi Mi; ShanghaiTech University, China

As a new class of semiconducting materials with excellent optoelectronic properties, metal halide perovskites have been applied in various fields such as solar cells, photodetectors, and electroluminescence. However, the toxicity of the lead element contained in these materials limits their application scenarios. Tin, a low-toxic element in the same main group as lead, is considered the most suitable alternative to lead. However, the performance of tin perovskite materials is currently far inferior to lead-containing materials, especially in terms of the short carrier lives and low open-circuit voltages of photovoltaic devices. Current research community generally attribute these phenomena to the material defects of tin perovskites, but the nature and regulation of these defects remain obscure. Under the guidance of theory, we have systematically studied this issue for tin perovskites from both aspects of bulk and surfaces, and prepared a series of high-quality single crystal and thin film samples. We directly characterized the types of defects, their concentrations and influence on semiconductor properties, revealing that the dominant defects in tin perovskites are not directly caused by oxidation of Sn^{2+}. We found that substituted thiourea molecules as Lewis-base ligands can deactivate the Sn^{2+} 5s electron pair and create an appropriate intermediate phase structure, thereby slowing down the crystallization rate, inhibiting surface and bulk defects of the crystal, and obtaining high-quality thin films. On the other hand, by decorating the thin-film surfaces with molecular dipoles but not changing the bandgap of perovskite layer, we elevated its conduction band minimum (CBM) to better match the energy level of the electron transport material (ETM). The above measures have rendered thin films of tin perovskite with charge carrier lifetimes longer than 0.5 μs and diffusion lengths on the micrometer scale, and boosted the open-circuit voltage of solar cell devices to 1.0 V (only ~0.1 V loss), approaching the level of lead-containing materials. The energy conversion efficiency reached 16%, setting a new performance record for lead-free perovskite solar cells. Their stabilities are also significantly enhanced, demonstrating a promising application prospect.

EL04.18.10

Selectively Regulating Sn^{2+} Crystallization in Mixed Sn–Pb Perovskite for Efficient and Stable Narrow-Bandgap Solar Cells

Qixi Mi, Donghao Miao and Zihao Zhu; ShanghaiTech University, China

In high-performance perovskite tandem solar cells, the bottom cell is responsible for harvesting near-infrared photons in sunlight and its narrow bandgap at 1.2–1.3 eV is achieved by alloying Sn^{2+} and Pb^{2+} in the perovskite structure. Owing to the tendency of Sn^{2+} toward premature crystallization, solution deposition of mixed Sn–Pb perovskite films faces challenges in phase segregation and defect formation. In this work, we employed an organic molecule trimethylthiourea (3T) as a Lewis-base ligand for Sn^{2+} in the precursor solution and on film surfaces of the mixed Sn–Pb perovskite. According to infrared spectroscopy, the 3T ligand preferentially coordinated to Sn^{2+} over Pb^{2+} in the precursor solution. As a result, crystallization process of the mixed Sn–Pb perovskite went through with regulated crystallization kinetics and enhanced composition homogeneity, giving rise to smooth and compact films consisting of micron-sized crystallites showing preferential (100) orientation. Enhanced film quality also yielded charge-carrier lifetimes as long as 0.9 μs and device fill factors over 80%. We subsequently fabricated complete photovoltaic devices having the structure ITO/perovskite/C_{60}/Ag. Thanks to the high-quality perovskite layer and the absence of a hole transport layer (HTL), our mixed Sn–Pb perovskite solar cells exhibited energy conversion efficiencies up to 21% and storage stability of at least 6000 hours, which are excellent performances for HTL-free, narrow-bandgap perovskite solar cells. Our results present an effective method to enhancing film deposition of mixed Sn–Pb perovskite, and lay a solid foundation for high-efficiency tandem perovskite solar cells.

Diammonium Spacer-Induced Stable Zigzag Type 2D Dion-Jacobson Lead/Tin-Based Perovskite Solar Cells

Mi Hee Jung; Sejong University, Korea (the Republic of)

The advent of hybrid halide two dimensional (2D) perovskite have shown considerable attention because they exhibit the improvement of the perovskite solar cells compared with their 3D analogs. However, their bulky organic space group, leading to the higher bandgaps and exciton binding energy, limited the charge transport in solar cell. Herein, the 3-(aminomethyl)pyridinium ($3API_2$, $C_6H_{10}N_2I_2$) dication is incorporated into $FA(Pb_{0.5}Sn_{0.5})I_3$ to develop the zigzag type 2D Dion-Jacobson-phase perovskites, which show the low band gaps in the range of 1.44 to 1.53 eV for the concentration from 5 mol% to 20 mol% due to the structural distortion. The introduction of $3API_2$ cation increases the carrier conductivity and produce a high-quality perovskite film with no pinhole and connected grains, which is favorable to efficient carrier transport. Consequently, solar cells employing the 10% mol $3API_2$ added $FA(Pb_{0.5}Sn_{0.5})I_3$ as a light absorber achieves a power conversion efficiency of 5.46% with an open-circuit voltage of 0.47 V, a fill factor of 58.07% and a short-circuit current density of 20.18 mA/cm^{-2}. With this class of new 2D Dion-Jacobson perovskite composition, this work suggests the potential future directions for improving performance and device stability of perovskite solar cell.

EL04.18.12

Numerical Simulation Approach for High-Efficiency Inverted Perovskite Solar Cells Using Self-Assembled Monolayers

Lee Donghyeon, Sua Park, Shinhyun Kim and Min-cheol Kim; Pusan National University, Korea (the Republic of)

Inverted perovskite solar cells (IPSCs) with p(hole transport)-i(perovskite)-n(electron transport) structures offer several advantages, such as low-temperature fabrication and their applicability in flexible and tandem structures [1]. Despite these benefits, initial studies focused more on n-i-p structures due to the initially low efficiency of p-i-n structures [2]. Recently, self-assembled monolayer (SAM) materials with attractive synthesis cost, low parasitic absorption, tunable energy level, notable defect passivation ability for perovskite have been explored as effective hole transport layer for IPSCs, leading to remarkable efficiency improvements up to 25.4% [3-5]. However, SAMs consist of monolayers or nanometer-scale films, making it difficult to accurately characterize to determine their morphology and electrical properties. This results in an insufficient understanding of their electrical characteristics and limits simulation-based performance enhancements. In this study, we quantified the properties of various SAM materials such as 2PACz, MeO-2PACz, MeO-4PACz, Me-4PACz, 3PATAT-3C, commonly used as hole transport layers in IPSCs using high-resolution surface measurement techniques like Atomic Force Microscopy (AFM) and Ultra-violet Photoelectron Spectroscopy (UPS), X-ray Photoelectron Spectroscopy (XPS). These properties are necessary for the numerical simulation of internal carrier behavior. Then, we calculated the optimal parameters of light absorbing perovskite layers such as layer thickness, composition, and band gap for specific SAM materials by numerical method, a solar cell capacitance simulation-1d (SCAPS-1D). With this numerical simulation, we can select the optimized perovskite layers for each SAM materials to enhance the performance of the IPSC.

Ethanol Purification Enables High-Quality α-Phase $FAPbI_3$ Perovskite Microcrystals for Commercial Photovoltaic Applications

Hyun Seo Kim[1,2]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Korea Institute of energy Technology, Korea (the Republic of)

Perovskite solar cells (PSCs) have been recognized for their ease of fabrication, and potential for low-cost production, feasible bandgap tunability, long charge-carrier diffusion length making them promising candidates for next-generation solar technology. In order to effectively nestle at the commercial development level of PSCs, it is crucial to develop reliable and sustainable processes for mass production of high-quality perovskite materials. Traditional toxic solvents pose environmental and health risks (EHS). One of the considerations is the reduction or elimination of the usage of toxic and unsustainable solvents by replacing them with 'green solvents' in processes. The terminology 'green solvent' reflects not only the minimization of the direct EHS impact of a chemical process, but also the indirect effects, such as the energy demand and cost of production, storage, recycling, or waste treatment after usage.

Using ethanol as 'green solvents' for synthesizing $FAPbI_3$ perovskite microcrystals offers significant environmental, health, and safety advantages. Ethanol's lower toxicity enhances workplace safety, reducing health risks for workers handling the solvent and exposure to hazardous chemicals.

Additionally, using ethanol to synthesize $FAPbI_3$ yields positive results from a Life Cycle Assessment (LCA) perspective. It is also easily biodegradable in natural environments, minimizing long-term environmental pollution upon disposal. Moreover, ethanol is readily recyclable, allowing it to be reused through re-distillation after initial use. Therefore, these characteristics make ethanol highly beneficial for the large-scale production and commercial application of $FAPbI_3$, significantly contributing to the development of sustainable processes.
The perovskite microcrystals purified using eco-friendly ethanol, exhibited superior properties compared with those based on other solvents. In the film state, it shows lower Urbach energy, higher photoluminescence (PL) intensity, and prolonged carrier lifetime, indicating effectively controlled trap states. When applied to the solar cells, the ethanol-assisted perovskite microcrystals result in more efficient devices and improved reproducibility than the other solvent-processed perovskite microcrystals. The results presented in this study pave the way for a new approach to commercialization, potentially reducing environmental and human hazards during mass production while improving reproducibility and photovoltaic performance.
To investigate the effects of the processing solvent on the photovoltaic properties, we fabricated PSC devices with the architecture ITO/SnO_2/$(FAPbI_3)_{0.95}(MAPbBr_3)_{0.05}$/spiro-OMeTAD/Au. The photovoltaic parameters were a power conversion efficiency (PCE) of 22.5%, open-circuit voltage (V_{OC}) of 1.18 V, short-circuit current density (J_{SC}) of 24.6 mA cm^{-2} and fill factor (FF) of 77.6% for the control device, and a PCE of 23.4%, V_{OC} of 1.19 V, J_{SC} of 24.6 mA cm^{-2}, and FF of 80.0% for the target device, demonstrating the effectiveness of the EtOH processing method.
Future studies should focus on optimizing this process and exploring other potential green solvents to further enhance the commercial viability of PSCs. This research paves the way for more sustainable and high-performance commercial photovoltaic devices. [1]

EL04.18.14

Towards Understanding the 2D Passivation of 3D Perovskites Through Structure-Activity Relationships Figen Varlioglu[1], Aliekber Karabag[1], Zeynep Karabag[1], Ummugulsum Gunes[2], Olga Syzgantseva[3], Gao Xiaoxin[2], Mohammad K. Nazeeruddin[2], Selcuk Yerci[1,4] and Gorkem Gunbas[1,4]; [1]ODTÜ-GÜNAM, Turkey; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]Lomonosov Moscow State University, Russian Federation; [4]Middle East Technical University, Turkey

Perovskite solar cells (PSCs) became the “next big thing” in solar energy research due to wide possibility of cost-effective fabrication approaches, high efficiencies and its undeniable match with silicon towards tandem solar cells. Unfortunately, reproducibility and long-term stability for PSCs are not even comparable with the commercial silicon technology. Several factors, both external and internal, affect the stability of PSCs, hence effective encapsulation cannot be the single remedy. Interface engineering is one of the critical aspects for enhanced performance and stability, and surface passivation with 2D perovskites have emerged as one of the leading approaches. Several large cations have been utilized in the literature for 2D/3D PSCs with promising results. However, due to the delicate nature of perovskites, different perovskite formulations used in these studies and the differences in device architecture makes it impossible to have clear structure-activity relationship.
In our ongoing efforts for deeper understanding of the 2D/3D perovskite interface, we designed and synthesized several large ammonium cations based on PEAI (phenylethylammonium iodide) with different substituents at different positions. All these salts (12 different) were then utilized in 2D/3D perovskites solar cells with same perovskite formulation and same device architecture. Among these salts several have showed solid performance and significantly improved stability. For example, *o*-OMe-PEAI, a methoxy substituted PEAI salt, utilized 2D/3D perovskite solar cells revealed PCEs as high as 23.34% and the device treated with *o*-OMe-PEAI maintained 95% of

its initial yield while the reference device only retained 59% (*Cell Rep. Phys. Sci.,* **2023**, *4*, 101380). Another derivative, *m*-CPEAI, a chlorine substituted PEAI utilized devices showed a high PCE of 23.16%, and showed remarkable stability where after 1000 hours of continuous illumination, *m*-ClPEAI-treated devices retained 87% of initial efficiency compared to the 36% retained by the reference (*Adv. Energy Mater.*, **2023**, *13*, 2370184).
Detailed DFT analyses showed that *o*-OMe-PEAI incorporated cells demonstrate favorable formation energy and desired vertical orientation along with optimal surface coating which resulted in the improved performance. However, similar DFT analyses revealed that lower formation energies, but the higher interfacial dipoles achieved by *m*-ClPEAI was responsible for the enhanced performance. The results clearly demonstrated in addition to the chemical identity, the positioning of the substituents have a major effect on the performance of the resulting devices and the beneficial effects resulted on the interface can arise from different physical phenomenon which needs to be incorporated into future design strategies.
Shorter chain ammonium cations such as phenylmethylammonium iodide (PMAI) passivates the 3D perovskite surface but do not actually for 2D-perovskite lattice. However, both performance and stability enhancements were demonstrated. In a recent study, we showed that five-membered heterocyclic aromatics (furan, thiophene, selenophene) substituted PMAI salts passivates the perovskite surface effectively and results in increased performance. The effect of substitution was also clear here where thiophene substituted derivative outperformed the counterparts (Reference PCE: 20.63%, thiophene: 22.93%, selenophene: 21.45% and furan: 21.87%). The stability enhancement was also significant where the reference cell had a 50% loss of efficiency after 1250 hours, whereas thiophene-based PAI treated cells retained nearly all their initial performance.
We are now creating a larger library of ethylammonium and methylammonium based cations with electronically distinct substituents and positional geometries to device a general set of design rules that will enable us to design next generation of material towards highly stable commercial 2D/3D PSCs.

EL04.18.15

Exploring Low-Energy Pathways for Self-Healing Defects in $CsPbBr_3$—A Computational Study Kumar Miskin[1], Yi Cao[1], Madaline Marland[1], Jay Rwaka[1], Farhan Shaikh[1], David Moore[2], John Marohn[3] and Paulette Clancy[1]; [1]Johns Hopkins University, United States; [2]National Renewable Energy Laboratory, United States; [3]Cornell University, United States

Metal halide perovskites (MHPs) have become a mainstay of recent research into solar cell materials, given their photovoltaic properties and remarkable solar efficiency in the lab. However, their efficiency and stability, especially at scale, are intricately linked to the material's ability to manage defects, which can act as recombination centers and limit their overall performance.
The all-inorganic perovskite, $CsPbBr_3$, has shown promising durability against environmental degradation factors, making it a prime candidate for defect studies aimed at improving device performance and longevity. While the available literature contains some defect formation energies, mechanistic understanding of defect motion is currently limited, especially for all-inorganic MHP materials. Our work investigates atomic-scale mechanisms behind defect migration and recombination in $CsPbBr_3$, using a Nudged Elastic Band method combined with Density Functional Theory calculations (NEB-DFT). This approach allows us to estimate activation energies from defect formation and migration, providing insight into at least some of the dominant defect pathways. Motivated by Tirmzi *et al.*'s experimental measurements of the slow recovery of light-induced conductivity in $CsPbBr_3$, we have identified some low-energy pathways that could lead to the self-healing of defects, a phenomenon that would significantly enhance the material's defect tolerance compared to conventional photovoltaic materials. Our NEB-DFT results match the sole experimental activation energy, shedding light on plausible defect migration pathways in $CsPbBr_3$. These low-energy pathways for defect self-healing may have significant implications for the design of semiconductor materials with improved light absorption and catalysis properties, aligning with the symposium's focus on advances in photocatalysis, operando material characterization, and material design for

solar energy conversion.

EL04.18.16

Formamidium-Based Quasi-2D Dion Jacobson Perovskites for Efficient and Durable Wide Band Gap Solar Cells

Ayush Agrawal, Jin Hou, Faiz Mandani and Aditya D. Mohite; Rice University, United States

In the last decade, three-dimensional (3D) metal halide perovskite solar cells have displayed tremendous progress in photoconversion efficiencies. The tunable bandgaps enable mixed halide perovskite compositions to be used as the wide bandgap (WB) sub-cell in perovskite-perovskite tandems. However, halide segregation and ion migration under photo-illumination create bandgap instability that limits the long-term durability of these wideband gap subcells. Quasi-2D halide perovskites, on the other hand, have demonstrated better durability against moisture and photo illumination due to their large organic cations but still lag in efficiency due to large exciton binding energies creating charge extraction barriers. Here, we synthesize Formamidinium (FA+) based 2D Dion Jacobson (DJ) perovskite with a band gap of 1.8eV, which is ideally suited for building bottom cells for perovskite-perovskite and perovskite/Si tandems. Films fabricated using the phase-selective memory seeds process preserved the phase purity of the n=3 2D perovskite[1]. More importantly, FA 2D DJ perovskite films demonstrate 2x more stability against the triple-cation 3D perovskite films in heat and 85% humidity. These properties make FA 2D DJ perovskites promising candidates for wide bandgap subcells in perovskite-perovskite tandem.

Evaporated Organic-MoO_3 Composite Hole Transport Layers Toward Stable Conventional Perovskite Solar Cells

Jisu Hong, Zhaojian Xu, Tuo Hu, Sujin Lee, Antoine Kahn and Barry P. Rand; Princeton University, United States

The release of iodine species and subsequent diffusion in perovskite solar cells (PSCs) is problematic due to their volatile and corrosive nature. Since hole transport layers (HTLs) have been shown to be a channel for iodine diffusion and metal anode corrosion in conventional PSCs, developing an HTL that inhibits iodine diffusion is necessary. Efficient oxidation (i.e., doping) of HTLs is crucial in that it improves the hole transport of organic HTLs with low electrical conductivity and mitigates the redox reaction between organic HTLs and iodine. In this study, molybdenum trioxide (MoO_3) is employed for efficient oxidation, replacing the conventional dopant lithium bis(trifluoromethane)sulfonimide (LiTFSI) having stability issues including hygroscopicity, Li^+ diffusion to perovskite layer, and aggregation and pinhole formation in HTLs. Co-deposition of 2,2',7,7'-tetra(N,N-di-p-tolyl)amino-9,9-spirobifluorene (spiro-TTB) and MoO_3 via thermal evaporation leads to an HTL with appropriate ionization energy of -5.06 eV, electrical conductivity of 6.02×10^{-5} S cm^{-1}, and homogeneous morphology. To investigate the stability of PSCs using the composite HTL, three types of PSCs with different HTLs are fabricated; the 2,2',7,7'-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene (spiro-OMeTAD) control HTL with conventional dopants, the double HTL with doped spiro-OMeTAD and spiro-TTB:MoO_3 layers, and the spiro-TTB:MoO_3 composite HTL. Since the efficient oxidation of spiro-TTB by MoO_3 and stable morphology under thermal stress mitigate iodine diffusion through the spiro-TTB:MoO_3 HTL, the PSC employing the composite HTL outperforms the control device employing the doped spiro-OMeTAD in the thermal stability test performed at 85 °C. While the control device reaches 80% of the initial efficiency after 1 h of aging, the device with the composite

HTL survives for 200 h. The PSC with the double HTL exhibits moderate stability by surviving for 45 h.

EL04.18.18

Thermal Stability of Lead-Halide PSCs Toward Space Applications—Investigating the Impact of Thermal Fatigue on the ETL-Perovskite Interface Khari Fletcher, Juan-Pablo Correa-Baena and Carlo Andrea Riccardo Perini; Georgia Institute of Technology, United States

Lead-halide perovskites (LHPs) have become the focus of emerging photovoltaics due to favorable properties like high carrier mobility, defect tolerance, and tunable bandgap - which are the cause for their rapid increase in power conversion efficiency (PCE) in the last decade. However, LHPs possess intrinsic thermal instability which induces rapid degradation in films and solar cell devices. Under high temperature conditions, LHP thin films degrade via ion migration and transition into a photo-inactive phase. When Perovskite Solar Cells (PSCs) are placed under such conditions, CTE mismatch between material layers of about one order of magnitude generates overwhelming forces and induces microscopic and macroscopic failure. Within interlayers (the junction between two layers), CTE mismatch can cause detrimental strain on bonds, eventually causing them to break. This significantly decreases performance by reducing charge transfer and leads to macroscopic adhesion failure where entire layers can delaminate or wrinkle. However, the behavior of PSCs under low-to-high temperature cycling still requires further investigation. Here, we investigate the impact of surface interactions on thermomechanical integrity throughout the device under thermal and mechanical fatigue. Literature suggests that substrate rigidity heavily influences the stress relaxation mechanism present, whether delamination or wrinkling. The role of substrate rigidity on stress relaxation under mechanical cycling will be examined via compression testing. Likewise, the integrity of interlayer bonds under thermal fatigue will be examined via temperature cycling in a thermal-vacuum chamber and XPS, XRF, and electronic performance measurements before and after thermal aging.

Fundamental Optical Constants and Anti-Reflection Coating of Melt-Grown, Polished $CsPbBr_3$ Crystals

Michael C. Brennan[1,2], Douglas M. Krein[1,2], Emmanuel Rowe[1,3,4], Christopher McCleese[1,2], Lirong Sun[1,2], Kyle G. Berry[1], Peter Stevenson[1], Michael Susner[1] and Tod Grusenmeyer[1]; [1]Air Force Research Laboratory, United States; [2]Azimuth Corporation, United States; [3]National Research Council, United States; [4]Middle Tennessee State University, United States

Lead halide perovskites are notorious for water-sensitivity and low hardness. Consequently, polishing $CsPbBr_3$ crystals to achieve high-quality surfaces is challenging. We present a breakthrough mechanical polishing methodology tailored to the specific needs of these soft, moisture-sensitive semiconductors. Three-dimensional optical surface profiles over ~1 mm^2 areas demonstrate high-quality surfaces with root-mean-square roughness values (<10 nm) that are unparalleled for melt-grown $CsPbBr_3$. We additionally delve into the polished wafers' fundamental optical constants and introduce an anti-reflection coating method, setting new standards for short-wave infrared transparency in $CsPbBr_3$. These pivotal processing guidelines pave the way for advancing halide perovskite applications beyond academic curiosity.

EL04.18.20

Utilizing Automation for the Synthesis of Single Crystalline Hybrid Perovskite Materials Christopher McCleese[1,2], Steven Wolf[1,2], Ecklin Crenshaw[1,2], Yi Xie[3], Michael C. Brennan[1,2], David B. Turner[1,2], Raul Castenada[4], Hendrik Heinz[5], Seth R. Marder[5], David B. Mitzi[3] and Tod Grusenmeyer[1]; [1]Air Force Research Laboratory, United States; [2]Azimuth Corporation, United States; [3]Duke University, United States; [4]New Mexico Highlands University, United States; [5]University of Colorado Boulder, United States

Hybrid perovskites offer the opportunity to produce new materials based on the wide range of possible chemical substitutions that can be made and crystal dimensionalities that can be formed. However, the rate limiting step in discovering these new materials is the time it takes to grow and characterize the crystals. For solvothermal methods, typically a single hot plate is used and it can take days to grow crystals. Therefore, automation is a powerful tool to expedite the materials discovery process. In this talk, I will introduce our Hamilton Microlab Star Plus liquid handling robot and its current capabilities. For our first trial, the robot was used to explore solvothermal growth conditions for three dimensional $MAPbBr_3$ single crystals. Solvothermally grown crystals were characterized by programming the robot to measure the transmission spectrum of the crystals using an in-line UV-visible spectrophotometer. We have also utilized the robot to grow low dimensional chiral perovskite crystals. In this work we investigated how the ratio of lead to chiral cation affects the crystallization and the yield of crystal growth. Furthermore, we show how the robot allows for high-throughput crystal growth by scaling up to 24 different growths on single hot plate. This growth and characterization methodology can be used to rapidly produce new perovskites and the resulting data could potentially be used to build a materials database to help guide the growth of perovskites with desired properties.

EL04.18.21

Advancements and Challenges in Scaling 4-Terminal Perovskite/Silicon Tandem Solar Modules Prem Jyoti Singh Rana; Tandem PV, United States

The Perovskite solar cell has placed them as a leading candidate for next-generation photovoltaic technology due to rapid advancement, high power conversion efficiencies and relatively low production costs. However, transitioning from lab-scale devices to large-area modules poses significant challenges that must be addressed to achieve commercial viability. Key strategies for scaling up PSCs involve optimizing the perovskite layer deposition process to ensure uniform film formation over large areas, minimizing defects, and enhancing the stability and durability of the cells. Techniques such as blade coating, slot-die coating, and vacuum deposition technique are evaluated for their scalability and compatibility with industrial production lines. Additionally, the integration of advanced passivation layers and multi-layer architectures is investigated to mitigate issues related to charge recombination and interface degradation. Tandem PV aims to produce 2 m2 silicon/perovskite tandem modules that are 26% efficient with a high durability of at least 25 years. In scale, we are using in-line tools for scalable module fabrication such as slot die coating and laser scribing as well as metrology. I will present progress made towards our three priorities of value, scale, and durability using our R&D fabrication line producing films, cells, and 100-280 cm2 minimodules as we plan for the pilot manufacturing production line.

Novel Organic Electron Transport Layers Using NDI and PDI Derivatives Deposited via Thermal Evaporation for Perovskite Solar Cells Jack Lawton, Carlo Andrea Riccardo Perini, Xiangyu Xiao, Justine Wagner, Eric Shen, Juan-Pablo Correa-Baena and John Reynolds; Georgia Institute of Technology, United States

Organic transport layers are of significant interest in the field of hybrid perovskites due to their chemical adaptability and compatibility with industry favoured deposition techniques such as thermal evaporation. These methods are desired in industry given that they circumvent the need for undesirable process solvents and allow for the uniform coating of large area substrates. Hence, discovery and optimisation of organic Electron transport layers (ETL) provide an avenue for easier integration of perovskite photovoltaics into industry and eventual commercialisation. However, identification of effective ETLs is generally difficult owing to the necessity for both chemical and electrical compatibility with the perovskite layer.
This study introduces a library of conjugated molecules, deposited via thermal evaporation, for use as ETLs in

photovoltaic devices. The molecules, derived from naphthalene diimide (NDI) or perylene diimide (PDI), were modified with a range of terminal groups. These modifications tune the polarity and chemical nature of the molecules leading to a wide range of chemical behaviours such as hydrophobicity/philicity, hydrogen bonding and halogen bonding. Band alignment with the perovskite was also varied through extension of the conjugated system. The thin films were characterised using XPS, contact angle measurements, FTIR and ellipsometry. Our results show that some molecules exhibit stable evaporation profiles with no degradation, while others only partially evaporate or fail to evaporate entirely. Additionally, sensitivities to process solvents used in perovskite deposition were exhibited by some ETLs which manifested as changing chemical behaviours such as surface wettability and in some instances near total removal of the ETL. NIP devices were made to test the overall effectiveness of the organic ETLs and promising device results were obtained, with devices exhibiting unoptimised performances ranging from 7% to 14.8%.

EL04.18.23

Introducing Halide Perovskites as Future Capable Thermoelectric Materials Amin Nozariasbmarz; Rowan University, United States

Halide perovskites have emerged as a promising material class in various energy conversion research fields, including photovoltaics, photodetection, light emission, memristors, ferroelectrics, and photothermal conversion, due to their exceptional optoelectronic and charge carrier transport properties. However, the thermoelectric properties of halide perovskites have received limited attention despite their potential. These materials are classified as phonon glass and electron crystal, exhibiting ultralow thermal conductivity and a superior Seebeck coefficient, coupled with decent mobility and charge carrier tunability. Nevertheless, they face challenges such as instability, poor electrical conductivity, and a low power factor. Among halide perovskites, Pb- and Sn-based materials have demonstrated superior thermoelectric properties. For future thermoelectric applications, reliable synthesis methods and accurate thermoelectric property measurements are essential. In this talk, we introduce perovskites as a new thermoelectric material system and discuss their research potential and future perspectives for energy harvesting and sensor applications.

EL04.18.24

Heteroanionic 2D Ruddlesden-Popper Perovskites $A_2CdI_2Cl_2$ (A = Cs, MA)— Synthesis, Structure and Optical Characterization Kulatheepan Thanabalasingam[1,2], Mihir S. Singh[1,2] and Kyle M. McCall[1]; [1]The University of Texas at Dallas, United States; [2]University of Texas at Dallas, United States

Halide perovskites are next-generation photovoltaic candidates due to their remarkable properties, such as defect tolerance, low thermal conductivity, and efficient light emission, which arise in part from the structural dynamics and disorder of the crystal lattice. However, the limits of this disorder are unclear – that is, how far can the perovskite structure be stretched while maintaining similar properties? The 2D Ruddlesden-Popper perovskites (RPs), $A_{n+1}B_nX_{3n+1}$, are quasi-2D <100> structure variants of 3D perovskites where B^+ ion occupies in corner-connected octahedra in *ab* plane, while A^+ ions space out the layers. Here, we study inorganic and hybrid mixed-anion 2D RP materials to understand the structure-property relationship and gain insights into the origin of their optical properties. In this presentation, we report the synthesis, crystal structure, and optical properties of two novel RPs, $Cs_2CdI_2Cl_2$ and $MA_2CdI_2Cl_2$ (MA = methylammonium).

All-inorganic $Cs_2CdI_2Cl_2$ crystals were grown using a solvothermal reaction in a 1:1 HCl and HI mixture, while the hybrid $MA_2CdI_2Cl_2$ was grown using a hydrothermal reaction in distilled water with a few drops of hypophosphorous acid and followed by slow evaporation crystallization. Powder X-ray diffraction of $Cs_2CdI_2Cl_2$ and Rietveld refinement confirm that the material crystallizes in the tetragonal *I4/mmm* space group. This is the highest allowable symmetry for Ruddlesden-Popper perovskites, and is isostructural with $Rb_2CdI_2Cl_2$, $Cs_2SnI_2Cl_2$, and $Cs_2PbI_2Cl_2$ analogues. This series is thus ideal for probing the impact of A and B site variation in these mixed-anion compounds, which host heteroleptic coordination of the B site with both I and Cl ions. On the other hand, $MA_2CdI_2Cl_2$ crystallizes in the orthorhombic *Fmm*2 space group, confirmed by single crystal X-ray diffraction. The octahedral units of this structure are tilted due to the orientation of the MA cation in the void, causing the reduction in symmetry. Photoluminescence of $Cs_2CdI_2Cl_2$ shows a broad yellow emission centered at 570 nm with 340 nm excitation. Comparison of these new 2D RPs with the known compounds $Rb_2CdI_2Cl_2$ and $Cs_2PbI_2Cl_2$, which have exhibited broadband emission and photoconductivity, respectively, will enable us to connect structural features, including the presence or absence of a lone pair, with optical properties to close the structure-property relationship loop. In this presentation, we will discuss the synthesis and crystal growth of these materials, their crystal structures, and their optical properties measured by photoluminescence and UV-Vis absorption spectra.

EL04.18.25

Absorption Properties of Hybrid 2D Perovskite Structures for Photodetector Applications Jesse Laursen, Carlo Andrea Riccardo Perini and Juan-Pablo Correa-Baena; Georgia Institute of Technology, United States

The field of optoelectronics has seen great strides taken in recent years with the development of halide perovskites. To date, most work on halide perovskites has focused on solar cells and photodetection technologies have attracted less attention. In particular, hybrid organic-inorganic 2D perovskites have the potential for photodetectors if properly coupled with an organic absorber. This configuration can provide improved structural stability alongside highly tunable band edges, which is ideal for the collection and transfer of charge carriers necessary in light detectors. In this work, I will explore how altering the chemical composition of a 2D perovskite inorganic layer affects its band edges. I will study the changes in the excited state populations and lifetimes using spectroscopic methods such as transient absorption. Pathways for effective carrier transport from the organic to the inorganic will be studied. Finally, I will discuss device optimization for photodetector applications with the 2D perovskite. This work will enable new understanding of the role chemistry plays on band edges in 2D perovskites and their effect on photodetection mechanisms.

EL04.18.26

Vapor Transport Deposition of Perovskite Photovoltaics Tamar Kadosh[1], Wan-Ju Hsu[2], Emma Pettit[2], Shreyas Srinivasan[1], Harry Tuller[1], Russell Holmes[2] and Vladimir Bulovic[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Minnesota, United States

Hybrid halide perovskites have demonstrated remarkably high solar to electrical energy conversion efficiencies and are therefore of great interest for rapid commercialization. Popular solution-based fabrication routes based on hazardous solvents cannot be readily up-scale as required. Vapor Transport Deposition (VTD) is an alternative, low-cost manufacturing technique that has been proven before for other solar cell materials. Vapor-based processes promise to overcome many challenges imposed by solution-based techniques. Being solvent-free, they bypass solvent related challenges, namely uniform coverage of large areas, chemical compatibility, and toxicity. As a low-cost alternative to thermal evaporation, VTD has the potential to deposit organic and inorganic perovskite precursor materials either sequentially or via co-deposition. Furthermore, VTD potentially offers higher tunability of deposition parameters, to enable film growth with improved composition and microstructure control.
We are currently working with a custom-made VTD system, with which we achieved champion MAPI cells of close to 12% power conversion efficiency. Now, our work is focused on optimization of deposition of lead iodide and formamidinium iodide with the aid of carrier gases. We report our progress in investigating the influence of underlaying layer, substrate and sublimation temperatures, chamber pressure and flow rate ratios on the morphology and stoichiometry of the forming perovskite film, and in turn, its photo-active and electronic

properties.

EL04.18.27

Enhanced Thermoelectric Performance and Stability of 2D Sn-Based Perovskite—Choice of Spacer and Doping Strategy Zhilin Ren, Yueyang Wang, Ji Tae Kim, Dongkeun Ki and Aleksandra Djurišić; The University of Hong Kong, Hong Kong

Hybrid halide perovskites are gaining increasing attention for their ultra-low thermal conductivity, making them highly promising thermoelectric materials. Since the thermoelectric figure of merit (*ZT*), which evaluates device thermoelectric efficiency, is determined by thermal conductivity (κ), Seebeck coefficient (*S*), electrical conductivity (σ), and temperature at the same time, the resulting *ZT* represents a compromise between these values. In addition to low κ, perovskite materials have excellent composition tunability and great potential for achieving higher *ZT*. However, while researchers have made great efforts to improve the thermoelectric performance of perovskites, their thermoelectric performance is still limited by the low electrical conductivity and poor stability upon exposure to ambient air (moisture and oxygen). In this work, we focused on Sn-based halide perovskite for its remarkably higher σ than Pb-based perovskite. Based on previously published two-dimensional (2D) PEA_2SnX_4 perovskites (PEA denotes phenethylammonium, X for halide) as a thermoelectric material, we investigated different 2D Sn-based perovskite materials to identify compositions leading to good performance. As all halide perovskites have low thermal conductivity, we focused on investigating the effects of composition on electrical conductivity and stability. Both bromide or iodide-based perovskites with both Ruddlesden Popper (RP) and Dion-Jacobson (DJ) spacers were studied in this work, among which TEA_2SnI_4 perovskite was outstanding for its higher σ and S compared to PEA_2SnI_4 and best ambient stability (TEA stands for 2-thiopheneethylammonium). Moreover, different dopants were applied to PEA_2SnI_4 and TEA_2SnI_4 for higher σ, among which F4TCNQ and SnI_4 were found to be effective in increasing conductivity.

EL04.18.28

High Performance Organic and Inorganic Metal Halide Perovskite Phototransistors Jamal Aziz; Bergische Universitat Wuppertal, Germany

Perovskite has emerged as the promising material for optoelectronic applications, especially solar cells, owing to its high absorption coefficients. However, the research on perovskite based electrical devices raised serious concerns based on their operational instabilities and their ionic nature. This effect leads to perovskite-based field effect transistors (FETs) with low carrier mobility, high hysteresis, and high operating voltages due to long channel lengths. Here we have reported phototransistors based on $MAPbI_3$ and $CsPbBr_3$ perovskite with silicon back gate. Firstly, we reported bottom gate / top contact (BGTC) perovskite transistors with long channel lengths (170 µm) but however they exhibit poor electrical and light dependent response. In contrast, the bottom gate / bottom contact (BGBC) perovskite transistors with short channel lengths (6 µm) exhibit optimal performance. Ambipolar transport characteristic was observed at room temperature. The hole mobility presents light dependence whereas electron mobility is nearly the same under light for both organic and inorganic metal halide transistor. The photoresponsivity of 60 mA/W and detectivity of 4×10^{12} Jones was observed for $CsPbBr_3$ phototransistors. The hysteresis effect of both organic and inorganic metal halide transistor was studied by changing the voltage bias and the monochromatic light intensity. The hysteresis effect in both perovskite transistors is attributed to the charge trapping process. Overall, this work paves the way for perovskite based flexible, wearable and disposable electrical devices with optimal performance.

EL04.18.29

Suppressed Photooxidation in PbSn Perovskite Solar Cells by Field-Modified Selective Contact Yuan Liu,

Up-to-date as of November 14, 2024

Chongwen Li, Bin Chen and Edward Sargent; Northwestern University, United States

Mixed PbSn perovskites are necessary components in all-perovskite tandem and triple-junction solar cells. However, the lifespan of PbSn subcells is severely limited by Sn oxidation. Here, we studied the degradation mechanism of PbSn perovskite devices and discovered that the inefficient extraction of holes from the hole transport layer (HTL) into the conductive electrode results in the hole-induced oxidation of Sn2+ to Sn4+. Such accumulation set the HTL in a higher oxidation state than the redox potential of Sn2+ to Sn4+, leading to a thermodynamically preferred oxidation reaction between the hole and Sn2+.
To address this issue, we aimed to eliminate the HTL while minimizing interface recombination at the newly formed perovskite-electrode contact. Here, we embed high-κ dielectric nanoparticle islands in the perovskite-electrode interface to improve the local electric field, thereby promoting efficient charge extraction from perovskite to the electrode.
We have achieved power conversion efficiencies of 23.7% in PbSn perovskite solar cells, with encapsulated devices retaining 80% of the initial PCE > 1500 hours of maximum power point tracking (MPPT) at room temperature (ISOS-L1) and > 600 hours of operation at 65 °C (ISOS-L2) in a reliability chamber with active heating and temperature monitoring. This is the first time a report of > 20 % of PCE PbSn devices surviving the ISOS-L2 accelerated test over 600 hours.

EL04.18.30

Boosting Stability and Performance of Perovskite Devices Using 2D Ruddlesden–Popper Perovskites Suman Kalyan Pal, Milon Kunder and Koushik Gayen; Indian Institute of Technology Mandi, India

Two-dimensional (2D) Ruddlesden-Popper (RP) metal halide perovskites represent a class of multifunctional semiconductors. In these materials, excitons are generated due to significant quantum and dielectric confinements within their multiple quantum-well structure [1]. Compared to 3D counterparts, 2D RP perovskites offer enhanced stability and greater compositional tunability, making them attractive for optoelectronic devices. However, the localized and bound nature of excitons in 2D perovskites can hinder device performance by promoting nonradiative recombination and suppressing carrier transport [2]. In this presentation, I will discuss various strategies to improve the stability of perovskite devices while maintaining their efficiency. We have successfully developed a 3D/2D hybrid solar cell by treating a 3D perovskite film with 2-thiopheneethylammonium iodide (TEAI) [3]. This innovative 2D passivation technique effectively reduces defects and ion migration, leading to enhanced charge carrier transport. As a result, the device stability is significantly improved, along with overall performance. Additionally, we investigated the impact of direct passivation of 3D perovskites using 2D perovskite crystals on solar cell performance [4]. This passivation strategy significantly enhances the morphological and optoelectronic properties of the 3D/2D heterostructure, optimizing energy band alignment and facilitating efficient charge carrier transport at interfaces. This improvement boosts the power conversion efficiency and long-term stability of solar cells. Finally, I will present the operation of a resistive random-access memory (ReRAM) device based solely on pure 2D RP perovskites [5]. Our ReRAM devices demonstrate reliable and reproducible switching properties, which are maintained for up to 45 days under ambient conditions (relative humidity ~47%).

Optical Properties of Organic-Inorganic Hybrid $(TMS)_3Cu_2I_5$ Thin Films Formed by Mist Deposition Keisuke Watanabe and Hiroyuki Nishinaka; Kyoto Institute of Technology, Japan

In recent years, Cu-based metal halides such as $Cs_3Cu_2I_5$[1] have garnered considedrable attention as lead-free metal halides due to their excellent optical properties. These materials exhibit blue emission with a high photoluminescence quantum yield (PLQY) under UV irradiation, high ambient stability, and non-toxicity. These properties make them promising candidates for optical applications, including LEDs,[2] photodetectors[3], and scintillators[4]. Additionally, similar to conventional Pb-based perovskites, Cu-based metal halides can also tune their emission wavelength by adjusting the halogen composition. However, the tunable emission is limited to the blue and green regions, and the green-emissive $Cs_3Cu_2Cl_5$ suffer from low ambient stability, degrading under air conditions. To address these challenges, we explored organic-inorganic hybrid materials as potential candidates for long-wavelength emissive materials with high PLQYs. Among them, $(TMS)_3Cu_2I_5$[5] (TMS: trimethyl sulfonium) is a novel material that exhibits yellow emission with a PLQY of 26% in single crystals and high ambient stability. Despite these promising properties, $(TMS)_3Cu_2I_5$ has been minimally studied, with research focused on single crystal growth and not extending to thin film deposition, which is crucial for device applications. In this study, we successfully deposited $(TMS)_3Cu_2I_5$ thin films using mist deposition with various precursor composition ratios and investigated their optical properties.
We prepared the precursor solution by dissolving various ratios of (TMS)I and CuI in DMF and DMSO. The precursor mist, generated by ultrasonic transducers, was transferred to heated substrates using carrier gas to form thin films. We analyzed the composition of the deposited $(TMS)_3Cu_2I_5$ thin films using energy dispersive X-ray spectroscopy (EDX), confirming of the presence of S, Cu, and I, with sulfur originating from TMS. The film compositions were Cu-rich compared to the precursor solution ratios. When the precursor solutions ratio of (TMS)I / CuI was 2.25, the concentration ratio of S:Cu:I reached approximately 3:2:5. The thin films exhibited bright yellow emission with a peak at 550 nm under UV irradiation. Photoluminescence (PL) measurements revealed broad emission spectra with a full width at half maximum (FWHM) of 0.42 eV. Photoluminescence excitation (PLE) spectra showed two distinct peaks at 287 nm and 313 nm. The Stokes shift of $(TMS)_3Cu_2I_5$ was calculated 1.72 eV. This large Stokes shift is advantageous for LEDs application by reducing self-absorption. These PL/PLE results align with previous reports on the single crystals. We further evaluated the PLQY of $(TMS)_3Cu_2I_5$ thin films. The PLQY increased as the film composition approached stoichiometry, reaching 60% in the thin films. This enhancement is attributed to the suppression of non-radiative recombination centers caused by impurities as the composition of the thin films reached near stoichiometry.
In the symposium, we will discuss the more detailed crystal structure, composition in the thin films, and optical properties of $(TMS)_3Cu_2I_5$ thin films deposited by mist deposition.

Nucleation or Coarsening—How Additives Actually Govern Perovskite Grain Size Kai O. Brinkmann[1,2], Timo Maschwitz[1,2], Lena Merten[3], Feray Ünlü[4], Andreas Kotthaus[1], Cedric Kreusel[1,2], Manuel Theisen[1,2], Henrik Weidner[1,2], Martin Majewski[5,6], Anael Jaffres[7], Alexander Hinderhofer[3], Oliver Ronsin[5,6], Christian Wolff[7], Stefan Kirsch[1], Sanjay Mathur[8], Frank Schreiber[3] and Thomas Riedl[1,2]; [1]Bergische Universitat Wuppertal, Germany; [2]Wuppertal Center for Smart Materials and Systems, Germany; [3]Universität Tübingen, Germany; [4]Helmholtz-Zentrum Berlin, Germany; [5]Forschungszentrum Jülich GmbH, Germany; [6]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [7]École Polytechnique Fédérale de Lausanne, Switzerland; [8]University of Cologne, Germany

Perovskite solar cells currently enter a stage, where market introduction is within reach. For serious upscaling, control over the quality of the perovskite material is most critical. To this end, the community currently relies heavily on laboratory experience, engineering, and fine-tuning approaches. A key challenge is the controlled growth of perovskite crystallites while processing thin films. Several strategies are currently in use, such as anti-solvent or additive engineering. While the impact of these strategies is well-evidenced in the resulting layers, the underlying mechanisms that govern the crystallization process are still subject to a vigorous debate. A frequently cited theory is that the nuclei for the perovskite crystallization evolve from intermediate solvate clusters that might form colloids that act as seeds[1,2] As of yet, however, insights that unambiguously link the complex formation in the precursor inks to the perovskite formation are lacking.

In this work we propose an alternative hypothesis on the mechanism by which most popular crystallization agents mediate the grain formation in the final perovskite layer and explain, why solid predictions based on nucleation are hard if not impossible. We begin our study with thiourea, an additive which we previously utilized successfully for a plethora of different perovskite compositions[3,4]. Specifically, we probe the precursor stage and transition over in-situ investigations during thin film deposition to the final films and their implementation into perovskite solar cells. While we are able to confirm and complement reports in literature on colloidal lead-complexes in the perovskite precursor ink, that grow in size with increasing concentration, we present strong evidence, that the modification of the lead complex formation or a retardation of the nucleation process might not be the dominant mechanism. We show, that the key impact of Thiourea and other popular additives unfolds during the annealing step, when solvent removal, nucleation and initial perovskite crystallization has already taken place. We model the process of grain growth by phase field simulation, using a coarsening growth process limited by the mobility of the perovskite constituents that in turn is mediated by the specific crystallization agent. We substantiate the general validity of our insights for various iodine-based perovskite compositions and several popular additives. Hereby we find the proposed mechanism to be not only viable to explain the effect of additives, but also to compare the additive approach to several post-processing approaches like thermal hot-pressing, where the mobility of the constituents is manipulated by other means.[5]
Our finding provides a decisive piece to complement the nucleation theory and to bridge the gap between the precursor phase and the final perovskite film, constituting a crucial step beyond heuristics and towards actual additive- and crystallization-engineering.

Ag$_{0.875}$Cu$_{0.120}$Zn$_{0.005}$ Alloy Electrodes to Enhance the Long-Term Stability of Perovskite Solar Cells Keshav K.

Sharma and Ramesh Karuppannan; Indian Institute of Science Bangalore, India

This study investigates the use of thermally evaporated $Ag_{0.875}Cu_{0.120}Zn_{0.005}$ alloys as back electrodes in triple-cation perovskite solar cells, aiming to enhance efficiency and durability. XRD and XPS analysis over a period of 90 days and 30 days, respectively, confirmed the AgCuZn alloy electrode is more resistant to moisture-induced degradation than Ag, demonstrating improved stability. Our results show that solar cells with pure Ag electrodes achieve a power conversion efficiency (PCE) of 16.34%, while those with AgCuZn alloy electrodes exhibit improved performance metrics, including a higher PCE of 16.90%. Notably, AgCuZn electrodes demonstrate superior durability, maintaining operational integrity for 310 hours in unencapsulated cells, compared to 180 hours for Ag electrodes. The AgCuZn alloy also exhibits high optical reflectivity, corrosion resistance, and good adhesion to the hole-transport material layer. These findings have significant implications for the development of cost-effective, efficient, and durable solar energy conversion systems.

***In Situ* Energetics Modulation Enables Efficient and Stable Inverted Perovskite Solar Cells** Bingyao Shao and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

In contrast to conventional (*n-i-p*) perovskite solar cells (PSCs), inverted (*p-i-n*) PSCs offer enhanced stability and integrability with tandem solar cell architectures, which have garnered increasing interest. However, *p-i-n* PSCs suffer from energy level misalignment with transport layers, imbalanced transport of photo-generated electrons and holes, and significant defects with the perovskite films. Here, we introduce tris(2,4,6-trimethyl-3-(pyridin-3-yl)phenyl)borane (3TPYMB), a nonionic *n*-type molecule that, through hydrogen bonding and Lewis acid-base reactions with perovskite surfaces or grain boundaries, enables in situ modulation of perovskite energetics, effectively mitigating the key challenges of *p-i-n* PSCs. The in-situ energetic strategy with 3TPYMB enables simultaneous improvements on these three fronts that limit the performance of *p-i-n* PSCs: aligning the energy levels of the perovskite with those of the transport layers, balancing electron and hole transport within the perovskite, and reducing defects in both the bulk and surface of the perovskite.
As a result, the champion *p-i-n* PSCs achieved a certified quasi-steady-state power conversion efficiency of 24.55 ± 0.33 %, with a reverse scan efficiency of 25.58%, as certified by the accredited third-party NREL PV laboratory. These PSCs also exhibited exceptional stability, with unencapsulated devices retaining 97.8% of their initial efficiency after 1,800 hours of continuous operation at maximum power point under N_2 atmosphere, 1-sun illumination, and 60 °C conditions. Supported by both theoretical and experimental evidence, this work provides a multifaceted solution for overcoming the barriers that have hindered the progress of efficiency and stability of *p-i-n* PSCs, pushing PSC performance to new heights.

Amidination of Ligands for Chemical and Field-Effect Passivation Stabilizes Perovskite Solar Cells Yi Yang, Bin Chen, Mercouri G. Kanatzidis and Edward Sargent; Northwestern University, United States

Surface passivation has driven the rapid increase in the power conversion efficiency (PCE) of perovskite solar cells (PSCs). However, state-of-art surface passivation techniques rely on ammonium ligands that suffer deprotonation under light and thermal stress. We developed a library of amidinium ligands, of interest for their resonance-effect-enhanced N-H bonds that may resist deprotonation, to increase the thermal stability of passivation layers on perovskite surfaces. This strategy resulted in an over tenfold reduction in the ligand deprotonation equilibrium constant and a twofold increase in the maintenance of photoluminescence quantum yield after aging at 85°C under illumination in air. Implementing this approach, we achieved a certified quasi-steady-state PCE of 26.3% for inverted PSCs; and we report retention of ≥ 90% PCE after 1100 hours of continuous one-sun maximum power point operation at 85°C.

Ultra-Low Frequency Raman and Infrared Vibrational Modes in Metal-Halides Vincent Jae-Yeon Lim[1], Marcello Righetto[1], Siyu Yan[1], Jay Patel[2], Thomas Siday[1], Benjamin Putland[1], Kyle M. McCall[3,4], Maximilian Sirtl[5], Yuliia Kominko[3,4], Jiali Peng[6], Qianqian Lin[6], Thomas Bein[5], Maksym V. Kovalenko[3,4], Henry Snaith[1], Michael Johnston[1] and Laura Herz[1]; [1]University of Oxford, United Kingdom; [2]King's College London, United Kingdom; [3]ETH Zürich, Switzerland; [4]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [5]Ludwig-Maximilians-Universität München, Germany; [6]Wuhan University, China

Lattice dynamics are critical to photovoltaic material performance, governing dynamic disorder, hot-carrier cooling, charge-carrier recombination and transport. Soft metal-halide perovskites exhibit particularly intriguing dynamics, with Raman spectra exhibiting an unusually broad low-frequency response whose origin is still much debated. Here, we utilise ultra-low-frequency Raman and infrared terahertz time-domain spectroscopies to provide a systematic examination of the vibrational response for a wide range of metal-halide perovskites and other metal-halides: FAPbI3, MAPbIxBr3-x, CsPbBr3, PbI2, Cs2AgBiBr6, Cu2AgBiI6, and AgI. Stark differences between Raman and IR spectra are presented in this work, wherein such central Raman response is clearly visible in Raman spectra, but is seemingly absent in IR spectra. After careful assessment from our data and literature, we are able to rule out extrinsic defects, octahedral tilting, cation lone pairs and ‘liquid-like’ Boson peaks as causes of the debated central Raman peak. We discuss different reduction schemes to better represent the vibrational density of states from different spectroscopic measurements. Further, we propose that the central Raman response results from an interplay of the significant broadening of Raman-active, low-energy phonon modes that are strongly amplified by a population component from Bose-Einstein statistics towards low frequency. These findings elucidate the complexities of light interactions with low-energy lattice vibrations in soft metal-halide semiconductors emerging for photovoltaic applications.

Lead Immobilization Using Tetrabutylammonium Alginate for Passivation Defect in Sustainable Stable Inverted Perovskite Solar Cells Jing Li and Yao Lu; Queen Mary University of London, United Kingdom

Abstract

Despite advancements in power conversion efficiency (PCE) of lead halide perovskite solar cells (PSCs), stability issues still hinder the commercialization of PSCs. Unbound lead can cause defects in perovskite crystallization, leading to instability and even lead leakage. In this study, we synthesized an amphiphilic polymer, tetrabutylammonium alginate (TBA-Alg), which cross-links at the perovskite surface and grain boundaries to effectively manage lead ions and passivate defects. Incorporating TBA-Alg polymer into perovskite, the hydrophilic alginate groups anchor free lead ions, forming ordered crystallization sites, while the hydrophobic tetrabutylammonium groups with alkyl chains provide waterproof properties. This process optimizes perovskite crystallization, reduces charge recombination losses, and enhances moisture resistance, thereby improving the stability of the perovskite film. As a result, the polymer-incorporated inverted PSCs achieve 25.01% efficiency and maintain 95% of their initial performance for 2,000 hours under continuous illumination. Exhibited high stability under thermal and ambient conditions.

Universal Formation Mechanism of Halide Perovskite Thin Films Martin Ledinsky, Ales Vlk, Robert Hlavac,

Lucie Landova and Antonin Fejfar; The Czech Academy of Sciences, Czechia

Metal halide perovskites (MHPs) have gained significant scientific interest due to their outstanding optoelectronic properties and high efficiencies in solar cell photoconversion. There are many ways to prepare MHPs of reasonable quality, the solution process is still the best in this manner. But the vacuum-based methods, which are relevant for industry and large area deposition, are not lacking far behind. The final product is always the MHP thin film of similar morphology and structure. The only substantial difference is the dimension of the grains, which used to be larger for solution processed films. Therefore, logical question arises, what are the differences in the MHP film formation?

Recently, with the insight of in-situ photoluminescence (PL) and GIWAXS measurements, we have studied the MHP film deposition by solution processes.[1] Based on these results, we divided the MHPs growth into three stages. In short, we see fast growth of MHPs grains from GIWAXS in the first growth stage, accompanied by proportional increase in PL signal. However, in the second stage the growth speed significantly decreases, and the PL signal is highly quenched. This observation means that the free grown grains are of low defect densities, but once they start to connect the grain boundaries are formed, where defects are concentrated. This leads to rapid decrease of the PL signal. The last stage documents partial degradation at long deposition times only. Surprisingly, very similar observation was done by in-situ measurement of evaporated MHPs[2] and films prepared by pizza oven deposition.[3] Preliminary results shows the same tendencies for pulsed laser deposited MPHs as well.

Deeper understanding to this universal formation mechanism of MPHs thin films give us a unique opportunity to enhance its optoelectronic quality. One critical aspect is formation of large grains, the second one is the passivation process mainly at the grain boundaries. In-situ PL characterization is able to guide us through these processes.

Optimizing Perovskite Solar Cell Stability Through Automated, Multimodal and Non-Contact Characterization

Dane W. DeQuilettes, Anthony Troupe and Brandon Motes; Optigon, Inc., United States

Metal halide perovskites are a promising photovoltaic technology with power conversion efficiencies that rival commercial technologies. However, current devices suffer from poor stability, durability, and reliability. Currently, the entire community is trying to identify the perovskite formulations, additives, charge transport layers, and encapsulation strategies that may enable decade module lifetimes. The parameter space is large and therefore requires accelerated learning cycles to rapidly identify the optimal material sets. In particular, it has been challenging to develop accelerated testing protocols that are predictive of field performance and give insights into sources of degradation. In order to overcome this challenge, we have developed and built an automated, multi-modal characterization tool that can perform material and device stability testing under various environmental conditions and illumination intensities. This tool is unique in that after various stress tests it can automatically perform several important measurements such as in-situ time-resolved photoluminescence (PL), spectrally resolved PL, transmission, and Raman spectroscopy to enable root-cause analysis of degradation modes. We use the tool to study the stability of ~100 perovskite samples prepared with different ink chemistries, passivation layers, and encapsulants. With this large data set, we are able to perform higher dimensional data analysis (i.e. machine learning) to identify the key material parameters and correlate them with material degradation rates under continuous illumination. This work provides a deeper mechanistic understanding of perovskite device stability and the key optoelectronic signatures that track with reductions in stability. The tool is capable of generating previously inaccessible large data sets that are required to optimize perovskite stability and supports root-cause analysis of traditional ISOS and IEC protocols.

Active Learning for the Hybrid Perovskite Discovery—Co-Navigating the Literature and Experimental Synthesis Jordan Marshall, Utkarsh Pratius, Elham Foadian, Sheryl L. Sanchez, Sergei V. Kalinin and Mahshid Ahmadi; The University of Tennessee, Knoxville, United States

Hybrid perovskites has emerged as one of the most fascinating materials classes, attracting broad attention due to their applications in photovoltaic, optoelectronic, quantum optics, and many other applications. The fundamental bottleneck for exploring HP now is the enormity of the corresponding search space and strong dependence of functionalities on the processing parameters. Even for the 3D endmembers the substitutions on all three sublattices create the enormous combinatorial space of solid solutions. For the 2D perovskites, materials discovery becomes a problem of joint navigation of vast compositional spaces of inorganic matrix and small molecule spacers, further complicated by the strong dependence of phase evolution and stability on synthesis parameters (solvents, antisolvents, temperature, etc). Given the rapidly growing volume of literature in this field, complexity of the coupled chemical, microstructural, and physical phenomena in perovskites, and multiple communities with often dissimilar languages exploring these materials, building comprehensive picture of *__known__* phenomena in these materials are a daunting task. While the use of LLMs can in principle allow for comprehensive analysis, the associated costs are well outside of a single group. Here, we present an active learning framework for co-navigating the literature and planning experiments on hybrid perovskite synthesis. The ML agent is used dynamically with human in the loop to rapidly assess the literature and build the cause-and-effect relationships. Based on these, the new suggestions for papers analyze based on abstract are formulated as dynamic exploratory loop. The automated synthesis and rapid characterization of optical and photovoltaic properties form the experimental loop run in tandem. The first results of this dynamic co-scientist approach will be presented.

Perovskite-Based Upconversion Materials for Solution-Processed Silicon-Based Near-Infrared Detectors
Nidhi Dua[1], Mohammed S. Hassan[2,1], Sandeep Dhaka[3,1] and Madhusudan Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]City University of Hong Kong, Hong Kong; [3]Delhi University, India

Solution-processed rare-earth based upconversion materials support anti-Stokes processes leading to conversion of low-energy photons through the presence of a sensitizer facilitating resonant energy transfer. Traditional lanthanide-based upconversion materials (~ $NaYF_4$:X:Y) exhibit sensitivity at specific infrared wavelengths owing to strict selection rules permitting 4f-4f transitions. In this work, we report on the synthesis of perovskite material, $CsPbBr_3$ which is used as an upconversion thin film for silicon-based lost-cost detectors. X-ray diffraction (XRD, Rigaku Miniflex) was used to verify successful synthesis of the orthorhombic phase[1] of $CsPbBr_3$ nanoparticles, with a particle size of 14 nm estimated by transmission electron microscopy (TEM, FEI Tecnai TF20). Absorbance (Perkin Elmer Lambda 1050) data reveals a peak at 507 nm, which correlates to an estimated optical band gap

~2.38 eV derived from the Tauc plot. Excitation at multiple infrared wavelengths (range: 700 nm to 850 nm) results in upconverted green emission peaks (~ 522 nm), attaining maximum upconversion photoluminescence (UCPL) intensity at 850 nm (photon count: 2.29 x 10^5 photons) with a monotonic decrease in photon count with increase in energy (photon count: 6.89 x 10^3 photons at 700 nm). To prove the viability of the retrofitting approach, the perovskite film was spin-coated (APEX IC NXG-P2) on a glass slide and then placed inverted over a lost-cost commercial detector (~ $5, Amazon.in, QE=5.7% at 460 nm). Preliminary third quadrant measurements reveal a measured short-circuit photocurrent of 0.35 μA/cm^2 at 800 nm excitation (0.21 mW), with a sub-linear incident power dependence. Measured responsivity increases by 3.03% at 575 nm, with comprable increases in specific regions (550 nm to 650 nm) of the incident spectrum when the perovskite layer on glass is retrofiited with the detector. These results suggest that perovskite-based upconversion thin films can be viable for increasing the broadband response of Si-based photodetectors in the near-infrared band.

Tuning the Structure and Dynamics of 2D Hybrid Perovskites Through the Structure of the Organic Cation

Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional hybrid perovskites are promising materials for a wide range of opto-electronic applications. Their properties markedly differ from those of their three-dimensional analogues, but they also offer additional routes to engineer their properties by introducing specific functionality in the organic component. One of the key features of 2D hybrid perovskites is their relatively soft structure that allows substantial structural fluctuations, both during synthesis and after deposition. The softness of the material leaves considerable room to manipulate the structure of the inorganic layer through external stimuli such as pressure and adsorption of molecules on the surface, or internal effects such as strain cause by the organic separating layers. The nature of the organic component directly affects the structural and dynamic properties of the inorganic lattice. [1] Such changes in the structure and dynamics translate to changes in the electronic properties of the materials, for instance leading to changes in optical and conductive properties or the introduction of chirality in the materials. Therefore, by controlling the structure and interactions in the organic part it is possible to tune important physical parameters of the materials, including the charge carrier mobility, exciton binding energy, carrier lifetime and the decay pathways of charges and excited states.

In this work we computationally explore approaches to engineer the structural and dynamics properties of the 2D perovskite materials by introducing specific organic moieties that have additional functionality. The layer of organic molecules influences the structure and dynamics of the inorganic layer, which also has an immediate effect on the electronic structure. We have performed classical molecular dynamics simulations using custom forcefields for a variety of 2D halide perovskites, including Ruddlesden-Popper and Dion-Jacobson structures. It is shown that the nature of the organic cation determines the average structure and the structural dynamics to a large extent. This indicates that these properties can be tuned significantly by exploiting specific intermolecular interactions in the organic layer. The structure and dynamics of the organic layer directly affect the structure and dynamics of the inorganic layer, for instance the disorder in the octahedral tilt angles. This should lead to marked effect on the steady state electronic properties but also offers a handle to influence the strength and nature of the electron-phonon coupling in these materials.

The soft nature of of 2D hybrid perovskites suggest a marked dependence of the electronic properties on external stimuli, for instance the strain in the material. Strain can be introduced by applying external pressure, either uniformly of by bending of the material. Using pressure dependent molecular dynamics simulations we also show that the response to external pressure depends strongly on the nature of the organic layer and also here substantial tuning is possible through structural engineering. This can eventually be exploited for sensing applications.

Fluorescent Pigments for Application in Downshifting Ultraviolet Light Otávio J. de Oliveira, Natália F. Coutinho, Thais S. Crestani, Ana Paula d. Modesto, José M. da Silva Filho, Tárcio A. Barros and Francisco C. Marques; Universidade Estadual de Campinas, Brazil

Although silicon and perovskite solar cells have achieved efficiency surpassing 26 %, several factors still limit achieving higher efficiency. One proposed mechanism to circumvent this limitation is using wavelength shifter materials to use ultraviolet light better. Here we investigate the properties of thin film of low-cost photoluminescent pigment currently used in coatings, graphic arts, cosmetics and adhesives. The aim was to evaluate the capability of shifting the ultraviolet light to the wavelength where silicon solar cells are more efficient (around 600 nm). Precursor solutions were prepared by dissolving the pigments in ethanol. Thin film deposition was performed by spin-coating technique with good uniformity. After each deposition, the substrates were placed on a heating plate to evaporate the solvent. The pigments were characterized by X-ray diffraction, AFM, UV-Vis transmittance, and photoluminescence. The XRD diffractograms are compatible with the expected structure of organic pigments. Photoluminescence measurements show the PL emission covers a range of 500 – 650 nm, which is in the region of the highest efficiency of silicon solar cells. UV-Vis spectra show absorption bands related to specific pigment structures. The absorption occurs in the wavelength range from 300 to 700 nm, being more intense in the UV range. This absorption corresponds to the one associated with converting UV light to visible light. The PL emission, on the other hand, is shifted to the 550 to 700 nm range. This result shows that the film made of pigment, deposited by spin coating, works as a wavelength shifter.

EL04.18.44

Investigating the Formation Dynamics and Stability of the 2D/3D Interface in Perovskite Thin Films Murillo H. Rodrigues[1], Josiane Sobrinho[1], Ingrid Barcelos[2], Cilene Labre[2], João B. Souza Junior[3] and Ana Flavia Nogueira[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Centro Nacional de Pesquisa em Enegia e Materiais, Brazil; [3]LNNano, Brazil

The quest for novel sustainable energy production and storage technologies is crucial for addressing the challenges associated with energy demand and the depletion of fossil fuels. In this regard, perovskite solar cells have garnered significant attention due to their high efficiency achieved within a few years, along with relatively low production costs. However, their longevity remains inferior to the conventional silicon technology due to instability under ambient conditions. One approach to address this stability issue is fabricating structured 2D/3D perovskite films; while low-dimensional 2D perovskites exhibit higher environmental stability, 3D perovskites contribute to enhanced efficiency. Despite the progress in the field of 2D/3D structures, there remains a lack of detailed understanding of the 2D/3D perovskite interface and its behavior under environmental stressors [1-3]. In light of this, we employed advanced in situ characterization techniques to monitor and evaluate the formation dynamics and stability of 2D/3D perovskites under stress conditions. Two 2D-forming cations – phenylethylammonium iodide (PEAI) and oleylammonium iodide (OLAI) – were investigated, and 2D layers were grown on CsFAMAPbI3 films. In-situ photoluminescence (PL) measurements revealed the formation of n=1 and n=2 structures for both materials. Notably, OLAI tended to convert n=1 to n=2, whereas PEAI preferentially formed n=1 after annealing. Confocal imaging indicated that the exposure of films to 485 nm light induced the degradation of 2D layers in the case of PEAI, whereas the conversion of n=1 to n=2 was observed for OLAI. In-situ X-ray diffraction (XRD) was conducted to monitor potential structural changes in the 2D/3D films under thermal stress of 85-celsius degrees for 18 hours; results suggested the amorphization of the 2D structure when using PEAI, whereas OLAI displayed improved crystallinity. Scanning electron microscopy (SEM) images of films before and after thermal stress indicated that the 2D layers mitigate the degradation of the 3D perovskite. However, OLAI formed a compact layer, which undergoes morphological changes to nanoplates covering the entire film surface after thermal stress, while PEAI showed several voids before and after the annealing. Cathodoluminescence mapping, both top-view and cross-sectional, demonstrated that 2D structures preferentially grow at grain boundaries. In-situ liquid cell transmission electron microscopy (TEM) was employed to investigate the growth of OLAI. The results revealed that after OLAI injection, 2D growth initially occurred at PbI2 on the surface of perovskite films, followed by growth at grain boundaries and facets, and eventually, growth induced by beam damage. These findings enhance our understanding of the selective nature of 2D structure formation and the superior stability of OLAI compared to PEAI.

The Effect of Buried Interface on the Orientational Crystallization and Thermal Stability of Halide Perovskite Thin Films Josiane Sobrinho[1], Murillo H. Rodrigues[1], Diogo M. Guillhermitti Neto[1], Ingrid Barcelos[2], Cilene Labre[2], João B. Souza Junior[3] and Ana Flavia Nogueira[1]; [1]Universidade Estadual de Campinas, Brazil; [2]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [3]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil

The need for sustainable and renewable energy sources has led to the development of new photovoltaic technologies, with perovskite solar cells (PSCs) showing great potential as the next generation of solar cells. However, to fully realize the potential of PSCs, improving device stability is a challenge that still needs to be addressed [1]. In this work, we demonstrate how the orientational crystallization of perovskites plays a crucial role in film stability, and how the perovskite underlayer dictates the oriented growth. We investigated the crystallographic, morphological, optical, and electrical properties of $Cs_{0.10}FA_{0.90}PbI_3$ films grown on FTO/SnO_2 and FTO/NiO_x/MeO-2PACz – the typical underlayers in devices with n.i.p. and p.i.n. architecture, respectively. Films of the same composition grown on FTO were also prepared for comparison. In all cases, X-ray diffraction (XRD) patterns showed preferential growth along the (100) plane of the cubic perovskite structure. However, an increase in (111) plane orientation from SnO_2 to FTO to MeO-2PACz was observed, which was further confirmed by selected area electron diffraction (SAED). When subjected to thermal stress at 85 °C for 500 hours under N_2 atmosphere, the more oriented films showed less segregation of PbI_2. PbI_2 is known to be detrimental to PSCs, as it increases series resistance, decreases fill factor values, and creates recombination pathways at interfaces, which affect open-circuit voltage [2]. Exposure of the films to ambient conditions for several days resulted in complete degradation of the perovskite layer, except for the perovskite film grown on FTO/NiO_x/MeO-2PACz, indicating better stability. It has been reported that water molecules adhere more favorably to the (100) facet than the (111) facet, suggesting that (111)-oriented films should exhibit greater moisture stability [3]. Cathodoluminescence (CL) mapping along with energy-dispersive X-ray spectroscopy (EDS) measurements indicated that the less oriented films also showed $CsPbI_3$ segregation after thermal stress. Topographical maps obtained by atomic force microscopy (AFM) revealed that the more oriented films had flatter grains with smaller grain size distribution, which could also impact the stability of the perovskite layer. Conductive AFM indicated that Cs-rich grains formed after thermal stress exhibited significantly lower conductivity than the FA-rich phase, contributing to increased resistance in the films. These results suggest that promoting oriented crystallization in perovskite thin films is crucial for improving stability against temperature and moisture, minimizing phase transitions, and enhancing carrier mobility.

The Influence of Grain Boundaries on Charge Transport in P-Type Polycrystalline Nanoribbon Transistors

Prakash Sarkar; Indian Association for the Cultivation of Science, India

Grain boundaries (GB) exert a profound influence on charge transport by introducing localized potential barriers and exhibiting elevated defect state densities, which are critical determinants in the performance of polycrystalline materials. There are a couple of models to estimate the density of states (DoS) of nanostructured materials in field-effect transistors (FETs) which probe interface traps between the semiconductor and dielectric, but not at the grain boundaries.In this study, we introduce an energy band profile that delineates the charge transport mechanisms at grain boundaries, utilizing Levinson’s and Seto’s grain boundary transport models. We then correlate these mechanisms with temperature-dependent hopping transport phenomena observed in copper iodide (CuI) polycrystalline nanoribbon (PNR) field-effect transistors (FETs). Experimentally PNRs are obtained by e-beam lithography and thermal evaporation of CuI. To consider the impact of GB density, the devices are fabricated with different channel aspect ratios by varying widths (80, 260, 570 nm) and lengths (20 to 90 µm). Owing to high hole concentration, PNR FETs operate in depletion mode at 300 K. At various low temperatures (80-300 K), the figures-of-merits of FETs are estimated to understand device performance. We determine GB barrier heights, activation energy, and density of GB trap states and find equivalence between the two models. Further, we calculate temperature-dependent hopping and trap-limited transport parameters to obtain DoS at Fermi energy, trapped and free charge carrier density, localization length, hopping distance, hopping energy, etc. at various channel lengths. Based on this quantitative analysis we propose a channel length-dependent GB barrier height variation due to the in-plane electric field and elucidate CuI energy band levels.

Fabrication of Stable Tin Based Perovskite Solar Cells—Additive and Device Engineering Ashraful Islam, Md. Emrul Kayesh and Md. Abdul Karim; National Institute for Materials Science, Japan

Perovskite solar cells (PSCs) have attracted much attention because of the fast progress of their power conversion efficiency (PCE), from 3.8% to 25.7% in the past 14 years [1-2]. However, the toxicity of Pb effectively hinders the large-scale commercial production of PSCs. Therefore, researchers have turned their attention to Sn based perovskite due to their similar or even superior optoelectronic properties such as optimum band gap, higher charge carrier mobility, and low exciton binding energy [3-5]. Recent advancements have increased the power conversion efficiency (PCE) of Sn-PSCs to 15.7% [6]. Nonetheless, the facile Sn^{2+} oxidation, low-quality film, high p-type doping behavior, and energy level mismatch of the electron transport layer (ETL) have hindered the development of Sn-PSCs. In this work, we performed additive engineering with a bifunctional additive for both perovskite and ETL to grow highly crystalline and stable uniform perovskite film and ETL with reduced conduction band offset. As a result, we achieved high PCE with superior device stability for Sn PSCs. We achieved an impressive PCE of ~14.8%. These works made us able to certify Sn based PSCs devices from the AIST, Japan. More importantly, these devices exhibited exceptional light soaking stability and retained above 90 % of their initial PCE at MPPT for 1500 hours under continuous 1 sun illumination.

EL04.18.48

Dielectric Breakdown of 2D Hybrid Organic-Inorganic Perovskites Mengru Jin[1], Eugenia S. Vasileiadou[2], Ioannis Spanopoulos[3], Arushi Chaudhry[1], Mercouri G. Kanatzidis[2] and Qing Tu[1]; [1]Texas A&M University, United States; [2]Northwestern University, United States; [3]University of South Florida, United States

2D hybrid organic-inorganic perovskites (HOIPs) have emerged as promising low-cost, high-performance direct bandgap semiconductor materials in a plethora of energy and electronic applications, offering enhanced environmental stability compared to their conventional 3D analogs. While the breakdown of HOIPs under an electric field is commonly found in optoelectronic devices under reverse bias conditions and during the switching of memories/memristors based on these materials, a fundamental understanding of their dielectric breakdown behavior is still missing. Here, we investigate the dielectric breakdown of a prototypical family of 2D HOIPs, $(BA)_2MA_{n-1}Pb_nI_{3n+1}$ (BA = butylammonium, MA = methylammonium cation, and n = 1 to 5) in the out-of-plane direction, using conductive atomic force microscopy. The dielectric breakdown of mechanically exfoliated 2D HOIP flakes manifests a rapid current rise in the I-V curve, and results in a pit locally. The irreversible defects generated by the breakdown are largely concentrated on the top layer, resulting in layer-by-layer damage and material removal in 2D HOIPs from the top. The breakdown voltage V_{BD} increases with the thickness while the breakdown strength follows a decline trend. A lower ramping rate gives a lower E_{BD} value owing to the longer time provided for the defects to nucleate and grow. The distribution of the breakdown characteristics of 2D HOIPs follows the Weibull statistics, and the Weibull modulus shows an increasing trend as the thickness increases, which implies the breakdown process can be described by the classical percolation model. 2D HOIPs with higher n number have higher E_{BD}, probably due to better electrical and thermal conductivities. The measured E_{BD} is on the order of 10^8 V/m, showing the great intrinsic resilience of 2D HOIPs to dielectric failure. Our results provide indispensable insights into the failure of 2D HOIPs under the electrical field in electronic and optoelectronic devices, which are critically needed to improve the stability and durability of the devices. The high breakdown strength (on par with or better than that of many dielectric materials) and the band alignment tunable through the chemical composition, together with the dangling bond-free 2D interface and the scalable solution processability, promise 2D HOIPs great potential in application as dielectric materials for future 2D electronic devices.

EL04.18.49

All-Optical Mid-Infrared Photodetectors Based on Two-Dimensional Metal Halide Perovskites Yanyan Li[1,2], Shunran Li[1,2], Du Chen[1,2], Conrad A. Kocoj[1,2], Ankun Yang[3], Benjamin T. Diroll[4] and Peijun Guo[1,2]; [1]Yale University, United States; [2]Energy Sciences Institute, United States; [3]Oakland University, United States; [4]Argonne National Laboratory, United States

Two-dimensional (2D) metal halide perovskites (MHPs) have gained significant research interest due to their excellent stability and tunable optoelectronics properties compared with their three-dimensional (3D) counterparts. A major challenge with 2D-MHP is their ultralow thermal conductivity, which is generally considered a drawback for optoelectronic applications. In our work, we transform this limitation into an advantage by utilizing the low thermal conductivity along with their temperature-sensitive excitonic resonances to develop thermal-based, spectrally tunable mid-infrared (MIR) photodetectors. Our approach leverages the thermal response of 2D-MHPs to create a photodetector capable of operating at room temperature, eliminating the need for the complex cooling systems typically required by traditional infrared detectors. To enhance the sensitivity of the device, we employ dielectric membrane-based structures, enabling detection limits as low as 10 pW●μm^{-2}. Our work introduces a new application for 2D-MHPs in the field of infrared detection, offering a scalable, cost-effective solution that could pave the way for the development of next-generation optoelectronic devices.

EL04.18.50

Experimental Demonstration of Hot Carrier Solar Cells by Ultrafast Photovoltaic Spectroscopy Tuhin Ghosh[1], Jianbo Gao[1] and Letian Dou[2]; [1]Brock University, Canada; [2]Purdue University, United States

Despite over half a century of progress in silicon photovoltaics, their efficiency remains limited by the well-known Shockley–Queisser (SQ) limit, which arises from the thermalization of hot carriers. To surpass the SQ limit, the novel concept of hot carrier solar cells, which feature a similar and simple device architecture to single-junction devices, is among the most promising highly efficient technologies. However, the lifetime of hot carriers is extremely short, on the order of a few hundred of picoseconds, due to rapid interaction with phonons. As a result, carrier lifetime and dynamics are often characterized using optical spectroscopies such as pump-probe transient absorption, time-resolved photoluminescence, or up-conversion photoluminescence.

In this report, we have developed an ultrafast photovoltaic spectroscopy technique with sub-40 picosecond time resolution to directly capture the photocurrent while solar cells are operational. We have measured ultrafast photocurrents in perovskite solar cells with more than 20% alloyed cations. A typical time-resolved photocurrent exhibits a fast rise time of 40 picoseconds, followed by decay dynamics that are dependent on the applied bias voltage. By sweeping the voltage, we observed that the transient open-circuit voltage (Voc) exceeds the bandgap, which is a hallmark of hot carrier solar cells. Additionally, Voc decreases as the thickness of the perovskite layer increases. The hot carriers remain ‘hot,’ as the photocurrent peak is not sensitive to temperature changes. Our findings present the first experimental demonstration of hot carrier solar cells characterized by the unique ultrafast photovoltaic spectroscopy.

Reaching the Goldilocks Zone—Mastering the Defective Nature of Perovskite Solar Cells Yen-Hung Lin; The Hong Kong University of Science and Technology, Hong Kong

While inherently “defect-tolerant,” metal-halide perovskite solar cells require precise control over growth and defect passivation to achieve peak efficiencies and enhanced operational stability in optoelectronic applications, the crux of maximizing performance is mitigating non-radiative defect-mediated recombination through the means of passivation. In this talk, I will present our perspective on how one could formulate a practical mitigation plan to tackle such a challenge that dictates most perovskite solar cells' performance.

8:30 AM EL04.19.02

Suppressing Cation Migration in Passivation Layers for Perovskite Solar Cells Cheng Liu, Bin Chen, Mercouri G. Kanatzidis and Edward Sargent; Northwestern University, United States

Two-dimensional (2D) and three-dimensional (3D) perovskite heterostructures have played a key role in advancing the performance of perovskite solar cells. However, the migration of cations between 2D and 3D layers results in the disruption of octahedral networks, leading to degradation in performance over time. We hypothesized that perovskitoids, with robust organic–inorganic networks enabled by edge- and face-sharing, could impede ion migration. We explored a set of perovskitoids of varying dimensionality and found that cation migration within perovskitoid–perovskite heterostructures was suppressed compared with the 2D–3D perovskite case. Increasing the dimensionality of perovskitoids improves charge transport when they are interfaced with 3D perovskite surfaces—this is the result of enhanced octahedral connectivity and out-of-plane orientation. The 2D perovskitoid provides efficient passivation of perovskite surfaces and enables uniform large-area perovskite films. Devices based on perovskitoid–perovskite heterostructures achieve a record certified quasi-steady-state power conversion efficiency of 24.6% for centimetre-area perovskite solar cells. We removed the fragile hole transport layers and showed stable operation of the underlying perovskitoid–perovskite heterostructure at 85°C for 1250 hours for encapsulated large-area devices in ambient air.

8:45 AM EL04.19.03

Isolating Chemical Reactivity of Perovskite/Transport Layer Interfaces to Advance Stability Jack R. Palmer[1], Danrui Hu[1], Clare L. Lanaghan[2], Oluka Okia[2], Md Aslam Uddin[2], Neil P. Dasgupta[2,2] and David Fenning[1,1]; [1]University of California, San Diego, United States; [2]University of Michigan, United States

Detailed understanding of the degradation pathways in perovskite solar cells will be essential to their deployment. Layers directly interfacing with the perovskite active layer are of particular importance due to the chemical reactivity of the organic A-site cation. However, the reactivity of the perovskite with the transport layer materials can vary widely depending on the interface chemical composition and its preparation. To systematically design more stable perovskite solar cells, the isolated, independent effect of each transport layer interface on stability should be understood. Here, we leverage a symmetric device stack with the same transport layer on each side to isolate the chemical reactivity of the perovskite with widely used electron and hole transporting materials, including NiO_x, SnO_x, and SAMs. We accomplish this by depositing perovskite atop the transport layer then diffusion bonding two such half-stacks using hot-pressing lamination, creating a self-encapsulated stack where the perovskite layer is sandwiched between identical transport layers. This symmetric design allows for light and heat durability testing of the perovskite with a single transport layer interface at a time. To evaluate relative durability, we subject the laminated stacks to 1-sun and 85°C elevated temperature conditions while recording degradation *in situ* via visible light imaging. Post-mortem analysis including PL, XRD, ATR-FTIR, and SEM reveal clear chemical trends in stability. From this foundational knowledge, we examine the tuning of the interface chemistries by atomic layer deposition to passivate the chemical reactivity. We find that targeted interface treatments can significantly reduce the reactivity of metal-oxide interfaces and dramatically extend perovskite stability.

9:00 AM EL04.19.04

Deterministic Fabrication of Arbitrary Perovskite—Perovskite Heterostructures Faiz Mandani, Aditya D. Mohite, Jessica H. Persaud and Siraj Sidhik; Rice University, United States

Heterostructures play a crucial role in the semiconductor industry as they offer unique optoelectronic properties. However, the conventional methods used for fabricating heterostructures involve specialized and costly processes such as chemical vapor deposition, epitaxial growth, or e-beam deposition. Halide perovskites have emerged as a promising material for various optoelectronic applications due to their tunable bandgap, high carrier mobility, and solution processability. In recent years, considerable efforts have been made to develop perovskite heterostructures using vapor phase techniques. However, the development of a universal solution processed approach for fabricating multilayer perovskite heterostructures has remained a challenge. To address this, we conducted detailed perovskite-solvent interaction studies to gain a deeper understanding of perovskite solvation dynamics. In this study, we present a solvation-based approach to synthesize perovskite seed solutions, enabling the fabrication of 2D/3D, 3D/2D, and even 3D/3D heterostructures. This approach allows us to create an arbitrary number of layers with any perovskite phase while maintaining high optoelectronic quality and scalability. To demonstrate the universality of our approach, we successfully created formamidinium lead iodide (FAPbI3)/Dion-Jacobson 2D (3D/2D) perovskite and methylammonium lead iodide (MAPbI3)/MAPbI3 (3D/3D) heterostructures. We validated the quality and characteristics of these heterostructures through optoelectronic and cross-sectional analyses. The resulting heterostructures had the desired phase (n-value specificity) and significantly enhanced durability relative to the FaPbI3 control. Grazing incident wide angle x-ray scattering (GIWAXS) analysis indicated that (FAPbI3)/Dion-Jacobson bilayers had triple the durability (monitored via FAPbI3-δ phase formation) as compared to the FAPbI3 control. High quality perovskite n-i-p devices with >24% power conversion efficiency of the (FAPbI3)/Dion-Jacobson bilayers were fabricated compared to the 22% FAPbI3 controls. The introduction of this universal approach marks a significant milestone in solution processed heterostructures, extending its applicability beyond perovskites to the broader field of semiconductors. This advancement opens up new possibilities for the synthesis of high-quality, scalable heterostructures, revolutionizing the semiconductor industry.

9:15 AM EL04.19.05

Interface Engineering for Efficient and Stable NiO$_x$-Based Inverted Perovskite Solar Cells Chunlei Zhang, Bo Li, Danpeng Gao, Jianqiu Gong, Shuai Li and Zonglong Zhu; City University of Hong Kong, Hong Kong

Organic-inorganic hybrid perovskite solar cells (PSCs) have emerged as a burgeoning paradigm in the realm of photovoltaic technologies. Within this domain, a great research endeavour has been channelled toward the exploration of hole transport materials (HTMs) for inverted PSC architectures. Among these, nickel oxide (NiO$_x$) has garnered widespread adoption, owing to its constellation of virtues, including straightforward synthesis, facile processing, elevated optical transparency, and superlative chemical robustness. Despite the encouraging strides made with inverted PSCs in recent years, the photovoltaic conversion efficiencies (PCEs) achieved by NiO$_x$ alone far remain eclipsed by those achieved using high-performance organic HTMs. This discrepancy is ascribed to the incongruent energy levels, the intrinsic low electrical conductivity, and the heightened interface defect density associated with NiO$_x$. Additionally, the NiO$_x$ layer is often beset by a complex assortment of high-oxidation-state nickel species (Ni$^{>3+}$), which convolute its surface chemistry and precipitate the deterioration of perovskite materials.

In an endeavour to surmount these challenges, we reveal the origin of open-circuit voltages (V_{OC}) loss in NiO$_x$-based tin PSCs and the influencing mechanism of hole-extraction barrier formation at the NiO$_x$-perovskite interface due to Sn oxidation. Specifically, the undercoordinated Ni$^{\geq 3+}$ defects act as Lewis acids and oxidants on divalent Sn ions with low oxidation activity energy at the buried interface. To address this issue, we introduced a novel self-assembled monolayer (SAM), (4-(7H-dibenzo[c,g]carbazol-7-yl)ethyl)phosphonic acid (2PADBC), as an interfacial modification layer between perovskite and NiO$_x$. Passivation of reactive Ni$^{\geq 3+}$ defects yield a significantly increased V_{OC} from 0.712 V to 0.825 V, boosting the PCE to a champion 14.19% for small-area devices and a 12.05% for large-area (1cm^2) devices. Furthermore, the 2PADBC modification improved the operational stability of NiO$_x$-based tin PSCs, which maintains over 93% of their initial efficiency after 1000 hours.

Furthermore, we have adeptly engineered and synthesized a novel donor-acceptor (D-A) type semiconductor, denoted as BTF14, which is predicated upon a fluoranthene imide scaffold. This semiconductor can serve as a multifunctional interfacial material, poised to enhance the performance of NiO$_x$-based inverted PSCs. By integrating BTF14 into the device architecture, we have facilitated improved charge transfer kinetics, augmented the crystalline quality of the perovskite film, and substantially mitigated defect density at the perovskite/NiO$_x$ interface. Consequently, this integration has culminated in a remarkable elevation of the PCE to 24.20%, accompanied by an imperceptible presence of hysteresis. Furthermore, BTF14 has demonstrated an adeptness at diminishing the concentration of deleterious Ni$^{>3+}$ species on the NiO$_x$ surface. It also fosters robust interfacial interactions between the NiOx and the perovskite layers, thereby bolstering the operational stability of the device. Impressively, more than 77% of the initial PCE was retained after 1000 hours of continuous operation at an ambient temperature of 60°C.

9:30 AM EL04.19.06
A Study on Bio-Inspired Synergistic Effect Through DNA Incorporation in 2D Perovskites for Next-Generation RRAM Devices Abhinav Gorthy[1], Kavya S. Keremane[2], Ramesh Srinivasan[1], Luyao Zheng[2], Neela H. Yennawar[2], Bed Poudel[2] and Rashmi Jha[1]; [1]University of Cincinnati, United States; [2]The Pennsylvania State University, United States

The escalating demand for enhanced storage density in the realm of Non-Volatile Memory (NVM) necessitates innovative solutions. Among various innovations and ideas, the Resistive Random Access Memory (RRAM) stands out due to its exceptional ability to store high-density data in a compact area [1]. RRAMs are known for their low power consumption, easy fabrication process, and excellent scalability. Typically, RRAMs are fabricated with a Metal-Insulator-Metal (MIM) structure, where binary states (0 and 1) are distinguished by varying resistance levels when an electric field is applied between the two metal layers. Most RRAM devices use a metal oxide insulator layer, which forms conductive filaments through the generation of oxygen vacancies [2] [3]. However, many researchers have demonstrated that bio and organic materials can also form conductive films. These materials are environmentally friendly and offer several advantages over metal oxides, including abundant availability, structural manipulability, and improved sustainability and recyclability. Incorporating eco-friendly materials has already gained attention in solar cells, particularly those using organic-inorganic halide perovskites (OHPs) due to their photovoltaic properties [4]. While some researchers have used OHPs as a functional layer in RRAMs, these materials often suffer from stability issues and are sensitive to temperature, humidity, moisture, and light. Our research focuses on chemically stabilizing OHPs by incorporating a polymer such as Deoxyribonucleic acid (DNA). The hydrophilic nature of DNA due to the presence of phosphate groups in its backbone interact with perovskite via the cations and form strong electrostatic bonds, enhancing stability. Our experiments have shown that this idea resulted in reliable resistive switching and improved overall stability. We will report characteristics of various RRAM devices with various DNA incorporated into OHP matrix. This work highlights the potential of green electronics in advancing emerging memory technologies.

9:45 AM EL04.19.07
Thin Film Stoichiometry and Defects Management for Low Threshold and Air Stable Near Infrared Perovskite Laser Chunsheng Jack Wu[1,2], Heyong Wang[1], Andrea Olivati[1,2], Giulia Folpini[3,1] and Annamaria Petrozza[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Consiglio Nazionale delle Ricerche, Italy

While significant efforts have been devoted to optimizing the thin-film stoichiometry and processing of perovskites for applications in photovoltaic and light-emitting diodes, there is a noticeable lack of emphasis on tailoring them for lasing applications. In this study, we reveal that thin films engineered as efficient light-emitting diodes, with passivation of deep and shallow trap states and a tailored energetic landscape directing carriers towards low-energy emitting states, may not be optimal for light amplification systems. Instead, amplified spontaneous emission is found to be sustained by shallow defects, driven by the positive correlation between the ASE threshold and the ratio of carrier injection rate in the emissive state to the recombination rate of excited carriers. This insight has informed the development of an optimized perovskite thin film and laser device exhibiting a low threshold (≈ 60 μJ/cm2) and stable ASE emission exceeding 21 hours in ambient conditions.

Mixing Chalcogenides into Halide Perovskites Jiayi Li[1], Santanu Saha[2], Zhihengyu Chen[3], Yang Wang[4], Jeffrey A. Reimer[4], Karena Chapman[3], Marina Filip[2] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]University of Oxford, United Kingdom; [3]Stony Brook University, The State University of New York, United States; [4]University of California, Berkeley, United States

The bandgaps of 3D lead-halide perovskites are dramatically varied by changing the halide. As the electronegativity of the halide decreases, so does the bandgap, leading to gaps that are suitable for absorbing sunlight in a solar cell. Unfortunately, the stability of halide perovskites also decreases as we move to the larger and less electronegative halides, like iodides. We recently found a way to circumvent this dichotomy by mixing organochalcogenides (RS-; R = organic group) with halides in perovskites. We can now access the higher stability of bromide or chloride perovskites, while the chalcogen (S, Se) orbitals form the highest-energy filled electronic bands, affording lower bandgaps than pure-bromide or -chloride perovskites. I will present our latest findings on how mixing halides and chalcogenides can tune the bandgap of the perovskites, in the ideal range for various photovoltaic applications. I will discuss the potential, as well as the remaining challenges, for extracting photocurrent from this new family of perovskites that may combine the properties of lead-halide and lead-chalcogenide solar absorbers.

11:00 AM EL04.20.02

Crossover of Frenkel and Wannier-Mott Excitons Through Halide Composition Tuning in Mixed Halide Perovskites Jagjit Kaur and Sudip Chakraborty; Harish-Chandra Research Institute, India

We have envisaged the excitonic effect in $Cs_3Bi_2X_9$ (X=I, Cl, Br) based on first principles many body calculations using GW coupled with Bethe Salpeter Equation (BSE) formalism. Through the fine tuning of halide composition space, we could find a distinct crossover between Frenkel and Wannier-Mott Excitons in these vacancy-ordered mixed halide double perovskites. Our systematic electronic structure calculations considering relativistic spin-orbit coupling effect reveals long excitonic radiative lifetimes, which could be highly desirable for solar cells applications. The intriguing halide composition factor and the corresponding repercussion on the transition between Frenkel and Wannier-Mott Excitons could be correlated with the exciton radiative lifetime and photovoltaic efficiency variation in this exciting family of inorganic perovskites. Our theoretical investigation suggests the strong dependency of exciton binding energy on the halide compositional space, while it could be connected with the optical absorption spectra of the individual systems for the quest of lead-free stable and efficient next generation solar cells.

11:15 AM EL04.20.03

***In Situ* Degradation Pathway Analyses on Hybrid Perovskites with Mixed Cations and Anions** Emanuele Smecca[1], Vitantonio Valenzano[2], Ioannis Deretzis[1], Salvatore Valastro[1], Sonia Carallo[1], Silvia Colella[1], Giovanni Mannino[1], Aurora Rizzo[1], Antonino La Magna[1] and Alessandra Alberti[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università del Salento, Italy

Multi-cation and multi-anion hybrid perovskites are one of the most attractive materials currently under investigation for tandem photovoltaic application because of the possibility they offer to finely tune the band gap, thus allowing the coupling with other semiconductors. If mixing different ions in the perovskite compositions could, on one side, give the possibility to create different useful materials with different properties, on the other side it could be detrimental to the hybrid perovskite stability. The presence of different ions leads to the formation of different polytypes that could open new pathways for the degradation of the prepared films. In this work, we have investigated the role of different polytypes on the degradation and stability of mixed hybrid perovskites by in situ X-ray diffraction analyses. We found that the use of even a small amount of methylammonium cations opens a new route for the degradation of the perovskite film triggering a more advanced degradation beyond the loss of the methylammonium cations. By in-situ analyses during focused thermal treatments, we unveil an interplay between the different polytypes triggered by temperature. In particular, we show how the 4H-polytype of the formamidinium lead iodide ($FAPbI_3$) is recovered with an annealing at 100°C in N_2 that restores the 3C-polytype. We propose the use of 1,3:2,4-bis-O-(4-methylbenzylidene) D-sorbitol (MDBS) additive as a remedy to increase the stability of the perovskite film even in presence of the methylammonium cation by making the perovskite films more compact thus reducing the surface/volume ratio.

11:30 AM EL04.20.04

The Impact of Mg Dopant Concentration on the Performance of SnO_2 Electron Transport Layers in Perovskite Solar Cells Gennaro V. Sannino[1,2], Adriana Pecoraro[1], Pasqualino Maddalena[1], Annalisa Bruno[3], Paola Delli Veneri[2], Michele Pavone[1] and Ana B. Muñoz-Garcia[1]; [1]University of Naples Federico II, Italy; [2]ENEA, Italy; [3]Nanyang Technological University, Singapore

Recent experiments have highlighted the advantageous role of moderate magnesium (Mg) doping in tin dioxide (SnO_2) as an electron transport layer (ETL) in perovskite solar cells (PSCs), achieving high efficiencies driven by improved open-circuit voltage (V_{OC}).[1] The origin of this improvement is debated, attributed either to enhanced film quality or to changes in electronic structure from Mg doping. This study uses density functional theory (DFT) calculations to investigate the structural, electronic, and defect properties of SnO_2 with varying Mg doping levels.[2] Results indicate that low Mg content raises the conduction band minimum (CBM), enhancing V_{OC}, while high Mg concentrations result in interstitial Mg defects, decreasing V_{OC} and creating intra-gap states that reduce PSC performance. These findings offer an atomic-level understanding of Mg doping effects on SnO_2, guiding the design of ETL materials with tailored electronic properties for advanced solar cells. The study also provides a comprehensive computational analysis of Mg-doped SnO_2, from bulk properties to surface work functions, to explain the variations in V_{OC} observed experimentally.

Efficient Wide-Bandgap Perovskite Materials for All-Perovskite Multijunction Solar Cells Junke Wang, Shuaifeng Hu and Henry Snaith; University of Oxford, United Kingdom

All-perovskite multijunction solar cells promise to deliver power conversion efficiencies (PCEs) beyond the theoretical limit for single-junction devices at low costs. However, the sub-par performance of the wide-bandgap perovskite limits the efficiency gains of tandem solar cells. In this contribution, we unveil localized compositional heterogeneity as a crucial factor in limiting the performance and longevity of wide-bandgap perovskite solar cells. We present our newest mitigation strategies using templated growth of Br-rich perovskites to improve their halide homogeneity and photostability, improving the open-circuit voltage to above 85% of the theoretical limit from 1.8 to 2.3 eV optical bandgap. We demonstrate efficient all-perovskite 2J, 3J, and 4J solar cells, each presenting PCEs beyond 27% at 1 cm^2 device area.

Robust Mixed Ionic-Electronic Conduction in Hydrophobic Semiconducting Polymers via Composites Formation Aristide Gumyusenge; Massachusetts Institute of Technology, United States

In this talk, I will present our latest efforts in developing composite films with mixed ionic-electronic conduction for use in high-performing organic electrochemical transistors (OECTs). Our research introduces a novel strategy that combines conjugated polymers with an ion-conductive matrix, achieving efficient and stable mixed conduction. Using spectroscopy and pulsed gating measurements, we correlate the composite structure with device performance. I will discuss how our approach enables ion-responsiveness in essentially any semiconducting polymer, thereby unlocking the polymer library for electrochemical applications in biosensing, neural interfaces, and wearable electronics. With this approach, we believe device engineers can access a wider range of active materials, overcoming the one-material-fits-all bottleneck that could potentially hinder further advancements in organic electronics.

Both functionality and the complexity of biological systems challenge current human technologies. Contrary to biological systems, present artificial means of information processing rely on CMOS-based hardware with rigid, fixed architectures and limited interaction modalities. Despite the recent advances in neuromorphic software implementations, hardware alternatives remain elusive. This work proposes a biocompatible and biomimetic system capable of information processing under physiological conditions in the context of reservoir computing as a step towards bridging both worlds.

Reservoir computing relies on non-linear, physical dynamical systems (reservoirs) coupled with minimal conventional artificial neural networks to perform non-conventional computing. The core and reservoirs in this study are three-dimensional (3D) biomimetic macroporous hydrogel scaffolds (cryogels) comprised of sulfated/sulfonated polymers (SSPH) such as heparin, a highly negatively charged natural glycosaminoglycan (GAG) covalently crosslinked with synthetic 4-arm poly(ethylene glycol) (starPEG) via carbodiimide chemistry at subzero temperature [1, 2]. Mechanical and morphological properties of the sponge-like scaffolds can be controlled via the composition of the precursor solution and the freezing conditions during their synthesis. Poly(3,4-ethylene dioxythiophene) (PEDOT) is electropolymerized from EDOT solutions into these highly hydrated and tough scaffolds which are contacted with Pt-coated electrodes. The resulting sets of highly branched fiber-like structures composed of PEDOT:SSPH organic mixed ionic-electronic conductors (OMIEC) are stably embedded in the pore walls of the cryogel scaffolds.

To employ the cryogels as reservoirs, we developed 3D printed structures that integrate positional fixation for cryogel cylinders, up to 24 platinum electrodes, and liquid handling ports while allowing visual monitoring of the reservoir in a sealed environment. Interfacing with the artificial neural network layer is achieved by the electrical connection of the platinum electrodes to analog I/O multichannel boards and a PC running Python scripts. Ultimately, reservoirs are fabricated by electropolymerized PEDOT fiber-like structures in the scaffold and exploiting the resulting dynamic behavior derived from ionic-electronic transport coupling.

This work showcases the OMIEC character of the PEDOT:SSPH fiber-like structures by demonstrating their organic electrochemical transistor (OECT) p-type depletion mode behavior under a three-terminal configuration. In addition, parametrical exploration of the PEDOT integration process highlights the intertwining of PEDOT and GAG morphologies, contrary to 2D and free-standing fibers previously reported [3] in which PEDOT:dopant morphology is highly dependent on the electropolymerization signal parameters. Memory-capacity measurements combined with simple predictive tasks confirm the neuromorphic computing capabilities of the proposed system.

Furthermore, network density and performance limits are still to be assessed. The 3D system increases the degrees of freedom and connectivity of the recurrent network and creates integration challenges. Subsequent steps towards *in vitro* applications are planned. The potential of the cryogel scaffolds as delivery systems for signaling proteins due to their GAG component was previously reported [2]. The biomolecular toolbox compatible with the biomimetic, highly hydrated reservoirs tempt to elucidate the full potential of their modulation by biochemical signals. Coupling biochemical affinity, ionic-electronic transport, and *in situ* real-time computing with the possibility of hosting cells would be a step towards merging the biological and semiconductor worlds.

***In Operando* Characterization of Organic Mixed Ion-Electron Conducting Materials** Tom van der Pol, Silan Zhang, Han-Yan Wu, Chi-Yuan Yang and Simone Fabiano; Linköping University, Sweden

Organic mixed ion-electron conducting materials (OMIECs) bridge the gap between rigid electronics and soft biological systems as they transduce ionic and electronic signals while exhibiting similar mechanical properties as soft tissue. These materials generally operate in a complex environment, including an electrolyte containing positively and negatively charged ions. Thereby, the material characteristics of OMIECs during operation can differ strongly from their ex-situ properties, which markedly calls for in-operando characterization to study their behavior. Here, we apply several in-operando characterization techniques to state-of-the-art OMIECs and uncover previously undetected ion-backbone interactions. Through in-operando Fourier-transformed infra-red (FT-IR) spectroscopy, we find these ion-backbone interactions are crucially important to explain OECT characteristics as they govern the formation of multiply charged species. We find that the same interactions instigate changes in the film morphology, whereby the choice of electrolyte dictates the nature of the changes. Our results provide insight into the electrochemical doping mechanism of these polymers and uncover structure-property relations governing their device functions. These insights enable targeted optimization of both polymer structure and employed electrolyte, as well as provide an instrument for possible new applications.

Neuromorphic Functions in Melanin/PEDOT:PSS Blends Natan L. Nozella[1,2], Guilherme S. Selmi[2,3], Nayrim B. Guerra[1], Marcelo R. Piton[2], Rafael F. de Oliveira[1,2,3] and Carlos F. Graeff[1]; [1]University of São Paulo State–UNESP, Brazil; [2]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [3]University of Campinas (UNICAMP), Brazil

Inspired by the functioning of the human brain, organic semiconducting materials and devices present a natural alternative for producing neuromorphic systems. Here, we fabricated and evaluated electrochemical neuromorphic organic devices (ENODEs) using as active layer different blends of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and a synthetic melanin (Mel) (0, 10, 20, 33, and 50 wt%). Mel is a natural pigment endowed with several interesting properties such as improved ionic-electronic coupling and high volumetric capacitance, along with sustainable characteristics such as biodegradability and processing in water[1]. Synaptic functions such as short-term and long-term synaptic plasticity have been analyzed. The pair pulsed depression (PPD) response indicated that the ENODE device works in processing mode retaining the memory of the first pulse stimulus. Compared to the pure PEDOT:PSS ENODEs (6.25 ± 0.25 ms), the retention time double for 20 wt% of Mel samples (15.3 ± 2.2 ms) and tripled in 33 wt% of Mel ENODEs (19.5 ± 0.5 ms). We associate such improved retention with the increased ion retention ability exhibited by samples having larger amounts of Mel. The Mel/PEDOT:PSS ENODes was also evaluated by long-term potentiation (LTP) and depression (LTD) measurements and demonstrated good assessment of the multimemory level of exhibiting characteristic curves indicated by well-defined write and erase cycles with good memory level retention. The addition of 50%wt Mel in the blend, allows the ENODes to demonstrate good assessment of the multimemory level of exhibiting characteristic curves indicated by well-defined write and erase cycles with good memory level retention, discrete and stable different memory states, far surpassing the response of devices made of pure high conducting PEDOT:PSS films Such a distinguishable performance is related to the improved ionic-electronic coupling of Mel and its low electronic conductivity that mitigates the rapid current decay of devices having high amounts of PEDOT:PSS. This result also corroborates the improved retention time observed for the Mel/PEDOT:PSS devices. As reported in the literature, materials having low charge densities are preferable for synaptic transistors[2], since the voltage pulse can create charge level differences that allow access to multiple memory levels. In summary, the synaptic functions tested indicated that Mel/PEDOT:PSS devices could be strong candidates as neuromorphic in sustainable bioelectronics with promising characteristics due to the biocompatible melanin easy and sustainable incorporation.

Fabrication of Vertical Organic Electrochemical Transistor from n-Type Ion Gel Based on Benzodifurandione-Based Oligo(p-phenylene vinylene)s Seung Yeon Ki, Seonkwon Kim, Soo Young Cho, InCheol Kwak, Seonmi Eom, Yonghyun A. Kwon and Jihyeon You; Yonsei University, Korea (the Republic of)

Organic electrochemical transistors (OECTs) using aqueous gate dielectrics have garnered significant interest for bioelectronic applications, but their viability for long-term use in neuromorphic computing and synaptic devices is limited due to their short-term functionality. To address this issue, two benzodifurandione-based oligo (p-phenylene vinylene) polymers, BDOPV-TCNVT and ClBDOPV-TCNVT, were synthesized and their properties were investigated in quasi-solid-state ion gel-gated vertical OECTs (v-OECTs). Compared to BDOPV-TCNVT, the chlorinated ClBDOPV-TCNVT demonstrated lower frontier molecular orbitals and easier electrochemical doping. The as-spun ClBDOPV-TCNVT exhibited a higher volumetric capacitance (1.94 F cm−3) than as-spun BDOPV-TCNVT (1.49 F cm−3), primarily due to easier ion infiltration resulting from its lower crystallinity and mixed chain orientation. The quasi-solid-state v-OECTs based on both polymers (as-spun) showed transconductance (gm) values of 0.06–0.08 mS. However, following thermal treatments, the gm gradually decreased for both polymers due to enhanced edge-on ordering and tighter interchain packing, which hindered ion penetration. Despite the challenges with electrochemical doping by quasi-solid-state ion gel-gated dielectrics, the enlarged area and decreased channel length in v-OECTs enhanced gm compared to parallel OECTs. This suggests that v-OECTs, with their larger channel area and shorter channel length, can improve transconductance. Additionally, it was found that thermal treatments improved electron mobility in organic field-effect transistors (OFETs) due to enhanced molecular packing, but this packing hindered ion penetration in v-OECTs. The importance of tailored material designs for optimizing v-OECTs, focusing on achieving efficient vertical charge transport and ion infiltration is noticeable. This could address the current limitations and expand the applications of OECTs in bioelectronics and neuromorphic computing.

From Rigid to Conformable Miniaturized Focused Ultrasound Neurostimulators Tiago Costa; Delft University of Technology, Netherlands

Low-intensity focused ultrasound (LIFU) was discovered to have an excitatory effect in neuronal circuits approximately 15 years ago. Ever since that seminal work was published [1], hundreds of researchers worldwide have continuously investigated LIFU for brain stimulation, both for neuroscience and clinical translation. The reason for the excitement around LIFU is apparent: the low absorption and scattering together with the millimetric wavelengths of ultrasound in soft tissues, such as the brain, means that ultrasound can be transmitted from a distance, such as from the surface of the skull or brain, and be accurately focused with a neuromodulatory dosage in a millimetric spot anywhere in the brain, without affecting nor damaging the neurons in the propagation path [2]. Consequently, LIFU can be a happy medium between the precision of electrical deep brain stimulation and the non-invasiveness of transcranial magnetic stimulation while potentially having a considerably higher benefit-risk ratio [3]. The fact that there are currently ~100 clinical trials exploring LIFU for diseases such as Parkinson's, Alzheimer's, and Treatment Resistant Depression further showcases the great potential of this neuromodulation technology.

In the past 15 years, however, focused ultrasound transducer technology has not accompanied the fast developments of LIFU discoveries. These transducers, which generate focused ultrasound waves, still have a handheld/helmet bulky-form factor and require benchtop electronics [2]. Consequently, they are not compatible with the scales of rodents for pre-clinical research, are prohibitively large, and are power inefficient for use as a wearable LIFU neurostimulator.

Similar to the developments we saw in electrical stimulation, where large electrodes and bulky implantable pulse generators (IPGs) are being miniaturized into chip form factors, the field of ultrasound transducer technology is demanding the same revolution. In this talk, I will describe my group's efforts towards this goal by focusing on novel ultrasound transducer microfabrication and microsystem integration methods and next-generation ultrasound electronics for two specific cases: full monolithic integration of ultrasound transducers on top of the integrated electronic chips for maximum level of miniaturization towards freely-moving experiments in rodents [4-6]; integration of ultrasound transducers and electronic chips in flexible substrates for large-aperture conformable ultrasonic neurostimulators, for deep brain stimulation in humans.

Biodegradable Neural Probes for Transient Neuromodulation Applications Maria Cerezo Sanchez[1,2], Danial Kiamarsi[1,2], Angel Canal-Alonso[1,2] and Hadi Heidari[1]; [1]University of Glasgow, United Kingdom; [2]NEUROBITE Technologies, United Kingdom

Brain disorders are a major health concern, with an estimated 220 million people affected by neurological disorders, accounting for 10-15% of the overall disease burden. For instance, certain sectors, such as the stroke care one, face challenges in the form of lack of personalised and intensive post-stroke rehabilitation. Implantable neural probes that record and stimulate affected areas and deliver drugs locally, thereby promote new connections, have gained interest as an alternative for treating these neurological conditions and monitoring the efficacy of the treatment. However, several concerns must be addressed before these probes can be deemed safe and effective for use in humans.

Transient electronics, in particular transient implantable medical devices like neural probes, have emerged as an excellent candidate for implantable and medical devices as they offer advantages such as being less invasive, more patient-friendly and retrieval-surgery-free by substituting permanent implants. Furthermore, transient implants have the potential to significantly reduce issues like infections, tissue rejection, and some of the other long-term complications that traditional permanent implants suffer from. However, the fabrication of transient neural probes is quite challenging since most of the biodegradable materials used for the fabrication of transient devices are incompatible with traditional cleanroom methods, such as wet etching. One way to mitigate the issue is to use advanced techniques like shadow masking, printing and lasers which offer numerous advantages in terms of scalability, design flexibility and material versatility. In this study, we developed Brain Implantable Transient Electronics (BITE) probes to interface with the central nervous system to monitor and modulate neural activity in the deep brain. To achieve this goal, shadow masking was investigated as an alternative for cleanroom-based and wet etching fabrication protocols, with the focus being on neurostimulation electrode fabrication since these permit bigger feature sizes.

A conformable, flexible, and biodegradable substrate was prepared using cost-effective biodegradable materials such as chitosan, with biodegradable electrode materials like Zinc and Molybdenum. In addition to this, biopolymers such as Polycaprolactone (PCL) and Poly-L-Lactic Acid (PLLA) were also investigated due to their reported stability before they degrade. The approach successfully demonstrates large-area and batch production of flexible, implantable, biocompatible, and biodegradable transient neural probes (TNPs). Electrochemical impedance spectroscopy (EIS) analysis revealed an impedance of 10kΩ at 1kHz for chitosan and Zinc TNPs, demonstrating their adequacy for neural recording applications. The fabricated TNPs exhibited excellent stability under multiple bending angles, demonstrating their conformability for the electrode-tissue interface. Further, the fabricated electrodes were shown to be biocompatible using L-929 cells, with these being the golden standard for cytotoxicity testing. These results suggest excellent suitability as biomaterials for implantable neural probes. Future steps will include further in vitro testing in neuroblastoma cell cultures as well as in vivo testing to evaluate performance, efficacy, and biocompatibility in a live animal model.

These advancements pave the path for the next generation implantable devices, with widespread applications such as Intracranial Pressure (ICP) monitoring and post-stroke neuromodulation, offering more patient comfort through the elimination of retrieval surgeries, whilst at the same time providing a sustainable approach to healthcare technologies.

2:00 PM *EL05.02.03

Multi-Conductive Layer Flexible Bioelectronic Implants for Neural Recording and Stimulation Shahab Rezaei-Mazinani[1], Remy Cornuejols[1,2], Amélie Albon[1], Anton Ivanov[2], Antoine Ghestem[2], James Alexander Taylor[3], Suyash Joshi[3], Martin Baca[1], Sofia Drakopoulou[1], Tania Rinaldi Barkat[3] and Christophe Bernard[2]; [1]École des Mines de Saint-Étienne, France; [2]Aix-Marseille Université, France; [3]Universität Basel, Switzerland

Advancements in flexible bioelectronic implants are enhancing minimally invasive neural activity recording and stimulation. Increasing electrode density by superimposing conductive leads, is one of the major approaches for fabrication of high-resolution implants. The superimposition can enhance the number of electrodes without increasing device width, but this introduces crosstalk issues due to capacitive coupling (CC). We present an investigation into CC in devices containing multi-gold layer thin-film arrays, based on PEDOT:PSS electrodes, and with parylene C (PaC) insulation layer between leads. These results show that capacitance due to CC decreases non-linearly and then linearly with increased insulation thickness. We identify an optimal PaC thickness that reduces CC without significantly increasing device thickness. We developed multilayer electrocorticography implants with the optimal insulation. They exhibit an *in vivo* performance comparable to single-layer devices, confirming their suitability for high-quality recordings. Additionally, we demonstrate that depth implants with the same architecture offer alternatives to conventional rigid devices for chronic brain stimulation, thanks to high charge injection capacity and better tissue compliance. We developed intracortical depth implants targeting the rat hippocampus for safe and extended micro-stimulation and recording. Acute *in vivo* experiments identified parameters for maximal LFP generation in CA1 in response to electrical stimulation of Schaffer collaterals. A 16-day study in freely moving rats demonstrated consistent LFP generation in CA1 in response to axonal stimulation in Stratum Radiatum. Together, our results demonstrate an excellent performance of flexible bioelectronic implants for acute and chronic stimulation and recording, as well as their high potential in neuroscience research.

2:30 PM EL05.02.04

An Integrated Organic Spiking Neuron/Synapse Architecture with an Unconventional Form-Factor for "Physiological Neuromorphic Systems" Giovanni Maria Matrone[1], Zachary Laswick[1], Ruiheng Wu[1], Abhijith

Surendran[1], Yoeri van de Burgt[2] and Jonathan Rivnay[1]; [1]Northwestern University, United States; [2]Technische Universiteit Eindhoven, Netherlands

Signal communication mechanisms within the human body rely on the transmission and modulation of action potentials[1]. Neural networks exploit the interaction of spiking elements (afferent neurons and interneurons) and neuromodulator junctions (chemical and electrical synapses), to process the information acquired through biological receptors. Replicating these interdependent functions with organic/hybrid artificial neurons and biohybrid synapses is an essential first step towards merging neuromorphic circuits and biological systems[2,3]. Organic materials have been employed to build electronic circuits that mimic both the spiking behaviour of neurons[2,4] and their synaptic transmission[5] thus replicating afferent neurons and interneurons functions. Indeed, a combination of bioelectronic devices may recreate a "neuronal pathway" that in nature relies on the cooperation of neurons, receptors and chemical synapses[2]. Although the most recent organic neuromorphic circuits emulate biological functions which are essential for basic signal processing[2,4], communicating seamlessly with the central nervous system (CNS) requires an even higher level of bio-realism with devices that are able to capture neurotransmitter signaling at physiological levels (synapses with tens of nM limit of detection) but also to closely match the frequency, amplitude and activation threshold of biological spikes (neurons), including attaining a bio-plausible power consumption (at least nJ range). Moreover, synapses and neurons in the CNS operate with high energy efficiency also due to their intimate "hardware" integration, which allows to locally modulate and exchange signals without losses.

Here it is presented a neuromorphic platform based on the Hodgkin-Huxley (HH) circuit model which integrates in a single architecture an organic synapse and an antimbipolar OECT to replicate both afferent neurons "sensory coding" and the interneurons neuromodulatory functions, while operating in "physiological conditions". Exploiting a vertical transistor architecture, a bio-hybrid synapse realised through the electrodeposition of PEDOT is integrated on top of a BBL-based anti-ambipolar OECT.

This architecture allows to co-allocate the fundamental neuronal mechanisms of synaptic weight modulation and spike generation. Indeed, the modulation of the conductance state of the PEDOT device (bio-hybrid synapse) through the neurotransmitters dopamine allows to selectively tune the anti-ambipolar characteristics of the whole device (BBL in series with PEDOT OECT), replicating both short-term and long-term potentiation mechanisms. Additionally, the use of different supporting polyelectrolytes for PEDOT electrodeposition is explored to tune the mixed ionic electronic conduction properties of the bio-hybrid synapse to increase its dynamic range and responsivity to electro-active neurotransmitters allowing to reach a "physiological" limit of detection of 10 nM. This in-series OECT is part of a HH circuit, representing its Na^+ channel, allowing to translate physiological changes in the concentrations of dopamine and serotonin in the electrolyte environment, directly into spikes encoded signals. The total neuromorphic system's energy consumption, as predicted by electronic circuit simulations, is reduced to 1 nJ, while the platform footprint is reduced to 7 mm x 7 mm. As such, due to its unconventional architecture, this system constitutes a building block for programmable neural pathways and it is compatible with in-sensor applications footprint and sensitivity requirements for locally executing bio-inspired pre-processing functions, thus allowing for a seamless and dynamic communication with the nervous system.

Solid-State Homojunction Electrochemical Transistors and Logic Gates on Plastic InCheol Kwak[1], Soo Young Cho[1], Yonghyun A. Kwon[1], Seonkwon Kim[1], Seung Yeon Ki[1], Jihyeon You[1], Han Young Woo[2] and Jeong Ho Cho[1];

[1]Yonsei University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Organic electrochemical transistors (OECTs) have attracted significant attention due to their unique ionic–electronic charge coupling, which holds promise for use in a variety of bioelectronics. However, the typical electronic components of OECTs, such as the rigid metal electrodes and aqueous electrolyte, have limited their application in solid-state bioelectronics that require design flexibility and a variety of form factors. Here, we demonstrated the fabrication of a solid-state homojunction OECT consisting of a pristine polymer semiconductor channel, doped polymer semiconductor electrodes, and a solid electrolyte. This structure combined the photo-crosslinking of all of the electronic OECT components with the selective doping of the polymer semiconductor. Three Lewis acids ($AuCl_3$, $FeCl_3$, and $CuCl_2$) were utilized as dopants for the metallization of the polymer semiconductor. The $AuCl_3$-doped polymer semiconductor with an electrical conductivity of ~100 S cm^{-1} was successfully employed as the source, drain, and gate electrodes for the OECT, which exhibited a high carrier mobility of 3.4 cm^2 V^{-1} s^{-1} and excellent mechanical stability, with negligible degradation in device performance after 5000 cycles of folding at a radius of 0.1 mm. Homojunction OECTs were then successfully assembled to produce NOT, NAND, and NOR logic gates.

ECRAM—Progress, Challenges and Opportunities Alec Talin; Sandia National Laboratories, United States

Electrochemical random access memory (ECRAM) is a three terminal device that operates by tuning electronic conductance in functional materials through solid-state electrochemical redox reactions. This mechanism can be considered as a gate-controlled bulk modulation of dopants and/or phases in the channel. Early work demonstrating that ECRAM can achieve nearly ideal analog synaptic characteristics has sparked tremendous interest in this approach. More recently, the realization that electrochemical ion insertion can be used to tune the electronic properties of many types of materials including transition metal oxides, layered 2D material, organic and coordination polymers, and that the changes in conductance can span orders of magnitude, from gradual increments needed for analog elements, to large, abrupt changes for dynamically reconfigurable adaptive architectures, has further attracted interest in ECRAM as the basis for analog synaptic elements for inference accelerators as well as for dynamical devices that can emulate a wide range of neuronal characteristics for implementation in analog spiking neural networks (SNNs). At its core, ECRAM shares many fundamental aspects with rechargeable batteries, where ion insertion materials are used extensively for their ability to reversibly store charge and energy. Computing applications, however, present drastically different requirements: systems will require many millions of devices, scaled down to tens of nanometers, all while achieving reliable electronic-state tuning at scaled-up rates and endurances, and with minimal energy dissipation and noise. In my presentation, I will discuss recent progress for several different types of ECRAM, including devices based on inorganic, polymer and coordination compounds, and with Li, protons, and oxygen vacancies as mobile ions. I will also discuss strategies for realizing tunability, reconfigurability and long term stability and state retention all in one device.

4:00 PM EL05.02.07

Electrochemical Protonic Modulation of Monolayer MoS_2 for Programmable Resistors and Dynamically Tunable Transistors Mantao Huang, Longlong Xu, Sheldon Zheng, Jing Kong and Bilge Yildiz; Massachusetts Institute of Technology, United States

Electrochemical random-access memories (ECRAMs) are promising three-terminal programmable resistors for powering deep neural network hardware accelerators. We investigate ECRAMs with 2H-MoS_2 monolayer as the channel. Our findings demonstrate that the supply of protons to the 2H-MoS_2 channel enables reversible non-volatile conductance modulation with microsecond voltage pulses. The response of the device to the applied gate voltage exhibits both a non-volatile electrochemical effect and a volatile electric field effect. Notably, the programming results in a significant shift of the threshold voltage of the MoS_2 monolayer upon electrochemical gating, allowing for a large range (10^5) of non-volatile conductance modulation at a constant back gate voltage. The observed threshold voltage shift suggests that the hydrogen supplied to the MoS_2 and its surrounding interfaces increases the n-type doping of the channel. This work opens up new possibilities for the development of programmable resistors and tunable transistors with potential applications in hardware neural networks and other in-memory computation architectures.

4:15 PM EL05.02.08

Dynamic Modulation of Space Charge Resistances in ECRAM Devices Miranda Schwacke, Matthäus Siebenhofer, Thomas Defferriere, Harry Tuller and Bilge Yildiz; Massachusetts Institute of Technology, United States

With the rapid rise in the prevalence of artificial intelligence, the energy consumed by training neural networks has also skyrocketed. Electrochemical random-access memory (ECRAM) is a promising technology for brain-inspired, energy efficient training of neural networks. Resistance modulation in ECRAM devices is achieved by electrochemically controlled dynamic intercalation of small cations like H^+ and Mg^{2+} into the channel material, accompanied by electron doping. In this work we aim to understand the role that channel microstructure and space charge regions play in resistance modulation. Using electrochemical impedance spectroscopy (EIS), we find that for polycrystalline WO_3, a very common channel material for ECRAM, the resistance of undoped films is dominated by space charge resistances originating from grain boundaries. Upon intercalation of small concentrations of cations, the space charge resistance rapidly decreases compared to the bulk resistance, with the bulk resistance dominating the total resistance for higher cation concentrations. The experimental results are supported by an equilibrium electrostatics model of space charge regions in M_xWO_3. This work provides new insights into ECRAM working mechanisms, which could enable the informed design of devices and help them meet the demanding requirements for application in energy-efficient training of neural networks.

4:30 PM EL05.02.09

Effects of Acidic and Basic Interface Metal Oxides on H-ECRAM Performance Jordan Meyer, Mantao Huang and Bilge Yildiz; Massachusetts Institute of Technology, United States

Three-terminal electrochemical random-access memory (ECRAM) is promising for energy-efficient neuromorphic computing, owing to device non-volatility and reversible, symmetric switching behavior. The conductance of a channel material, typically WO_3, represents analog states, changing in response to ion intercalation, protons in the case of H-ECRAM. Kinetic bottlenecks impede write voltage below 1 V and nanosecond programming. Typical performance enhancements are high ionic conductivity electrolytes and scaling of channel and electrolyte thicknesses.[1] As the device stack shrinks, the interfaces may also be potential kinetic bottlenecks.[2]

We hypothesized that the interface reaction at the electrolyte-channel interface depends on the strength of proton bonding to oxygen ions. From acid-base scales, more basic metal oxides tend to have stronger O-H bonds, which may increase the barrier to proton transfer and suppress interface kinetics. To explore this concept, we deposited a range of thin, amorphous metal oxide coatings at the electrolyte-channel interface. We evaluated H-ECRAM device performance under cycling and extracted exchange current density (j_0) values with electrochemical impedance spectroscopy (EIS) to describe the interface kinetics. Both the magnitude of conductance change and j_0 values decreased with basic coatings (more basic relative to WO_3). This decrease followed the ordering of the metal oxide coatings on the acid-base scale used.[3] X-ray photoelectron spectroscopy (XPS) showed that WO_3 film

work functions decreased with more basic coatings, with only minor increases in oxidation state and sheet resistance. The absence of major changes in oxidation state and sheet resistance suggests these coatings may affect mainly the proton transfer at the interface, correlating with acid-base scale trends.
These results show the tunability of H-ECRAM device performance at the electrolyte-channel interface. Acid-base scales may guide interface design that lowers write voltages further and supplements existing strategies to reduce write voltage for fast programming.

4:45 PM EL05.02.10
Ceria-Based Ionic Conductor in Metal-Oxide Electrochemical Random-Access Memory for High-Speed Neuromorphic Computing Applications Jaehyeong Lee[1], Hyeongjin Moon[1], Jinha Choi[1], Jeonghoon Son[2], Seungkun Kim[2], Jongchan Ryu[1], Hongju Kim[1], Seyoung Kim[2], Sangbum Kim[1] and Yun Seog Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Electrochemical random-access memory (ECRAM) has emerged as a promising synaptic transistor for energy-efficient analog artificial neural networks, with the potential to significantly reduce the cost required to train large-scale models. Among various types of ECRAM, oxygen-ion-conducting metal-oxide-based ECRAM offers advantages over proton-conducting counterparts, including higher thermal and chemical stability, as well as improved retention. Moreover, the compatibility of oxygen ion-conducting materials with existing CMOS technology facilitates easier integration into current manufacturing processes for integrated circuit devices. However, conventional oxygen ion-conducting electrolytes such as HfO_2 and ZrO_2 often exhibit low ionic conductivity at room temperature, resulting in slow speed in weight-updating operations.

In this study, we employ a Sm-doped CeO_2 (SDC) thin film as the electrolyte layer. SDC has demonstrated promising oxygen-ion conductivity as well as high surface exchange coefficient in solid oxide fuel cell applications. We deposit SDC thin films with varying Sm concentrations using a co-sputtering technique, which allows control of the doping level by adjusting the RF power during the deposition process. Electrochemical impedance spectroscopy is carried out to evaluate their electrochemical characteristics to determine the optimal doping level for device operations at room temperature. We fabricate metal-oxide ECRAM devices utilizing the optimized SDC electrolyte film, achieving weight-updating operating speeds in the tens of nanoseconds. Furthermore, we model the ECRAM device to analyze the significantly improved speed and further enhance the performance of metal-oxide ECRAM for high-speed neuromorphic computing applications.

Designing Polymeric Mixed Conductors for Photoelectrochemical Transistors with a Memory Sahika Inal; King

Abdullah University of Science and Technology, Saudi Arabia

The ability to sense and react to environmental stimuli is a crucial material property to harness in the development of next-generation sensors, actuators, and robotics. In this presentation, I will introduce the materials design guideless to build a conjugated polymer-based aqueous gated neuromorphic device with the ability to respond to a stimulus and store the information generated. I will show how annealing boosts polymer crystallinity, elevating the mixed conductivity and reducing excess electrolyte uptake during device operation. By controlling water uptake in the film and leveraging its strong absorption in near-infrared, we develop a water-compatible memory device mimicking the behavior of biological photoreceptors. In the high mobility film, photocurrent is retained through frequency-dependent training with light, emulating the learning process of neurons. This system is seamlessly integrated into an adaptable circuit with outputs controlled by various stimuli, including light, effectively mimicking the function of a light-sensitive neuron. Similar transistor active-matrix arrays are capable of adaptive sensing, memorization, and pre-processing of visual information. While highlighting the unique characteristics of these devices, I will delve into the potential pathways through which the polymer film can sustain long-term performance.

8:30 AM *EL05.03.02
Effect of Subcellular Nanopillars with a High Aspect Ratio on the Cell-Electrode Coupling for Neuroelectronic Interfaces Andreas Offenhaeusser[1] and Colin Fernandes[1,2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany

Over the past twenty years, nanoscience has advanced rapidly, leading to significant developments not only in materials science and physics, but also impacting various fields from life sciences to engineering. Among these advances, micro- and nanoelectrodes ranging from micron to sub-micron in size, have been particularly important in neurosciences, where they are the primary functional elements of neuroelectronic devices designed for recording and electrical stimulation. Here we report on improvements in electrode fabrication and design, and the integration of nanoelectrodes with microelectrodes. In addition, as electrode dimensions decrease, new electrostatic and electrochemical effects emerge that enhance intracellular sensing applications. In particular, tight physical coupling between the electrode and the neuron leads to higher signal-to-noise ratio (SNR) of extracellular recordings due to better isolation of the electrode from noise, and recent applications of high aspect ratio nanostructures for neural applications show substantial passive improvement of extracellular recordings. Tight cell-electrode coupling relies on the reorganization of structural proteins within the cell, but the details of the mechanisms behind this reorganization are not fully understood, hindering the design of an ideal structure for high SNR passive recordings.
In this study we push cell-electrode coupling in the nanoscale through the engineering of high-aspect ratio nanopillars with diameters below 100nm. These nanostructures allow us to uniquely probe neurons as they approach the diameter of curvature of sub-cellular features. These sub-cellular nanopillars are then integrated onto micro electrode arrays (MEAs) and in high-density large-scale arrays to investigate the neurons through a range of experiments. The fabrication of the nanopillars utilizes the nanometer resolution of electron beam lithography (EBL) combined with the conformality of atomic-layer deposition (ALD).
To investigate the cell-chip coupling, E18 rat cortical neurons were cultured on the nanopillars on different platforms. The physical and structural characteristics were investigated through critical point drying (CPD), focused ion beam (FIB) milling of ultra-thin plasticization (UTP) preserved cells, and immunostaining. Whereas, the electrophysiological coupling was explored through nanopillar MEA recording with simultaneous patch clamp.

9:00 AM ^EL05.03.03
Intelligent Nanoelectronics Zeinab Jahed; University of California, San Diego, United States

There remains a pressing need for electrophysiology techniques that are capable of accurate and high throughput recording of electrical signals for applications in disease modeling and drug screening. Extracellular microelectrode arrays can record signals from hundreds of cells in a non-invasive fashion and are successfully used in live animals and humans. However, extracellular electrodes can only detect the firing patterns- namely the presence and frequency of an action potential (AP), missing critical information about their true waveforms. To obtain the true waveform of an AP, the electrodes must obtain “intracellular access” by penetrating the cell membrane. This intracellular recording provides a depth of essential information including ion channel activities, cell subtype, and effects of drugs on the AP shape. However, intracellular recordings are more invasive, lower-throughput, and not currently possible in vivo. **Critical Need:** A method that could reliably reconstruct the true waveform of APs merely from non-invasive and high-throughput extracellular recordings would be of great interest to the cardiac electrophysiology field. In this work we present an intelligent nanoelectrode that can reconstruct intracellular signals from extracellular recordings. This is interdisciplinary research project that leverages the developments from two fields: 1) **nanoelectrode arrays** with the promise to simultaneously record intra- and extra- cellular signals from thousands of interconnected cardiac cells for **single cell electrophysiology** and 2) Advancements in AI, especially **physics guided learning** that allow fast and precise signal reconstruction. We believe our new technique will dramatically accelerate new discoveries in the cardiac biophysical and biomedical research fields.

9:30 AM EL05.03.04

An Organic Electrochemical Neuron for a Neuromorphic Perception System Yao Yao[1], Robert M. Pankow[2], Wei Huang[1], Tobin Marks[1] and Antonio Facchetti[3,1]; [1]Northwestern University, United States; [2]The University of Texas at El Paso, United States; [3]Georgia Institute of Technology, United States

Human perception systems are highly refined, relying on an adaptive, plastic and event-driven network of sensory neurons. Drawing inspiration from Nature, neuromorphic perception systems hold tremendous potential for efficient multi-sensory signal processing in the physical world, however the development of an efficient artificial neuron with a wide calibratable spiking range and reduced footprint remains challenging. Here we report an efficient organic electrochemical neuron (OECN) with reduced footprint (<37 mm^2) based on high-performance vertical OECT (vOECT) complementary circuitry enabled by a new n-type polymer for balanced p-/n-type OECT performance. The OECN exhibits outstanding neuronal characteristics, capable of producing spikes with a widely calibratable state-of-the art firing frequency range of 0.130-147.1 Hz. Leveraging this capability, we developed a neuromorphic perception system that integrates mechanical sensors with the OECN and integrates them with an artificial synapse for tactile perception. The system successfully encodes tactile stimulations into frequency-dependent spikes, which are further converted into postsynaptic responses. This bioinspired design demonstrates significant potential to advance cyborg and neuromorphic systems, providing them with perceptual capabilities.

9:45 AM EL05.03.05

Smart Cell Analysis Needle System for Point-of-Care Characterization of Cell Therapeutics Yiyuan Yang[1,2,3]; [1]Massachusetts Institute of Technology, United States; [2]National University of Singapore, Singapore; [3]Northwestern University, United States

Therapeutic cell transplantation has been becoming a promising strategy to treat a wide range of diseases including but not limited to neurologic and endocrinologic disorders, cardiac diseases, diabetes, and tumors. The efficacy of cell treatment highly depends on the viability and cell count at the time of cell administration. Thus, evaluation and adjustment of therapeutic regimen require precise evaluation of cell viability, concentration, as well as their types and relative compositions in mixed suspension. Current approaches cannot offer real-time assessment on cell characteristics during cell transplantation as they require bulky instruments and complex sampling procedures. These procedures often damage cell samples, especially in the case of cell clusters that require dissociation before characterization. In addition, the cell conditions vary from the time of sampling and characterization to the time of transplantation due to the time delays occurred during cell preparation and transportation. To address these concerns, we here report the development of a smart cell analysis needle system (SCANS) that incorporates multi-model sensing and artificial intelligence (AI) to provide accurate assessment of the viability, concentration, and type of the cells. The entire system is included in the form of flexible electronics, enabling its convenient deployment between the commercial injection needles and syringes to realize real-time measurement of cell characteristics during dynamic flow at the point of administration. Application of AI in SCANS effectively improve the range and resolution of cell analysis by realizing accurate prediction of cell characteristics from data excluded from training sets. We anticipate a ready translation of SCANS approach in daily clinics of cell therapy.

10:00 AM BREAK

10:30 AM *EL05.03.06
Building Blocks for Bioelectronic Medicine Geert Langereis[1,2]; [1]imec, Netherlands; [2]Eindhoven University of Technology, Netherlands

Pharmaceutical innovations over the past half century have enabled effective treatment and prevention of a wide range of illnesses. However, the development time of drugs has increased, while the drugs need to be optimized for more specific conditions. This has resulted into prices that are unjustifiable and unaffordable. Besides that, systemic pharmacological treatments have side-effects and limited efficacy. A possible outcome is to use nanotechnology and smart electronics to interfere with the human body, for example by direct stimulation of the nervous system. We speak of BioElectronic Medicine (BEM) that has the additional advantage of software/firmware interaction to optimize the treatment on the fly, it can be switched on and off instantaneously, and it is a hormone free treatment. We know already the cardiac pacemaker, and implantable stimulators for Alzheimer's disease, lower back pain and epilepsy. It is known that this portfolio can be expanded because all organs in the human body are in fact modulated by the nervous system. The mentioned examples are implantable devices, because that is preferred for severe chronic conditions, but it is possible a therapy is implemented as a wearable or an implant/wearable combination.

There is a similarity between the envisioned BEM implants. All units need hermetic and biocompatible packaging to make them suitable for a long-term implant. Because these are electrical solutions, all systems need powering by means of a battery, a wireless powering solution, or a combination of both for rechargeable systems. In addition, such implants need electrodes or other means to interact with human physiology, and most solutions can benefit from sensors. Finally, there must be logic to process data and a wireless link to the outside world for configuration and information. The similarity in the building blocks resulted in nanotechnology and microelectronic solutions that can be ranked and replicated.

Future BEM systems will be smaller to enable laparoscopic less-invasive implant procedures. They will have closed loop control mechanisms that are more adaptive by which the efficacy is increased. Besides that, we observe a need for more electrodes and a higher data-rate. These trends are challenging the design of new building blocks. It will be clear that the age of BEM is just starting and will augment or even change our healthcare system.

11:00 AM *EL05.03.07
Organic Electrochemical Neurons for Neuromorphic Perception Simone Fabiano; Linköping University, Sweden

Neuromorphic sensing and processing have the potential to enable bioelectronic devices that can perform localized and highly individualized signal processing within living tissues and the nervous system. Traditional silicon-based neuromorphic devices face challenges in bio-integration due to high circuit complexity, poor biocompatibility, and low energy efficiency. Emerging bioelectronic technologies, such as organic electrochemical transistors (OECTs), offer solutions to these limitations. OECTs efficiently couple ions and electrons, facilitating effective signal transduction and making them ideal for interfacing electronics with biological systems. In this presentation, I will explore the use of OECTs to develop organic electrochemical neurons (OECNs) capable of ion-mediated spiking. These devices leverage ion-tunable antiambipolarity in mixed ionic-electronic conducting polymers to mimic the dynamics of biological neurons. This allows for the efficient transduction and processing of sensory information, demonstrating the potential for high-frequency, low-energy neuromorphic devices capable of anticoincidence detection. This innovation could significantly advance closed-loop implantable devices for next-generation bioelectronics and robotics.

11:30 AM *EL05.03.08
Organic-Based Devices for Neuromorphic Computing Alberto Salleo; Stanford University, United States

Polymer-based artificial synapses have shown outstanding performance in terms of switching speed, switching energy and endurance. The working principle of these devices leverages the dynamics of ion diffusion in polymers. The same dynamics can be used to fabricate organic circuits that mimic spiking neurons that exhibit adaptive behavior. These circuits comprise p- and n-type devices which are fabricated separately on chips and subsequently connected. Furthermore, the same materials set is used to fabricate multi-gate devices that reproduce the features of dendrites, specifically spatial and temporal pulse sequences. Device and circuit design allows to tune the temporal response of organic synapses, neurons and dendrites. Semiconducting polymers are thus attractive to fabricate all components suitable for neuromorphic computing.

SESSION EL05.04: Bio-Interfaces and Bioelectronics II

1:30 PM *EL05.04.01
Next Generation Reservoir Computing for Biomimetical Neuromodulation Angel Canal-Alonso[1,2], Maria Cerezo Sanchez[1,2], Danial Kiamarsi[1,2] and Hadi Heidari[1]; [1]University of Glasgow, United Kingdom; [2]NEUROBITE Technologies, United Kingdom

Neurostimulation has emerged as a promising therapeutic approach for managing medical conditions such as epilepsy, cluster headaches, and depressive disorders. The employment of invasive neurostimulation techniques necessitates rigorous measures to curtail side effects. One of the known side effects is the informational lesion caused by the interference of the stimulation signals within the brain’s own communication networks. The so-called informational lesion is produced by the artificial depolarization of the membranes of the affected by the stimulation and by the interference with the individual neurons' ability to time their spike responses. This issue could be ameliorated by the use of biomimetic signals that closely resemble natural brain dynamics.

In this sense, it has already been shown in the literature that in Mesial Temporal Lobe Epilepsy, mimicking the temporal patterns of the hippocampus can control ictogenesis. Additionally, an artificial bridge between the entorhinal cortex (EC) and the CA3 field of the hippocampus has been demonstrated to avoid seizures in an *in vitro* model. These promising results encourage the development of new neuromodulation techniques based on the restoration of hippocampal loop connectivity.

To this end, in this research, we propose a neuromodulation system based on Next Generation Reservoir Computing (NGRC) to mimic hippocampal signals adaptively in response to the dynamical changes in the cortex.

Reservoir Computing (RC) algorithms are a subset of techniques belonging to the recurrent neural networks area that excel in recovering information from dynamical systems through time-series data. RC algorithms leverage a high-dimensional dynamic reservoir that processes input signals and transforms them into a state space where linear readouts can be used to generate the desired output. This approach allows RC algorithms to efficiently model complex temporal patterns without requiring extensive training, which is a significant advantage over traditional recurrent neural networks.

RC algorithms have been proposed to be mathematically equivalent to non-linear vector autoregression (NVAR). NVAR is capable of performing at the same level as RC but with significantly less training time, data, and power consumption. NVAR's efficiency makes it particularly suitable for applications where computational resources are limited, such as in implanted medical devices. By reducing the training overhead and energy requirements, NVAR-based systems can offer a more practical and sustainable solution for continuous, real-time neuromodulation.

In this study, we implement said algorithm using EC multi-electrode array signals as the input and CA3 signals from the same brain slice as the target output. We conducted a hyperparameter search to establish the ideal configuration for this application. The features that have been demonstrated to avoid ictogenesis are strongly linked to the spectral components of the CA3 signals, rather than their morphology. Therefore, we established a custom loss function using the difference in Welch’s Power Spectrum Density of the generated and target signals during training. This approach ensures that the generated signals maintain the critical spectral characteristics necessary to prevent seizures.

The trained algorithm has been quantized and deployed on a development board (ROCK 4C+) to demonstrate the feasibility of “on edge” computing for the system. This deployment showcases the potential for real-time, low-power neuromodulation directly at the point of care. The next steps include testing the system with an *in vitro* model of epilepsy and developing a hardware implementation of the network to miniaturize the system, making it implantable. This miniaturization is crucial for practical clinical applications, allowing for long-term implantation and continuous neuromodulation without the need for bulky external hardware.

2:00 PM *EL05.04.02
Brain Organoid Reservoir Computing for AI Feng Guo; Indiana University Bloomington, United States

Current silico-computing hardware and systems are facing challenges related to power consumption and sustainability, particularly to train big artificial intelligence (AI) models. To address these challenges, neuromorphic hardware inspired by the structure and function of the human brain is undergoing development. Here, we report a hybrid neuromorphic computing system by integrating conventional silico-computing hardware with a human brain organoid. We leverage the organoid neural network for reservoir computation and demonstrate its real-world applications such as speech recognition and the prediction of nonlinear equations. This new approach may hold promise for advancing biocomputing, brain-machine interfaces, and translational medicine.

Making Brain and Artificial Neurons Talking Through Neuromorphic Devices Stefano Vassanelli[1,2]; [1]Università degli Studi di Padova, Italy; [2]CNR ICMATE, Italy

In brain-computer interfaces electronic devices are used as sensors and actuators to record and stimulate biological neurons while signal processing is delegated to digital computers. The development of neuromorphic devices emulating synapses, spiking neurons and networks leads to a paradigm shift where biological neurons are interconnected to artificial counterparts for seamless communication and brain-inspired processing. On the basis of experimental examples, we'll argue about limitations, challenges and opportunities arising from brain-neuromorphic hybrid systems,

3:30 PM *EL05.04.04
Retina-Inspired Near-Sensor Compressive Readout Architecture for High-Bandwidth Brain-Computer Interfaces Dante Muratore; Delft University of Technology, Netherlands

Brain-computer interfaces of the future will be used to treat neurological disorders for which a cure does not exist yet. For this futuristic view to become a reality, we must overcome many technological challenges. A major goal is to increase the number of neurons that we can simultaneously interact with. As custom signal specifications for brain-computer interfaces become clearer and are diverging from those needed for basic neuroscience, there is an opportunity for wireless application-specific implants that can record action potentials from tens of thousands of channels at the same time. These systems will create a massive amount of raw data that needs to be compressed on the implant to lower the power consumption of the wireless data link. The limited power budget in the implant and the large amount of raw data make this particularly challenging, as simply temporarily storing a few samples from all channels on-chip would already consume too much power. Hence, compression needs to happen near the sensor and in real time to reduce data movement and storage in the implant. Fortunately, there is an opportunity for compression since the neural signal recorded from a multielectrode array is sparse in space and time, i.e., neurons do not fire often, and not many neurons fire at the exact same time.
In this talk, I will present a system that takes inspiration from how the retina works to reduce the amount of raw data recorded while maintaining important information from the neural signal. The resolution in the retina decreases as a function of eccentricity, being maximum in the center region called the fovea. The high-resolution fovea occupies a small part of the retina, while the peripheral retina captures the remainder of the visual scene at low resolution. In fact, at approximately 15° outside the fovea, the visual acuity of a healthy person is equal to that of a legally blind patient. The reason we can look at the world and reconstruct a high-resolution image, in spite of the small size of the fovea, is that our eyes constantly explore the scene in a series of active fixations connected by rapid eye movements (saccades). The eye focuses the fovea on certain features of the visual image and moves quickly between them. These different views are then integrated by the brain to produce a coherent representation of the visual scene. Similarly, the retina-inspired system that I will present can record with high fidelity from the electrodes carrying important information (fovea) while performing lossy compression on the remaining

electrodes (periphery). To mimic the saccades that occur in the eye, the recording system selects in real-time the electrodes that need to be recorded with high resolution. To achieve this, we developed two chips: the first chip implements a 32x32 recording array that can perform lossy compression on an arbitrary subset of channels and be reconfigured on the fly; the second chip performs spike sorting on-chip directly from the compressed data, learns which electrodes are currently carrying useful information with very low latency (~50 µs) and reconfigures the first chip accordingly. Together, these solutions provide analog-to-information conversion for 1024 36x36 µm2 channels with <1 µW/channel and compression rates larger than 1000x. In the talk, I will also describe how this recording strategy can scale to even higher channel count, enabling the next generation of massively parallel brain-computer interfaces.

4:00 PM *EL05.04.05

Magnetoelectric Power for Networks of Wireless Implantable Devices Jacob T. Robinson[1,2]; [1]Rice University, United States; [2]Motif Neurotech, Inc., United States

Networks of miniature bioelectronic implants promise precise measurement and manipulation of complex physiological systems within the body. By distributing sensing and stimulation nodes throughout the heart, brain, or peripheral nervous system, we can better track and treat diseases and support advanced prosthetic technologies. One significant challenge in creating these bioelectronic networks is the inefficiency of wireless power and data transfer through biological tissue, especially as the number of implants increases. Here, we present a solution using magnetoelectric (ME) wireless data and power transfer. This technology allows networks of millimeter-sized bioelectronic implants to function with increasing power transfer efficiency as more devices are added to the network.

As an example, we show a proof-of-concept network of miniature cardiac pacing devices that can receive power and transmit data from the surface of a beating porcine heart. The scalability of ME WPT enables robust and efficient power transfer in bioelectronic implant networks, paving the way for building wireless closed-loop systems.

Introduction: Enhancing electrical neuromodulation treatments involves increasing the number of stimulation sites and personalizing their placement. Traditionally, this has been limited by the number of contacts that can be wired to a central controller. Wireless power transfer (WPT) technologies, including RF, volume conduction, ultrasound, and light, offer potential solutions. However, these methods face challenges in powering networks of devices efficiently. ME WPT, with its high power densities and wide misalignment tolerances, shows promise for wireless networks of implantable devices. We hypothesized that ME WPT would be suitable for powering such networks due to its minimal mutual coupling and large misalignment tolerances.

Efficient Power Transfer to Networks of Devices: We characterized the power transfer efficiency (PTE) of individual ME films powered by a planar transmitter (TX) coil. We found a linear relationship between the ME film received voltage and the axial magnetic field. The system PTE increased linearly with the number of implants, achieving up to 1.3% efficiency with six films receiving 2.2 mW each. This demonstrates the potential for efficient power transfer in networks of ME-powered implantable devices.

Limits of Scalability for ME-Powered Networks: We investigated the scalability limits of ME-powered networks by simulating the placement of multiple devices below a TX coil. A network of 25 films spaced 1 cm apart caused less than a 1% change in transmitter inductance and achieved an estimated system efficiency of up to 5%. Adding a second layer of 25 films at 2 cm distance increased the network to 50 devices, with an estimated efficiency of 7.5% and a 1.4% change in transmitter inductance.

Discussion: ME power transfer shows significant potential for enabling scalable networks of wireless, battery-free devices for neurostimulation. Its ability to pass through biological tissue with minimal loss at low frequencies allows for efficient power transfer to multiple devices. This technology can simplify the implementation of distributed systems, reducing the need for complex wiring and allowing for precise placement of devices tailored to individual patients' needs. Future developments may include bidirectional communication capabilities, leading to intelligent networks of implanted and wearable devices that enhance human health.

4:30 PM EL05.04.06

Brain Implantation of Tissue-Level-Soft Bioelectronics via Embryonic Development Hao Sheng, Ren Liu, Qiang Li, Zuwan Lin and Jia Liu; Harvard University, United States

Recording neural activities throughout brain development is critical to understanding how neurons self-assemble into an organ capable of learning, behavior, and cognition[1,2]. However, the significant morphological changes occurring during brain development pose a challenge for implantable bioelectronics to continuously monitor neural activity throughout this process. To date, it has not been possible to perform the ideal experiment: recording brain-wide neural activity at the cellular level with millisecond temporal resolution in animals throughout brain development[3].

In this presentation, I will begin by introducing a class of bioelectronic devices and methods to integrate the device within the developing brain of vertebrate animals throughout embryogenesis. Specifically, I will introduce sub-micrometer-thick, tissue-level soft mesh electronics containing a stretchable electrode array that can be implanted into the embryo neural plate. During organogenesis, the neural plate undergoes a 2D-to-3D reorganization process[2], folding, proliferating, and expanding into the precursors of the nervous system. The endogenous forces involved in this process seamlessly and non-invasively distribute and integrate the sensor network across the 3D volume of the neural tube and brain, creating a “cyborg” embryo. I will also demonstrate that the presence of microelectronics had no discernible impact on embryo development or subsequent behaviors.

Next, I will demonstrate how this technique enables tissue-wide, continuous recording of neuronal electrical activity during embryo development with millisecond temporal resolution. I will present an example of a cyborg frog embryo, illustrating the gradual development of localized neural activity in the frog brain: during the early stages of brain development, slow-wave synchronized electrical activities propagate across the neural tube from the forebrain to the midbrain. As development progresses, these synchronized signals gradually decouple, and calcium wave-like signals emerge, possibly indicating the increasing localization of brain activity. At last, isolated single-unit action potential-like spikes appear as the frog tadpole's brain function matures.

Additionally, I will discuss our efforts to increase the channel count of the mesh electronics using electron-beam lithography. The new electronics with high-density, soft electrode arrays enable the simultaneous recording of more neurons during brain development. Activities from individual neurons can be captured by multiple electrodes, allowing for precise single-unit spike sorting. Together with new computational data analysis pipelines, this technology allows for the tracking of electrical activities from the same units throughout brain development.

Finally, I will demonstrate the application of the mesh electronics across a broader range of animal models, including axolotl embryos, mouse embryos, and neonatal rats. Specifically, I will demonstrate the application to axolotl brain development, a unique model widely used for studying both brain development and regeneration. Continuous recording during embryonic brain development illustrates the evolution of well-isolated individual neurons and their positional migration. In addition, a spinal cord injury-regeneration experiment suggests similar neuronal activities involved in both development and regeneration. I will also demonstrate the successful implantation of the soft and stretchable mesh electronics in mouse embryos and neonatal rats, recording electrophysiological signals in the developing mammalian brain.

Flexible Organic Electrochemical Memory on 2µm-Thick Ultrathin Substrate and Bio-Signal Processing

Shohya Matsuda[1,1,2], Teppei Araki[1,1,2], Takaaki Abe[1], Kazuya Kiriyama[1], Ashuya Takemoto[1], Mihoko Akiyama[1,1], Naoko Kurihira[1], Yumi Hirose[1], Yuko Kasai[1], Takafumi Uemura[1,2], Shintaro Izumi[1,3], Yoeri van de Burgt[4] and Tsuyoshi Sekitani[1,1,2]; [1]Osaka University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Kobe University, Japan; [4]Eindhoven University of Technology, Netherlands

A neuromorphic device (NMD) enables low-energy and highly efficient computation of large amounts of data as a non-von Neumann computing device. Here, NMD is described in organic electrochemical memories (OECMs) fabricated on an ultrathin substrate and their stable electrical performance under mechanical deformation. The flexible OECMs have increased the potential for biocompatibility of a wearable device integrated to detect and predict diseases during daily life.

Previously, NMD with versatile materials fabricated using memristors has performed low energy consumption and conducted efficient operations [1]. The performance of NMD has been grown and being revealed on the importance of the higher linear conductance change contributing on the higher calculation accuracy [2]. In addition, mechanical durability in the operation of NMD is attractive to realize high intelligence wearable devices involving human movements and reduce discomfort during long-term wear [3-5].

In this study, flexible OECMs are fabricated by layering metals, conductive polymers, all-solid-state electrolytes, and 2 µm-thick ultrathin substrates. The conditions of the linear conductance change in OECMs have been found by comprehensively assessment on the time constants of the peripheral circuits including the OECM. As a result, the memory value changes of up to 9 bits can be identified by ensuring the conductance linearity. The freestanding electrolyte gel is fabricated by mixing two polymers and exhibits high conductivity (1.6 S/m) similar to liquid electrolytes. Moreover, OECMs using the electrolyte gel operate stably even under bending deformation (bending radius 0.75 mm) and enable recording arrhythmia of pseudo electrocardiograms. Thus, the pathognomonic signal detection with developed flexible OECMs has stepped forward to realize an intelligent wearable device.

Development of 'Artificial' Memristive Synapses Using Various sp2 C (Graphene-Like) and sp3 C (Diamond) Heterojunctions as Neuromorphic Devices Sanju Gupta[1,2]; [1]Gdansk University of Technology, Poland; [2]The Pennsylvania State University, United States

Inspired by human brain functionality and its low power consumption (10 W), memristors for neuromorphic computing have gained significance for implementing solid-state neurons and synapses due to their nanoscale footprint and reduced complexity. We report the fabrication of various carbon-based heterojunctions comprising graphene-like (sp^2C)-diamond (sp^3C) interfaces using microwave plasma-assisted chemical vapor deposition as "artificial" synapses, the key elements mimicking the characteristics of biological synapses and memory functions, that are game-changing energy saving devices. The resulting heterojunctions behave as memristors (*i.e.,* resistors with tunable memory) having multiple resistance states and nonvolatile memory functions, a phenomenon that refers to the ability of synapses (neuronal links) to adapt in response to an increased or decreased activity, essential to human memory and learning. We performed *I–V* characteristics in response to photoirradiation at 300 nm, 532 nm, and 633 nm from laser emitting diodes and temperature (up to 250 °C) exhibiting linearity and symmetry when subjected to identical input pulses, essential for their role in online training of neural networks. Interestingly, high or low resistance states (equivalent short-term and long-term potentiation) can be controlled by combined bias voltage and irradiation, giving a resistive switching ratio of $\sim 10^3$, observed in sparse materials and/or heterostructures. We attribute the observed behaviors to redox reaction at the sp^2-sp^3 interfaces and the role of hydrogen and oxygen movement by bias. Finally, heterostructure arrays could be usable as electrical and photo-controlled devices with potential switching, photo sensing (image sensors), and memory functions.

EL05.05.02

Large Area, Highly Deformable All-Solid Organic Synaptor Implemented by Gas Phase *In Situ* Ion-Doped Ultrathin Polyelectrolyte Youson Kim, Ji-Man Yu, Changhyeon Lee, Booseok Jung, Jin-Ki Kim, Joon-Kyu Han, Junyeong Yang, Seong-Yun Yun, Yang-Kyu Choi and Sung Gap Im; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The ion gel-based synaptic transistor (synaptor) mimics a biological synapse by regulating ion movement. Through ionic charge accumulation, which forms an electrical double layer (EDL) at the interface between the dielectric and semiconductor and is managed by gate biasing, the channel conductance is modulated. This process is similar to the biological nervous system, where ions like Ca2+, Na+, and K+ control the membrane potential of nerves. Nonetheless, ion-conductive materials face challenges such as long-term stability, large-scale integration, and effective ion doping strategies. Moreover, there is a demand for solid-state ionic conductors that provide mechanical flexibility and can be processed over large areas, properties that are essential for wearable electronics, which need to be stable for long-term use and capable of withstanding physical deformation. To address the aforementioned issues, a novel method for solid-state electrolyte synthesis, the in-situ ion-doped polyelectrolyte (i-IDOPE), has been proposed and utilized to demonstrate a bio-inspired organic synapse device (BioSyn). At the molecular scale, a polyelectrolyte containing the *tert*-amine cation, inspired by the neurotransmitter acetylcholine was synthesized using initiated chemical vapor deposition (iCVD) with *in-situ* doping, a one-step vapor-phase deposition used to fabricate solid-state electrolytes. This method resulted in an ultra-thin, but highly uniform and conformal solid-state electrolyte layer compatible with large-scale integration, a form that was not previously attainable. At a synapse scale, synapse functionality was replicated, including short-term and long-term synaptic plasticity (STSP and LTSP), along with a transformation from STSP to LTSP regulated

by pre-synaptic voltage spikes. On a system scale, a reflex in a peripheral nervous system was mimicked by mounting the BioSyns on various substrates such as rigid glass, flexible polyethylene naphthalate (PEN), and stretchable poly(styrene-ethylene-butylene-styrene) (SEBS) for a decentralized processing unit. Finally, an image classification ability of BioSyns was computed through semi-empirical simulations of MNIST pattern recognition, incorporating the measured LTSP characteristics from the BioSyns. The simulation confirmed that over 90% of accuracy was achieved even under bending and stretching conditions.

EL05.05.03

Unravelling Polarity Preference and Electrode Layer Interactions on Wurtzite Aluminum Nitride-Based Memristors for Neuromorphic Synapses

Zicong Marvin Wong, Gang Wu and Ramanarayan Hariharaputran; Agency for Science, Technology and Research, Singapore

Aluminum nitride (AlN) memristors show great promise for neuromorphic computing due to their exceptional properties, including ultrafast switching, low current requirements, high on/off ratios, and CMOS compatibility. These characteristics make them ideal for emulating artificial synapses, crucial components in neuromorphic systems. Optimizing device performance depends heavily on AlN surface polarity and understanding the interactions between AlN and electrode layers.

This study investigates the properties of electrode layers on AlN slabs and their influence on surface stability and polarity preferences. Using first-principles simulations, we calculate formation energies of various electrode layers on AlN slabs of each polarity and analyze the resulting trends. We also examine Bader charges of the electrode layers to elucidate interfacial interactions. Our results indicate that the interaction between electrode layers and AlN slabs is thermodynamically favorable and primarily electrostatic or ionic in nature. On Al-polar AlN slabs, the preferred stacking sequence of electrode layer elements aligns with the Wurtzite structure of the AlN slabs, minimizing lattice distortion and destabilization. We observe that the Born effective charge of interfacial atoms on AlN slabs varies with the electronegativity of electrode layer elements, potentially impacting interface polarization and piezoelectric properties, which could influence neuromorphic device performance.

Our findings suggest that electrodes with stabilized interaction can be designed on AlN slabs with preferred polarity by considering the electronegativity or Bader charges of the electrodes. This study provides valuable insights for optimizing AlN-based memristive devices in neuromorphic computing applications, contributing to the development of bioinspired information processing systems and adaptive bio-interfacing.

EL05.05.04

Enhanced Long-Term Synaptic Plasticity of Self-Rectifying Artificial Synapse Device with Pt/Ga_2O_3/NbO_x/ZnO/Pt Structure

Daejae Seo, Peter H. Chung and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Neuromorphic computing, which mimics neuron-synapse structure of human brain, has been explored extensively to overcome the limitation of Von-Neumann system. Neuromorphic systems require synapse devices that enable analog or multi-state weight update and stable long-term plasticity for energy-efficient training and inference operations. For the synapse device, memristor device which shows analog or multi-state resistance change has been investigated to mimic the biological synaptic weight update. Although the weight update behaviors have been demonstrated in a variety of memristors, it is still challenging to achieve long-term plasticity with good retention of weight states. In addition, self-rectifying characteristics of memristor synapse devices are highly beneficial to construct high-density crossbar array of synapse device because sneak path current problem can be effectively alleviated even without an additional selector device.[1]

In this study, high self-rectification ratio and long-term synaptic plasticity with good retention was demonstrated with Pt/Ga_2O_3/NbO_x/ZnO/Pt device. In this device, ZnO, a well-known n-type semiconductor, was employed to achieve large analog conductance change with respect to the redistribution of oxygen vacancies. Ga_2O_3 had a role to present self-rectifying characteristics owing to its ultrawide-bandgap of about 4.9eV.[2] NbO_x was used as a good oxygen ion reservoir due to its high oxygen binding energy. Ga_2O_3 and ZnO were deposited by RF magnetron sputtering in Ar condition, with the thickness of 10nm and 15nm, respectively. NbO_x was deposited by reactive sputtering using Nb target in Ar and O_2 condition, with the thickness of 18nm. Both top and bottom electrodes were deposited by E-beam evaporator. The device had circular shape with diameter of 100mm.

The current-voltage (*I-V*) sweep measurement showed that the conductance increased when the positive bias was applied and decreased upon applying negative bias. The current at +3V was about 10^4 times larger than the current level at -3V, exhibiting high self-rectifying characteristic of the device. In addition, pulse measurement showed analog conductance change with dynamic range of about 10 by applying 30 times of +3V pulses with a width of 0.64ms. Analog conductance modulation originated from the oxygen ion migration between ZnO and NbO_x. The increased conductance retained stably to have a long-term synaptic plasticity, remaining 10 times higher current level compared to the initial state after 30 min. This good retention properties came from the captured oxygen ions within NbO_x layer that has strong binding energy to oxygen. The performance of the device was evaluated with pattern recognition accuracy using CrossSim:Training.

The comparative study with two reference devices, i.e., Pt/NbO_x/ZnO/Pt and Pt/Ga_2O_3/ZnO/Pt, revealed that Pt/NbO_x/ZnO/Pt device had about 1000 times smaller self-rectification ratio, indicating that Ga_2O_3 layer was responsible for the self-rectifying property. Also, from much poorer retention of Pt/Ga_2O_3/ZnO/Pt with current which decayed to the initial current level in short time, it was confirmed that NbO_x layer was responsible for the long-term retention property as oxygen ion reservoir.

EL05.05.05

An Organic Platform with Neurotransmitter Closed-Loop Control for Actuation and Reinforcement Learning Tasks

Daniela Rana[1,2], Ugo Bruno[3,4], Claudia Lubrano[1,2] and Francesca Santoro[1,2,4]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany; [3]Istituto Italiano di Tecnologia, Italy; [4]Università degli Studi di Napoli Federico II, Italy

In the brain information is transferred between neurons at synapses, which are sites where chemical interactions between neurotransmitters and receptors generate an electrical potential. Furthermore, neurotransmitter availability can alter the electrochemical information transfer, influencing neuronal plasticity, which is the foundation of the brain's capacity for learning. Nowadays, brain-computer interfaces (BCIs) can be used to treat neuronal communication impairment, but bidirectional device-nervous system connectivity remains a barrier.

The most promising method for this is to exploit the parallel computing paradigm, which is inspired by the brain architecture. Organic electrochemical transistors (OECTs) based on PEDOT:PSS are good candidates for BCIs, because of their ionic-to-electronic signal transduction and biocompatibility[1,2].

In this work, we implemented an integrated organic platform that can work in tandem with mainstream silicon technologies to realize brain-inspired computing. After conditioning due to neurotransmitter oxidation[3], hydrogen peroxide allowed for the partial recovery of the PEDOT:PSS doping level. The artificial "synaptic weights", which were based on the PEDOT:PSS conductance, were adjusted to alter the electrical dynamics of the circuit, demonstrating the computational power of the closed-loop system implemented. Additionally, the same neurotransmitter-mediated OECT was used to connect the motors of a robotic hand to regulate the hand's opening and closing. This platform was included reinforcement learning for robotic hand gripping of balls of varying diameters. When the hand was not in contact with the ball, the punishment was expressed by injecting additional neurotransmitter; when the hand established a firm grasp, the reward was maintaining the motors in standby. The robotic hand had a sensor pressure applied to it, and as soon as the ball contacts its fingers, an Arduino board provided electrical feedback[4].

The same system could be adopted for other computational tasks, such as the stimulation of a biological neural network, in response to a specific range of neurotransmitters concentration and specific electrical activities.

By implementing local adaptive computing in brain computer interfaces, this closed-loop technology may one day be utilized to reestablish synaptic transmission.

Inkjet-Printed Ambipolar Vertical Organic Electrolyte-Gated Transistor with a Laser-Cut Channel for Synaptic Applications Juan Wang, Laura Teuerle, Li Chen and Hans Kleemann; Technische Universität Dresden, Germany

Significant progress has been made in developing bio-inspired synaptic systems and artificial multisensory neurons for memory and perception in recent years. In particular, the vertical electrolyte-gated transistor has gained considerable attention due to its unique features arising from ionic and/or electronic current modulation, such as high transconductance, and high operating frequency. These attributes make this device highly suitable for artificial synapse applications. The channel length (L) of the vertical electrolyte-gated transistor is determined by the vertical separation between the source and drain, which naturally corresponds to the thickness of the organic semiconductor. This feature allows for downscaling the ionic-electronic transport pathway to the hundred-nanometer range. However, the need for sophisticated nanolithography techniques in the fabrication process has hindered the large-scale commercial application of vertical electrolyte-gated transistors. In response to this challenge, we propose a simple device fabrication technique that utilizes inkjet printing and laser structuring to achieve high-performance ambipolar vertical electrolyte-gated transistors, demonstrating great promise for synaptic applications. The integration of inkjet printing and laser structuring techniques enables precisely patterned solid-state electrolytes, organic semiconductors, and gate contact, resulting in tunable transconductance and threshold voltage. We believe that this work presents a simple and effective fabrication protocol for devices, offering excellent application potential for vertical-channel organic electrolyte-gated transistors in large-scale commercial fields.

EL05.05.07

Self-Powered Dye-Sensitized Solar Cell-Based Synaptic Devices for Multi-Scale Time-Series Data Processing in Physical Reservoir Computing Hiroaki Komatsu, Norika Hosoda and Takashi Ikuno; Tokyo University of Science, Japan

Continuous monitoring and anomaly prediction of time-series data on infrastructures, natural environments, and human health using artificial intelligence (AI) is being developed. As the number of sensors increases, challenges such as higher network load, delaying data transfer, and increased power consumption on the server arise. To address these challenges, it is necessary to develop efficient in-sensor edge AI devices specialized for time-series data processing.
The optoelectronic artificial synapse, inspired by the human visual system, represents a novel device integrating AI functionalities into optical sensors. This device not only performs sensing but also has AI capabilities for pattern recognition and predictive analysis, enabling advanced data processing and decision-making. Notably, the application of optoelectronic artificial synapses in physical reservoir computing (PRC) has garnered interest as an AI device capable of efficiently processing time-series data.
Recent studies have demonstrated the efficacy of optoelectronic artificial synapses using materials such as InGaZnO[1], α-In_2Se_3[2], and GaOx[3] for PRC applications. However, conventional PRC systems with optoelectronic artificial synapses face challenges in adjusting response speeds. Fixed response speeds can decrease processing accuracy when analyzing phenomena with varying timescales. In addition, these devices operate based on photocurrent, leading to high power consumption due to the requirement of applying a bias voltage. Therefore, there is a need for photovoltaics-based artificial synapses with variable response speeds.
In this study, we propose a novel type of artificial synapse based on dye-sensitized solar cells (DSCs). This device can be driven by incident light input. Moreover, DSCs exhibit a unique characteristic where the response speed of the open-circuit voltage changes according to light intensity. Leveraging these features, we developed a self-powered artificial synapse with adjustable response speeds. This device is self-powered and exhibits synaptic properties such as paired-pulse facilitation (PPF) and paired-pulse depression (PPD) in response to varying light intensities. The PPF index, indicating the degree of facilitation, reached a maximum of 223%. Using a short-term memory task, we evaluated the time-series data processing performance for our PRC system. The results indicated that the pulse width (T_{pmax}), which achieves the maximum memory capacity, shortens as the light intensity increases. Specifically, when the light intensity increased from 0.075 to 10 mW, T_{pmax} decreased from 500 to 50 ms. This finding suggests that the response speed of our PRC system can be modulated by varying the light intensity. As a demonstration, we performed action motion recognition to estimate which action was being performed from videos of human movements such as bending, jumping, running, side-stepping, and waving. Our PRC system can classify human actions with 92% accuracy. In this session, we will discuss the correlation between the response speed of artificial synapses and their computational performance, focusing on the effect of light intensity on carrier transport.

Ionic-Electronic Coupled Polymer Semiconductor with Efficient Ion Transport and High Scalability for Neuromorphic Applications Hayoung Oh[1], Hyukmin Kweon[1], Yuchan Heo[2], Sebin Kim[3], Hayoung Lim[1], Won Bo Lee[3], BongSoo Kim[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Ulsan National Institute of

Science and Technology, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

Recently, efforts to overcome the limitations of high energy consumption because of the enhanced performance of electronic devices have emerged, with neuromorphic electronics based on parallel processing attracting attention as a new paradigm. Organic electrochemical transistors (OECTs) are promising candidates for neuromorphic electronics due to their ability to realize ion-to-electron transduction with low power consumption. Ion-to-electron transduction enables the implementation of ion-driven biological synaptic functions in OECTs. Since this transducing ability is determined by ionic currents in polymer semiconductor (PS), enhancing the flow of ionic circuits has been a major challenge. To address this, ion-compatible PS based on molecular tailoring methods such as side chain engineering has been intensively developed; however, limited scalability makes it difficult to apply them to practical neuromorphic devices.

In this study, to improve ion transport and scalability simultaneously in OECTs, we demonstrate ionic-electronic coupled PS (ICPS) utilizing ethylene oxide (EO)-integrated photo-crosslinkers. The formation of ICPS network occurs by reacting nitrene (-N) groups of the crosslinkers activated under UV light, with alkyl side chains of PS. This methodology provides an accelerating effect of ion transport via EO without affecting the crystalline structure of the PS. On the basis of this, the ICPS achieved signal amplification of ionic currents as the length of the EO moieties increased, implying that the ion transport properties of the ICPS are strongly affected by the EO moieties. The incorporation of EO also creates an environment in which interactions with anions are stabilized, forming pathways that enhance ion mobility, thereby improving the penetration and diffuse out rates of ions (<50 ms). Furthermore, as a result of the superior chemical endurance of ICPS, high-resolution patterning (<10 um) was implemented through direct photolithography that simplifies the process compared to photoresist-based lithography. Consequently, the ICPS not only facilitates ion transport without degradation of electronic performance but also successfully secures high-density patterns. This demonstrates that our material design strategy for the ICPS can provide a new direction for the development of scalable, ion-compatible PS for integrated neuromorphic disciplines.

Electrolyte Gating WO_3 Synaptic Transistor with Crossbar Array Structure Jiyeon Kim, Minho Jin, Haeyeon Lee, Jiho Lee, Jong Chan Shin, Chan Lee, Hyunkyu Yang and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Neuromorphic computing is gaining attention compared to conventional computing systems based on the von Neumann architecture, which have limitations in processing speed due to delays when massive amounts of data are transferred between the central processing unit (CPU) and memory. To overcome this von Neumann bottleneck, synaptic devices that mimic the human brain have become attractive in neuromorphic systems. Especially, many researchers have been interested in electrolyte-gating transistors (EGTs) due to their low switching voltage, enabling low-power consuming devices. Also, their non-volatile memory characteristics can emulate potentiation in synapse, synaptic behaviors such as synaptic plasticity and linearity. Synaptic plasticity allows the human brain to process the signals and store information simultaneously. Biological plasticity can be achieved by converting connection strength between synapses, called synaptic weight, in response to neural activities. Linearity can be confirmed from the shape of the long-term potentiation (LTP) and long-term depression (LTD) region. Effectively emulating the biological synaptic behaviors in electronic devices would help to meet the needs of fast and efficient neuromorphic learning devices.

In this study, tungsten oxide and nafion were selected as a channel layer and electrolyte to implement EGTs, respectively. Tungsten oxide has a structural advantage because the vacant sites provide space for ion intercalation and shows electrochromic properties, coloring and bleaching by movement of ions between electrolyte and channel. When the ions in the electrolyte inserted into channel layer, coloration occurs. In

contrast, when the ions extracted from the channel, bleaching occurs. This reaction is electrochemical and reversible reaction, which are related to memory characteristics. Nafion has a high chemical stability and excellent ionic conductivity. Compared to proton, many studies have used Li ion for EGTs but Li ion has a fatal disadvantage, which is not complementary metal–oxide–semiconductor (CMOS) compatible. In addition, most of the previous studies have been focused on interpreting the characteristics of unit device but it is not suitable for industrial applications requiring arrays. By arranging transistors in array, each device can be operated independently, suggesting possibility of data visualization. In case of proton conducting EGTs, there are several limitations to make arrays. First of all, there are only few options on materials and engineering for proton gating electrolyte. Also, considering array of nafion electrolyte, it requires a delicate process such as photolithography to implement array but it is difficult because nafion dissolves in acetone. Herein, we proposed nafion patterning method and EGT arrays. Due to the electrochromic properties of tungsten oxide, reversible reaction can be shown between tungsten oxide and proton cation, which can be extended to non-volatile memory characteristics and synaptic behaviors. Furthermore, three-terminal transistor array was arranged with nafion electrolyte patterning. Our research provides the framework for oxide semiconductor EGTs with polymer electrolyte, requiring further research for real application in brain-imitating neuromorphic system.

EL05.05.10

Biopolymer-Based Hyperstable Multi-Layered Artificial Synapse with Ultra-Low Energy Consumption Yoojin Chang, Sangyun Na, Yun Goo Ro and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Recently, artificial synapses have attracted significant interest for mimicking the synaptic characteristics of the biological neural system, which are crucial for learning processes in neuroprosthetics, brain-machine interfaces, and deep learning technology. By emulating the neurotransmitter-based biological signal transmission system, artificial synapses have been achieved by integrating multi-terminal transistors or two-terminal memristors, which can conduct synaptic characteristics *via* migration and accumulation of ions in response to various external stimuli including electric fields, pressure, and light. Multi-terminal transistors in three-electrode systems (gate, source, and drain) obtain synaptic characteristics by regulating the conductance of ionic channels between source and drain electrodes, resulting in non-volatile memory. Because of their structural similarity with biological neural systems in terms of ion migration from source to drain, transistor systems have been widely applied in the development of artificial synapses. However, transistor structures require complicated fabrication processes and consume higher energy than biological synapses owing to the necessity of a gate electrode. Alternatively, two-terminal memristors in metal-resistive layer-metal structures achieve synaptic characteristics by regulating ion flux between metals. Memristor structures offer advantages such as simple device structure with facile fabrication compared to multi-terminal transistors, and low energy consumption owing to robust resistance tunability, enabled by enhanced ion conductivity through ion-doped semiconductors or polymers. Meanwhile, the necessity for developing biopolymers has been addressed owing to the increasing disposal of electronic devices (E-waste) containing plastics and toxic metals, which cause environmental pollution and ecocide, posing threats to both humans and nature. Despite the advantage of biopolymers, such as their abundance in nature and hydrophilic functional groups that facilitate ion migration, their susceptibility to moisture and heat has hindered their utilization in electronic devices.

Here, we develop a biopolymer-based hyperstable and low-energy modulated multi-layered artificial synapse (M-AS) based on a two-terminal structure. The artificial synapse is constructed with a stacked ion active layer (IAL)-ion binding layer (IBL)-ion active layer (IAL) structure, where IALs are crosslinked chitosan (CS) and guar gum (GG) double network with NaCl ions, and the IBL is a dielectric cellulose acetate (CA) that provides ion accumulating sites through ion-dipole coupling (IDC). Since CS and GG polymers assigned their hydrogen bonding to crosslinking, crosslinked CS/GG is less susceptible to moisture, achieving hyperstability. Additionally, IDC at the interface of IAL-IBL facilitates ion accumulation to generate synaptic characteristics including paired-pulse facilitation (PPF) and long-term plasticity (LTP), which can be improved by introducing CA with high dielectric properties. Especially, due to the utilization of highly mobile ions (NaCl) into the IALs to function as neurotransmitters, an extremely low threshold voltage (20 μV) is enough to operate M-AS with remarkably low energy consumption (0.85 fJ), which is lower than that of a biological synapse. Finally, our multi-layered artificial synapse demonstrates an artificial injury system responsive to temperature changes by integrating a thermistor as a mechanoreceptor and robotics to emulate biological responses to injuries such as burns and frostbite. This system effectively alerts to injuries via learning processes, with the severity of injury indicated by the number of activated LEDs and the healing process indicated by the retention of LED illustration.

Planar Ionotronic OECTs—Memtransistor Performance and Energy-Efficient Neuromorphic Functionality

Muhammed S. E and Bikas C. Das; IISER Thiruvananthapuram, India

The von Neumann bottleneck in conventional computing restricts the development of artificial intelligence (AI) systems by creating inefficiencies in data transfer and energy consumption. To address this, researchers are inspired to develop electronic devices similar to the biological synapse, which connect neurons and transmit signals efficiently through neurotransmitter release. Analogous to synapse, ionotronic memtransistor can emulate similar actions by the movement of ionic species under the influence of an electric field. Thus, building bionic neural networks and simulating synapses with ionotronic devices provides a new avenue for the realization of hardware-based AI. Here, we have fabricated a planar ionotronic organic electrochemical transistor (IOECT) by using ethyl viologen diperchlorate ($EV(ClO_4)_2$) in poly ethylene oxide (PEO) matrix as a solid-state redox electrolyte and DPP-DTT as the semiconducting channel to emulate the synaptic functionalities. The IOECT device shows good saturation current in the output characteristics with a current ON/OFF ratio of 10^8 and gate leakage current as low as 50 nA. Impedance spectroscopy and Raman scattering analysis at various biasing conditions were used to explain the mechanism of operation of the device. The device's fast response time in microseconds allows for energy-efficient operation, resulting in a 15.1 femtojoule (fJ) energy usage per synaptic event. Various synaptic functionalities were obtained, including four types of STDP Hebbian learning rule curves. More than 1000 distinct conductance states were tuned for potentiation and depression to simulate artificial neural network (ANN) pattern recognition algorithm with an efficiency of 98% for MNIST database and 88% for FMNIST database. Thus, our device opens a new paradigm for energy-efficient brain-inspired neuromorphic computing.

EL05.05.12

Enhanced Gas Sensitivity in Organic Field-Effect Transistors Comprising High-Surface Area Expanded Poly(tetrafluoroethylene) Membrane Gate Dielectrics

Christopher R. Bond and Howard E. Katz; Johns Hopkins University, United States

Organic field-effect transistors (OFETs) were fabricated using three high-surface area and flexible expanded-poly(tetrafluoroethylene) (ePTFE) membranes in gate dielectrics, along with the semiconducting polymer poly[2,5-bis(2-octyldodecyl)pyrrolo[3,4-*c*]pyrrole-1,4(2*H*,5*H*)-dione-3,6-diyl)-*alt*-(2,2':5',2":5",2'"-quaterthiophen-5,5'"-diyl)] (PDPP4T). The transistor behavior of these devices was investigated following annealing at 50, 100, 150, and 200 °C, all sustained for one hour. For annealing temperatures above 50 °C, the OFETs displayed improved transistor behavior and a significant increase in output current while maintaining similar magnitudes of threshold voltage shifts when subjected to static voltage compared to those kept at ambient temperature. Responses of OFETs to NO_2 gas were also tested as a further characterization and for possible applications. The ePTFE–PDPP4T interface of each membrane was characterized via scanning electron microscopy for all four annealing temperatures to derive a model for the hole mobility of the ePTFE–PDPP4T OFETs that accounts for the microporous structure of the ePTFE and consequently adjusts the channel width of the OFET. Using this model, a maximum hole mobility of 1.8 ± 1.0 cm^2/V-s was calculated for the polymer in an ePTFE–PDPP4T OFET annealed at 200 °C, whereas a PDPP4T OFET using only the native silicon wafer oxide as a gate dielectric exhibited a hole mobility of just 0.09 ± 0.03 cm^2/V-s at the same annealing condition. This work demonstrates that responsive semiconducting polymer films can be deposited on nominally nonwetting and extremely bendable membranes, and the charge carrier mobility can be significantly increased compared to their as-prepared state by using thermally durable polymer membranes with unique microstructures as gate dielectrics. This work also provides a unique approach towards the fabrication of high-performance, low-cost flexible electronics which could be transferrable to other non-PTFE polymer membrane dielectrics.

EL05.05.13

Investigation of Ion-Dipole Interaction in Ion-Gated Synaptic Transistors Incorporating Interfacial Fluorinated Molecules Minho Jin and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Electrolyte-gated transistors (EGTs) have been emerged as candidates for synaptic transistors in analog computing due to their outstanding characteristic of high energy efficency, fast computing speed, and potential for a wide range of applications. However, EGTs encounter a critical limitation into the application in analog computing systems, characterized by abrupt changes in ion movement under external electric fields. Also, the gating effect by ions is determined by the ions present at the channel/electrolyte interface, and such analysis and understanding in devices are still lacking. Therefore, considering this inherent nature in EGTs is crucial and requires a comprehensive understanding of electrostatic interactions to precisely modulate ion movement at the interaface.

In this study, we propose a novel solution focusing on ion-dipole interaction by introducing Heneicosafluorododecylphosphonic acid (DDPA) as a interfacial ion receptor on the InGaZnO oxide semiconductor channel. The advantage of using DDPA lies in its structure, which includes 9 fluoroalkyl chains and a trifluoromethyl group. This configuration creates a significant dipole moment, facilitating strong coulombic interactions with lithium ions, even with a molecular length of ~2 nm. This approach induces strong ion-dipole forces between lithium ions and the negatively charged DDPA at the channel/electrolyte interface. The incorporation of DDPA enables the trapping of lithium ions at the van der Waals (vdW) gap between each DDPA molecules. Consequently, lithium EGTs incorporating DDPA exhibit exceptional synaptic characteristics, such as nearly linear conductance switching and long-term retention exceeding 30 minutes, even at switching voltages below 3 V.

Furthermore, chemical analysis and density functional theory (DFT) calculations demonstrate that DDPA can facilitate sequential lithium ion trapping at the interface through ion-dipole interaction. We found that lithium is most energetically stable when positioned within the vdW gap between DDPA molecules, overcoming the vdW forces within the gap. Additionally, this resulted in observable changes in the binding energy of F 1s, as measured by X-ray Photoelectron Spectroscopy. Therefore, we confirmed that analysis results were consistent with claims regarding the effects of DDPA. This presented novel method provides ideas for modulating ion movement in EGTs, enhancing their potential for use in applications for multimodal analog computing.

Intelligent In-Cell Electrophysiology—Reconstructing Intracellular Action Potentials Using a Physics-Informed Deep Learning Model Trained on Nanoelectrode Array Recordings Keivan Rahmani[1], Ethan Foster[2], Ching Ting Tsai[2], Yang Yang[2], Aayush Gupta[1], Bianxiao Cui[2], Rose Yu[1], Francesca Santoro[3], Csaba Forro[2] and Zeinab Jahed[1]; [1]University of California, San Diego, United States; [2]Stanford University, United States; [3]RWTH Aachen University, Germany

Intracellular electrophysiology, crucial in neuroscience, cardiology, and pharmacology, explores and provides insights into cellular electrical properties. Traditional techniques like patch-clamp are precise but invasive and low-throughput, necessitating the development of alternative methods that offer similar precision with higher throughput and less invasiveness.

Nanoelectrode Arrays (NEAs) comprise nano-scale electrodes capable of recording extracellular signals and, through methods such as electroporation, gain transient intracellular access. NEAs offer a high-throughput alternative for recording intracellular (iAP) and extracellular action potentials (eAP). However, accessing intracellular potentials with NEAs remains a challenge due to their limited control.

In this study we introduce a technique for intracellular electrophysiology supported by artificial intelligence (AI) that leverages thousands of synchronous eAP and iAP pairs collected from stem-cell-derived cardiomyocytes on NEAs (under revision in Nature Communications). Our method of data collection utilized neighboring channel pairs on the NEA, capturing their corresponding eAP and iAP. We validated our method by first comparing iAP waveforms simultaneously collected from NEAs and patch-clamp from the same cells. Despite some discrepancies in amplitude, normalization confirmed the accuracy of NEA recordings. Furthermore, by analyzing action potentials from two closely positioned channels on an NEA, we confirmed that these recordings are almost identical, effectively representing each other. This finding underpinned our strategy of using eAP and iAP pairs from adjacent channels as representatives of each other. These eAP-iAP pairs were obtained by administering various ion-channel-affecting drugs such as propranolol, dofetilide, flecainide, and nifedipine. Analyzing the collected pairs revealed high correlations between eAP and iAP waveform features like amplitude and spiking velocity, indicating that eAPs could effectively predict intracellular shapes.

Next, we used the collected data to train the Physics-Informed Attention-UNET (PIA-UNET). Our model integrates a modified Aliev-Panfilov model into its loss function to ensure the physiological plausibility of the reconstructed signals. This hybrid approach combines the strengths of deep learning with the physics of electrophysiological modeling, allowing for accurate and robust reconstruction of iAP waveforms from eAP recordings. The PIA-UNET model demonstrated high accuracy, with a coefficient of determination (r2 = 0.99) between predicted and actual iAP values, and a mean absolute error (MAE) of 0.028 ± 0.006 on the test set.

We demonstrated our model's potential for non-invasive, long-term, and high-throughput assessments of drug cardiotoxicity. Our model accurately reconstructs iAPs from non-invasive eAP recordings, enabling detailed drug effect studies on cardiac cells—key for cardiotoxicity screening. In experiments, we showed its capability to assess changes in iAP waveforms over time when exposed to a shape-altering drug like propranolol, not included in the training data. Our model reliably detected changes in action potential durations (APDs) across multiple cells, providing population-level drug effect insights.

Although this demonstrates one specific application, it opens the door for future research in electrophysiology. The approach can be extended to various electrogenic cell types and drug interactions. Expanding the dataset to encompass a broader range of cellular responses and pharmacological compounds will enhance the model’s robustness and applicability. The integration of AI with NEA technology marks a significant advancement, offering a non-invasive, high-throughput, and precise tool for intracellular electrophysiology studies. This holds promise for advancing our understanding of cellular electrical properties and improving drug safety assessments.

Poly(3-alkoxythiophene)-Based Block Copolymer as Organic Electrochemical Transistor Material

Junfu Tian[1] and Iain McCulloch[1,2]; [1]University of Oxford, United Kingdom; [2]Princeton University, United States

In recent years, there had been a burgeoning interest in organic electrochemical transistors in due to their unique ability to modulate charge carrier conductivity upon electrochemical doping, rendering these devices useful in bio-analyte detection, neuromorphic computing, electrocardiographic sensing and many other biomedical applications [1]. To enhance ionic affinity in aqueous electrolyte, many OECT-active polymers, such as pgBTTT [2] and polylactam-based P75 [3], are grafted with oligoethylene glycol side chain to facilitate ion penetration. Glycolation has been established as a successful strategy for OECT material design, but heavily glycolated polymers have been reported to undergo irreversible swelling during device operation, impose limited solubility in the polymerisation solvent and result in less-ordered microstructure compared to alkylated analogues [4]. Side-chain free polyarenes such as BBL [5] and PBFDO [6] have been explored, but processing and fabrication of these materials generally requires overcoming their limited solubility in common organic solvents.

Herein, we developed a series of novel block copolymers comprising an electroactive poly(3-alkoxythiophene) (P3OAT) block and a flexible polymer block. Serendipitously, pristine P3OAT can be electrochemically doped in aqueous electrolyte, possibly owning to its high lying HOMO energy level and mesoporous film structure. However, its operation in OECT device is not very reversible and possesses a slow turn-on time (τ_{on}). PEGylation of poly(3-alkoxythiophene) was shown to enhance its hydrophilicity and ionic affinity, resulting in faster τ_{on} and higher volumetric capacitance, but slightly lowering carrier mobility due to its insulating nature. In addition, we explored the anchorage of base-labile poly(lactide) block. Following etching, the fabricated film possesses microstructure with large pores to mediate ion entry, with pore dimensions controlled by the degree of polymerization (DP) of labile block.

Multifunctional Logic and Synaptic Switchable Devices Based on Polymer Blended Perovskites Inspired by the Optic Nerves of Drosophil Dante D. Ahn[1,2], Woochul Kim[1], Minz Lee[1] and Yusin Pak[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Drosophila's eyes are known for their exceptional sensitivity to moving objects, significantly higher than that of human eyes. This study aims to develop polymer blended perovskite optoelectronic devices with motion detection and self-computation capabilities, inspired by the visual system of Drosophila. By mimicking these natural visual functions, we aim to contribute to the development of high-performance artificial vision systems.

Inspired by the structure of T4 and T5 neurons in the optic nerves of Drosophila, which detect movement, we designed an asymmetric electrode structure that exhibits bipolar photoresponse in a single device. This device shows bipolar photoresponse depending on the position where light is incident, enabling the implementation of six linear logic functions. Logical operations play a crucial role in artificial vision systems, allowing for the effective detection and differentiation of moving objects. Furthermore, to implement nonlinear logic operations (such as XOR and XNOR operations), we developed a triple hybrid material by blending polymers with perovskite. The blended polymer acts as an artificial trap site within the material, extracting an opposite polarity voltage when weak light is applied as the photogenerated charges fill the trap, and extracting the original polarity voltage when strong light is applied as the trap is quickly filled.

Using bipolar photoresponse, we successfully implemented eight multifunctional logic gates, operating linearly and non-linearly, in a single device. These multifunctional logic gates can function effectively in both static and dynamic environments within artificial vision systems. Specifically, they allow for the switching between logic gate and synaptic operations based on the signal interval, operating as logic gates in static environments and as synapses in dynamic environments.

This functional flexibility enhances the adaptability of artificial vision systems, broadening their applicability across various environments. For instance, in static environments, the system can accurately recognize the shape and position of objects, while in dynamic environments, it can respond sensitively to movements and changes. The polymer blended perovskite optoelectronic device developed in this study offers the advantage of performing complex visual functions simultaneously, unlike traditional single-function devices. This can significantly improve the efficiency and performance of artificial vision systems, suggesting innovative applications in fields such as autonomous vehicles, robotic vision systems, and medical image analysis. Additionally, the design of this device, utilizing asymmetric electrode structures and bipolar photoresponse mechanisms, holds potential for application to other types of sensors and devices. This could contribute to the development of various types of artificial sensory systems.

The polymer blended perovskite optoelectronic device developed in this study successfully implemented motion detection and self-computation functions in artificial vision systems. This is expected to make a significant contribution to the development of future artificial intelligence vision systems. In particular, the implementation of multifunctional logic gates represents a crucial technological advancement that can greatly enhance the adaptability and efficiency of artificial vision systems.

EL05.05.17

Realizing the Gestalt Principle of Closure with Ultra-High Denisty Three-Dimensionally Integrated Perovskite Nanowire Array Based Artificial Neural Network

Swapnadeep Poddar and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

The application of halide perovskite (HP) thin-film based resistive random access memories (RRAMs), in the domain of neuromorphic computing, has been hindered by the material and electrical instability of HP thin-films, leading to less than ideal performance metrics such as poor retention, jittery conductance levels and sub-par endurance. To overcome these limitations, we engineered a unique switching matrix that substitutes the thin-film design with vertically arranged, three-dimensional, high-density monocrystalline HP nanowires (NWs), which are embedded in a porous alumina membrane (PAM) and enclosed between electrical contacts.

Specifically, we developed robust, lead-free, HP based artificial synapses utilizing monocrystalline, ultra-high density (10^{10} cm^{-2}) methyl ammonium bismuth iodide ($MA_3Bi_2I_9$ or MBI) nanowires (NWs) rooted in a nano-engineered PAM forming a stable structure that enhances the synaptic and neuromorphic device performance. This innovative approach offers outstanding passivation, providing the necessary electrical, thermal and material stability to the environmentally sensitive HP by significantly minimizing surface diffusion pathways, thus preventing moisture-induced damage.

The MBI NW devices exhibited two key behaviors: short-term plasticity (STP) and long-term potentiation (LTP). These behaviors were elicited in response to input sensory electrical pulses of varying amplitude, duration, and interval. The devices transitioned from STP to LTP mode with an increased number of stimulating pulses and in the LTP mode showed a response to the rate and number of incoming LTP pulses and the pre-/postsynaptic delay between pulses.

The origin of the conductivity change in the monocrystalline MBI NWs was traced through first principle ab initio molecular dynamics simulations. The simulations revealed that the rotation of the MA+ clusters in the MBI crystal structure results in charge transfer between MA^+ and $Bi_2I_9^{3-}$, leading to the observed plasticity or gradual conductivity change.

The MBI NW devices demonstrated at least 40 accessible conductance states which could be retained for more than 10^5 seconds. These states showed minimal jitter, with a variation (2σ where 'σ' is the standard deviation/mean) of less than 10%, and an endurance of approximately 10^5 cycles.

We further developed a single-layered artificial neural network (ANN), utilizing MBI NW synapses as the unit blocks. This ANN was trained using synaptic weights obtained from delta rule-based simulations for a letter recognition scheme. The ANN successfully discriminated between fragmented and non-fragmented letters, demonstrating the potential for pattern recognition tasks emulating human cognition. Additionally, through the

use of the MBI NW-based ANN, it was experimentally shown that as more parts of a single letter are missing, the ability of the MBI NW artificial synapses to differentiate and maintain synaptic connectivity decreases, similar to our human perceptual tendencies.
In conclusion, this study not only pushes the boundaries of halide perovskites in neuromorphic processing tasks but also exemplifies the Gestalt principle of closure. This principle posits that humans tend to perceive incomplete or fragmented forms as complete, thereby bridging the gaps in sensory input. The successful implementation of this principle in a letter recognition scheme using an MBI NWs-based ANN demonstrates the potential for neuromorphic hardware to perform complex processing tasks that emulate human cognitive processes.

Electron-Free Theranostic Smart Contact Lens for Monitoring and Self-Administration of Intraocular Pressure in Glaucoma Yuting Cai and Ana Claudia Arias; University of California, Berkeley, United States

Glaucoma is a significant global health concern that will damage the optic nerve, often due to high eye pressure, leading to vision loss or blindness if untreated. Approximately 76 million people worldwide were estimated to have glaucoma in 2020, and this number is projected to increase to over 111 million by 2040 due to aging populations. The emergence of smart contact lenses (SCLs) as an innovative wearable medical platform has seamlessly integrated intraocular pressure (IOP) monitoring and management into advanced glaucoma care. Researchers have embedded various strain sensors into contact lenses to manually release anti-glaucoma drugs based on changes in intraocular pressure. However, prior investigations primarily focused on electronic SCLs incorporating data-transfer circuits, metallic electrodes, rigid chip/antenna, and other external receivers close to the eye. These components compromise user comfort, biosafety, and visibility within the field of vision. The complex fabrication process will also make it unaffordable for most patients.More importantly, existing SCLs cannot automatically release drugs to regulate changes in intraocular pressure based on variations in IOP. Because most glaucoma patients are elderly, manually operating these SCLs to release drugs becomes exceedingly challenging. Here, we demonstrate an all-polymer theranostic SCL (AP-TCL) integrated with a highly sensitive microfluidic IOP monitor and a multi-stage drug delivery system for monitoring and programmed self-administration of IOP. The microfluidic IOP monitor shows high sensitivity, good reversibility, and biocompatibility, while the therapeutic system can be utilized for on-demand and programmable automatic delivery of IOP-lowering medications when IOP exceeds the normal range. The AP-TCL system offers a cost-effective and fully biocompatible platform for personalized glaucoma management, with minimal risk of complications.

EL05.05.19

Exclusive Sensing of Biotoxic Aromatic Compounds Through Metastable Catalytic Material-Based Device
Tiago Elias Abi-Ramia Silva, Matteo D'Andria, Tim Rothacher and Andreas Güntner; ETH Zürich, Switzerland

Chronic exposure to volatile organic compounds (VOCs) presents a significant occupational hazard.[1] Specifically, benzene is a VOC with strict exposure limits by the World Health Organization due to its elevated biotoxicity.[2] Detecting benzene at the required parts-per-billion (ppb) levels is challenging due to the presence of chemically similar, more concentrated confounders (e.g., toluene and xylene). Here, we present a detector capable of measuring benzene down to 100 ppb with high selectivity over toluene and xylene. It is based on metastable $CoCu_2O_3$ nanocrystals[3] captured by combustion-aerosol technology, as confirmed by x-ray diffraction and transmission electron microscopy. When combined with a chemoresistive sensor, $CoCu_2O_3$ can filter various VOCs while benzene remains unscathed and can be accurately quantified, as confirmed by catalytic conversion measurements and mass spectrometry. Other commonly applied solvents (e.g., acetone and IPA) were removed at concentrations three orders of magnitude higher than benzene. The resulting detector works even under challenging, realistic conditions, as will be demonstrated in my presentation.

EL05.05.20

Doped Organic Electrochemical Transistors—Effect on Channel/Electrodes Interfaces (Contact Resistance)

Luis Abraham Lozano Hernandez[1], Patrice Rannou[2], Yvan Bonnassieux[3] and Sébastien Sanaur[1]; [1]École des Mines de Saint-Étienne, France; [2]Grenoble INP, France; [3]LPICM, Ecole Polytechnique, France

Organic electrochemical transistors (OECTs) are being widely studied due to their numerous applications such as organic bioelectronics, neuromorphic systems, sensors, etc. OECTs transport benefits of both electrons and ions due to the organic mixed ionic-electronic conductors (OMIECs) that allow ions to penetrate the channel throughout its volume. However, the design rules to fully optimize the OECTs are still unclear. It is possible to “tune” the performance, this is the transconductance (g_m), of OECTs according to the Bernard model for variations in channel length, thickness and width, but effects due channel morphology/structure is not considered. The effect of gate-voltage-dependent resistance, better known as contact resistance (R_C), is critical to performance. This parasitic R_C can be obtained using the transmission-line method (TLM) and is present in the interface between the source/drain electrodes and the channel. Here results of the doping effect of Lithium bis(trifluoromethanesulfonyl)imide (LiTFSi) on R_C, more specifically in the source-drain/channel interfaces, are analyzed. Unlike organic field-effect transistors (OFETs) in which through molecular contact doping (a dopant layer is deposited between the channel and the metallic contacts) or OECTs using source/drain-electrode surface modification , we use LiTFSi in ultra-low quantities. This ultra-low LiTFSi content is defined by the ratio between the number of LiTFSi molecules and the number of olygo(ethylene-glycol) (OEG). By introducing this LiTFSi in the bulk of the channel, the R_C is enhanced in several orders. Our results showed that an ultra-low presence of LiTFSi improves (reduces) the R_C by ~ 1-2 orders of magnitude. This R_C improvement has been observed in p-type (p(g2T-T)) and n-type (p(gNDI-gT2)) polymers and can be reduced to very low values of approximately 0.002 Ω cm. Both polymers present OEG chains that facilitate the transport of Li^+ ions through the bulk of the channel and could lead to the explanation for this R_C improvement. On the other hand, in some devices the performance (transconductance) increases significantly up to 3 times due this low R_C values.

EL05.05.21

Decoding Silent Speech Cues for Efficient Human-Robot Collaborations

Penghao Dong and Shanshan Yao; Stony Brook University, The State University of New York, United States

Silent speech interfaces offer an alternative and efficient communication modality for individuals with voice disorders and when the vocalized speech communication is compromised by noisy environments. Despite the recent progress in developing silent speech interfaces, these systems face several challenges that prevent their wide acceptance, such as bulkiness, obtrusiveness, and immobility. Herein, we present the material optimization, structural design, deep learning algorithm, and system integration of mechanically and visually unobtrusive silent speech interfaces that can realize both speaker identification and speech content identification. Conformal,

transparent, and self-adhesive electromyography electrode arrays are designed for capturing speech-relevant muscle activities. Temporal convolutional networks are employed for recognizing speakers and converting sensing signals into spoken content. The resulting silent speech interfaces achieve a 97.5% speaker classification accuracy and 91.5% keyword classification accuracy using four electrodes. We further integrate the speech interface with an optical hand-tracking system and a robotic manipulator for human-robot collaborations in both assembly and disassembly processes. The integrated system enables the control of the robot manipulator by silent speech and facilitates the hand-over process by hand motion trajectory detection. The developed framework facilitates natural robot control in noisy environments and lays the ground for collaborative human-robot tasks involving multiple human operators.

EL05.05.22

The Design and Development of a Magnetic Particle Imaging System for Local Field Stimulation Xavier Smith; Massachusetts Institute of Technology, United States

Acute, non-invasive multi-domain stimulation and recording techniques permit functional spatiotemporal and electrophysiological reconstructions of neurobiological systems within the human body, giving us valuable tools to mechanistically describe normal and dysfunctional neurological human behavior. An avenue that shows promise towards investigating this approach lies within high-intensity, radio-frequency magnetic fields, due to the weak diamagnetic response of lipid content and water and negligible attenuation due to its centimeter-ranged skin depth in the radio-frequency range, respectively. One emerging, adjacent application that meets these requirements is a tomographic contrast imaging technique called magnetic particle imaging. Using high-intensity (~40mT), low frequency (0-50Hz) external magnetic “focus” fields, the technique induces the non-linear magnetization response of superparamagnetic iron-oxide nanoparticles to create a point-spread function over a field of volume with a spatial aperture inducing a linear magnetization response called the field-free region. The field-free region is rastered over the field of volume with a high-intensity, high-frequency external magnetic “drive” field, and the time-varying magnetization response is recorded and deconvolved from the linear shift-invariant system. While recent advances in magnetic particle imaging have been focused on expanding the benchmark resolution in the sub centimeter range of the field-free region over rat-sized organs of interest , there remains a gap in implementation of utilizing the high spatiotemporal resolution technique to apply local neuromodulatory stimulation using magnetic nanotransducers with spatial precision directly proportional to the size of the field-free region. Results have shown that nanoparticles exhibiting magnetoelectric transduction techniques respond to external fields of 10-50mT and 150kHz, producing voltages enabling local field stimulation, highlighting the specific requirements for the construction and optimization of the magnetic particle imaging technique. Here we present the design, implementation, and analysis of a three-dimensional magnetic particle imaging system engineered specifically to operate at 150kHz for providing 40mT to magnetic nanotransducers over a field of volume of ~3cm by 3cm by 3cm. The preliminary work detailed here will highlight the analysis of the hysteretic and relaxation dynamics influencing the geometric and electromagnetic design decisions behind the development of the system. Experimental structures for grid rasterization verification will be described, as well as a detailed model of in-vivo particle concentration, targeting, and local field potential verification. These analysis techniques will be paired with staple reconstruction algorithms to handle low-rank matrices due to ambient thermal fluctuations. We offer a design and implementation of a novel technique to probe neurobiological systems of interest, allowing a more precise and functionally accurate non-invasive tool to guide the development of effective neuromodulatory techniques.

EL05.05.23

Recreating the Biological Steps of Viral Infection on a Cell-Free Bioelectronic Platform to Profile Viral Variants of Concern Zhongmou Chao, Ekaterina Selivanovitch and Susan Daniel; Cornell University, United

States

RNA viruses such as SARS-CoV-2 and influenza frequently mutate due to they lack of error-repair mechanisms while replicating the RNA genome. To assist speeding up the societal response over emerging viruses of concern, platforms that can study the infection pathway of a virus and rapidly determine its propensity for infection are needed. We have recently developed a cell-free bioelectronic platform based on supported lipid bilayers (SLBs) to recreate the entry pathways of SARS-CoV-2, and have accurately quantified the fusogenicities of different mutants by the electrical signals that matches with previous reports. Our results suggest the specific binding between Spike protein containing viral pesudoparticles and SLBs recapitulated with ACE2 receptors does not change membrane resistance, while the fusion events catalyzed by proteases such as cathepsin and TMRPSS2 increase membrane resistance significantly. Not limited to SARS-CoV-2, our system also shows promises in detecting the fusion between live measles viruses and cell-free expressed influenza viruses with SLBs, confirming the robustness and customizability of SLB-on-electrode platform in studying the early steps of viral entry into host cells.

EL05.05.24

A Stretchable Low Hysteresis Capacitive Sensor for Dynamic Muscle Monitoring in Sports and Rehabilitation

Jiawei Tan, Mahammadreza Bahramian, Kaiji Zhang, Junjie Fang, Murtadha Al Msari, Andre Li, Katherine Lim, Thoun Nandi, Zelo Jade and Sam Emaminejad; University of California, Los Angeles, United States

In fields such as sports and rehabilitation, monitoring muscle function is essential for preventing injury, optimizing performance, and ensuring the recovery of damaged muscles. However, current muscle monitoring techniques often rely on rigid or bulky sensors that are not well-suited for dynamic tissue deformation. This mechanical mismatch can lead to inaccurate readings or discomfort during use. Therefore, developing a soft, stretchable, and durable sensor is key to enhancing muscle monitoring applications.

In this study, we present a novel stretchable capacitive sensor designed specifically for muscle force gauging. The sensor employs a sandwich structure consisting of stretchable elastomeric barriers (SEBs) as the middle layer and stretchable silver (Ag) paste as the conductive elements on either side. The stretchable capacitive sensor utilizes a sandwich structure to balance mechanical flexibility with reliable electrical performance. At the core of this structure is the SEB layer, which serves as a dielectric medium. This middle layer provides mechanical decoupling, allowing the sensor to stretch and deform along with the muscle tissue while maintaining stable capacitance. On either side of the SEB, a stretchable Ag paste is used to form the conductive layers. These layers are crucial for capturing changes in capacitance due to muscle deformation, enabling the sensor to function as a muscle force gauge.

To validate the performance of the stretchable capacitive sensor, we conducted a series of in vitro tests. When subjected to strain, the sensor demonstrated consistent changes in capacitance, reflecting muscle contraction and relaxation. The sensor maintained its functionality under various levels of mechanical deformation, including 100% strain, without compromising its ability to track dynamic muscle movements. One of the key performance characteristics was the low hysteresis of the sensor during repeated cycles of stretching and relaxation. Low hysteresis is crucial for ensuring that the sensor's output to improve the precision of muscle monitoring. The next phase of this work will involve testing the sensor in vivo, particularly in a muscle stimulation model. The stretchable capacitive sensor will be placed on target muscles, and voltage stimulation will be applied to induce muscle contractions. By capturing the resulting deformation, the sensor will provide real-time monitoring of muscle force. This information is critical for tracking muscle fatigue, which can help prevent injuries in athletes by identifying early signs of overexertion.

Future developments for this stretchable capacitive sensor will focus on integrating wireless communication modules for remote monitoring. Wireless data transmission will allow users to freely move while receiving real-time feedback on muscle state. Additionally, biocompatibility testing, and long-term stability studies will be critical to ensure that the sensor can be safely used in prolonged clinical applications or during high-intensity athletic training, injury prevention and rehabilitation

Engineering Synaptic Plasticity in WO3-Based Ion-Gated Transistors for Neuromorphic Systems Ramin Karimi Azari, Luan P. Camargo, Patrick Danga and Clara Santato; Polytechnique Montréal, Canada

Neuromorphic computing, based on analog neural networks, aims to reduce computational power significantly by minimizing the need for data transfers between memory and logic components. Within neuromorphic computing, the artificial synapse serves a dual purpose as both a storage and computational unit, paving the way for resilient learning and power-efficient in-memory computing. Diverging from conventional computing paradigms, neuromorphic systems replicate the structural and functional attributes of the human brain. This emulation allows for parallel processing, improving efficiency in handling complex tasks.
Metal Oxides (MOs)-based IGTs and the tailoring of their properties for synaptic behavior, achieved by leveraging their unique electronic structure, composition, crystallinity, morphology, intrinsic, and/or extrinsic defects, as well as doping, have gained significant attention.
In this study, we used tungsten trioxide (WO_3) as channel material. WO_3 is earth-abundant with non-toxicity, high stability under ambient conditions, and biocompatibility. WO_3 can exist in different crystal structures, including orthorhombic, monoclinic, and hexagonal phases. The current modulation in MO IGTs arises from both electrostatic and electrochemical processes. The crystal structure of the metal oxide is anticipated to have an impact on ion permeability, leading to variations in doping, channel conductivity, and redistribution time of the anions in the IGT channel.
In our WO3 synaptic transistor, the channel conductivity, analogous to the excitatory postsynaptic current (EPSC), was modulated by the amplitude, width, interval, and the number of applied input gate-source voltage (Vgs) pulses. The fluctuations in conductance correspond to the learning and forgetting processes of the artificial synaptic device, with an increase signifying learning and a decrease in signifying forgetting.
Another fundamental aspect that we investigated in WO3-based IGTs is their plasticity, denoting the strengthen of synaptic weight or connection. Synaptic plasticity is typically divided into two categories, namely short-term (STP) and long-term (LTP), determined by the duration of their persistence.

8:30 AM ^EL05.06.02

Wearable Synaptic Transistors Dmitry Kireev; University of Massachusetts Amherst, United States

Both wearable and neuromorphic applications have been on the rise this decade. However, a classical evolutionary approach was to take existing solutions and re-shape them into a wearable form factor. In contrast, graphene has shown a revolutionary advantage to wearables as well as neuromorphic devices. This work shows a unique solution that allows the skin as the synaptic bio-input with the vision to create advanced neuromorphic sensing and self-aware stand-alone “smart” bioelectronic systems.

Leveraging our recent concept of graphene-based soft, flexible, and power-efficient neuromorphic transistors (BLASTs), we extended them into skinBLASTs, arranging the graphene-Nafion structure into the wearable and skin-conformal format. The performance of such devices is astonishing: the porcine-based network performs close to ideal, with a more significant performance degradation seen in the human-based network. These neuromorphic bioelectronic tattoos have the potential for developing self-aware and stand-alone smart wearables, crucial for understanding and improving overall human performance.
Finally, we show that interbody neuromorphic communication is possible by employing the flexible neuromorphic tattoos that are controlled through the skin, opening unique routes for advanced in-body neuromorphic computing systems.

9:00 AM EL05.06.03
Glassy Carbon Microneedle Electrode Arrays for Conformable Electrical Interfacing of the Skin Emilio Fernández-Lavado, Ivonne J. Koedam, Outman Akouissi and Stephanie P. Lacour; École Polytechnique Fédérale de Lausanne, Switzerland

In the field of bioelectronic wearable systems for healthcare, there is a growing demand for reliable, non-invasive technologies capable of continuous monitoring of electrophysiological signals and precise electrical stimulation through the skin. Traditional wet skin interfaces, requiring gels or liquids to maintain low electrode impedance, often result in variable signal quality and user discomfort. Recent advancements focus on dry skin interfaces using microneedle electrodes that penetrate the epidermis, reducing skin-electrode impedance and eliminating the need for conductive gels. Glassy carbon has emerged as a promising material for these interfaces due to its high hardness, wide electrochemical stability window, and ease of patternability through the carbonization of polymer precursors like SU-8 photoresist. However, integrating rigid microneedles into a thin, flexible polymer substrate to enhance skin conformability remains a challenge. This study presents the design, fabrication, and characterization of glassy carbon microneedle electrode arrays (GC-MEAs) on flexible substrates for skin electrical interfacing. We optimized the fabrication process by combining photolithography, pyrolysis, and transfer printing techniques, enabling the scalable production of large, customizable GC-MEAs with lengths ranging from 150 to 400 μm and base diameters from 50 to 150 μm on flexible polyimide printed circuit boards. Extensive characterization tests demonstrated the suitability of glassy carbon for a reliable dry skin interface, with a hardness of 3.5 GPa and a conductivity of 10^3 S/m. Numerous experiments, including hematoxylin-eosin (H&E) staining and impedance spectroscopy, confirmed effective skin penetration using various explanted animal skin models. The successful integration of glassy carbon microneedles on flexible substrates opens up a wide range of potential applications for health wearable systems. Future work will focus on collecting valuable electrophysiological data (EMG, ECG, EEG) from both animals and humans using this technology, as well as on modulating the nervous system via transdermal electrical stimulation.

9:15 AM EL05.06.04
Graphene Oxide–DNA/Graphene Oxide–PDDA Sandwiched Membranes with Neuromorphic Function Jia Hui Bong, Sergey Grebenchuk, Konstantin G. Nikolaev, Celestine P. Chee, Kou Yang, Siyu Chen, Denis Baranov, Colin R. Woods, Daria V. Andreeva and Konstantin S. Novoselov; National University of Singapore, Singapore

The behavior of polyelectrolytes in confined spaces has direct relevance to the protein mediated ion transport in living organisms. In this paper, we govern lithium chloride transport by the interface provided by polyelectrolytes, polycation, poly(diallyldimethylammonium chloride) (PDDA) and, polyanion, double stranded deoxyribonucleic acid (dsDNA), in confined graphene oxide (GO) membranes. Polyelectrolyte–GO interfaces demonstrate neuromorphic functions that were successfully applied with nanochannel ion interactions contributed, resulting in ion memory effects. Excitatory and inhibitory post-synaptic currents were tuned continuously as the number of pulses applied increased accordingly, increasing decay times. Furthermore, we demonstrated the short-term memory of a trained vs untrained device in computation. On account of its simple and safe production along with its robustness and stability, we anticipate our device to be a low dimensional building block for arrays to embed artificial neural networks in hardware for neuromorphic computing. Additionally, incorporating such devices with sensing and actuating parts for a complete feedback loop produces robotics with its own ability to learn by modifying actuation based on sensing data.

Biomimetic Polymer Electronics—From Bioadhesive and Immune-Compatible Biosensors to Skin-Like Neuromorphic Circuits Sihong Wang; The University of Chicago, United States

The effective use of electronic devices for acquiring biological information and delivering therapeutic interventions hinges on two key aspects: acquiring physiological data through contact with soft bio-tissues and high-throughput processing using machine learning. Ensuring high-quality signal transduction requires interfaces between bioelectronic devices and bio-tissues that combine signal amplification with stable, conformable contact. Organic electrochemical transistors (OECTs) are advanced technologies for high-performance bio-sensing and neuromorphic computing. However, challenges such as rigid mechanical properties, lack of tissue adhesion, and immune reactions hinder the formation of stable bio-interfaces.
In my talk, I will first present our material and device designs for OECT-based biosensors that incorporate bioadhesive properties, immune compatibility, and tissue-like softness, achieving these biomimetic properties while maintaining state-of-the-art electrical performance. I will discuss the strategies and advantages of using these properties in bioelectrical and biochemical sensing. Additionally, I will cover our research on imparting intrinsic stretchability to neuromorphic devices and circuits, which provide advanced computing performance, demonstrating their practical applicability for machine-learning-based health data analysis.

10:30 AM *EL05.06.06
Organic Circuits and Systems for Neuromorphic Perception for Soft Robotics and Soft Functional Materials
Robert A. Nawrocki, Mohammad Javad Mirshojaeian Hosseini, Kateryna Vyshniakova, Jinsheng Fan, Huiwen Bai and Yi Yang; Purdue University, United States

Soft robots, machines made from soft and compliant materials, aim to address limitations of hard and rigid robots critical when working in close contact with humans or other applications that require soft and conformal form factor. However, at present, the majority of sensors, actuators, and electronics used in control of soft robots still relies on hard and rigid materials. We present an update of our efforts to develop soft and flexible functional materials, with embedded sensors and neuromorphic electronics, as building blocks of soft robotics and soft functional materials.

We employed various deposition techniques, including direct ink writing, inkjet printing, and fused deposition modeling three-dimensional printing, to fabricate piezoelectric PVdF force/pressure and temperature sensors. We developed new methods of improving sensor sensitivity, including electric poling, that allow for embedding force / pressure sensors with structure of any arbitrary 3D shape [1, 2]. We also developed a low cost, impedance-based chemical aqueous ammonia sensor [3]. In addition, we have developed a new technique to additively manufacture organic electronics, for future integration with sensors and structures [4] for soft robots and soft functional materials.

Neuromorphic electronics, largely based on Spiking Neural Networks (SNN), provide distributed computation to emulate brain processing principles. With synapses and somas as their essential components, they function based on modulation of spike frequency and pulse width. Characterized by low power consumption, a target application of SNN hardware implementation, known as neuromorphic systems, are embedded computing [4]. However, they are typically implemented using hard, rigid, and non-biocompatible silicon technology, incompatible with brain's soft tissue.

In soft organic electronics, we have fabricated physically flexible, spiking somatic [5] and synaptic [6, 7] circuits. Complimentary p- and n-type organic transistors were fabricated on 50 µm thin Polyimide substrates, with DNTT and PDI8-CN2 used as p- and n-type organic semiconductors, and Parylene diX-SR as the transistor and fabrication-integrated capacitor dielectric. Results show that organic spiking Integrate-and-Fire Axon-Hillock [5] artificial soma integrates input currents and produces proportional output spikes. Also, organic Log-Domain Integrator [6] and Differential-Pair Integrator [7] synaptic circuits produce proportional output currents based on continuously tunable synaptic weights. Other critical tunable circuit functions, including gain, time-constant, and synaptic capacitance, are also shown. Synaptic circuit response due to input spikes of different frequencies are also demonstrated. These neuromorphic primitives can be used for constructing an entire spiking neuron, as well as a network of such neurons. We also demonstrated sub-300 nm thin organic circuits, including multi-stage amplifiers and ring oscillators, for future use in neuromorphic computing in robotics applications [8, 9].

Tissue-Like Interfacing of Electrochemical Neuromorphic Organic Devices Daniela Rana[1,2], Chi-hyeong Kim[3], Meijing Wang[3], Fabio Cicoira[3] and Francesca Santoro[1,2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany; [3]Polytechnique Montréal, Canada

Neural information processing has been taken into consideration for the development of systems able to perform learning and decision tasks, while overcoming the von Neumann bottleneck in hardware system which use parallel computing for the optimization of the computation in terms of energetic efficiency. Non-volatile memory is one of the main requirements for the devices at the basis of neuromorphic hardware technologies responsible for the elaboration of signals[1]. Among the different applications, neurohybrid platforms attracts interest from the utility for the building of brain-machine interfaces. Conductive polymers have been largely used for their advantages in the operability with biological environments[2,3]. Electrochemical organic neuromorphic devices (ENODes) are rapidly developing for the mimic of neural information processing and the resembling of volatile and non-volatile memories depending on the tuning of some device features[4–6]. Short- and long-term synaptic plasticity is a key characteristic in creating functional neuromorphic interfaces that showcase spiking activity and learning capabilities[7].

With the goal to couple ENODes with the neurons and cerebral environment, it is worth investigating the

neuromorphic behavior of ENODEs when they interface with electrolytes that have a consistency like brain tissue in mechanical properties, as this can affect the modulation of ion and neurotransmitter diffusion.
Here, we present ENODEs with two different planar geometries, based on printed PEDOT:PSS SV3 and on spin coated PEDOT:PSS PH1000 gate and transistor channel. These were interfacing with liquid (water-glycerol mixtures) and solid electrolytes (agarose gel) to investigate the steady-state and the transient behaviour in different conditions. The last one also reflects the short-term plasticity, and particularly the paired-pulse facilitation patterning. Moreover, the electrolytes were loaded with a neurotransmitter and a gate pulse stimulation that oxidizing allowed for a long-term modulation and represented a non-volatile memory.
We found that both the composition of the electrolyte and the PEDOT:PSS formulation used as gate and channel material play a crucial role in the diffusion and trapping of cations that ultimately modulate the conductance of the transistor channels. It was shown that short-term plasticity can be achieved in both devices and the agarose gel allows for performances similar to the liquid electrolyte in terms of diffusivity of cations during the stimulation. On the other hand, the long-term plasticity can be achieved only with spin-coated ENODes and it can be performed with the tissue-like electrolyte made of agarose gel.
Our work on ENODe-gel coupling could pave the way for effective brain interfacing for computing and neuroelectronic applications.

Organic Electrochemical Transistors for Effectively Diagnosing Neurodegenerative Conditions Gurashish Singh, Paul Chazot, Raheleh Kafieh, Daniel T. Smith and Mujeeb U. Chaudhry; Durham University, United Kingdom

Over the past six decades, life expectancy has substantially increased by approximately 20 years, a demographic shift that has not been accompanied by corresponding evolutionary adaptations. This extended lifespan has consequently led to a higher prevalence of age-related diseases, particularly neurodegenerative disorders, which now impact approximately 1 billion individuals worldwide. The early and precise detection of these disorders is paramount, as timely therapeutic interventions can substantially enhance patient outcomes. The complexity of neurodegenerative diseases often results in diagnostic challenges, further complicating effective treatment strategies.
This research investigates the potential of Organic Electrochemical Transistors (OECTs) to advance diagnostic methodologies for the early detection of neurodegenerative diseases. OECT-based biosensors, with their capability to rapidly and accurately detect intricate biological interactions and function effectively in aqueous

environments, offer significant promise for enhancing diagnostic accuracy and improving patient care. By facilitating the differentiation between various neurodegenerative disorders and refining therapeutic approaches, these biosensors have the potential to revolutionize healthcare delivery for these conditions.
The development of OECT technology and its integration with complementary diagnostic techniques to improve pre-diagnostic accuracy and robustness will be discussed. This innovative approach supports the creation of highly portable, low-profile health monitoring systems, which enable continuous, non-invasive monitoring of critical biomarkers. Such advancements could greatly improve personalized medical care by providing real-time insights into a patient's health status while leveraging the convenience and ease of wearable technology.

11:30 AM EL05.06.09

Ionic Gel-Based Somatosensory Neuromorphic Device with Diverse Neuronal Spiking Behaviors Hayeon Jeong[1,2,3], Unhyeon Kang[2], Suyoun Lee[2], Cheolmin Park[1,3] and Hyunjung Yi[2,3]; [1]Yonsei University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]YU-KIST Institute, Korea (the Republic of)

The development of neuromorphic devices that emulate the sensory and processing capabilities of the human somatosensory system is of significant interest for neuro-robotics and medical devices. Here, we present an iontronic somatosensory neuromorphic device that shows various neuronal spiking behaviors in response to tactile and thermal stimuli by utilizing ion gel-based capacitive artificial receptors and threshold switching devices. The capacitance of the ionic artificial receptor varies with mechanical and thermal stimuli. It controls the switching dynamics of the threshold switching device, thereby regulating the frequency and pattern of the spiking voltage signals of the somatosensory neuromorphic device. Moreover, the capacitive artificial receptors exhibit various time-dependent responses, leading to diverse tactile response characteristics. A soft iontronic somatosensory neuromorphic device composed of a simple circuit with a capacitive sensor and the switching device can be combined with spiking neural networks for recognizing complex stimuli. We envision that the iontronic somatosensory neuromorphic device with various spiking dynamics holds great promise for multifunctional neuromorphic tactile systems.

11:45 AM EL05.06.10

Substitution of Ionic Input to Voltage Modulation in Peptide-Based Bimodal Memristor Jeong Hyun Yoon and Jang-Yeon Kwon; Yonsei University, Korea (the Republic of)

In recent times, artificial intelligence (AI) has been applied across numerous domains, including image recognition, video analysis, and autonomous driving, serving as a novel computing paradigm. These applications typically involve handling large volumes of unstructured data, demanding experience-based learning analogous to the human brain operation. However, traditional computing architectures, where memory and data processing units are distinct, result in significant time and energy inefficiencies due to the data transfer required between these units during experience-based learning.

To address this challenge, neuromorphic devices inspired by the biological synapse structure have emerged as alternatives to conventional CMOS devices, based on the fact that the human brain operates on a remarkably low power consumption of around 20W. Although they were fabricated based on the structure of actual synapses, there remains a gap between the reported neuromorphic devices and the actual mechanisms at neurotransmitter modulation in biological synapses. Therefore, our research team has developed a memristor using a tyrosine-rich peptide (TRP) as the resistive switching layer. The peptide film exhibits coupled proton and electron transfer due to the redox-active properties of Tyrosine, resulting in high proton conductivity under high humidity conditions. Using this phenomenon, a memristor device incorporating the TRP film as the resistive switching layer was fabricated and RS behavior driven by both electrical (voltage) and ionic (humidity) inputs was observed. Nevertheless, employing humidity as an ionic input presents several drawbacks; lack of the controllability compared to voltage input, making it challenging to update input values in real time and leading to lower reproducibility, which could potentially exacerbate the stochastic behavior previously identified as an issue in memristors.

In this work, the external humidity, which works as the ionic input of the memristor device, was substituted with voltage modulation applied to the Pd proton-conducting electrode placed adjacent to the memristor device. This approach enables set voltage reduction, analogous to those seen in high RH conditions. Additionally, voltage modulation through precisely controlled ionic input successfully reduced the coefficient of variation for set voltage distribution from over 0.5 in the humidity operation mode to below 0.3. Ultimately, proton insertion through the Pd electrode promotes a carrier-rich environment in the resistive switching layer, leading to more gradual switching behavior compared to the intrinsic Y7C memristor, resulting in a 24% enhancement in image recognition accuracy.

SESSION EL05.07: Neuromorphic Systems and Sensors II

From Nanoionic Processes to Neuromorphic Sensing Regina Dittmann; Forschungszentrum Jülich GmbH, Germany

Memristive devices based on the valence change mechanism are highly interesting candidates for non-volatile data storage and for hardware representations of synapses and neurons in neuromorphic circuits. Although it has been early proposed that the switching mechanism is based on the field-driven movement of oxygen vacancies within nanosized filaments [1], details of the underlying physical-chemical processes are difficult to access experimentally. However, these details are highly relevant for the kinetics of the devices and the time stability of the resistances states. We employed photoemission electron spectoscopy (PEEM) to study the movement of oxygen vacancies during device operation and after resistance relaxation [2, 3]. By combining PEEM data with simulations of the ionic and electronic transport, we gained a deep understanding of the interplay between oxygen vacancy movement, the modulation of space charge zones and the switching performance.
We use the knowledge to design VCM devices with tailored resistance relaxation [4] to gain spatio-temporal information in a neuromorphic sensing circuit, the time-difference encoder, developed at the University of Groningen [5].

Dynamic Control of the Thermal Resistance in (Pt/Cr)/SrTiO3 Devices Victor Alvarez[1,2], Rafael Ramos[1,2], Victor Leboran[2], Regina Dittmann[3], Alex Sarantopoulos[3] and Francisco Rivadulla[1,2]; [1]Universidade de Santiago de Compostela, Spain; [2]Centro Singular de Investigación en Química Biolóxica e Materiai Moleculares, Spain; [3]Peter Grünberg Institute, Germany

Achieving a dynamic control of the heat flow in crystalline solids is key due to the relentless miniaturization of electronic devices. In this regard, the possibility to modulate the local concentration of oxygen vacancies in transition-metal oxides, associated to the resistive switching effect, has emerged as a possibility of designing thermal switches. In this work, we demonstrate a reversible effect on the thermal boundary resistance across SrTiO3/Pt, Cr interfaces, associated to an electric field-driven accumulation/depletion of oxygen vacancies .

Using frequency domain thermoreflectance (FDTR) we measured a variation of 20% in the thermal boundary resistance of Pt/STO and Cr/STO devices, at room temperature. Relaxation experiments demonstrate the correlation between the thermal and electrical resistance states.

Our experiments demonstrate the possibility to modulate the oxygen vacancies at metal-oxide interfaces for thermal switching devices.

2:15 PM EL05.07.03

Subthreshold Behavior in Organic Electric Chemical Transistors—Beyond the Thermodynamic Limit Bryan D. Paulsen[1], Dilara Meli[2], Maximilian Moser[3], Ruiheng Wu[2], Iain McCulloch[4] and Jonathan Rivnay[2]; [1]University of Notre Dame, United States; [2]Northwestern University, United States; [3]University of Oxford, United Kingdom; [4]Princeton University, United States

Organic Electrochemical Transistors (OECTs) are important building blocks of next generation biosensing and neuromorphic circuits. By leveraging the volumetric ionic-electronic coupling inherent in Organic Mixed Ionic Electronic Conductors (OMIECs), OECTs produce low-voltage high-gain devices that can directly transduce and amplify ionic biotic signals, or exploit ionic-electronic coupling to induce memory behavior for synaptic-like behavior, amongst other applications. This has made OECTs often the device of choice in neuromorphics, biohybrid systems, and smart sensing. Improving the understanding of the physics of OECTs and OMIECs has enabled rapid advances. Most interest has focused on device gain (transconductance) or material mixed transport figure of merit (μC*); with contact resistance, energy levels/threshold voltages, and disorder also receiving study and attention. Much less attention has been given to OECT subthreshold behavior, that is the degree of abruptness of the initial turn-on of OECT electrical conductance. Neglect of this topic is unfortunate, as study of subthreshold behavior is important for fundamental understanding of OECT functioning, as well subthreshold being a regime of device operation that manifests ultra-low power and ultra-high device stability. Understanding and rationalization of OECT behavior often relies on making analogies to organic field effect transistor (OFET) physics. OFET models, following their MOSFET predecessors, impose a strict thermodynamic lower limit on the subthreshold swing (S.S.) of 60 mV/dec at room temperature. This analogy has been so widely held that a S.S. approaching 60 mV/dec in OECTs has often been interpreted as evidence of device “ideality”. However, the applicability of such a limit to OECTs is not self-evident.

We have investigated a series of oligoethylene glycol bithiophene chalcogenophene alternating copolymer OMIECs as channel materials in OECTs. Remarkably we found that the tellurophene-bithiophene copolymer OMIEC based OECTs broke the apparent thermodynamic limit, manifesting a subthreshold slope of 44 mV/dec at room temperature, well below the widely accepted 60 mV/dec limit at room temperature. We compared this OMIEC with analogous polymers with varied chalcogenophene heteroatom substitution using AC and DC OECT measurements, spectroelectrochemistry, and in situ and ex situ X-ray scattering. These investigations revealed an apparent structural origin to the anomalously low S.S. (and concomitant improved electronic transport characterizations), namely highly ordered and oriented three-dimensional crystallites that persist even during electrochemical cycling in aqueous environments. The thorough characterization of the OMIEC series reveal the delicate balance between OMIEC microstructure, subthreshold behavior, frontier molecular orbital energy level, OECT threshold voltage, bulk electronic transport, and bulk ionic transport. This elucidates clear design rules to engineer desire subthreshold behavior, including achieving S.S. below the thermodynamic limit. The theoretical sources of an anomalously low S.S. below the thermodynamic limit are considered, including the electrochemical D.O.S., charge density dependent electronic carrier mobility, and the impact of non-Faradaic gates. Further, a meticulous review of the literature reveals inadvertent reports of S.S. below 50 mV/dec going back multiple decades. These results demand a reconsideration of the fundamental device physics of OECTs, show the unique ways OECTs exceed the performance of more traditional electronics, and open new avenues for OMIEC based OECTs to be leveraged in neuromorphic, biohybrid, and smart sensing applications.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

3:30 PM *EL05.07.04
Charge Carrier Density in Organic Semiconductors Modulates the Effective Capacitance: A Unified View of Electrolyte Gated Organic Transistors Fabio Biscarini[1,2], Rian Zanotti[2,3], Matteo Sensi[2], Marcello Berto[2], Alessandro Paradisi[2], Michele Bianchi[2], Pierpaolo Greco[1,4], Carlo Augusto Bortolotti[2] and Michele Di Lauro[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Modena e Reggio Emilia, Italy; [3]Università di Modena e Reggio Emilia, Italy; [4]Università di Ferrara, Italy

A framework for electrolyte gated organic transistors (EGOTs) which unifies the view of interfacial capacitive coupling of electrolyte-gated organic field-effect transistors (EGOFETs) with the volumetric capacitive coupling in organic electrochemical transistors (OECTs) is proposed. The EGOT effective capacitance arises from in series capacitances of the electrolyte/gate electrode and electrolyte/channel interfaces, and the chemical capacitance of the organic semiconductor channel whose weight with respect to the interfacial capacitance is modulated by the charge carrier density, hence by the gate voltage. The expression for chemical capacitance is derived from the DOS of the organic semiconductor, that we assume exhibits exponential energy disorder in the HOMO-LUMO gap. The analytical expression of the EGOT current is assessed on experimental data and shown to accurately predict the shape of the whole transfer curve of an EGOT thus allowing us to extract accurate values for the switch-on voltage and the interfacial transconductance, without assumptions on specific response regime and, in OECT, without invoking the volumetric capacitance. Interestingly, our EGOT model recovers EGOFET and OECT as limit cases and, in the latter case, explicitly represents the volumetric capacitance in terms of the energy disorder and the band gap of the organic semiconductor. Finally, I will discuss how spiked voltages are input into the framework to describe the neuromorphic response of EGOTs.

4:00 PM *EL05.07.05
Neuromorphic Sensing and Computing by Memristive Devices at the Interface with Biology Sandro Carrara;

École Polytechnique Fédérale de Lausanne, Switzerland

The concept of *in-Memory Computing* is nowadays a well-established principle. Instead of separating the processing and the memory units, as usually done in von Neumann architectures, it proposes new neuromorphic architectures based on memristive devices providing simultaneous storing and computing. Indeed, this invited presentation proposes the new concept of *in-Memory Sensing-and-Computing* as a disruptive novel approach in neuromorphic computing. This novel concept is based on the fusion of three neuromorphic functions: sensing, computing, and memory. This novel concept is demonstrated by using simple architectures based on a new kind of single-devices simultaneously providing these three functions: the memristive sensors. Moreover, the demonstration of the new concept is provided at the interface with biological systems. In particular, the proposed novel approach is shown by a breakthrough- demonstration in cancer diagnostics: the estimation of the risk of prostate cancer based on simultaneous measures of several cancer biomarkers. So, this invited presentation discusses the first-ever-reported direct computations of cancer risks on cancer biomarkers simultaneously detected with memristive biosensors, meanwhile providing data storing too. The Memristive biosensors are quite a novelty emerged in literature with first publications starting from 2011 only. These new kind of memristive devices are of interest for many reasons but especially for their excellent Limit-of-Detection, which is down to attomolar-ranges in cancer markers detection. They are typically fabricated as silicon nanowires, and manufactured with standard lithographic processes. This means that the whole architecture may be fabricated with the CMOS technology (Complementary Metal–Oxide–Semiconductor) and the biosensors may be directly microfabricated onto the same CMOS dye. Therefore, this talk opens to an important new area of research and development: the possibility to provide simultaneous sensing, computing, and storing with innovative neuromorphic CMOS architectures at the interface with biology.

4:30 PM EL05.07.06

Integrated Floating-Gate Organic Electrochemical Transistor for In-Memory Sensing Giorgia Rinaldi[1], Simone L. Marasso[1,2], Matteo Cocuzza[1] and Alberto Salleo[3]; [1]Politecnico di Torino, Italy; [2]Institute of Materials for Electronics and Magnetism, IMEM-CNR, Italy; [3]Stanford University, United States

Traditional sensing technologies rely on data transfer between sensor, memory and processing units. Traditional architectures encounter the problem of the memory wall, which restricts the processing speed to the rate at which data can be accessed or stored in memory. As data-intensive applications continue to grow, bio-inspired sensing systems have recently been developed to tackle these limitations. Biological neurons can indeed integrate sensing, memory and processing in a single element, making them extremely efficient in terms of energy, time and area. In-memory sensing technologies emulate this architecture, moving towards local and autonomous operation of point-of-care sensing devices. Furthermore, this all-in-one architecture prevents data from being uploaded to external servers, ensuring safer storage of the sensitive clinical data acquired by the sensor.

This work presents a floating-gate organic electrochemical transistor (FG-OECT) able to work both as a sensor and as a memory.

Organic mixed ionic-electronic conductors (OMIECs) are optimal candidates for in-memory sensing, as they have already been employed for both biosensing and neuromorphic computing. Organic electronic devices are notably characterized by low voltage of operation, high conductivity and excellent tunability, making them extremely versatile devices relevant to different fields.

Thanks to the floating-gate architecture, the memory can be decoupled from the sensing region, preventing contamination of the channel material with the analyte and allowing optimal materials to be employed for the two purposes. In particular, the memory gate is made of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), granting state retention to the system thanks to the electrochemical doping/dedoping process of both the gate and the channel. Differently, the sensing gate is made of gold, providing an easier functionalization of the electrode with artificial bioreceptors for capacitive sensing. Figures of merit for both biosensing and memory properties have been addressed, including transconductance, state retention and number of states.

4:45 PM EL05.07.07

Olfactory Sensing with Large Arrays of Chemiresistive Light Emitters Hyunah Kwon[1,2], Alexander Song[1,2], Ocima Kamboj[2], Fred Hamprecht[2] and Peer Fischer[1,2]; [1]Max Planck Institute, Germany; [2]Heidelberg University, Germany

At present, no existing technology can match the extraordinary sensitivity and specificity of natural olfactory systems. This presentation will focus on the development of an advanced “artificial nose” that emulates the mammalian olfaction system's ability to detect and differentiate complex odor mixtures. The key idea lies in employing a significantly larger array of sensors than are currently used in existing electronic noses, combined with an innovative optical and parallel readout system that circumvents the complexities of traditional electrical sensor arrays. This approach promises to significantly improve the ability to discern odors.
In the mammalian olfaction system, molecular odorants are initially detected by olfactory receptors (ORs). Mammals typically possess many different kinds of ORs, with dogs having about 1,300 and humans around 400. The combination of responses from different ORs enables the discrimination of a very large number of molecules (smells). Signal processing the response from these sensors is another important ingredient in our sense of smell. While humans may not have as many OR types as some animals, humans compensate this with a large number of glomeruli, providing sophisticated olfactory input to the brain for interpreting signals. In contrast, conventional artificial electronic noses typically contain only 5-20 sensors, much less than mammalian olfactory receptors, and thus have low selectivity.
Our approach introduces several novel concepts. First, we utilize high-throughput techniques to grow nanostructured materials with an extensive surface-to-volume ratio for enhanced binding of analytes. We are able to reach more than thousands of distinct sensing components in a sensor array with a simple physical vapor deposition technique. Most importantly, we implement an optical read-out system where the modified electrical response of each sensing unit generates unique optical signals (fingerprints) that are read out optically. This allows for a much larger array than has been possible to date. Finally, we use advanced pattern recognition techniques to analyze the sensor outputs and optimize the way the sensors are arranged.
This work significantly advances the ability of artificial noses to detect smells and odors from complex mixtures. Potential applications of such a system are vast, ranging from environmental monitoring to medical diagnostics, where there is a critical need for rapid, accurate analysis of air quality or a patient’s breath. The goal is to develop the technology that hopefully will allow artificial noses to begin to rival natural olfactory systems.

Predictive Design of Threshold Switching Voltage in Electron Doped VO2 for Neuromorphic Computing
Shloka Shriram[1], Suvo Banik[2], Shriram Ramanathan[3] and Subramanian Sankaranarayanan[2]; [1]Princeton High School, United States; [2]University of Illinois at Chicago, United States; [3]Rutgers, The State University of New Jersey, United States

Vanadium dioxide undergoes a insulator-metal transition (IMT) in the vicinity of room temperature. In two-terminal devices, the phase transition can be initiated by applying bias voltage that results in a threshold switching behaviour. Such devices are of interest for use as artificial neurons and synapses in neuromorphic computing hardware. The transition temperature can be reduced from nearly 340K in pure crystals to 300K by choice of electron dopants such as tungsten. Understanding the atomic mechanisms of tuning the transition temperature with dopants is an active area of study as this has significant implications for design of low power switches for artificial neurons in neuromorphic computing. Here, we will first present our results on the rate of decrease of the transition temperature with increasing tungsten concentration and compare against experimental studies on threshold switching voltage scaling with doping. We find the slopes are quite similar (21 K/at% compared to 19.6 V/at%) suggesting a strong correlation in the phase switching mechanism related to Joule heating. We will discuss a predictive model using combination of semiconductor impurity conduction theory and symbolic regression (SR) to extract a general relationship between doping density and insulator-metal transition temperature that extends beyond the linear regime. This analysis strongly indicates the effectiveness of electron doping in de-stabilizing the insulating state compared to structural distortions from iso-valent dopants (e.g. Ti) . Then, we will present results on high energy ion implantation modelling of various electron donors into VO2 for systematic tuning of the transition properties and compare against experiments. Combined, these studies will be useful for the design and fabrication of low power switching oxide IMT devices in neuromorphic computing.

ReRAM-Based Neuromorphic Devices with Signal Enhancement Properties Hyeon-kyo Song, Soodeok Han, Won Young Choi, Seojun Lee and Jin-Seok Hwang; VanaM Inc., Korea (the Republic of)

Synaptic mimicking devices not only have the potential to replace existing memory-based storage media, but also to integrate with CMOS technology or independently mimic the functions of brain cells. With the advent of various AI models like Chat-GPT, the hardware requirements for conventional von Neumann computing systems have significantly increased. To address this, parallel processing systems based on graphics cards have been utilized, and recently, application-specific integrated circuits (ASICs) designed specifically for AI systems have been employed. However, substantial power consumption and large-scale infrastructure are still required. As AI technology becomes increasingly integrated into daily life, the development of low-power, compact intelligent semiconductors for ICT convergence devices have become essential, accelerating research beyond the von Neumann architecture. The human brain, composed of 100 billion neurons and 100 trillion synapses, is more energy-efficient in data analysis and processing than any existing computing system. Neuromorphic computing, which mimics the functions of the brain, is expected to be a major direction for future AI development.

ReRAM, a typical synaptic device made mostly of oxides, operates through the movement of oxygen ions or charge trapping through vacancies. Unlike conventional memory systems, this allows various resistance levels to be used, thus enabling synaptic learning. However, this mode of operation, which is controlled by voltage, presents a challenge: as the resistance decreases as the learning progresses, higher drive voltages are required to maintain the linearity of the learning.

We have fabricated a signal-amplifying layer using the Mott insulator VO_2 and created a bi-layer structure with an extremely thin Al_2O_3 layer on top to implement resistance change characteristics for a synaptic device. The Mott insulator VO_2 exhibits an insulator-metal transition where resistance decreases as temperature increases. As the resistance of the synaptic device decreases, the high current generated can create Joule heating, which can induce an additional reversible resistance reduction characteristic. This allows for a more linear reduction in resistance change at the same voltage.

The resistance change characteristic is implemented through the movement of oxygen ions in the insulator layer, where a highly resistive Al_2O_3 is placed. When oxygen ions move towards the metal side at the interface, the barrier

becomes extremely thin, enabling tunneling and forming a low resistance state. Conversely, when oxygen ions move towards the bulk region, the barrier thickness increases, forming a high resistance state. This characteristic allows for resistance change implementation in an extremely thin local area. Additionally, this asymmetric structure can provide the advantage of self-rectification.
Through this work, we introduced the concept of signal amplification by incorporating Mott insulators and successfully implemented a ReRAM-based synapse mimetic device with improved linearity.

Reliable Accessibility of Intermediate Polarization States in Textured Ferroelectric $Al_{0.66}Sc_{0.34}N$ Thin Film Tae Yoon Lee and Seung Chul Chae; Seoul National University, Korea (the Republic of)

Ferroelectric materials are promising candidates for neuromorphic computing synaptic devices due to the nonvolatile multiplicity of spontaneous polarization. To ensure a sufficient memory window, ferroelectric materials with a large coercivity are urgently required for practical applications in highly scaled multi-bit memory devices. Herein, a remarkable reliability of intermediate ferroelectric polarization states is demonstrated in a textured $Al_{0.66}Sc_{0.34}N$ thin film with a coercive field of 2.4 MV/cm. $Al_{0.66}Sc_{0.34}N$ thin films were prepared at 300 °C on Pt (111)/Ti/SiO_2/Si substrates using a radio frequency reactive sputtering method. $Al_{0.66}Sc_{0.34}N$ thin films exhibit viable ferroelectricity with a large remanent polarization value of >100 mC/cm^2. Through the conventional current-voltage characteristics, polarization switching kinetics, and temperature dependence of coercivity, the reproducibility of multiple polarization states with apparent accuracy is attributed to a small critical volume (3.7×10^{-28} m^3) and a large activation energy (3.3×10^{27} eV/m^3) for nucleation of the ferroelectric domain. This study[1] demonstrates the potential of ferroelectric $Al_{1-x}Sc_xN$ for synaptic weight elements in neural network hardware.

Harnessing Stochasticity in 2D Materials—A First-Principles Study of Phonon-Assisted Defect Charge Dynamics in WS_2 Chenmu Zhang, Evgeni Penev and Boris I. Yakobson; Rice University, United States

Stochasticity plays an important role in cryptography, stochastic and neural-like computing, facilitating low-cost, error-tolerant solutions to complex problems such as integer factorization, invertible logic and optimization. Specifically, we investigate phonon-assisted defect charge dynamics in 2D materials, e.g. a sulfur vacancy in WS_2 monolayer (V_S-WS_2), using first principles calculations [1]. We find that a true random bit generation scheme based on V_S-WS_2 optimally balances bitrate, energy efficiency, and tunability of bit probability. The entropy source based on V_S-WS_2 enables unbiased random bit generation at bitrates of 30 Mbps, which can be further optimized up to terabits per second by minimizing the energy barrier (E_b) for defect-to-band electron transition through 3% tensile strain of the host-material. Further advantages of V_S-WS_2 include a large current contrast between two states, significant tunability of bit probability, and reduced energy consumption. Furthermore, we explore the conditions needed to achieve a low E_b, unveiling new possibilities in 2D material-based entropy sources. The essential insights into phonon-assisted defect charge dynamics combines with practical designs for high-performance, energy-efficient stochastic devices.

Evaluation of Electrical Characteristics of Flash Type 2X2 Arrays Neuromorphic Transistors with Mesh Structural Floating Gate Hyeongjin Chae, Soyeon Jung, Jaemin Kim, Taehwan Koo, Juyeong Chae and Moongyu Jang; Hallym University, Korea (the Republic of)

With the rapid growth of the AI and big data industries, the importance of data processing, calculation, learning, and reasoning capabilities is emerging. Traditional von Neumann systems are limited by the bottleneck between computing unit and data storage, as well as high power consumption. As a solution to this, research on neuromorphic devices that mimic human brain neural networks is actively underway. In this study, we developed a flash-type 2X2 array neuromorphic transistor that expresses various synaptic weights with a single electrical measurement by applying a mesh-structured floating gate[1] [2] [3]. We also performed electrical characterization to confirm the excellent performance of repeatability, long-term plasticity, and reproducibility, which are the evaluation factors of synaptic devices. This shows the possibility of utilization in real industry.

In previous studies, we developed the structure of a single transistor and evaluated its electrical characteristics. The structure of a single transistor has a gate stack structure of Pt/Cr/HfO_2/Pt/Cr/HfO_2/SiO_2/Si using SOI wafer as a substrate. In particular, the Pt/Cr floating gate formed on the upper part of HfO_2/SiO_2 has a mesh structure. This is an island structure, similar to a quantum dots floating gate, that can operate successfully even if some of the mesh structure is damaged. Compared with a single floating gate, the mesh structure floating gate has better electron storage effect, higher surface density, and lower leakage current[4]. This was confirmed by electrical characterization.

Based on the information confirmed in previous studies, a 2X2 array neuromorphic transistor incorporating array technology was developed. The 2X2 array consists of parallel connections of single transistors. The electrical characteristics are evaluated by adjusting the applied voltage of the source, drain, and control gate regions of transistors arranged in a 2X2 array. The electrical characterization shows that the synaptic weights of arrayed transistors are more diverse than single transistor. It also shows good results in terms of repeatability, long-term plasticity, and reproducibility.

Through this study, it is possible to confirm the excellent performance of the 2X2array neuromorphic transistor expanded in previous studies. This means the implementation of a neural network and makes it possible to consider the possibility of expansion to a heavy arrays in the future. It also shows practicality in AI and big data industries.

Research and Analysis of Flash-Type 2×2 Neuromorphic Transistor Arrays Manufactured by CdSe Quantum Dots Taehwan Koo, Jaemin Kim, Soyeon Jung, Hyeongjin Chae, Juyeong Chae and Moongyu Jang; Hallym University, Korea (the Republic of)

This research describes the fabrication and analysis of a flash-type transistor 2×2 array device using quantum dots. Quantum dots are nanocrystals with a size of several nanometers, and research on the application of these

quantum dots is being carried out in various semiconductor and semiconductor applications such as displays and solar cells. The cores of the quantum dots used in this study are InP, CdSe, etc. and have been treated with ligands to convert them to hydrophilic, to prevent agglomeration, and for uniform distribution and stability. The flash-type transistor was fabricated in the structure of Pt/Cr/Al_2O_3/QDs/Al_2O_3/SiO_2/Si. In this structure, the quantum dots act as floating gates. Quantum dots are spin-coated to form thin films on the order of 100 nm. The spin coating process reduces the process time and cost compared to other thin film processes. In this study, an oxide film(SiO_2) was formed using a furnace, After then high-k material was deposited using ALD, and Cr, Pt was deposited using a sputter as the top electrode.
In the previous works in our group, The Capacitance - Voltage characteristics were studied in MOS Capacitor structure rather than transistor Current - Voltage characteristics [1]. In this study, We checked the synaptic weights to ensure that we have a ΔVt of more than 1 volt, and we have four connection strengths. I_D-V_D and I_D-V_G measurements were taken to verify the behavioral characteristics of the transistor. Through this, threshold voltage (V_T), on-off current ratio (I_{on}/I_{off}), etc. were checked, and synaptic weights were checked through programming and erasing [2]. Measurements and analyses, we confirmed its potential as a neuromorphic-based transistor and aimed to evaluate the characteristics of multiple transistors in an array. The array process is essential for neuromorphic systems with parallel structures. The device using the array process has the advantage of evaluating multiple of transistor characteristics through a single measurement, and it is expected that the data can be processed efficiently by software as a neuromorphic device.

No Strain, No Piezoelectric Gain—Pushing Piezoelectric Boundaries via Strain Engineering in Composition-Tuned Wurtzite Scandium-Doped Aluminium Nitride in Neuromorphic Devices Zicong Marvin Wong, Gang Wu, Teck Leong Tan and Ramanarayan Hariharaputran; Agency for Science, Technology and Research, Singapore

Piezoelectric materials play a crucial role in the development of neuromorphic devices, particularly for emulating biological synapses and enabling adaptive bio-interfacing. In this study, we investigate the structural and piezoelectric properties of scandium-doped aluminum nitride ($Al_{1-x}Sc_xN$) using density functional theory (DFT) calculations, with a focus on strain engineering for optimizing piezoelectric performance.
Our results reveal a phase transition from the wurtzite to the rock-salt structure at approximately 60% Sc composition. Interestingly, we find that, actually, between 50% to 60% Sc, the wurtzite structure transitions to a hexagonal layered structure, which does not display any piezoelectric response. Below 50% Sc, the wurtzite structure exhibits desirable piezoelectric properties, making it an ideal candidate for neuromorphic applications. This finding highlights the importance of carefully controlling the Sc doping level to maintain the desired wurtzite phase and piezoelectric behavior. Subsequently, we explore the effects of various Sc doping levels below 50% Sc on the structural optimization and piezoelectric coefficients using the special quasirandom structure (SQS) approach. This is followed by the investigation of biaxial strain engineering which reveals that the tensile strain required to achieve maximum piezoelectric coefficients decreases with increasing Sc content. This observation suggests that Sc doping can be leveraged to enhance the strain-induced piezoelectric response, potentially leading to improved performance in neuromorphic devices that rely on piezoelectric actuation or sensing.
By combining compositional tuning and strain engineering, this study provides valuable insights into the design and optimization of high-performance piezoelectric materials based on $Al_{1-x}Sc_xN$ for neuromorphic computing applications. The ability to tailor the piezoelectric properties through controlled doping and strain engineering opens up new avenues for developing adaptive bio-interfaces and bioinspired information processing systems.

EL05.08.08

Synaptic Function Emulation with Amorphous SZTO/SIZO Bilayer Transistors and P(VDF-TrFE) for Neuromorphic Applications Sandeep K. Maurya, Tae H. Kim, Hyun S. Oh, Hyeon Dong Kim and Sang Yeol Lee; Gachon University, Korea (the Republic of)

Synaptic devices like synaptic memristors and synaptic transistors enable neuromorphic computing, emulating the functions of the human brain. These devices excel in conducting highly efficient parallel computing, effectively addressing the limitations of the von Neumann architecture. Devices based on field-effect transistors (FETs) can be used to emulate synaptic function due to its flexibility in choosing material, controllable parameters, and well-known working mechanisms.

Here we report a simple amorphous SiZnSnO/SiInZnO (SZTO/SIZO) bilayer thin film transistor coupled with a flexible copolymer, poly(vinylidene fluoride-trifluoroethylene) (P(VDF-TrFE)), as the gate insulator. Bilayer (SZTO/SIZO) was used for fabrication of synaptic device due to its high field effect mobility of over 30 $cm^2V^{-1}s^{-1}$ and exceptional stability under temperature, negative gate bias, and positive gate bias stress. The P(VDF-TrFE) layer was subjected to heating at 140 °C, resulting in the formation of the β-phase, which significantly enhances its ferroelectric characteristic. Complete device structure consists of Al/Ti/ P(VDF-TrFE)/ZrO_2/SZTO/SIZO/substrate with channel width and length of 250 and 50 μm, respectively. The synaptic devices exhibit counterclockwise hysteresis, indicating the presence of a ferroelectric layer as the gate insulator. A memory window exceeding 8 V was observed during sweeping between -20 to 30 V, with a saturation current above 1μA at 30 V. The postsynaptic currents (PSCs) were measured using 50 potentiation and 50 depression input pulses ±10 V for 1 s. Maximum conductance of over 90 nS have been calculated using the presynaptic gate voltage and post synaptic drain current. A multilayer perceptron (MLP) neural network was constructed using “MLP NeuroSim+ V3.0” software with 400 input neurons, 100 hidden neurons, and 10 output neurons, interconnected with artificial synapses. The training dataset included a manually written numeral from the Modified National Institute of Standards and Technology (MNIST) database. The neural network simulation demonstrated recognition accuracy exceeding 50% for the handwritten digits. Optimizing the ferroelectric layer and enhancing our understanding of the gate insulator-channel interface could pave the way for developing high-performance synaptic devices in the future.

A Variation of Ginzburg-Landau Free Energy and Associated Analog Behavior of Ferroelectric $Hf_{1-x}Zr_xO_2$ Thin Films Hong Heon Lim and Seung Chul Chae; Seoul National University, Korea (the Republic of)

With the rapid development of artificial intelligence (AI) technology, the demand of energy-efficient non-volatile electronic devices is increasing significantly. The energy inefficiency of today’s computing system is largely attributed to the von Neumann bottleneck caused by the separation of logic and memory unit. As innovative alternative to overcome this disadvantage, neuromorphic computing system has been studied extensively, requiring artificial neurons and synapses that have multiple conductance levels. Ferroelectric materials are considered promising candidates since their multilevel states of spontaneous polarization have a potential to realize synaptic weight elements. Although numerous ferroelectric materials have been reported, ferroelectric hafnium oxide-based thin films have attracted attention due to their robust ferroelectric properties and good compatibility with complementary metal-oxide-semiconductor (CMOS) technology. However, researches on stoichiometric characteristics related to ferroelectric synaptic weights are still lacking.
In this work, we investigated the ferroelectricity of hafnium zirconium oxide (HZO) thin films by varying the zirconium composition ratio. 1x nm polycrystalline $Hf_{1-x}Zr_xO_2$ ($0.31 \le x \le 0.58$) thin films were prepared by atomic layer deposition (ALD) on Si substrate. Besides we obtained 3-bit multilevel states of subloop hysteresis for each thin film. $Hf_{0.59}Zr_{0.41}O_2$ thin film showed the largest remnant polarization value of 24.8 $\mu C/cm^2$ and superior

reliability of intermediate ferroelectric polarization states. In order to explain the reason for its reliability, we examined the critical volume for nucleation of the ferroelectric domain through the conventional electrical measurements and the phase-field simulation based on time-dependent Ginzburg-Landau model. Our results suggest the possibility to implement analog behavior of ferroelectric HZO thin films.

Intermediate States in Artificial Spin Ice Inspired Computation Hanu Arava[1], Ignacio Tapia[2], Timothy Cote[3,1], Justin Woods[1], Frank Barrows[4], John Fullerton[1] and Paula Mellado[2]; [1]Argonne National Laboratory, United States; [2]Adolfo Ibáñez University, Chile; [3]Northwestern University, United States; [4]Los Alamos National Laboratory, United States

Computing with dipolar coupled nanomagnets provides us with a unique future towards energy efficiency and exploration of opportunities in innovative computing architectures for beyond-Moore applications such as brain-inspired computation. An often-neglected problem with nanomagnet computation is the presence of intermediate states, which are metastable states that arise during computation. These errors, leading to a low operational reliability of a device, are often attributed to lithographic defects, inefficient field/thermal protocols, and local disorder. In this work, we theoretically and experimentally demonstrate that operational inefficiency in nanomagnet based computing is primarily due to the presence of metastable intermediate states. We make use of a simple toy model of four nanomagnets arranged onto a square plaquette to systematically engineer intermediate states with tunable energies, thus leading to tunable outcomes. These intermediate states naturally arise as they connect an initial input with the final output through multipolar moment reorientations dubbed an energy relaxation pathway. We show that the outcome is the aftermath of the energy landscape profile which is deeply connected to the geometrical arrangement of the nanomagnets, and in turn is controlled by emerging multipolar moments. Finally, we argue that designer lattices can and must be considered to side-step or leverage intermediate states for novel computing opportunities. We hope our proposed design framework will assist future research in artificial spin ice, nanomagnetic logic, and spintronics communities, encouraging them to consider geometry-induced energetics in designer lattices.

EL05.08.11

A Novel Method to Fabricate IGZO FeFET Using Multi-Layered Stressor Capping of HZO for Neuromorphic Computing Jae Seong Han, Ju Hyun Lee, Kyungmoon Kwak, Kyungho Park, Jong Bin An, Sujin Lee, Subi Choi and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Since the first demonstration of the ferroelectricity in doped hafnium oxide (HfO_2) in 2011, the hafnium zirconium oxide (HZO) has risen as a promising candidate of the ferroelectric memory device due to its nature of back-end-of-line (BEOL) compatibility and scalability. Besides, indium gallium zinc oxide (IGZO) which was reported in 2004 for the first time, is also emerging as the channel material for the future memory device in that IGZO has low off-state leakage and low processing temperature of about 300°C. In this manner, the integration of HZO to the IGZO based field effect transistor (FET) and its application to neuromorphic system using gradual switching characteristic of HZO have been intensively studied. Generally, the fabrication of ferroelectric FET (FeFET) using IGZO channel requires a complicated capping metal etching since the ferroelectricity of HZO is obtained when the tensile stress is induced by the capping metal during the cooling process of the rapid thermal annealing (RTA). However, the etching process may cause the degradation in the back surface of HZO, causing the interface degradation between HZO and IGZO which leads to the critical stability issue for the device. Another approach involves direct capping using IGZO as it can induce tensile stress to the HZO as much as conventional capping metals can, but the semiconducting property of IGZO is severely degradaded due to the oxygen outgassing during the RTA process. In this work, we propose a multi-layered stressor consisting of tungsten (W) and IGZO for the

FeFET fabrication to induce sufficient tensile stress to the HZO and at the same time, maintaing the semiconducting property of the IGZO.
We firstly confirmed the ferroelectricity of metal–ferroelectric–metal (MFM) capacitors where the tensile stress was applied by various capping layers such as W, IGZO, and W/IGZO. The 10 nm-thick HZO was deposited using atomic layer deposition (ALD) method. For the IGZO-capped and W/IGZO-capped capacitors, the capping layers were totally removed and W electrode was re-deposited to form the identical MFM structure. A conventional W-capped capacitor exhibited a remanent polarization ($2P_r$) of 46.05 µC/cm^2, while the IGZO-capped and W/IGZO-capped capacitors showed $2P_r$ values of 25.83 µC/cm^2 and 34.93 µC/cm^2, respectively. This result indicates that the W/IGZO capping layer can induce larger tensile stress for HZO crystallization compared to the IGZO capping layer. Based on this result, we fabricated FeFET using W/IGZO capping layer where the ferroelectric HZO was used as a gate insulator. Here, the W and IGZO was subsequently patterned and used as a source/drain electrode and channel, respectively. The transfer characteristic showed clear counterclockwise hysteresis, which confirms the ferroelectricity in the gate insulator. Under ± 3 V of gate voltage sweep, our FeFET showed large memory window of 1.76 V, and the on-off ratio of about 10^6. For comparison, another FeFET was fabricated using IGZO-capping method, and the device did not have semiconducting property without post annealing process in the air due to the outgassing during the RTA process. After the post annealing process, the IGZO-capped FeFET showed the semiconducting property with counterclockwise hysteresis, but the memory window was only 1.12 V. We anticipate that the W layer on IGZO can work as a blocking layer for oxygen outgassing of IGZO during the RTA process. Finally, to confirm the neuromorphic characteristics, synaptic current was measured by applying voltage pusle of ± 2.5 V. As a result, it was confirmed that our FeFET showed proper synaptic characteristics such as potentiaion and depression.

EL05.08.12

Gd-Doped CeO_2/CeO_2 Bi-Layer Memristors-Based Reservoir Computing—Study on Optimal Parameters of Memristors for Pattern Recognition Sola Moon[1], Cheolhong Park[1], Yunyoung Jung[2], Hyunhyub Ko[1] and Tae-Sik Yoon[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Pentasecurity Inc, Korea (the Republic of)

Reservoir computing (RC) is a new powerful framework for effectively processing complex data, including pattern recognition, speech recognition, time series analysis, and natural language processing. Unlike DNNs, requiring the entire weight network to be trained by the gradient method, RCs have an advantage in increased learning speed with reduced cost because training is performed only at the readout while maintaining the rest of the network fixed. Among several device candidates for hardware implementation of RC systems, memristor is a proper and efficient device for RC framework because it has nonlinear functions and exhibits memory characteristics [1]. Analyzing the time-dependent weight dynamics of memristors is important to extract various spatial and temporal characteristics of the reservoir in performing spatiotemporal operations in RC. These features include high dimensionality of reservoir, nonlinearity with respect to weight update, nonlinear short-term plasticity (STP), and class separation property. In particular, the weight update is performed consecutively to obtain time-varying reservoir state, where a paired-pulse facilitation (PPF) occurs that impacts on the nonlinearity characteristics of the weight updates. In addition, the reservoir state must have short-term decay characteristics to process spatiotemporal information via effectively separating complex sequential information without superimposing reservoir states.
In this study, we experimentally demonstrate RC system with Pt/Gd-doped CeO_2 (GDC)/CeO_2/Pt memristors exhibiting time-dependent weight update and decay characteristics, which benefit to realize RC systems. The bi-layered oxide memristors based on the same CeO_2 matrix, i.e., GDC/CeO_2, are characterized to have more stable and controllable redistribution of oxygen vacancies between CeO_2 and GDC layers under the electric field. CeO_2 has a high oxygen ion conductivity and variable valence states of Ce cations, which are favorable properties as a

resistive switching material. GDC was also reported to have increased oxygen ion conductivity via increased oxygen vacancy concentration as a result of Gd doping in CeO_2. The proposed GDC/CeO_2 bi-layered oxide memristor has been demonstrated to have analogous synaptic weight update, PPF, STP characteristics and their adjustment could be improved compared to the single-layered CeO_2 or GDC memristors [2]. This GDC/CeO_2 memristors were employed to perform RC by storing reservoir states with controllable weight update and decay characteristics that effectively separate complex sequential information without superimposing the states. The RC performance of the memristor was evaluated by a 4-bit pattern verification as applying various pulse signals to the memristor using Modified National Institute of Standards and Technology (MNIST) handwriting database to train and test the RC system. Pattern recognition simulations showed accuracy levels of up to 90 % in bilayer memristors, confirming the potential of these bilayer memristors as artificial synapses for neuromorphic computing. In addition to the experimental study, the short-term decay characteristics were fitted using an exponential decay curve to obtain the value of �� (time constant). Then, we propose optimal parameter values of the memristor for RC system by tuning �� and PPF index to trace the conditions that can distinguish between reservoir states. Therefore, the dynamics of memristors in complex spatiotemporal tasks could be investigated to derive optimal parameters, which can then be implemented in RC systems to achieve high-performance recognition and prediction.

Linear Analog Weight Update and Long-Term Plasticity in Pt/p-$LiCoO_x$/n-IGZO/Pt and Pt/p-$LiCoO_x$/p-NiO/Pt Memristors by Controlling Li Ion Distribution for Neuromorphic Computing

Boyoung Jeong, Peter H. Chung, Jimin Han, Taeyun Noh and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Emerging data-centric applications such as artificial intelligence, IoT, and autonomous driving systems requires novel high energy-efficient computing architectures overcoming von-Neumann bottleneck problem of delayed data transfer in current computing systems. Neuromorphic computing is one of promising candidates for new computing architectures, mimicking human brain that processes complicated tasks with a low energy consumption of ~ 20 W [1]. To realize neuromorphic computing, a highly linear and symmetric weight update and its long-term plasticity with a low operation voltage for potentiation and depression are essential features of an artificial synapse. In this study, two types of memristors are proposed as artificial synapses controlling movable Li^+ ion redistribution that is responsible for conductance modulation in these devices. Because Li^+ ion is highly movable element and act as dopant in metal-oxides, it can change the resistance states in many metal-oxide systems. Therefore, it has a potential to provide a plausible route to realize low-power artificial synapse through controlling its distribution in the memristors.

The first one is the pn-junction memristor with Pt/p-$LiCoO_x$/n-InGaZnO(IGZO)/Pt structure and it is operated by modulated interfacial energy barrier between p-$LiCoO_x$ and n-IGZO as a result of Li^+ ion migration. Because Li^+ ions act as p-type dopants in IGZO channel layer [2], Li^+ ions in p-$LiCoO_x$ layer migrate to n-IGZO layer upon voltage application and modulate the interface energy barrier between p-$LiCoO_x$ and n-IGZO. This voltage-driven Li^+ ion migration enables the analog conductance modulation in pn-junction memristor. In particular, because Li^+ ions are highly movable even under low bias, the conductance could be tuned by two orders of magnitude even at low voltage less than ±3 V. In addition, engineering of the device structure, including insertion of ion blocking layer, local encapsulation of Li^+ ions, and use of UV/ozone treatment on the layers could enhance long-term plasticity through controlling Li^+ ions more stably. Thanks to its pn diode characteristics, it can also mitigate sneak current

problems in high-density crossbar array architecture as a self-rectifying synaptic memristor.
The other one is Pt/p-$LiCoO_x$/p-NiO/Pt memristor (pp-junction), which is operated by modulated interfacial energy barrier between p-NiO and Pt bottom electrode with respect to the Li^+ ion distribution in NiO layer. Because this device utilizes the low energy barrier modulation between p-NiO and high work function Pt electrode, the weight update could be highly linear and symmetric through even minute change in the barrier height. Also, this modulation comes from the redistribution of movable Li^+ ions, the operation voltage could be reduced to the range of ±2 V. In addition to analog weight update, the pp-junction memristor shows good synaptic properties such as paired pulse facilitation (PPF), short-term and long-term plasticity (STP and LTP) depending on stimulation conditions. The four retained long-term resistance states could be achieved with respect to the applied voltage amplitude. Use of tunable interfacial energy barrier by Li^+ ion redistribution facilitates analog conductance modulation in a high speed with a low voltage.
These results demonstrate potential applications of Pt/p-$LiCoO_x$/n-IGZO/Pt and Pt/p-$LiCoO_x$/p-NiO/Pt memristors as artificial synapses with linear, symmetric, and analog conductance change at low operation voltage with a long-term plasticity by energy barrier modulation with Li^+ ion distribution.

Self-Selective Crossbar Synapse Array with n-ZnO/p-NiO_x/n-ZnO Structure for Neuromorphic Computing

Peter H. Chung and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Artificial synapse devices are essential elements for highly energy-efficient neuromorphic computing, which can overcome the current bottle neck issue of the von Neuman computing system.[1,2] They are implemented as crossbar array architecture, where highly selective synaptic weight update for training and sneak leakage-free inference operations are required. In this study, self-selective bipolar artificial synapse device was proposed with n-ZnO/p-NiO_x/n-ZnO heterojunction and its analog synapse operation with high selectivity was demonstrated in crossbar array architecture without the aid of selector devices.

In unit device, the dynamic range of weight update reached 17.6 times of initial value and the updated memory retained about 34.6 % after 30 min, exhibiting both short-term plasticity and long-term plasticity. The nonlinearity factor in half-voltage operation scheme, which is the ratio of current at full voltage to half voltage, was 19.4 and the dynamic range of the full-biased cell was 27 times wider than that of the half-biased cell.

In 32×32 crossbar array structure, with 10 μm line width, the device showed analog weight update with dynamic range of more than 100 times of the initial state. The direct measurements of weight update in the crossbar array exhibited a high conductance change reaching about 14.4 times in the full-biased selected cell, while it was less than 1.8 times in the unselected cells (non-biased and half-biased). The pattern recognition accuracy simulated with the obtained multiple cycles of synaptic weight update profile using CrossSim ver. 2.0 Training exhibited about 89.0 % of accuracy within 20 epochs of training.

The high nonlinearity of the device was from the additional current flow by Zener tunneling effect. In the low field regime, the diffusion current overcoming the p-n junction barrier dominated. However, when strong field was applied, Zener tunneling current flowed additionally from the valence band of the p-NiO_x to the conduction band of the n-ZnO due to the bending of the band in the reverse bias depletion region, which provided highly nonlinear current-voltage characteristics at both voltage polarities for self-selecting function.

Analog synaptic weight update of the device originated from voltage-driven redistribution of oxygen ions inside n-p-n oxide structure. Application of positive bias at top electrode attracted oxygen ions to the upper region of ZnO and NiO_x and bent the energy band accordingly. It lowered the potential barrier height at the bottom p-NiO_x/n-ZnO junction, which increased the current in the low field regime by increasing the diffusion current. In addition, the increased band offset at the upper n-ZnO/p-NiO_x junction, as a result of oxygen redistribution, increased the current in the high field by lowering the Zener breakdown turn-on voltage. Therefore, the increased conductance as potentiation behavior could be achieved by applying positive bias at top electrode. Inversely, application of negative bias at top electrode repelled oxygen ions to the bottom region of the n-ZnO and p-NiO_x lowering the conductance back to the initial state as depression behavior.

Halide Perovskite Photovoltaics for In-Sensor Reservoir Computing

Divyam Sharma and Nripan Mathews; Nanyang Technological University, Singapore

As intelligent electronics get laden with multimodal sensors, the data transfer and computation increase their energy expenditure. Consequently, researchers aim to develop efficient computing paradigms or integrate energy harvesting from ambient sources. Halide perovskites possess unique photophysics and coupled ionic-electronic dynamics that actualize memory devices for brain-inspired computing. Synergising the computing capability with their conventional light harvesting efficacy could aptly address the aforementioned problem. In a novel approach, the **transient open circuit voltage (V_{OC}) of a methylammonium lead bromide-based solar cell is exploited to serve as a volatile and versatile short-term memory for optoelectronic in-sensor reservoir computing**. The proposed approach using photovoltaics for reservoir computing could self-power the optoelectronic memory element by innately generating voltages in response to light as opposed to photomemristors which require a read operation to probe the conductance state. Operating in open circuit conditions ensures **extremely low power consumption (<1pW)**. Drift diffusion simulations were performed to unravel how the entangled ionic-electronic processes manifest into short-term memory in the V_{OC} of halide perovskite photovoltaics. Based on this understanding, the recombination kinetics of could be engineered to modulate the timescales from 0.1ms to 100ms. The superior reservoir computing properties were validated by characterizing the echo-state properties and performing benchmarking task of image recognition with **highly reproducible (std. dev. = 0.12%) and robust (endurance > 10000 cycles) transformation of optical inputs into unique reservoir states**. To demonstrate **high non-linearity, second-order time-series prediction is performed (NMSE = 0.0281) for the first time in the optoelectronic mode**. Finally, an exemplary health-monitoring application is showcased by **monolithic reading and processing of a physiological time-series known as photoplethysmography (PPG) to identify atrial fibrillation**.

Photonic Synapse of CrSBr/PtS_2 Transistor for Neuromorphic Computing and Light Decoding Information

Muhammad Farooq Khan, Muhammad Asghar Khan and Jonghwa Eom; Sejong University, Korea (the Republic of)

Field effect transistors (FETs) based on two-dimensional (2D) layered material have gained a lot of potential in emerging technologies such as neuromorphic computing and ultrafast memory response for artificial intelligence (AI) applications. In this study, we proposed a facile and diverse approach to fabricate an optoelectronic artificial synapse for neuromorphic computing and light decoding information system by utilizing the 2D heterostructure of CrSBr/PtS_2 to overcome the complexity of circuits. The CrSBr layer is employed as a trapping layer, while PtS_2 is mounted on top of CrSBr and used as a channel layer. PtS_2 exhibits n-type semiconductor behavior with a sizeable clockwise hysteresis (memory window) depending on the thickness of the underlying CrSBr layer, which is attributed to the presence of charge-trapping defect states such as sulfur vacancies inside the CrSBr layer. Our heterostructure device with a 96.3 nm thick CrSBr device exhibited a large memory window of 11.9 V when the gate voltage was swept from -10 V to +10 V. Furthermore; the memory window can be modulated from 0.4 V to 11.9 V by the sweeping range of gate voltage from ±1 V to ±10 V. Additionally, synaptic behavior, including paired-pulse facilitation (PPF), excitatory postsynaptic current (EPSC), optical spike number dependence, gate dependence, and spike intensity dependence plasticity were effectively demonstrated using incident laser light of 365 nm wavelength. Moreover, our device achieves 26 distinct output signals depending upon the intensity of the incident laser light ranging from 10 $mWcm^{-2}$ to 385 $mWcm^{-2}$, which allows its applications for light-decoded information security systems. Thus, our investigation presents a unique approach to artificial intelligence and cyber security systems.

$CdIn_2S_4$-Based Memory Devices with Neuromorphic Capabilities Jakub Zdzieblowski[1], Nicolas Barreau[2] and Pawel Zabierowski[1]; [1]Warsaw University of Technology, Poland; [2]Université de Nantes, France

In this work, we demonstrate the first realization of devices based on cadmium-indium sulfide ($CdIn_2S_4$), capable of acting as a binary memory cell as well as exhibiting basic synaptic functions, i.e., potentiation, depression including optical stimulation, and leaky integrate and fire (LIF) behavior. Neuromorphic behaviors are controlled by more than one physical process and rely only on native defects of the $CdIn_2S_4$, thus offering a wide range of technological possibilities.
Cadmium-indium sulfide is a widely studied n-type chalcogenide semiconductor with a spinel structure, primarily researched for its applications in photocatalysis and photovoltaics. Past investigations have revealed its photosensitive nature, along with distinctive memory behaviors. The $CdIn_2S_4$ possesses several native defect states, including Cd_{In} and In_{Cd} antisite defects induced by inversion of the spinel structure. Ab initio simulations show that Cd_{In} and sulfur vacancy - another native defect in $CdIn_2S_4$ - form metastable complex states. Polycrystalline $CdIn_2S_4$ thin films were grown via physical vapor deposition on SLG/Mo substrates. By controlling the deposition temperature, we controlled the stoichiometry of the layer. Afterwards, the films were coupled with a polycrystalline ZnO:Al layer acting as a transparent electrode, with aluminum electrodes completing the device. The structure consists of a double rectifying junction: Mo/$CdIn_2S_4$ and $CdIn_2S_4$/ZnO. The barrier heights of both junctions can be gradually modulated electrically and optically, which is a core process responsible for its neuromorphic behavior. Applying a train of learning electrical pulses leads to gradual barrier reduction on one of the junctions, reducing the resistance and thus practically realizing electrical synaptic potentiation. Train of negative pulses resets the first barrier and impacts the opposite one. Applying sufficiently high voltage results in abrupt switching between two opposite states, notably transitioning between the state when the barrier on ZnO is completely reduced and the opposite state when the barrier on Mo is reduced, practically realizing a binary switching operation. The same switching procedure can be realized with a sufficient number of training pulses with an amplitude just below the switching voltage. Those processes combined mimic the 'Leaky integrate and fire' synaptic behavior, as the process decay time is relatively fast. Our measurements indicate that the switching mechanism is related to the repining of the Fermi level by defect states, and its intricate details are currently under our investigation. As the In_{Cd}&V_S complex is metastable, persistent photoconductivity phenomena occur. It is then possible to convert the charge state of the metastable defects by illuminating the compound with a particular wavelength, practically altering its conductivity, which can be done even with the $CdIn_2S_4$ bulk material alone. In devices, light pulses influence both junctions similarly to electrical pulses. As the absorption coefficient

monotonously grows with the photon energy, the learning function can be controlled with incident light wavelength.
All the switching behaviors, including switching voltage values and learning performance, strongly depend on stoichiometry and post-deposition treatment, which indicates the implicit influence of the $CdIn_2S_4$ native defects. It opens promising possibilities for utilizing defect engineering, including metastable defects, to create neuromorphic devices. This work marks an initial exploration into utilizing $CdIn_2S_4$ in neuromorphic computing, offering promising avenues for future advancement.

High-Throughput Manufacturing of Flexible 4K-Memristor Crossbar Circuit Jae Gwang Kim, Chongjie Gao, Xiaofei Wu and Shiren Wang; Texas A&M University, United States

Memristor crossbars offer a promising path towards high-density, low-power neuromorphic computing due to their ability to store large neural network models directly on-chip, minimizing off-chip communication bottlenecks. However, the production of high-density circuits predominantly depends on lithography technology, which necessitates lengthy processing times, ranging from days to several weeks, and a clean-room manufacturing environment. Herein, we demonstrate the high-throughput manufacturing of nonvolatile flexible memristors of the 4K-crossbar circuit based on ultrasonic-assisted spray printing under an open environment. This enables low cost and time efficiency and allows manufacturing without a clean-room environment. The as-manufactured 4K-memristor array demonstrates outstanding functionality with a switching error of less than 5% in a gray-scale 4K pixel image programming under mechanical stretching. A vector-by-matrix multiplication with an average 1 % relative conductance accuracy has also been successfully demonstrated experimentally, confirming the validity of analog-grade electrical features. The MNIST image classification with a large-scale multilayer perceptron classifier was also demonstrated in this paper.

EL05.08.19
Si-Integrated $BaTiO_3$—Emergent Platform for Integrated Optical Computing Alex Demkov[1,2], Agham B. Posadas[2] and Dan Wasserman[1]; [1]The University of Texas at Austin, United States; [2]La Luce Cristallina, Inc., United States

Traditional computing based on CMOS technology is nearing physical limits in terms of miniaturization, speed, and power consumption. Consequently, alternative approaches are under investigation. The most promising is based on a “brain-like” or *neuromorphic computation* scheme; another is quantum computing. Both of these approaches can be realized optically using silicon photonics (SiPh), in which the fundamental unit is an efficient, ultra-low power broadband optical modulator. A complete or partial switch from electrons to photons in computing would be revolutionary. Such technology ultimately requires the integration of both active and passive photonic elements on a single chip. As silicon modulators suffer from relatively high-power consumption and large size, materials other than silicon are now being considered for realizing these compact energy-efficient modulators. I will discuss our recent progress in integrating ferroelectric perovskite $BaTiO_3$ (BTO) with SiPh for the purpose of fabricating modulators that exploit the linear electro-optic effect, as well as other passive optic elements. As-grown Si-integrated BTO demonstrates low optical loss on the order of 1 dB/cm that is sufficient for passive elements. We also show microring resonators fabricated in the monolithic Si-integrated BTO system with 50 mm radius that demonstrate very large Q-factors ($Q > 5 \times 10^4$) confirming exceptionally low loss. Mach-Zehnder modulators based on BTO have demonstrated $V_\pi L$ as low as 0.23 Vcm (0.014 Vcm in plasmonic devices), modulation bandwidth of 100 GHz, and data rates above 250 Gb/s. In addition, Si-integrated BTO-based devices have shown robust cryogenic performance. Importantly, unlike $LiNbO_3$, BTO is fully compatible with Si foundry processing. These properties will enable neuromorphic circuit architectures that exploit shifting computational machine learning paradigms, while leveraging current semiconductor manufacturing infrastructure. This will result in a new generation of computers that consume less power and possess a larger bandwidth. A particularly elegant implementation of optical neuromorphic computing is a reservoir computer, a computational framework suited for temporal/sequential stream data processing. Such a computing system consists of a reservoir for mapping inputs onto a high-dimensional space and a readout for pattern analysis from the high-dimensional states in the reservoir. The reservoir is fixed and only the readout is trained with a simple method such as linear regression and classification. The major advantage of reservoir computing compared to other neural networks is its fast learning, which substantially reduces training cost. I will discuss our progress in implementing an integrated photonics reservoir.

EL05.08.20

Face Digital Image Speckle Correlation (DISC) Application as a Non-Invasive, Accessible Tool to Detect Acoustic Neuroma Corey Zhang[1], Yoonsoo Song[2], Jerry Gu[3], Shreyaa Sanjay[4], Zihan Jia[5], Eugene Jiang[6], Brooklyn Ratel[6], Divleen Singh[6], Shi Fu[6], Huiting Luo[6], Miriam Rafailovich[6] and Gurtej Singh[6]; [1]Eastlake High School, United States; [2]Maclay School, United States; [3]Princeton International School of Mathematics and Science, United States; [4]West Windsor-Plainsboro High School North, United States; [5]The Experimental High School Attached to Beijing Normal University, China; [6]Stony Brook University, The State University of New York, China

Acoustic neuroma, a benign tumor on the vestibulocochlear nerve, often causes hearing loss and facial asymmetry. Each year in the United States, approximately 3,000 individuals are diagnosed with the disease. The traditional method of early diagnosis using an EEG is inaccessible, costly, and uncomfortable. To address these challenges, our project aims to develop a face digital image speckle correlation (DISC) application for iOS to facilitate real-time diagnosis by mapping facial muscle movement through advanced image processing techniques. This approach provides a convenient, accessible, affordable, and non-invasive tool for early diagnosis in patients and doctors, eventually generating better outcomes.

We developed a DISC application that will assist the diagnosis of acoustic neuroma by standardizing and streamlining the process of photo-taking and cropping, which ensures that patients are consistently positioned, aiding doctors in accurately identifying facial asymmetry, thus enhancing diagnostic accuracy and accessibility.

For image processing and heatmap application, a Python script in a Jupyter Notebook managed image acquisition, preprocessing, and speckle correlation analysis. Utilizing OpenCV, we performed edge detection, contour detection, and region of interest extraction. The user interface, developed with Swift and Apple’s CoreML library, applied a mask to ensure correct user positioning during photo capture. Both images were converted to grayscale and downscaled to 10 by 10 pixels for easier processing.

Tests on project members demonstrated the DISC application’s effectiveness in generating heatmaps, accurately identifying facial asymmetry by highlighting stronger vector displacements in areas of facial movement, such as a smirk. Bilinear interpolation, used to calculate displacement at intermediate points within a planar face mesh, highlighted variations in facial movement, indicating potential asymmetry associated with acoustic neuroma.

The DISC application shows significant promise as a preliminary diagnostic tool for acoustic neuroma by effectively detecting facial asymmetry. By integrating Python and OpenCV for image processing with Swift and CoreML for facial segmentation, we have developed a robust and user-friendly platform. The deployment on Azure for OpenCV integration into Xcode to interlink all GUI elements ensures scalability and reliability.

Overall, the DISC application offers a user-friendly, time-efficient, and accurate solution for diagnosing acoustic neuroma through the detection of facial muscle movements by standardizing the photo-taking process and providing real-time analysis. As it assists early detection and prompts medical consultation, the application would ultimately ease healthcare barriers and improve patient outcomes.

Atom to System—A Bottom-Up Hardware-Software Co-Design Approach for Resistive Random-Access Memory-Based In-Memory Computing Md Tawsif Rahman Chowdhury and Gozde` Tutuncuoglu; Wayne State University, United States

Traditional computing technology suffers from significantly higher energy consumption and latency due to von Neumann bottleneck while performing data-intensive and low-latency tasks like high-throughput image recognition. Resistive random-access memory (RRAM) based crossbar arrays, capable of analog in-memory computing, offer a promising approach to enhance the efficiency of multiply-and-accumulate (MAC) operations paramount to machine learning algorithms such as neural networks and beyond [1]-[2]. However, aggregated effects from device and circuit level variabilities and other device non-idealities pose a significant threat to the widespread adaptation of this technology. Hence, extensive study is required to capture and predict the intricate details of these devices and systems.

Over the years, Design Technology Co-Optimization (DTCO) has become indispensable in the semiconductor industry [3] as it can lower costs during technology development and accelerate the time-to-market. We believe that a similar methodology is required to enhance the efficiency and reliability of RRAMs, making them a more viable option for future in-memory computing technologies. To address this, we propose a bottom-up atom-to-system-level hardware-software co-design approach tailored for RRAM devices to facilitate a comprehensive analysis linking the atomic insights to process development to circuit and software design capable of emulating different computing algorithms. This approach enables us to harness and engineer materials properties for optimized device and systems performance.

We plan to conduct first-principles density functional theory (DFT) calculations to comprehensively investigate the mechanisms behind defect formation and their influence on the material's electronic properties. Defects, such as grain boundaries or oxygen vacancies, can form conductive filaments, which provide pathways for electrical current to flow and enable resistive switching. These atomic-level simulations will then be followed by device-level simulations to fine-tune and optimize the fundamental behavior and interactions of materials, and to understand how these interactions influence device-level performance. This can then be utilized for process development, leading to reduced variability and enhanced device reliability. On the other end of the spectrum, software capable of incorporating these device-level insights into electrical circuits and systems to emulate specific computing tasks is developed. This parallelization and vertical integration of bottom-up hardware-software co-design methodology can contribute to the understanding of the stochastic nature of RRAM-based systems fully and leverage this understanding towards achieving fast, energy-efficient, and reliable practical solutions for next-generation computing.

A Compact and All-Round Spiking Artificial Neuron with Diffusive Memristor for Neuromorphic Computation

Ruoyu Zhao, Tong Wang and J. Joshua Yang; University of Southern California, United States

Artificial intelligence (AI) is approaching a stage where the limitations of current hardware technology in terms of energy and area efficiency significantly hinder system performance. Despite the deployment of tens of thousands of GPUs and megawatt-level power consumption, the most advanced AI system still doesn’t match the intelligence of the human brain, which operates at only 20W within a volume of one cubic decimeter. To overcome this challenge, neuromorphic computing aims to leverage emerging devices and circuits to emulate the behavior of biological neural networks for more powerful AI hardware. Here, we have developed a highly scalable and energy-efficient spiking artificial neuron, composing one asymmetric diffusive memristor (ADM), one transistor and one resistor, referred to as the 1M1T1R neuron.

The ADM is a type of memristive devices with asymmetric switching behavior due to the migration of conductive ions within the asymmetric device. We compared two types of ADMs with HfO_2 and SiO_2 switching layers and observed different operation voltages and currents. The HfO_2 ADM was selected for constructing the 1M1T1R neuron due to its suitable operation range. The rich and asymmetric ion dynamics of the ADM, combined with the unique circuit configuration of the 1M1T1R neuron, enabled us to experimentally demonstrate six critical neuronal functions: leaky integration, threshold firing, cascaded connection, intrinsic plasticity, refractory period, and stochasticity. These functions cover all essential behaviors for general spiking neural network applications. The 1M1T1R neuron demonstrated an energy consumption of just 1pJ per spike and has the potential to be scaled down to the size of a single transistor by stacking the memristor and resistor on the transistor's gate.

We also developed a compact model of the 1M1T1R neuron that faithfully reproduces its functionality. Utilizing this model, we designed a recurrent spiking neural network (RSNN) with customized forward and backward algorithms based on the 1M1T1R neuron's behaviors. The RSNN was tested on the Spiking Heidelberg Digits (SHD) spatiotemporal dataset, achieving an average testing accuracy of 91.35%. Additionally, tuning the neuron functions during RSNN testing resulted in more than a 10% variation in network performance, highlighting the significance of these functions. These findings pave the way towards highly energy- and area-efficient neuromorphic systems by exploiting the ion dynamics in emerging memristive devices and co-designing hardware behaviors and software algorithms.

Reconfigurable VO_2 Mott Memristor for Neuromorphic Electronics

Gwanyeong Park[1], Sanhyeon Choi[2,1] and Gunuk Wang[1]; [1]Korea University, Korea (the Republic of); [2]University of Southern California, United States

To develop memory-centric parallel computing architectures and artificial neural networks, it is essential to integrate numerous building blocks that offer a variety of switching characteristics. Incorporating a variety of materials and building blocks into a single device circuit, however, may result in severe issues, including incompatibility with fabrication processes and mismatching operating ranges. It is advisable to incorporate multiple switching modes into a single, simple device form, as this can enhance operating consistency and reduce the complexity of fabrication. Here, we have explored the potential of this approach through the VO_2-based mott memristor that can possess both analog nonvolatile and threshold volatile switching features. Basically, the VO_2-based mott memristor can easily reconfigure these threshold and nonvolatile switching modes by utilizing the varying voltage polarities. We speculated that the threshold switching is caused by a volatile transition from metal to insulator through phase change, while the nonvolatile switching is related to the conductive filament with a deficiency of oxygen in the oxide thin film. We conducted an analysis of the X-ray diffraction (XRD) patterns and depth-profiled X-ray spectroscopy (XPS) of the deposited VO_2 film. Our findings confirmed the presence of the monoclinic phase and the defective oxygen reservoir layer, which could support our switching mechanisms. Using a single VO_2-based mott memristor, we successfully demonstrated the neural and synaptic functions, such as long-term potentiation and depression, as well as the rate coding and leaky-integrated-and-fire (LIF) in various voltage schemes in the single device unit. The reconfigurable VO_2 mott memristor holds great potential for implementing memory-centric parallel computing architectures and artificial neural networks in a more efficient manner.

9:00 AM EL05.09.04
Non-Volatile Analog Synapse Characteristics in Bi-Layered Nb_2O_5/CeO_2 Memristors for Artificial Neural Network in Neuromorphic Computing Systems Kitae Park, Peter H. Chung, Jiyeon Ryu, Sola Moon, Daejae Seo, Hanju Ko and Tae-Sik Yoon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Data-centric applications such as artificial intelligence demand novel energy-efficient computing systems including processing-in-memory (PIM) and neuromorphic computing. Recently, non-filamentary valence change memory (VCM) type memristors have been widely researched as one of the promising candidates for PIM and neuromorphic systems because of their superior uniformity and stablity of analog resistive switching. The analog memristor crossbar array is an adequate platform for vector-matrix multiplication operations in artificial neural network. However, inferior retention properties of interfacial type VCM memristors due to the volatile redistribution of oxygen ions have not been fully resolved yet.
In this study, bi-layered memristors with cerium oxide (CeO_2) and niobium oxide (Nb_2O_5), i.e., Nb_2O_5/CeO_2, were investigated, where CeO_2 and Nb_2O_5 are suitable material for interfacial VCM owing to their tunable valance states (Ce^{3+}, Ce^{4+} and Nb^{5+}, Nb^{4+}, Nb^{2+}) and high oxygen ion diffusivity. [1], [2]
Active inter-migration of oxygen ions between CeO_2 and Nb_2O_5 enables analog resistance change as synaptic weight update with long-term stability. The bi-layered Nb_2O_5/CeO_2 memristors displayed polarity-dependent analog resistance switching properties. Upon positive pulsing, oxygen ions move from CeO_2 to Nb_2O_5; thereby increasing conductance of the device (potentiation). Then, they reversibly turn back upon negative pulsing, decreasing the device conductance (depression). It was also confirmed that the Nb_2O_5/CeO_2 memristors had enhanced dynamic switching range ($>10^5$), analog linearity, symmetry, and retention properties, as compared to single-CeO_2 device. Multi-level conductance states were found to retain non-volatile property even after repeated potentiation and depression cycles. The analog resistance change was originated from the changes in oxygen vacancy concentration in CeO_2 layer, which caused difference in Schottky barrier height between CeO_2 and bottom electrode. And Nb_2O_5 layer worked as oxygen ion reservoir supplying oxygen vacancies to CeO_2 and holding oxygen ions for non-volatile retention stability. TEM and XPS analyses revealed the presence of abundant oxygen vacancies in CeO_2 and Nb_2O_5 layer for the enhanced oxygen ions redistribution. Furthermore, the Nb_2O_5/CeO_2 memristor maintained highly selective synaptic weight update properties in array structures without additional selector. Thanks to non-linear current-voltage characteristics of Nb_2O_5/CeO_2 memristor, sneak leakage current and unintended weight update were efficiently prevented in the array architecture. Using the obtained weight update characteristics, the 94.6 % of pattern recognition accuracy was achieved in simulation of MNIST

handwritten patterns using NeuroSim program.
In conclusion, these enhanced synapse characteristics of bi-layered Nb_2O_5/CeO_2 memristor crossbar array demonstrated the potential of proposed device to be applicable to integrated neuromorphic system that implements training and inference operations for neuromorphic computing.

9:15 AM EL05.09.05

Linearly Programmable Two-Dimensional Halide Perovskite Memristor Arrays for Neuromorphic Computing

Seung Ju Kim[1,2], J. Joshua Yang[1] and Ho Won Jang[2]; [1]University of Southern California, United States; [2]Seoul National University, Korea (the Republic of)

Neuromorphic hardware, which provides high-performance AI processing capability with low power consumption, is an attractive and challenging field designed to overcome the existing von Neumann computing systems. To implement high-performance training in neuromorphic hardware, it is essential to develop artificial synapses that exhibit linear and symmetric programmability with a bipolar operation, analog multi-states with a high dynamic range, a high yield, a long retention, a low variation, and a small footprint. To achieve these requirements, memristors, non-volatile memory devices that store data by their conductance, have been widely studied as artificial synapses. However, traditional memristors lack a reliable microscopic structure to confine ion migration during switching, resulting in commonly observed large variability (from device to device and switching cycle to cycle) and abrupt switching (instead of linear and symmetric programming). To address these issues, numerous approaches have been explored, such as modulating conductance by adding gate-terminals or optimizing programming schemes. Only limited success has been achieved so far, which, on the other hand, typically incurs substantial area, circuitry, time, and/or energy overheads.
Recently, two-dimensional (2D) halide perovskites have arisen as a top candidate for artificial synapses due to their phase versatility, superior memristive properties, microstructural anisotropy in electrical and optoelectronic properties, and even excellent moisture resistance. Unfortunately, a common challenge in all memristors has also been identified in such halide perovskites, namely, asymmetric and nonlinear conductance change, which is a well-known roadblock for efficient training and accurate inference when such materials are used in neural networks.
Here, we achieve highly linear and symmetrical conductance changes (α_p: 0.002, α_d: -0.0015) in Dion-Jacobson 2D perovskites, which were unachievable previously in 2D perovskites. We further build a crossbar array based on analog perovskite synapses, achieving a high (~100%) device yield, low variation (~1.85%) with synaptic weight storing capability, multilevel analog states with long retention (~10^4 s), and moisture stability over 7 months. We explore the potential of such devices in large-scale image inference via simulations and show an accuracy within 0.08% of the theoretical limit. The remarkable device performances are attributed to the homogenous migration of halide vacancies by eliminating gaps between inorganic layers, confirmed by first-principles calculations and experiments. Due to the Dion Jacobson phase formed by changing large organic cations from monovalent to divalent ammonium cations ($A''A_{n-1}Pb_nX_{3n+1}$, A'' is divalent ammonium cation), two hydrogen bonds are formed between organic and inorganic layers, eliminating van der Waals gaps, resulting in homogeneous interfacial ion migration through the entire region of vertically aligned layers. Our materials design rule is generally applicable to other memristive material systems for achieving high-performance neuromorphic computing.

Leveraging Memristive Technologies for Advanced Cognitive Systems Erika Covi; University of Groningen, Netherlands

Up-to-date as of November 14, 2024

In the past two decades, the shift towards a distributed computing paradigm led our smart systems to become more and more interconnected. These systems need to elaborate increasingly amount of data while featuring low-power operation, area efficiency, and ability to interact with the external world in real time [1]. Memristive technology, with its unique characteristics and capabilities, holds great promise for the design of such cognitive systems [1,2]. The potential for energy-efficient and parallel computing, combined with the ability to integrate complex neural and synaptic dynamics within a single device, provides avenues for high-performance hardware implementations [3]. Moreover, by offering volatile and non-volatile memory in a small footprint, enabling dense integration, and facilitating in-memory computing, memristive technology presents advantages that, if correctly combined with CMOS technology, can extend the functionality of current artificial intelligent systems.
In this talk, we discuss the challenges and the opportunities to realise memristive neuromorphic computing by developing novel hardware architectures and learning algorithms specifically tailored to best exploit the intrinsic properties of memristive technology. Indeed, we show that memristive technology offers vast potential, but its effective utilization relies on the synergetic development of memristive devices, circuits, and algorithms to create performing hardware cognitive systems.

Memristor Devices and Systems for Analog and Neuromorphic Computing Wenhao Song, Ruoyu Zhao and J. Joshua Yang; University of Southern California, United States

Recent breakthroughs in memristive devices have paved the way for unprecedented opportunities in computing, including analog and neuromorphic computing. Analog computing is known for its high energy efficiency and throughput but often suffers from poor precision. To address this, we have investigated the sources of reading noise, successfully mitigating them to achieve an unprecedented 2048 conductance levels in individual memristors. This equates to 11 bits per cell, setting a record precision across various memory types. Recognizing the ongoing demand for single or double precision in numerous applications, we have proposed and developed a novel circuit architecture and programming protocol. This innovation allows analog memories to achieve arbitrarily high precision with minimal circuit overhead. Our experimental validation includes a memristor System-on-Chip fabricated in a standard foundry, demonstrating significant improvements in precision and power efficiency compared to traditional digital systems.
Neuromorphic computing, a paradigm with more bio-inspirations than analog computing, holds the potential to approximate natural intelligence while maintaining efficiency. The nonlinear dynamics of ion migration are crucial for biological intelligent systems, making them highly desirable for artificial neuromorphic computing systems. Certain volatile memristive devices function based on ion dynamics, similar to biological systems, and can emulate biological components like neurons efficiently. We have demonstrated comprehensive neurons exhibiting six key neuronal functions within a footprint no larger than a single transistor and with very low energy consumption.
These demonstrations highlight the transformative potential of memristive devices in computing, transcending historical limitations and ushering in a new era of precision and efficiency.

Hybrid Carbon Nanotube and P3HT Ion-Gated Transistors for Neuromorphic Computing Kevin Schnittker, Zahra Bahrami and Joseph Andrews; University of Wisconsin-Madison, United States

Inspired by the human brain, synaptic devices with low power consumption and high performance have been at the forefront of research. Organic ion-gated transistors have been a promising candidate, owing to their synaptic plasticity and ability to change output signal based on organic film morphology. In ion-gated transistors, synapse is achieved based on the redistribution of ions and extent of ion penetration in the active channel material when a gate voltage is applied. This research focuses on enhancing regioregular poly(3-hexylthiophene) (P3HT) crystallization and directly modifying ion penetration by creating a hybrid structure with carbon nanotubes (CNTs). CNTs have potential to improve mobility of the device and are flexible which enables advanced deposition techniques such as aerosol jet printing.

P3HT film morphology was modified by solvent vehicle, CNT:P3HT concentration, and heat assisted solution crystallization. Preliminary work suggests that the method described below demonstrates evidence of synaptic response. Specifically, P3HT:CNT ion-gated transistors were fabricated by submerging a 300 nm SiO2 prepatterned wafer in 0.01 mg/ml CNT solution for 1 hour followed by submersion in a 0.05 P3HT–chloroform solution for 24 hours. The transistors had channel widths and lengths of 500 microns and 25 microns, respectively. IV sweeps of the devices showed a mobility capacitance of approximately 177 F/cm*V*s when a -0.1 drain voltage was applied and gate swept between -2V and 2V. The recorded height of the polymer films was 7 nm (acquired through AFM measurements). Compared to other methods tested, these samples showed the highest mobility capacitance. Synaptic behavior was verified through pulse measurements where a paired pulse facilitation (PPF) index was found to be as high as 20%, indicating enhancement of the drain current after the second of two repetitive excitatory postsynaptic potentials.

In addition, IV sweep measurements that incorporated pre-biasing of the gate voltage prior to testing were conducted. This entailed applying a gate voltage of -2V for 20 seconds followed by an IV sweep from -2V to 2V. This test was repeated with gate voltages of -1.8V, -1.6V, -1.4V, -1.2V, and -1V. When pre-biasing with a -2V gate voltage the transconductance was 4.24e-4 while the -1V gate voltage resulted in a transconductance of 5.4e-5. This demonstrates an additional parameter that can be tuned to alter the device output, mobility, and synaptic behavior. Next steps include transitioning fabrication methods to be entirely printed via aerosol jet printing, enabling a broad range of applications, specifically in the field of flexible electronics.

Ion Intercalation in 2D Channel Materials for Fast Conductivity Modulation in Neuromorphic Computing Devices Vasileios Fotopoulos, Matthäus Siebenhofer, Mantao Huang and Bilge Yildiz; Massachusetts Institute of Technology, United States

Electrochemical ionic synapses (EIS), also known as electrochemical random-access memory (ECRAM), have emerged as programmable resistors for crossbar arrays, promising high energy efficiency for artificial neural networks.[1,2] An EIS consists of three key functional layers: ion reservoir, solid electrolyte, and channel. Voltage-driven intercalation of mobile ions (such as H^+, Li^+, or Mg^{2+}) finely tunes the channel's conductivity, facilitating a high degree of control over the resistance state of each device.[3,4] The use of bulk mixed ionic and electronic conducting oxides as channel materials, such as WO_3, MoO_3 or V_2O_5,[5] inevitably necessitates 3D ion redistribution and potentially causes undesirably long settling times of the channel conductivity. 2D channel materials, such as monolayers of transition metal oxides or transition metal dichalcogenides,[6] present an alternative to bulk channel materials. Our experiments have demonstrated successful modulation of the conductivity of a 2H-MoS_2 monolayer with hydrogen ions in ECRAM, highlighting its potential as a 2D channel material.

In this study, we aim to understand proton energetics and proton diffusion at the interfaces between SiO_2 (solid electrolyte) and MoS_2 (2D channel material) by using Density Functional Theory (DFT) simulations, as we believe these are the key ingredients to tune ECRAM devices with 2D channel materials towards optimal performance. We examine various proton configurations in the channel, electrolyte and at their interface and determine the most stable intercalation sites. According to our results, H^+ ions prefer to sit within the channel/electrolyte interface close to the O-terminated (001) SiO_2 surface. In addition, we focus on the effects of ion intercalation on the electronic structure of the channel and electrolyte material. Depending on the location of H, different charge redistribution patterns and the most stable charge states were identified, providing insight on the mechanism of the conductivity modulation in MoS_2. To investigate the kinetics of H intercalation into MoS_2 channels, we also study the migration of protons at the channel/electrolyte interface and across the van der Waals gap (approximately 3 Å), which is expected to present a bottleneck for the proton transfer.

Based on the understanding gained from this model system, this research provides valuable insight into the development of high-performance, energy-efficient neuromorphic computing hardware by modulating the conductivity in 2D channels for ECRAM devices.

11:30 AM EL05.09.10

Multi-Order Complexity Spiking Neurons Enabled by Printed MoS_2 Memristive Nanosheet Networks Shreyash Hadke, Carol N. Klingler, Spencer Brown, Meghana Holla, Xudong Zhuang, Linda Li, Santiago Diaz Arauzo, Anurag Chapagain, Siyang Li, Jung Hun Lee, Indira M. Raman, Vinod K. Sangwan and Mark C. Hersam; Northwestern University, United States

The recent explosion in data-centric workloads has highlighted the shortcomings of traditional von Neumann computing and necessitated the development of brain-inspired hardware for neuromorphic computation, biohybrid systems, and smart sensing. Mimicking the functionality of biological neurons is critical to realizing the full potential of these neuromorphic applications. While silicon-based circuits using traditional transistors have been used to build neuromorphic systems, the lack of emergent phenomena and biological features such as local activity, adaptation, and functional complexity in transistors necessitates the use of elaborate circuits to realize simple biological functionalities. Hence, devices that make use of elementary physical phenomena as computational primitives are crucial to efficiently implement biomimetic computation. In this regard, dynamical devices, where intrinsic device dynamics are used to replace elaborate digital circuits, are promising building blocks for neuromorphic systems. The dynamical nature of these devices is represented in terms of the order of complexity, which is the number of first-order differential equations needed to describe the system. Currently available memristive neurons have not yet shown simultaneous first-order, second-order, and third-order spiking, which is required to emulate the full functionalities of biological neurons. Similarly, biologically-relevant spike characteristics for brain-machine interfaces have also not been achieved. Moreover, material systems amenable to scalable, low-cost solution-based fabrication of memristive neurons have not been experimentally realized. These unmet needs for the development of artificial neurons have hindered the development of neuronal systems for biomimetic spiking neural networks.

In this work, we use printed MoS_2 memristive nanosheet networks to demonstrate multi-order complexity spiking neurons with biologically-relevant spiking characteristics. In particular, we use the dynamical local activity arising from thermally-activated transport in MoS_2 to show the first observation of current-controlled snap-back negative differential resistance (NDR) in percolating nanosheet networks. This snap-back NDR, which leads to volatile threshold switching memristive behavior, enables artificial oscillatory and spiking neurons using simple neuristor circuits. We use the resulting oscillatory neuristor to demonstrate retina-inspired artificial sensory neurons that can be triggered and modulated using light. Our spiking neuristor also achieves simultaneous first-order, second-order, and third-order complexity spiking. Finally, we confirm the biological relevance of our spiking neuristor by activating the neural circuitry in a mouse cerebellum using in vitro cell stimulation. The results demonstrate that neuristor waveforms can be used to effectively activate neuronal circuits, inducing action potential firing and synaptic release. These printed snap-back memristors have broad implications for neuromorphic computation, biohybrid systems, and smart sensing.

11:45 AM EL05.09.11

Enhancing Neuromorphic Computing Through Ferroelectric-Tuned a-SiZnSnO Based Synaptic Transistors and Multilayer Perceptron Neural Networks Sandeep K. Maurya, Hyeon Dong Kim and Sang Yeol Lee; Gachon University, Korea (the Republic of)

The von Neumann architecture underpins most of today's advanced computers. However, the efficiency of these systems is constrained by the speed at which data can be transferred between the central processing unit (CPU) and memory. Additionally, these computers consume a significant amount of energy when processing large amounts of data. In contrast, biological computing systems like the human brain can effortlessly handle complex problems while expending energy in the range of femtojoules per spike (fJ/spike). Therefore, brain-inspired artificial synapses neuromorphic computing devices can enhance the performance of the electronic systems beyond von- Neumann architecture.

Three terminal transistors are highly suitable for synaptic devices due to their parallel processing capability and memory functions. Additionally, a standard three-terminal field-effect thin-film transistor mimics biological synapses. In this analogy, the gate voltage (V_{gs}) functions as the presynaptic input terminal, while drain current (I_{ds}) serves as the post-synaptic output terminal. In this work, we have designed ferroelectric-tuned synaptic transistors via integrating a flexible copolymer, poly(vinylidene fluoride-trifluoroethylene) (P(VDF-TrFE)), as the gate insulator alongside an amorphous-SiZnSnO (a-SZTO) channel layer. To enhance the stability, we introduced an ultra-thin layer of ZrO_2 (5 nm) between a-SZTO and P(VDF-TrFE). This ZrO_2 layer was subjected to Ar plasma treatment to render it hydrophilic, ensuring the uniform deposition of P(VDF-TrFE) layer. Devices with ZrO_2 integration demonstrated excellent stability over prolonged durations. The P(VDF-TrFE) layer was treated at 140 °C to form the β-phase, where ferroelectricity becomes prominent. The a-SZTO ferroelectric TFT with P(VDF-TrFE) exhibits counterclockwise hysteresis, a typical characteristic of ferroelectric field effect transistors. Further, a memory window of over 17 V was observed when sweeping between ±30 V. The postsynaptic currents (PSCs) were measured by applying 150 potentiation and 150 depression input pulses with different polarities of ±7 V and ±10 V for 1 s. Under potentiation and depression conditions, the devices demonstrated stable long-term potentiation

(LTP) and long-term depression (LTD) behavior, respectively. A very high dynamic range (maximum conductance/ minimum conductance: G_{max}/G_{min}) of 515 was observed for the ±10 V pulse. Finally, a multilayer perceptron (MLP) neural network was constructed with 400 input neurons, 100 hidden neurons, and 10 output neurons, with artificial synapses connecting these neurons. The input dataset consists of a handwritten digit from the Modified National Institute of Standards and Technology (MNIST) database, using “MLP NeuroSim+ V3.0” for the simulation. The neural network simulation showed a high recognition accuracy of over 75% for the handwritten digits. The combination of high recognition accuracy and exceptional stability in these devices indicates their promising potential for use in neuromorphic applications.

SESSION EL05.10: Emerging Materials for Neuromorphic Engineering
Session Chairs: Erika Covi and J. Joshua Yang

Molecular Building Blocks for Artificial Intelligence Sreetosh Goswami; Indian Institute of Science Bangalore, India

Molecular electronic switches have been a research topic for about three decades. The first wave in the nineties revolved around the appealing concept that molecules might make controllable nano-scale switches by self-assembly. However, the molecules proved to be fragile, and their switching endurance was far too low to be useful. Recently, molecular memristive circuit elements based on redox-active transition metal complexes of azo aromatic ligands have demonstrated resistive switching performance superior to several inorganic oxides, which calls for a serious examination of their chemical and physical properties and potential applications. Beyond being a simple on-off switch or binary storage element, molecular memristors offer several unique features: deterministic (as opposed to stochastic) and uniform (as opposed to filamentary) resistance switching, multiple resistance levels, simultaneous memristance and memcapacitance, and multiple serial non-monotonic switching events. Can these characteristics offer a significant benefit to computing performance? In this presentation, I will introduce a new generation of molecular circuit elements designed to capture intricate, reconfigurable, dynamic logic within nano-scale material properties. These devices, teetering on the edge of instability, hold promise for emulating brain functions. Our exploration spans from fundamental device principles to the investigation of circuits and on-chip integration [1-6], aiming to establish promising platforms for artificial intelligence and machine learning in the post-Moore era.

2:00 PM EL05.10.02

Sodium-Controlled Interfacial Resistive Switching in Thin Film Niobium Oxide for Neuromorphic Applications Benedetta Gaggio[1], Atif Jan[1], Moritz L. Muller[1], Babak Bakhit[1,2], Markus Hellenbrand[1], Giuliana Di Martino[1], Bilge Yildiz[3] and Judith L. Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Linköping University, Sweden; [3]Massachusetts Institute of Technology, United States

The growth of data-intense computational workloads has highlighted the need to improve the energy efficiency of hardware materials. Memristive devices are promising candidates due to the potential for high-density integration and analogue processing functionality, which can be controlled by voltage-induced redox changes. However, conventional filamentary memristive systems suffer from low uniformity due to the stochastic nature of the switching mechanism, which results in limited training accuracy and efficiency in neuromorphic computing. Interfacial mechanisms involve homogenous, voltage-dependent migration of ionic species towards a thin film barrier, enabling the fine-tuning of the device's electronic conductivity in a non-volatile, reversible fashion. Ionically-driven mechanisms have been shown to result in gradual switching performances and high uniformity, similarly to artificial synaptic plasticity.

Orthorhombic T-Nb_2O_5 is a well-studied anode material with fast cation intercalation, yet its unique ionic transport properties have not been explored for ionically driven interfacial neuromorphic applications. In this study, we report neuromorphic performance based on interfacial switching modulated by the voltage-controlled motion of Na^+ ions in a $NaNbO_3/Nb_2O_5$ solid-state 2-terminal device. The accumulation/depletion of Na+ ions at the Schottky barrier drives non-volatile modulation of resistance states, evidenced by *in operando* Raman and *ex situ* spectroscopy methods. We report spike-amplitude dependent plasticity, yielding 80 distinct non-volatile resistance states. Moreover, paired-pulse facilitation and spike-timing dependent plasticity (STDP) measurements show that the modulation of synaptic weight is a function of applied pulse spike timing, which enables potential applications towards Hebbian learning. Compared to widely studied small cations (oxygen vacancies, H^+ and Li^+), Na^+ ions are key biomarkers that play a significant role in biological synapses, with potential applications in smart wearables, and a larger ionic radius that can improve retention dynamics. This study opens new possibilities in neuromorphic devices with sensory functions, where ions from the perceived surroundings actively drive changes in synaptic plasticity.

2:15 PM EL05.10.03

Memory Properties of a Carbon Nanotube Hybrid Material Lucia Vizcaino Anaya, Carlos Herreros Lucas, Jose M. Vila Fungueiriño and Maria del Carmen Gimenez Lopez; Universidade de Santiago de Compostela, Spain

Computing based on the human brain uses elements with memory and it is considered to overcome the technical barriers that restrict the development of conventional systems, since the information is stored and processed on the same physical platform and devices allow the miniaturizing to the nanoscale.
Carbon nanotubes are among the most common materials for electrodes due to their excellent functional properties (i. e., high electric conductivity and surface area) and structural features allowing hybridization with other molecules.
In this work, a hybrid material composed by redox active clusters and carbon nanotubes was synthesized for the design of a molecular memory. The special electrochemical activity of these clusters generates memory properties upon application of external electrical stimuli. Carbon nanotubes provide an ideal environment that allows the control and reversibility of the electrochemical switching of the clusters between two different states, emulating biological synaptic weight plasticity. Finally, a two-terminal device was built to test the real applicability

of the electronic properties of these clusters for memcomputing.
This research shows great potential application for the design of electronic devices for artificial synapse development.

3:00 PM *EL05.10.04
Exploring Novel Nanomaterials and Nanostructures for Neuromorphic Applications Dimitra G. Georgiadou; University of Southampton, United Kingdom

Neuromorphic computing holds promise for lowering the power consumption and increasing the computation speed of Artificial Intelligence (AI) applications, as it is emulating the parallel manner of memorising/processing information in the brain. Although Machine Learning (ML) algorithms have made in the recent years a gigantic leap into the field of neuromorphic computing, mainly leveraging on the availability of vast amounts of data for training and on their ability to process information also on the temporal domain, scalability remains a challenge. The answer to this issue may come from the development of neuromorphic hardware systems that enable novel architectures and more efficient computation and/or functionality.
In this talk, I will present work performed in my group in the field of opto/electronic neuromorphic hardware based on nanomaterials and nanodevices. We fabricate 2-terminal nanodevices with a 10-nm nanogap-separated coplanar large aspect ratio metal electrode architecture. This geometry resembles the actual dimensionality of the biological neuron and synaptic cleft. Furthermore, the coplanar architecture allows facile integration with light sources for optical -in addition to electrical- excitation. Next, we apply material engineering to create functional devices that are able of performing certain basic (paired-pulse facilitation, post-synaptic excitation/depression) and more specialised (reservoir computing, in-memory sensing, nociception) functionalities. We exploit the unique characteristics of certain material classes, for instance the redox activity of polyoxometalates, the optical activity of perovskites and the low-dimensionality of transition metal dichalcogenides.
Careful tailoring of the structure-property relationship and the thin film deposition process parameters allows us to select the most suitable system and optimise it for pattern recognition, computation or sensing applications. The combination of nanomaterials with nanogap electrodes holds promise for ultra-low-power devices that can further decrease the CO_2 footprint of AI. Moreover, the fact that all manufacturing steps are compatible with flexible substrates and the materials we use are relatively green, as we strive to eliminate toxic elements and solvents from the solution-processing routes we follow, renders our approach fully in line with Net Zero goals. Our work paves the way towards creating more sustainable electronic devices of the future, especially targeting niche applications in robotic sensing and edge-computing for wearable applications.

Analog Conductive-Metal-Oxide/HfO_x ReRAM Devices—BEOL Integration, Characterization and Modelling
Donato F. Falcone[1], Valeria Bragaglia[1], Wooseok Choi[1], Tommaso Stecconi[1], Stephan Menzel[2], Laura Bégon-Lours[1,3], Folkert Horst[1], Antonio La Porta[1], Nikhil Garg[4,5], Jean-Michel Portal[6], Eloi Muhr[6], Dominique Drouin[4], Fabien Alibart[4,5] and Bert Jan Offrein[1]; [1]IBM Research-Europe, Switzerland; [2]Forschungszentrum Jülich GmbH, Germany; [3]ETH Zurich, Switzerland; [4]Universite de Sherbrooke, Canada; [5]IEMN-CNRS, Universite de Lille, France; [6]IM2NP-CNRS, Aix-Marseille Universite Marseille, France

The increase in the number of parameters in modern neural network architectures has led to a significant rise in energy demand for training and inference operations when performed on conventional CMOS technology based on the von Neumann architecture. Recurrent data transfers between memory and processing units are a key source of speed and energy inefficiencies in the calculation of artificial neural networks (ANNs). Specialized hybrid

neuromorphic architectures, utilizing crossbar arrays of analog memristors, represent a promising energy efficient alternative for AI workloads [1]. Such architectures enable matrix-vector multiplications (MVMs) operations in the analog domain based on the in-memory computing paradigm.
Analog filamentary conductive-metal-oxide (CMO)/HfO_x redox-based resistive switching memory (ReRAM) technology has shown to exhibit excellent properties for inference and training of deep neural networks. Introducing a properly engineered CMO layer within the conventional Metal/Insulator/Metal ReRAM stack improves devices characteristics such as the number of analog states, stochasticity and endurance. The underlying mechanism could recently be attributed to a modulation of the defect density within the sub-band of the CMO layer [2], where the electric field and temperature confinement in the filamentary CMO/HfO_x structure is playing a major role. For creating a high performing synaptic analog signal processing accelerator, such CMO/HfO_x ReRAM devices must be densely embedded in the Back end of the line (BEOL) of existing CMOS technology.
In this work, we integrated CMO/HfO_x ReRAM devices into the BEOL of TSMC 130nm nMOS transistor technology in a 1Transistor-1ReRAM (1T1R) device configuration. We tailored the CMO/HfO_x ReRAM process flow for compatibility with the copper VIAs of the transistors, realizing a surface-contact bottom electrode ReRAM configuration. The statistical DC and pulsed electrical characterization of these 1T1R cells will be presented. Compared to a CMO/HfO_x 1R configuration, the resistive switching polarity was reversed for precise control of the current during the filament forming and the set processes of the ReRAM devices, by controlling the gate to source voltage of the nMOS transistor. Compared to 1R configuration, this approach allowed for a smaller filament radius, and therefore a lower average conductance switching regime, and a more gradual and controlled set transition, which resulted in a larger number of analog states. An analytical 3D Finite Element Model describing the transport in the optimized 1T1R structures and explaining the underlying physical mechanisms behind the reversed switching polarity compared to the 1R configuration, will be presented. Analog signal processing operations were conducted on 8x1 arrays of the 1T1R cells. The improved switching properties combined with the optimized polarity, make the 1T1R configuration of such CMO/HfO_x technology the fundamental building block for larger crossbar demonstrations of neural network training and inference in hardware.

3:45 PM EL05.10.06
Lead Halide Perovskites for Low-Energy Consumption Neuromorphic Applications Jeroen J. de Boer[1] and Bruno Ehrler[1,2]; [1]AMOLF, Netherlands; [2]University of Groningen, Netherlands

Lead halide perovskites are highly promising materials for a wide range of optoelectronic applications, such as photovoltaics and LEDs. One major challenge for these applications is the efficient conduction of mobile ions in these materials, which causes unwanted hysteresis when a bias voltage is applied. However, this property of halide perovskite materials makes them highly interesting for applications in neuromorphic computing, where large resistance changes of a device upon applying a bias voltage are desirable. Specifically, the efficient conduction of ions can be utilized for bringing about non-volatile resistance changes to change synaptic weights or volatile resistance changes to mimic the firing of a neuron, all while expending only little energy. Here, we present our recent work on applying halide perovskites in devices for neuromorphic computing. We focus on addressing the challenge of downscaling of halide perovskite devices due to the high solubility of halide perovskites in polar solvents that are commonly used in lithography. Using our procedure, we demonstrate microscale halide perovskite artificial synapses and the first fully on-chip integrated halide perovskite artificial neuron. Owing to the small device size, the energy consumption of the synapse was in the sub-picojoule range, while the energy consumption of the neuron was on the order of tens of picojoules per spike. Both of these energy consumptions are similar to or even lower than those of analogous biological processes. Our design lends itself to further downscaling and we discuss how this would reduce the energy consumption even more. Moreover, the similarity of the artificial neuron and synapse device design allows easy integration in ultralow-energy consumption neuromorphic chips. These chips could potentially emulate the analog and parallel way that information is processed in the brain to achieve orders of magnitude lower energy consumption computation compared to digital computers.

4:00 PM EL05.10.07

Reconfigurable Floating Gate MoS_2 Phototransistor for In-Sensor Multimodal Fusion Sijie Ma, Tianqing Wan and Yang Chai; The Hong Kong Polytechnic University, Hong Kong

In-sensor computing overcomes the restriction of transmitting massive data between sensors and processing units, thereby enabling more effective edge computing. Multimodal perception can capture more precise and comprehensive information compared to unimodal approaches. However, current sensory systems typically merge multimodal signals at computing terminals following parallel processing and transmission, which results in the potential loss of spatial association information and requires timestamps to maintain temporal coherence for time-series data. The floating gate MoS_2 phototransistors with reconfigurable photoresponsivity offer the agile optoelectronic properties to realize bioinspired in-sensor multimodal fusion for extracting spatial and spatiotemporal association, which effectively enhances the imformation processing at sensory terminals. For nonvolatile mode, we realize an optimal spatial estimation by combining visual-tactile signals through the light-assisted Fowler-Nordheim tunneling effect. For volatile mode, with ample trapping centers in MoS_2 phototransistors, we extract spatiotemporal information by real-time capturing and fusing visual-audio signals, realizing a dance-music synchronization recognition task without the additional timestamping process. This in-sensor multimodal fusion approach provides the potential to simplify the multimodal integration system, extending the in-sensor computing paradigm.

4:15 PM EL05.10.08

Boosting Near-Infrared Detection in IGZO-Based Phototransistors via $NaYF_4$:Yb/Tm Core Upconversion Nanoparticles Jong Bin An[1], Kyung Tae Park[2,3], I. Sak Lee[1], Jong Hyuk Ahn[1] and Hyun Jae Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Brigham and Women's Hospital, United States; [3]Harvard Medical School, United States

In the era of the Internet of Things (IoT), various types of sensors are actively embedded not only into simple wearable devices but also into next-generation industrial applications such as healthcare, robotics, and aviation. Among several types of sensors, photosensors are drawing significant attention because they can easily connect objects and people using optical signals. While various semiconducting materials have been introduced for photosensor applications, amorphous oxide semiconductor (AOS), particularly indium-gallium-zinc-oxide (IGZO), are considered some of the most appropriate candidates. This is due to their high field-effect mobility, low leakage current, excellent uniformity, and high compatibility with industry standards. However, the large band gap of IGZO (~3.5 eV) limits the detection range of IGZO thin-film transistors (TFTs) to the visible to near-infrared (NIR) spectrum, posing a significant hurdle for applications in security systems, information technology, health monitoring, and neuromorphic image sensors.
Herein, upconversion nanoparticle (UCNP) $NaYF_4$:Yb/Tm core was firstly introduced to detect NIR region of IGZO phototransistor. UCNP has emerged as a promising candidate for NIR sensing applications due to its absorption and converting characteristics of NIR light into visible or ultraviolet (UV) light. UCNP and IGZO are used as a NIR absorbing layer and UV & blue light absorbing channel layer, respectively. The optoelectronic characteristics under NIR region of UCNP on a-IGZO phototransistor are performed and compared with those of pristine IGZO phototransistor.

To confirm that fabricated $NaYF_4$:Yb/Tm core UCNP performs upconversion characteristics, PL analysis was conducted. Under the illumination of 980 nm laser, $NaYF_4$:Yb/Tm core UCNP showed sharp emissions centered at 347, 362, 450, 483 nm, which is ultraviolet (UV) and blue light region. This indicates that the 980 nm light is converted to UV and visible light, showing intense upconversion luminescence. Throughout these analysis, it is shown that the fabricated $NaYF_4$:Yb/Tm core UCNP can convert NIR region wavelength to UV and blue light regions which can be absorbed by IGZO due to its proper bandgap.
To analyze the improved performance of the light absorption characteristics of $NaYF_4$:Yb/Tm core UCNP on IGZO phototransistor, transfer curves under NIR illumination (808 nm ~ 1429 nm) were analyzed under the V_{DS} of 10.1 V. As a result, the $NaYF_4$:Yb/Tm core UCNP on IGZO phototransistor can detect a wide range of NIR region (808 nm – 1429 nm). Under the NIR illumination, as the effect of $NaYF_4$:Yb/Tm core UCNP, the photoresponsivity, photosensitivity, and detectivity were improved by 1.45 10^2 to 1.63 10^3 A/W, 9.02 10^1 to 2.21 10^6 , 5.98 10^7 to 5.58 10^{10} Jones, respectively, under 808 nm illumination compared to pristine IGZO phototransistors.
In summary, we fabricated $NaYF_4$/Tm core UCNP on IGZO phototransistor, analyzing its synthesis and characteristics using PL spectra. The upconversion characteristic of $NaYF_4$/Tm core UCNP under NIR illumination enhanced the photo-reactivity and optoelectronic properties of the IGZO phototransistor, demonstrating its effectiveness as the first AOS-based NIR phototransistor using UCNP material. Future work will focus on further analysis of the mechanism and additional experiments to highlight the advantages of our device.

SESSION EL05.11: Poster Session III: Device Fabrication and Characterisation for Memory and Neuromorphic Applications

Session Chairs: Sahika Inal and Ioulia Tzouvadaki
Thursday Afternoon, December 5, 2024
8:00PM - 10:00PM
Hynes, Level 1, Hall A

A Reconfigurable Binary/Ternary Logic Conversion-in-Memory Based on Drain-Aligned Floating-Gate Heterojunction Transistors

Chungryeol Lee[1], Changhyeon Lee[1], Seung Min Lee[1], Junhwan Choi[1], Hocheon Yoo[2] and Sung Gap Im[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

Reconfigurable electronics entails designing and implementing circuits that can be dynamically modified to enable more diverse and complex computations within a given footprint. Simultaneously, multi-valued logic extends the binary logic framework by incorporating additional logic states. When combined with reconfigurable electronics, multi-valued logic can significantly enhance data processing efficiency and integration density in conventional digital circuits.
Here, we introduce a novel heterojunction non-volatile memory transistor that allows for dynamic control of the negative transconductance characteristics by integrating non-volatile memory functionality into the heterojunction transistor. Unlike conventional flash memory, the proposed heterojunction non-volatile memory transistor employs a drain-aligned floating gate that partially overlaps with the channel. This design stems from the asymmetric configuration of the heterojunction transistor, where the p-type layer connects the source to the drain electrode, and the n-type layer interacts solely with the drain electrode through the intervening p-type layer. By varying the gate-to-drain electric field, the drain-aligned floating gate in the n-type semiconductor can effectively modulate the electron injection into the channel, thus enabling systematic control of the negative

transconductance characteristics during programming operations. Utilizing these dynamic negative transconductance characteristics, we achieved a high-performance binary/ternary reconfigurable inverter with a static noise margin of 85% for binary logic and 59% for ternary logic, as well as stable retention properties and excellent cycle durability. Notably, the static noise margin for ternary logic operation reported here surpasses previously reported values for ternary logic circuits based on different principles. Additionally, the binary/ternary reconfiguration can be achieved without complex circuitry or changes in supply voltage, enabling direct connection between binary and ternary logic systems. For instance, the proposed binary/ternary reconfigurable inverter can be cascaded to form high-level circuits, with each unit being fully reconfigurable. As a proof of concept, we demonstrated binary/ternary logic conversion-in-memory using a two-stage binary/ternary reconfigurable inverter, which produces output signals in three sequences at three logic levels, performing all functions of a standard ternary inverter, positive ternary inverter, and negative ternary inverter based on the memory states of the binary/ternary reconfigurable inverter.

EL05.11.02

Atomic Layer Deposition of Epitaxial Ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ Thin Films Jung Woo Cho and Seung Chul Chae; Seoul National University, Korea (the Republic of)

Ferroelectric hafnium oxide has been actively researched as an important class of material and as a candidate for non-volatile memory applications due to its various physical and electrical properties. According to former studies, the origin of ferroelectricity in hafnium oxide can be attributed to the formation of a non-centrosymmetric orthorhombic $Pca2_1$ phase. Even in a single orthorhombic phase, ferroelectric behavior can be tuned by applying mechanical stress or external fields to the epitaxial film. However, the practical implementation, particularly its epitaxial stabilization and a clearer understanding of its intrinsic ferroelectricity has been a significant challenge. Our study arouses the potential importance of atomic layer deposition (ALD) for mass production in modern industries, demonstrating its proficiency in achieving epitaxial growth of ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ (HZO) thin films on Yttria-stabilized zirconia (YSZ) substrates. Moreover, with distinct ferroelectric switching currents, our work reveals the ferroelectric characteristics of epitaxial HZO thin films deposited through ALD on YSZ-buffered Si substrates, which aligns well with CMOS technology.

EL05.11.03

Processing and Characterization of Polycrystalline Silicon for Ultra-Low-Power Neuromorphic Applications Soomin Kim[1], Seongjae Cho[1], Woo Young Choi[2] and Hyungcheol Shin[2]; [1]Ewha Womans University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Polycrystalline silicon (poly-Si) is increasingly incorporated not only in logic devices but also in memory devices towards the low-power neuromorphic systems. Its full compatibility with Si complementary metal-oxide-semiconductor (CMOS) makes it crucial in the recent semiconductor device and system technologies. Although poly-Si has been utilized in fabricating the thin-film transistors (TFTs), its microstructure and electrical characteristics need to be intensively studied for the application in the nanoscale device and circuit implementations. In this study, processing and characterization of poly-Si thin film are conducted in depth with the help of various analysis approaches including high-resolution transmission electron microscopy (HR-TEM), X-ray diffraction (XRD), energy dispersive spectroscopy (EDS), and atomic force microscopy (AFM). Furthermore, advanced dynamic random-access memory (DRAM) and charge-trap flash (CTF) memory based on the poly-Si channels were fabricated and their electrical performances have been closely investigated with an emphasis on their low-power operation capabilities. The reason that two different types of memories are studied lies in the fact that the traps and low crystallinity might provide the keys to performances improvements of DRAM and CTF flash memory with regard to data retention and inference energy. While researches have been dedicated to truncation of the bulky capacitor from the conventional DRAM cell, relatively short data retention of the capacitorless DRAM has been regarded as its drawback. In the poly-Si capacitorless DRAM, the grain boundary acts as transient charge trap sites, which allows for a substantially extended retention time without requiring complicated operation schemes to hold the carriers stored in the floating body. By reducing the frequency of refresh operation, lower power consumption and wider memory bandwidth are achieved at the same time. The processing conditions for the poly-Si channel were established and the thin-film characterizations were conducted in various aspects. 20-nm poly-Si thin films were deposited by low-pressure chemical vapor deposition (LPCVD) and annealed at different temperatures ranging from 500 °C to 1,000 °C for 24 hours to examine the change in morphology and crystallinity. It was confirmed by TEM and XRD analyses that the crystallite size increased with temperature. Annealing at 600 °C resulted in a grain size of 26.2±1.4 nm, which revealed that change in morphology could be expected while the atomic diffusion was experimentally minimal. Under the annealing condition, the crystallinities in the <111>, <220>, and <311> directions were notable. Poly-Si DRAM cell with a gate length of 500 nm and a channel thickness of 50 nm was fabricated. The critical dimensions and species were identified by HR-TEM and EDS, respectively. XRD and AFM were employed to identify the grain size and surface roughness of the poly-Si channel, which were 26.2 nm and 0.634 nm, respectively. Transient measurement results from the fabricated poly-Si capacitorless DRAM show that holes can be trapped and de-trapped by a set of gate and drain voltages, with a significantly increased data retention time reaching 1.2 s which is about 20 times longer than the industry reference of 64 ms. The prepared poly-Si thin film can be also introduced for the channel of CTF flash memory cell. The nonvolatile memories can be adopted in the hardware-driven ultra-low-power neuromorphic applications. The inference current was greatly reduced down to pA level in the poly-Si channel and the resultant inference energy was calculated to be below 10 fJ. A small change in electrical weight was obtained by precisely controlling the amount of change over the potentiation and depression, and a highly linear weight tunability was obtained over 20 levels from a CTF synaptic device. This research was supported by the Ministry of Science and ICT (MSIT) of Korea under the Grant 2020-0-01294.

Impact of the Incorporation of In and Cu Dopants into β-Ga_2O_3 Nanostructures for Resistive Switching Applications

Asma O. Al Ghaithi and Haila M. Aldosari; United Arab Emirates University, United Arab Emirates

The ultra-wide bandgap semiconductor beta gallium oxide (β-Ga_2O_3) has become a potential candidate for power electronics, ultraviolet optoelectronics, high-temperature gas sensors, and memristors. β-Ga_2O_3 exhibits outstanding properties, including a bandgap of 4.5–4.9 eV, a high critical electric field of around 8 MV/cm, a high Baliga's figure of merit (BFoM), and good stability at elevated temperatures. Doping and transitioning from bulk single crystal to micro- and nano-crystallite promotes the unique features of β-Ga_2O_3, resulting from larger surface-to-volume ratios, fewer defects, and reduced strain. This study investigates the impact of the incorporation of indium (In) and copper (Cu) with the precursor material during the synthesis process on the structural, morphological, and optical properties of the β-Ga_2O_3 nanostructures (NS) obtained by the conventional CVD method. The β-Ga_2O_3 NS were grown on a (100) p-type silicon substrate inside a quartz tube furnace at 900 °C for 2 h with an argon flow of 30 SCCM. Ga was used as a precursor material mixed with different ratios of In or Cu (1:0, 3:1, 2:1). Various characterization techniques were used in this investigation, including grazing-incidence X-ray diffraction (GIXRD), scanning electron microscopy (SEM), energy dispersive spectrometry (EDS), and UV-visible- NIR spectrophotometry. GIXRD scans showed that all NS exhibit the β-Ga_2O_3 phase with the monoclinic crystal structure (space group C2/m) and dominant orientation along the (111) plane. No additional peaks of other Ga_2O_3 polymorphs were detected, and the strong diffraction peaks indicate the high crystalline quality of the β-Ga_2O_3 NS. SEM images demonstrated that pure Ga formed short β-Ga_2O_3 nanorods of diameter varies from 400 nm up to 800 nm and length between 600 nm and 1 µm. Although the diameter remained the same, the nanorods became considerably longer, reaching a length of about 1 µm – 5 µm, when Ga was combined with In or Cu with a small amount. β-Ga_2O_3nanorods transitioned into nanoplates and nanosheets at a further increase in the In and Cu concentrations. EDS analysis revealed the presence of Ga and O and a small amount of In and Cu traces. All β-Ga_2O_3 NS has exceptional transparency in the visible and ultraviolet wavelength ranges, with an optical bandgap of 4.56 eV, which was slightly reduced to 4.50 eV as the concentration of In and Cu increased. The current-voltage characteristics of the NS demonstrated promising resistive switching characteristics, which included bipolar resistive switching, a low operation voltage, and strong repeatability and retention.

EL05.11.05

Subcycling-Induced Split-Up Behavior in Antiferroelectric ZrO_2 Thin Films Seung Hyup Lee and Seung Chul Chae; Seoul National University, Korea (the Republic of)

Antiferroelectric (AFE) ZrO_2 and HfO_2-based thin films are emerging as promising materials for energy storage and low-power memory applications due to their high compatibility with the complementary metal-oxide-semiconductor (CMOS) technology. Despite extensive research on their ferroelectric (FE) counterparts, many properties of AFE materials remain unexplored. For instance, while the subcycling-induced split-up of the transient current peak in FE Sr:HfO_2 was discussed in 2015, the split-up behavior of fluorite-type AFE thin films has not yet been investigated. Here, we introduce the subcycling-induced split-up behavior in 10 nm AFE ZrO_2 thin films. Using transient current-voltage measurements, we demonstrate that the position of the split-up dip can be controlled by adjusting the subcycling voltage, attributed to the differences between the non-switching (NSW) and switching (SW) domains. First-order reversal curves (FORCs) showed that the internal bias field splits up after subcycling. Additionally, we report that unipolar subcycling can induce an asymmetric split-up phenomenon. These findings enhance our understanding of the split-up behavior in AFE ZrO_2 thin films, potentially optimizing their practical applications.

EL05.11.06

Resistive Switching Performance and Modeling of Natural Organic Honey-Based ReRAM for Neuromorphic Computing Emdadul H. Minhaj, Zoe Templin and Feng Zhao; Washington State University, United States

The needs for fast and energy-efficient computing are growing in the era of artificial intelligence. Among the emerging architectures, neuromorphic computing is promising to meet such needs. By mimicking how biological neurons and synapses work in the human brain, this technology carries out simultaneous memory and processing functions for fast speed and high energy efficiency. Resistive random access memory (ReRAM) is a promising hardware candidate for neuromorphic computing systems. In recent years, ReRAM based on natural organic materials, mainly protein and carbohydrate, has been under investigation for sustainability by reducing e-waste with eco-friendly disposal. However, the progress in advancing these devices is limited by a lack of physical models to assist the device design and understanding of resistive switching functionality. In this paper, natural organic honey based ReRAM is fabricated and characterized, and a physics-based numerical model is proposed to explain the resistive switching behaviors. Honey, a natural preservative of polysaccharide, has been proven to be a viable material for sustainable ReRAM due to its nontoxic, ecologically benign, and biodegradable properties and resistive switching performance. The resistive switching characteristics of honey-ReRAM are used to verify the physical model, with SET and RESET process modeled by field-dependent filament nucleation and gap formation and evolution using Gibb's free energy minimization. To derive temperature and electric field distribution in the honey film, carrier continuity and heat equations are self-consistently solved within a finite-element-method solver. A 3D axisymmetric structure is built to perform the simulation, and the model provides insights into resistive switching behavior from a thermodynamic point of view. The results will benefit the design and optimization of not only honey but also other natural organic materials based ReRAM and accelerate the progress towards their implementation in neuromorphic computing systems.

EL05.11.07

Hydrogen-Based Electrochemical Random-Access Memories (H-ECRAM) with Low Device-to-Device and Cycle-to-Cycle Variabilities Longlong Xu, Mantao Huang and Bilge Yildiz; Massachusetts Institute of Technology, United States

Programmable resistors with low variability are the key to achieve high training accuracy in hardware neural networks for effective artificial intelligence applications. Traditional candidates for programmable resistors, such as resistive random-access memory (ReRAM), often face challenges with large variability due to their stochastic nature of operation. Electrochemical random-access memories (ECRAMs) are promising three-terminal non-volatile programmable resistors with low variability, which is enabled by the deterministic and controllable dynamic doping of the channel material. However, the device-to-device variation has not been systematically studied. In addition, the effect of extended defects, such as grain boundaries in the channel, on the device-to-device variability is not clear. In this work, we systematically quantified the variability of CMOS-compatible hydrogen-based ECRAMs (H-ECRAMs) with crystalline and amorphous channels, and of various channel sizes. By programming multiple devices with identical parameters and examining their conductance modulation range, we observed very low variations in the low-conductance regime, including approximately 15% device-to-device and less than 3% cycle-to-cycle variation, with an endurance exceeding 10^6 conductance updates. Furthermore, device-to-device variation showed no dependence on whether the channel was crystalline or amorphous, nor on channel sizes ranging from 10^2 μm^2 to 150^2 nm^2. These results demonstrate that ECRAMs meet the variability targets for programmable resistors and possess significant potential for downscaling, making them a promising candidate for use in hardware neural networks.

EL05.11.08

The Influence of Conducting Cation Selections on the Electrolyte-Gated Synaptic Transistors—Electrochemical and Mechanical Analysis Haeyeon Lee[1], Jiho Lee[1], Hyunkyu Yang[1], Sobin Alosius[2], Zhihao Xu[2], Tye Milazzo[2], Youn Sang Kim[1] and Tengfei Luo[2]; [1]Seoul National University, Korea (the Republic of); [2]University of Notre Dame, United States

Neuromorphic architecture is a protocol that emulates the brain's perception, learning, and information processing using parallel computing pipelines. In contrast to Von Neumann computation, this architecture is characterized by fast computation and power-efficient performance, making them effective for big data processing in artificial intelligence. Among the various devices developed to implement the architecture to date, electrolyte-gated synaptic transistors (EGTs) have attracted much attention due to the advantage of precise conductivity control, fast response time and low operating voltage via ion-assisted signal transmission. Their three-terminal design avoids issues like sneak paths and signal overlap seen in two-terminal devices. However, understanding the physicochemical factors and mechanisms of EGTs related to ion behavior remains limited, despite ions exerting a critical influence on synaptic performance in EGTs.

To address this, we propose a novel analytical method with electrochemical characterization using three alkali cations, Li+, Na+ and K+, and poly (ethylene oxide) in EGTs (AGTs). While they have similar chemical properties to monovalent ions, the ionic sizes vary significantly: 76 pm for Li+, 102 pm for Na+, and 138 pm for K+. We used cyclic voltammetry (CV) and X-ray photoelectron spectroscopy (XPS) to investigate the non-volatile memory mechanisms of EGTs. Additionally, electrochemical impedance spectroscopy (EIS), scanning electron microscopy (SEM), differential scanning calorimetry (DSC), and X-ray diffraction analysis (XRD) explored how electrolyte properties and ion dynamics influence the analog conductivity of EGTs.

The result shows that b-values extracted by CV measurements were 0.55, 0.63, and 0.77 for Li+, Na+, and K+, respectively, indicating the dominant reaction switches from redox reaction to electrical double layer capacitance

(EDLC) behavior as the ion size increases. In turn, Li-AGTs exhibited the best non-volatile memory, retaining 34.2% of the initial current after 100 s, while K-AGTs returned to the initial current of 1 μA due to ionic self-diffusion derived from EDLC. EIS measurements revealed a decrease in ionic conductivity with increasing ionic radius, with K-PEO having the lowest value of 4.65 × 10-7 mScm^{-1}. The XRD and SEM results showed that the larger ions have a lower solubility in the electrolyte, forming ionic entanglement and increasing crystallinity in K-PEO. The activation energies (Ea) for Li+, Na+, and K+ were 0.39, 0.67, and 1.66 eV, respectively. The crystallized K-PEO mitigated rapid ionic diffusion/drift transport, resulting in near-ideal nonlinearity values of 2.27 and -2.85 in the potentiation and depression regions. This systematic approach with electrochemical analysis facilitates intuitive interpretation, advancing the development of high-performance artificial synaptic EGTs.

EL05.11.09

Multiphysics Simulation of Bipolar Filamentary Resistive Switching by Coupling Phase-Field and Electrothermal Models Jinwoo Oh, Dongmyoung Jung, Yongwoo Kwon and Hyungtak Kim; Hongik University, Korea (the Republic of)

The most challenging part of the device simulation of resistive memory is dealing with the behaviors of the conductive filament (CF). In the case of bipolar switching by valence-change mechanism, the evolution of the CF is determined by the formation, annihilation, and migration of anion vacancies in the switching material which is usually a transition metal oxide. The CF and matrix are defective and non-defective phases with low and high resistance, respectively. Starting from a pristine state with a completely non-defective phase, the CF is formed, ruptured, and reconnected by applied biases.
In this presentation, we demonstrate our device simulation model capable of simulating a full switching cycle comprising forming, reset, and setting operations. Also, our simulation can model data retention. The phase-field model is adopted to represent a system with two phases: defective and non-defective, i.e., CF and matrix phases. The Cahn-Hilliard equation deals with the evolution of the two-phase system. The phase-field and electrothermal models are coupled in a finite-element package, COMSOL Multiphysics. The bipolar switching system is described as a metal-insulator-metal structure where the top interface has a constant vacancy concentration, implying that the oxygen-deficient top interface can be a sink for incoming vacancies resulting in the disappearance of the CF while it can be a source for outgoing vacancies resulting in the growth of the CF. The initial condition must include some perturbation in the system such as a pre-existing defect, interface roughness, and so on.
The central advantage of our model over other device simulations is that our model can predict the shape of the CF for different physical conditions including material properties, device architecture, initial defect configuration, and bias conditions. A CF area is not pre-defined. Our simulation can start from the forming operation and can repeat multiple reset-set cycles. More details will be shown in the actual presentation.

EL05.11.10

Frequency-Dependent Synaptic Dynamics of Al_2O_3/HfO_2 High-k Dielectric Double-Structured Transistor Based on the Trade-Off Between Charge Trapping and Ferroelectric Effects Ojun Kwon, Seyoung Oh and Byungjin Cho; Chungbuk National University, Korea (the Republic of)

The performance of artificial intelligence (AI) such as conversational chatbots and autonomous driving is limited by significant energy consumption and delays in task execution. To address this challenge, brain-inspired neuromorphic hardware that mimics the function of synapses and neurons has attracted considerable attention as next-generation AI hardware. For the focus on demonstrating the neuromorphic components, a number of attempts to enhance synaptic performance have been made: synaptic devices with linear and symmetrical weight updates, and excellent endurance. While numerous memorization mechanisms emulating biological synapses have been reported, the phenomenon of frequency-dependent interference during synaptic signal transmission

remains unexplored. A comprehensive investigation into how frequency influences signal transmission could significantly enhance the selectivity of weight updates, offering a promising solution to the complexities of neuromorphic circuitry.
In this study, we investigated frequency-dependent mixed synaptic plasticity, which is mainly due to Al_2O_3/HfO_2 high-k dielectric double layer. We successfully demonstrated 8×8 synaptic transistor arrays, consisting of an IGZO channel layer and Al_2O_3/HfO_2 high-k dielectric functional layer to emulate biological synaptic plasticity. Initially, we observed controllable variation in the I_{DS}-V_{BG} hysteresis loops depending on the sweeping speed of The V_{BG}. Interestingly, I_{DS}-V_{BG} hysteresis loop began with counter-clockwise direction and then crosses at 1.5 V, and finally then transition to a clockwise loop at a relatively slow V_{BG} sweep speed range. However, as the V_{BG} sweep speed increases, the clockwise loop gradually decreased. The V_{BG} sweep speed over 800 mV/sec, I_{DS}-V_{BG} curves exclusively showed only a counter-clockwise direction. These phenomena are apparently reproducible for repeated sweep, regardless of V_{BG} sweep range. It indicates that trade-off between charge trapping and the ferroelectric dipole effect exist, which is effectively controlled by operation speed. Therefore, the use of this novel device structure successfully mimics diverse patterns of synaptic function. During low-frequency stimulation, positive gate pulses induced depression, while negative gate pulses elicited facilitation response. Interestingly, high-frequency positive gate inputs induced facilitation, reversing the effect observed at low frequencies. Long-term potentiation and depression characteristics in the low-frequency region exhibited nonlinearity of 0.83, close to the ideal value of 0. In contrast, in high-frequency region, weight updates showed a higher nonlinearity of 4.08. The postsynaptic current changes stimulated by consecutive gate pulses maintained conductance state during retention tests in both frequency region, which demonstrates long-term memory characteristics. The synaptic transistor is a promising candidate for neuromorphic systems as an essential synaptic component, evidenced by its high recognition accuracy (~97.03%) in deep neural network simulations, based on the training and inference of handwritten digits. Furthermore, by adjusting only the frequency of input pulses while maintaining identical amplitude, both facilitation and depression responses could be simultaneously emulated, which is exactly different from the variable synaptic plasticity typically featured with different voltage polarity in most of previous reports. This unique capability mimics the diverse synaptic functions of biological synapses during signal transmission, paving the way for simpler neuromorphic circuitry to address increasingly complex tasks with greater efficiency and sophistication.

EL05.11.11

Kinetic Monte Carlo Simulations of AlScN Sputter Deposition Yang Hao Lau, Gang Wu, Bharathi M. Srinivasan, Fong Yew Leong and Ramanarayan Hariharaputran; Agency for Science, Technology and Research, Singapore

Their high coercive field and stable remanent polarization, coupled with their compatibility with complementary metal-oxide-semiconductor and proven industrial fabrication process, make AlScN thin films attractive for novel neuromorphic computing and memory devices, such as ferroelectric field-effect transistors and ferroelectric tunnel junctions.

However, ultrathin ferroelectric layers needed for more storage in miniaturized devices often have low remanent polarization, or even no ferroelectricity. While a solution to this problem is urgently sought, the reason behind the phenomenon is still poorly understood.

To determine if this issue has any microstructural underpinnings that can be addressed, we do kinetic Monte Carlo simulations of AlScN film deposition to check for any deviations from bulk microstructure that could account for film property degradation at low thickness. By varying simulation conditions, we also search for processing conditions minimizing such microstructural variation with the potential to preserve ferroelectric properties in ultrathin films.

Our approach can be more generally applied to other materials to suppress any similar property degradation in the ultrathin regime.

EL05.11.12

Effect of Thermal Annealing on Charge Trapping Characteristics and Synaptic Plasticity in Sol-Gel AlO_x-Based Floating Gate Devices

Sneha S. Bhise, Young-Seok Song, Dae-Hong Kim, Seungyeon Kim and Tae-Wook Kim; Jeonbuk National University, Korea (the Republic of)

The advancement of high-performance organic floating gate memory and synaptic devices represents a significant breakthrough in the field of electronics. These devices hold considerable promise for transforming data storage and processing, especially in applications that require low power consumption and flexibility with various substrates. Realizing such high performance necessitates an efficient charge-trapping medium that can effectively capture and retain charge carriers, which is crucial for information storage and processing. Multiple candidates have been proposed for the charge-trapping layer.

Our investigation employed a simple, cost-effective solution-processed sol-gel aluminum oxide (AlO_x) as the charge trap layer. We analyzed the properties of sol-gel AlO_x thin films at different annealing conditions (Pristine, 100 °C, 200 °C, 300 °C, 400 °C, 500 °C) utilizing X-ray diffraction (XRD), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). With the increase in annealing temperatures, it becomes apparent that the sol-gel AlO_x thin film undergoes the decomposition of organic residues and nitrate groups and the transformation of aluminum hydroxide into aluminum oxide.[1] At lower annealing temperatures, the organic floating gate device exhibited a wider hysteresis window (ΔV_{th}) and charge trap density (n), which became negligible at elevated temperatures, suggesting that the hysteresis window is influenced by hydroxyl groups.

Furthermore, we examined the potential of enhancing the synaptic behavior of the device by employing a solution-processed sol-gel AlO_x-based floating gate transistor. The synaptic weight stored in the channel conductance of the floating gate transistor is modulated by the positive and negative electrical pulse stimuli and the annealing temperature of the sol-gel AlO_x thin film layer. We examined essential characteristics of long-term potentiation (LTP) and long-term depression (LTD), including dynamic range (DR) and nonlinearity (NL), which play a significant role in the adaptive learning and decision-making capabilities of synaptic devices. [2] Devices annealed at 200 °C demonstrated favorable nonlinearity (NL) and dynamic range (DR) compared to those annealed at other temperatures.

EL05.11.13

Monolayer MoS2-Based High-Temperature Operating Neuromorphic Device

Govind Gupta[1,2]; [1]Council of Scientific & Industrial Research–National Physical Laboratory, India; [2]Academy of Scientific & Innovative Research, India

As technology becomes more widespread, there is an increasing demand for high-temperature neuromorphic devices to meet space exploration requirements and extreme industrial environments. Additionally, as the Internet of Things (IoT) expands, the need for more powerful and efficient computing and data processing capabilities is growing. To meet this demand, researchers are investigating the creation of neuromorphic devices that mimic the structure and function of the human brain. Here, we present a scalable monolayer MoS2-based neuromorphic device designed to operate effectively at high temperatures (~100C). Monolayer MoS2, a two-dimensional semiconductor material renowned for its exceptional thermal stability and mechanical flexibility, is utilized to develop the memristive device. The fabricated device withstands high-temperature conditions, is adaptable to various applications, and demonstrates excellent electrical characteristics, such as low power consumption, high switching speed, high resistance ratio (~100), low switching voltage, and reliable endurance

(~1000). In addition, the device exhibits neuromorphic behavior, replicating the synaptic plasticity observed in biological neural networks. This remarkable functionality has significant implications for artificial intelligence, enabling advanced cognitive computing tasks even in challenging environments. By combining materials science and neuromorphic computing, this research heralds the beginning of a new era in electronics. It merges resilience and intelligence, opening up unprecedented possibilities. The monolayer MoS2-based neuromorphic device is an exceptional example of human ingenuity and perseverance in overcoming the challenges of harsh environments as industries continue to push the boundaries of exploration and innovation. Its advancement meets the demand for high-temperature electronics and lays the groundwork for future innovations, allowing electronic systems to interact with and adapt seamlessly to environmental demands.

EL05.11.14

Enhanced Weight-Update Characteristics in Neuromorphic Computing Using Vertical Electrochemical Random-Access Memory with PEALD-TiO$_2$ Channels Hyeongjin Moon[1], Jaehyeong Lee[1], Geongu Han[2], Jinha Choi[1], Jongchan Ryu[1], Hongju Kim[1], Sangbum Kim[1], Jihwan An[3] and Yun Seog Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Seoul National University of Science and Technology, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)

Cross-point arrays of analog synaptic devices are expected to realize neuromorphic computing hardware for large-scale artificial neural networks with significant enhancements in speed and energy consumption compared to conventional hardware based on the von Neumann architecture. To achieve energy efficiency and the desired characteristics of analog synaptic devices for fully parallel vector–matrix multiplication and vector–vector outer-product updates, vertically-structured metal-oxide based electrochemical random-access memory has been proposed as a promising synaptic device. This is due to its CMOS-compatibility and minimal cell size, which provide enhanced synaptic device performance and characteristics, enabling increased scalability for energy-efficient neuromorphic computing. To realize the full potential of VECRAM devices and minimize the device-to-device variations, conformal deposition of thin films along the vertical sidewall by atomic layer deposition (ALD) technique is crucial. However, depositing a channel layer with proper electronic- and ionic-characteristics by ALD has been challenging due to the surface-reaction limited reactions in conventional ALD process.

In this study, we employ a plasma-enhanced ALD (PEALD) technique with an additional Ar plasma step to deposit a TiO$_2$ channel layer for VECRAM devices. By adjusting the power and duration of the Ar plasma step during the ALD cycles, we control the degree of crystallinity and off-stoichiometry of TiO$_2$ films. The ionic and electronic transport characteristics of PEALD-TiO$_2$ are evaluated by electrochemical impedance spectroscopy and compared to film deposited by conventional ALD. We fabricate VECRAM devices to investigate the effect of the PEALD-TiO$_2$ properties on synaptic device characteristics. The microstructure and the conformality of the channel layer on the vertical sidewall are characterized by electron microscopy. The VECRAM device with a PEALD TiO$_2$ channel exhibits improved linearity and improved variations in the weight-update operations, thereby demonstrating enhanced performance for high-density synaptic array-based neuromorphic computing applications.

EL05.11.15

Sampling Energy Landscapes in Germanium Telluride Glass Through Resistance Fluctuations Sebastian Walfort[1], Xuan T. Vu[2], Jakob Ballmaier[1], Nils Holle[1], Niklas Vollmar[1] and Martin Salinga[1]; [1]University of Münster, Germany; [2]RWTH Aachen University, Germany

The concept of energy landscapes is very successful in explaining activated biological, chemical and physical processes. For the highly disordered systems of supercooled liquids and glasses, it has found wide support in computer simulations of model systems, which can resolve detailed characteristics of the potential energy landscape governing their structural dynamics. In experimental studies, however, any details about an underlying landscape are usually obscured due to accessible sample sizes and the averaging nature of spectroscopic techniques. Here we demonstrate that individual resistance states can be resolved in a nanoscopic volume of germanium telluride glass. The fluctuations between these states are measured over a wide temperature range, six orders of magnitude in time and modeled with a hidden Markov model. The resulting attempt frequencies and activation energies reveal a complex free energy landscape, where transitions between states are not only governed by energetic barriers but limited by entropic contributions. Beyond their practical relevance for electronic memory and neuromorphic hardware applications, these results illustrate the feasibility of the experimental approach for fundamental investigations of the energy landscape of glasses and point to the importance of entropic effects for their structural dynamics. Our approach can provide new insights into all kinds of memristive materials, where equilibrium and non-equilibrium (noisy) state dynamics can be exploited for neuromorphic hardware applications exactly because of a close connection between electrical resistance and smallest reconfiguration on the atomic scale.

EL05.11.16

Prospects of (100)p-NiO/(0001)n-ZnO Heterostructures for UV Photodetection and Artificial Synaptic Devices

Amandeep Kaur, Bhabani P. Sahu and Subhabrata Dhar; Indian Institute of Technology Bombay, India

We investigate the photo-response properties of (100)p-NiO/(0001)n-ZnO heterostructures. Our study reveals that these devices can serve as effective UV photodetectors with response time of few hundred microseconds in the self-powered mode. Peak responsivity of these devices has been found to be as high as 5mA/W at zero bias condition. Furthermore, the response time of these detectors can be electrically controlled over a large range, from several microseconds to several hundreds of seconds, by applying bias above a threshold in both forward and reverse directions. The origin of which has been explained in terms of traps at the interface. Above the threshold bias, these devices exhibit synaptic behaviors, like the biological synapses, exhibiting short-term-memory (STM) to long-term-memory (LTM) transition as well as learning-forgetting processes. Moreover, in this system, memory can be partially or completely erased by electrical stimulation. These devices, which are found to consume as low as 128nJ of electrical and 179nJ of optical powers per synaptic event, demonstrate satisfactory performance in terms of repeatability and stability. These findings underscore the potential of (100) p-NiO/(0001)n-ZnO heterojunctions in the development of next-generation photodetectors and neuromorphic devices.

EL05.11.17

Thin-Film Design Strategy for Enhancing Cyclic Endurance in WO_3-Based Resistive Switching Memory Devices

Ziyi Yuan[1], Babak Bakhit[1], Zhuotong Sun[1], Markus Hellenbrand[1], Xinjuan Li[1], Simon Fairclough[1], Caterina Ducati[1], Haiyan Wang[2] and Judith L. Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Purdue University, United States

In today’s data-hungry world, data storage and computing technologies consume a huge share of the world’s electricity and have become one of the main global issues. To meet the net zero objectives, high-performance, energy-efficient memory and computing devices are urgently needed. Resistive switching non-volatile memory devices offer great promise, yet face major challenges, particularly in the endurance of filamentary-based devices, which limits their broader application. Here, we propose a novel thin-film design strategy to enhance endurance in resistive switching devices through nanocomposite engineering. Specifically, we developed a vertically aligned WO_x:CeO_x nanocomposite thin film structure. This structure gives excellent endurance performance of at least 10^6 cycles—an improvement of over ten times compared to existing similar devices in literatures. Furthermore, the devices exhibit robust data retention of at least 10^4 s, multi-level conductance states, and reliable device-to-device uniformity. These performance improvements are mainly attributed to the formation of vertically aligned nano-scale grains that provide uniformly distributed defective paths for conducting filament formation, unlike the random filament formation seen in traditional designs. The linear scaling of current with electrode area is found, indicating good scaling potential linked of the controlled spacing between the filaments of around 80 nm. We believe this carefully engineered vertically aligned nanocomposite structure offers a promising thin-film design for the next generation of non-volatile memory and neuromorphic computing applications.

EL05.11.18

Resistive Switching Mechanism in InP/ZnSe/ZnS Quantum Dots Based Neuromorphic Devices Geun Woo Baek, Yeon Jun Kim, Jaekwon Kim and Jeonghun Kwak; Seoul National University, Korea (the Republic of)

Colloidal quantum dots (QDs) have emerged as a highly promising material in the resistive switching device due to their advantageous properties, such as size-dependent tunable optical bandgap, facile fabrication process, and scalability. Nevertheless, there are limited reports on QD-based memristors, and the precise resistive switching mechanism remains elusive. In this study, we investigate the resistive switching mechanism of InP/ZnSe/ZnS QD-based memristors. To unveil the type of charge carriers (electrons or holes) that are filled into the trap sites of QDs, we incorporate a thin poly(methyl methacrylate) as a blocking layer between QDs and either bottom or top electrodes. Through this strategy, we can figure out the trapped carriers into QDs as well as demonstrate a stable InP/ZnSe/ZnS QD-based synaptic devices. To emulate synaptic functionalities, long-term potentiation/depression (LTP/LTD) are verified, exhibiting low non-linearity of 0.1 and 1, respectively. Finally, a single-layer perceptron simulation is conducted using Extended Modified National Institute of Standards and Technology based on the LTP/LTD characteristics, resulting in a maximum recognition rate of 91.46%.

EL05.11.19

Unveiling the Mechanism of Multilevel Resistive Switching in HfO2/TaOx Devices Through Atomistic Modeling Simanta Lahkar and Aida Todri-Sanial; Technische Universiteit Eindhoven, Netherlands

Memristors, devices whose resistance can be varied depending on the biasing history, have become increasingly important for neuromorphic computing applications [1]. A new kind of bi-oxide layer memristor, formed by stacking Tantalum Oxide (TaOx) and Hafnium Oxide (HfO2) layers of nanometre-thickness together has shown promising characteristics of gradual switching behaviour between multiple resistive states [2]. Experimental evidence has shown that this switching is a localized behaviour indicating an underlying filament-mediated mechanism[2]. However, several questions need to be answered to understand its filamentary switching mechanism, including (a) whether the filament is formed in the fully connected state, likely within HfO2 layer, along with an oxygen-rich region in the adjacent TaOx layer (referred to as ‘dome’) and (b) what are the atomic mechanisms underlying the state transition of the ReRAM device [1, 2]. In order to answer these questions we need to clarify the atomistic structure of the bi-oxide device after forming such that it can lead to the observed resistive switching polarity and characteristics. We address this challenge through an advanced charge transfer-based interatomic force modelling and molecular dynamics (MD) simulation technique to reveal the redox reactions and ionic transfers occurring at the HfO2/TaOx interface that dictate its post-forming structure and behaviour [3-5]. Based on our simulation results, we found that the stoichiometry of the layers is a critical parameter dictating the underlying mechanism, which could be optimized in order to tune the gradual switching behaviour of the device. This project has received funding from the EU’s Horizon program under Projects No. 101092096, PHASTRAC.

Achieving Light-Induced Bipolar Photosensing in III-Nitride Nanowires by Precisely Regulating Ambipolar Carrier-Transport Behavior Wei Chen, Haiding Sun, Huabin Yu, Yang Kang and Yuanmin Luo; University of Science and Technology of China, China

The functionality of semiconductor devices primarily relies on their band structure, which governs charge transfer behavior. Achieving precise control of band structures, especially on semiconductor surfaces and at interfaces, remains a long-standing challenge. As semiconductors are miniaturized from bulk to low-dimensional forms (like 2D materials, nanowires, and quantum dots), their unique physical and structural characteristics, especially the high surface-to-volume ratio, make them highly responsive to the surrounding environment. This responsiveness allows for easy alteration of their band structures by external factors. Therefore, the large surface area of low-dimensional materials holds significant promise for surface band engineering, offering opportunities to control charge transfer behavior in nanodevices and develop novel multifunctional nanoelectronics and nanophotonics devices.

Hence, in this study, we developed p-type aluminum-gallium-nitrogen (p-AlGaN) nanowires on an N-type silicon (Si) substrate and introduced a novel post-epitaxy technique to create carbon@p-AlGaN core-shell nanostructures with varying carbon layer thicknesses. As the carbon layer thickens, the electronic interaction at the carbon-AlGaN interface intensifies, causing the degree of surface band bending in the AlGaN alloy. We constructed an innovative electrolyte-assisted photodetector using carbon@p-AlGaN core-shell nanowires as photoelectrodes. By adjusting the carbon layer thickness, we controlled the degree of band bending on the nanowire surface, significantly influencing charge transfer at the p-AlGaN/electrolyte interface. This tunable charge transfer between the adjustable interface and the internal p-AlGaN/n-Si interface ultimately determines the device's photocurrent output, resulting in a spectrally resolved bipolar photocurrent device with adjustable polar switching points across a broad spectral range. Leveraging this unique optical response, we developed a reprogrammable optical switching logic gate capable of performing four logic operations ("XOR," "AND," "OR," and "NOT") within a single device architecture. Additionally, we created an image encryption transmission system where the optical signal is encrypted using the "XOR" logic operation, ensuring secure image transmission. Our proposed bipolar junction device, based on surface energy band engineering, offers a versatile and effective material architecture for creating multifunctional nanophotonic devices.

Nanograined MoS_2 Memristors—A Breakthrough in Uniformity and Endurance for Neuromorphic Systems
Gunhoo Woo[1], Jinil Cho[1], Jinhyoung Lee[1], Chanho Park[1], Jeongryul Yoo[1], Jinsoo Yoon[1], Jongwoo Kwon[1], Hocheon

Yoo[2] and Taesung Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

Memristors are emerging as promising candidates for electronic synapses and nonvolatile memory devices due to their high density, analog switching capabilities, and low energy consumption. However, conventional memristors face significant challenges, including device-to-device and cycle-to-cycle variations, because of destructive conductive filament (CF) formation processes. These issues hinder their practical application. This work presents a robust and reliable memristor array utilizing molybdenum disulfide (MoS_2) nanograins, termed nanoristors. MoS_2 films with 7–10 nm nanograins were synthesized via plasma-enhanced chemical vapor deposition. The resulting structure features tens of thousands of grain boundaries within a 1 μm × 1 μm area, enabling memory operation with remarkable uniformity and endurance exceeding 2300 cycles. Additionally, the vertical grain boundaries and defects facilitate Ag^+ ion diffusion, resulting in a forming-free operation with a low switching voltage of under 500 mV. The MoS_2 nanoristor also successfully emulated potentiation and depression characteristics crucial for online learning in neuromorphic systems. The efficacy of the MoS_2 nanoristor-based synapse device for face recognition was validated through device-to-system simulation. This innovative approach of fabricating nanograined MoS_2 offers highly uniform and robust memristor operation, potentially revolutionizing electronic synapses and memory devices in neuromorphic electronic systems.

EL05.11.22

First Demonstration of High Remanent Polarisation in 10 nm Polycrystalline $BaTiO_3$ Films Sean R. McMitchell, Pratik Bagul, Jan v. Houdt and Ingrid De Wolf; imec, Belgium

In recent years, the possibility to grow high-quality ultrathin ferroelectric films has revived interest in perovskite ferroelectrics for FeRAM applications, which were once believed to have reached their scaling limits. In these devices, the ferroelectric is sandwiched between two conductive electrodes and the information is stored by the polarisation direction in the ferroelectric film [1]. The high remanent polarisation and low coercive field of perovskites make them ideal ferroelectric materials for low-power memory applications. Ferroelectricity has been observed in ultrathin perovskite films down to 5 nm in epitaxy [2,3,4] but has yet to be demonstrated in polycrystalline films, which are preferred in production due to the placement of capacitors in the back-end-of-line for DRAM-like technologies.

In this work, the thickness scaling of polycrystalline $BaTiO_3$ down to 10 nm is demonstrated with remarkable remanent polarisation values. This work was enabled by the development of a novel platinum silicide based conductive electrode that also acts as an oxygen migration barrier at the high temperatures required for growth of $BaTiO_3$. This bottom electrode was used as a template to deposit $LaNiO_3$ (perovskite bottom electrode) followed by $BaTiO_3$ thin films with 10-40 nm film thickness using pulsed laser deposition (PLD). The polarisation electric-field (P-E) measurements revealed enhancements in the ferroelectric characteristics of $BaTiO_3$, with polarisation values ($P_r \sim 10\text{-}18\ \mu C/cm^2$) that are competitive with epitaxial $BaTiO_3$ thin films at these thicknesses. Polarisation enhancement mechanisms are linked to oxygen content, strain, and crystal quality.

These findings provide new insights into the scaling of perovskite ferroelectrics and open up new opportunities for integrating perovskite materials into CMOS technologies.

Solid State Chromism in Ferroelectric ε–WO_3—Elucidating Mechanism via Spectroscopic Study Mohammad Mahafuzur Rahaman, Anthony Annerino, Jacob Shell and Pelagia-Irene (Perena) Gouma; The Ohio State University, United States

Binary ferroelectric (BFE) oxides are crucial in science and technology due to their superior properties compared to conventional ferroelectric materials. Among various BFE oxides, ε-WO_3 stands out, having been stabilized at room temperature by our group using flame spray pyrolysis. This room temperature-stabilized ε-WO_3 polymorph exhibits blue coloration in its solid state when an electric field is applied, requiring 15 times less voltage than traditional electrochromic materials. This study explores the unique solid-state chromism of ferroelectric ε-WO3 under an applied bias and explains its mechanism. Raman and X-ray Photoelectron Spectroscopy (XPS) studies dismiss the possibility of coloration through double ion injection, as seen in conventional electrochromic materials, and instead suggest that the ferroelectric nature of ε-WO3 drives the coloration phenomenon. This chromic effect, observed in a single solid-state layer of ε-WO_3, paves the way for developing next-generation electrochromic devices using this ferroelectric polymorph of WO_3.

EL05.11.24
Cryogenic Bistable Current-Voltage Dependence in a Silicon pn-Junction formed by wafer-bonding Sunghoon Cho[1], Peter Moroshkin[2], Damir Kulzhanov[2], Jimmy Xu[2] and Ki Tae Nam[1]; [1]Seoul National University, Korea (the Republic of); [2]Brown University, United States

As the semiconductor industry readies itself for the 'post-Moore' era, it is already challenging to achieve further performance improvements through miniaturization alone. As a result, leading semiconductor companies like Intel, Samsung, and TSMC are developing 2.5D packaging technology with direct wafer bonding, which connects chips directly without bumps. The substantial benefits in minimizing the transmission delays and parasitics as well as in efficient power management and heat dissipation make direct wafer bonding an essential technology for development of high-performance chips. In parallel, the drive for higher-performance as well as quantum computing has extended exploration of silicon electronics into the cryogenic regime.
Here, we report on a novel phenomenon, a bistable current-voltage dependence, found in the cryogenic operation of a Si pn-junction. The pn-junction was formed by direct wafer-bonding of a heavily doped p-type silicon wafer to an n-type silicon wafer. Electrical property was measured with metal ohmic contacts on the top and bottom surfaces. The measurement results showed normal diode I-V characteristics at room temperature. However, when the device is measured at cryogenic temperatures below 30K, an S-shaped I-V dependence emerges and becomes more pronounced with decreasing temperature. This results in a bistable current switching response when sourcing voltage, due to the negative differential resistance between the two stable states. Underlying this interesting and potentially useful novel functionality is the presence of a 2nm thick SiO2 barrier layer formed right at the metallurgical interface between the two wafer during the particular wafer-bonding process. Our study aided by computational model simulation provides insights into switching mechanism(s) in relation to the structural features of the wafer-bonded pn-junction and suggests potential innovative uses of the functionality.

EL05.11.25
Reliable Analog AI Inference Acceleration Based on Stable and Accurate Nano-Resistor Array Giho Lee, Min-Kyu Song and Jeehwan Kim; Massachusetts Institute of Technology, United States

As artificial intelligence (AI) technology continues to excel in daily applications, the demand for seamless, private, and advanced AI functions is growing rapidly. On-device AI solutions, integrated into commercial mobile devices, eliminate the need for communication with external servers, improving both response times and data privacy. However, current on-device AI technologies consume significant power and are not yet capable of supporting the most advanced generative AI models due to limited computing capacity.

Memristor-based analog AI accelerators have shown promise in overcoming the von Neumann bottleneck, a critical barrier to enhancing AI computing speed and energy efficiency. Despite this potential, memristors face challenges related to conductance state reliability and the complexity of their programming algorithms and circuitry, limiting their practical application in industry.

In this work, we present an ultra-reliable nano-resistor array that enables ultra-reliable analog AI inference for well-defined tasks, minimizing the use of additional complex circuitry. The conductance states are fixed and geometrically programmed through a single micro-nano patterning process, eliminating the need for stochastic programming and reducing the complexity of the programming circuits found in memristor-based accelerators. We achieved 6.8-bit programming accuracy and 8-bit stability in conductance values. Furthermore, experimental results from multiply-accumulate (MAC) operations demonstrate the potential for 8.2-bit accuracy in a passive 28x28 array with simple circuit-level compensation. This nano-resistor array will offer a reliable and accurate platform for AI computing, specifically designed for daily AI tasks, while reducing peripheral circuitry.

EL05.11.26

Effects of Post-Synthesis Treatments on SnO_2 Aerogel for Electronic Applications

John F. Hardy, Madison S. King, Stephanie K. Hurst and Carlo R. daCunha; Northern Arizona University, United States

Aerogel constitutes a unique class of materials characterized by self-assembled arrays of interconnected crystallites, but while the mechanical properties of aerogels have been extensively explored, their electrical properties remain relatively unexplored. This study focuses on the synthesis and characterization of a semiconducting tin oxide (SnO_2) aerogel for electronic applications. SnO_2 is a wide bandgap, n-type semiconductor known for its high optical transparency and low electrical resistance. These SnO_2 properties in combination with the unique characteristics of aerogel enable the possibility for innovative applications in solar cell technologies, memory devices (e.g., resistive random-access memory), and neuromorphic computing. However, a challenge remains; while bulk SnO_2 exhibits an optical bandgap energy (E_g) of around 3.6 eV, previous literature indicates that SnO_2 in aerogel form displays a larger apparent E_g of around 4.6 eV. This increase in E_g is likely attributable to defects within the material such as dangling bonds likely caused by a Burstein-Moss shift due to the Sn-rich surface. To minimize defects within the material this research characterizes the aerogels after a post-annealing process in an environment with oxygen present and the effects of using H_2O_2 as a surface treatment without a post-annealing process.
An epoxide method was used to synthesize the SnO_2 aerogels. The material underwent annealing at atmospheric pressure in a tube furnace at temperatures of 100°C, 200°C, 300°C, and 400°C for 30 minutes each. The samples were exposed to oxygen during the annealing process to attempt to passivate any dangling bonds without surface treatment. Additionally, a sample without annealing was aged in a 3% H_2O_2 and H_2O solution to compare with the unannealed sample aged in only ethanol. Fourier transform infrared (FTIR) spectroscopy was utilized to identify any potential contaminants and unreacted precursors in each sample. X-ray diffraction (XRD) was used to calculate the crystallite size using the Debye-Scherrer equation and the microstrain on the crystal structure using the Williamson-Hall method. Finally, UV-Vis was performed to calculate the E_g through Tauc's equation and the Urbach energy (E_U) through the Urbach tail equation, which quantifies the disorder in the band edges of a

semiconductor.
The results of this study determined that annealing removes the impurities of the sample at each temperature and the apparent bandgap reduces with a linear trend from 5.32 eV to 4.06 eV with temperature. Shifts in the XRD peaks suggest that there is a phase change at 300°C from SnO_2 to SnO, and the E_U was seen to increase with annealing, the largest value being 1.13 eV at 300°C. This indicates a large amount of disorder and the presence of more localized states within the bandgap, and when the structure stabilizes after the phase change at 400°C, the structure displays the value of disorder of 0.42 eV which exhibits a sharper absorption edge with fewer localized states within the bandgap. In comparison, the use of H_2O_2 as a surface treatment resulted in a reduction of E_U from 0.2207 eV to 0.147 eV and decreased E_g from 5.32 eV to 3.64 eV.
This study concludes that while annealing improves some qualities of the material, this is likely due to the phase change within the material and not the reduction of defects. Whereas significant improvements in the optical characteristics using an H_2O_2 surface treatment were observed. The passivation of dangling bonds on the SnO_2 aerogel surface is the solution to minimizing the apparent E_g for future solar and neuromorphic applications.
Future work of this project consists of incorporating impurities such as indium chloride into the synthesized SnO_2 aerogels to further reduce the E_g for solar cells and neuromorphic technology.

EL05.11.27

Volatile Memristive Devices with Analog Resistance Switching Based on Self-Assembled Squaraine Microtubes as Synaptic Emulators

Gareth Redmond; University College Dublin, Ireland

In this work, the discovery of volatile memristive devices that exhibit analog resistive switching (RS) and synaptic emulation based on squaraine materials is presented. Specifically, organic microtubes (MTs) based on 2,4-bis[(4-(N,N-diisobutyl)-2-6-hydroxyphenyl]squaraine (SQ) are prepared by evaporation-induced self-assembly (EISA). The MTs are ca. 2 μm in diameter (aspect ratio: 10−130). While powder X-ray diffraction data for MTs identify monoclinic and orthorhombic polymorphs, optical data report the monoclinic phase with energetic disorder. By favorable energetic alignment of the Au work function with the SQ HOMO energy, unipolar (hole-only) symmetric metal−insulator−metal devices are formed by EISA of MT meshes on interdigitated electrodes. The DC I−V characteristics acquired exhibit pinched hysteretic I−V loops, indicative of memristive behavior. Analysis indicates Ohmic transport at low bias with carrier extraction by thermionic emission. At high bias, space-charge-limited conduction in the presence of traps distributed in energy, enhanced by a Poole-Frenkel effect and with carrier extraction by Fowler-Nordheim tunneling, is observed. These data indicate purely electronic conduction. I−V hysteresis attenuates at smaller voltage windows, suggesting that carrier trapping/detrapping underpins the hysteresis. By applying triangular voltage waveforms, device conductance gradually increases sweep-on-sweep, with wait-time-erase or voltage-erase options. Using square waveforms, repeated erase-write-read of multiple distinct conductance states is achieved. Such analog RS behavior is consistent with trap filling/emptying effects. By waveform design, volatile conductance states may also be written so that successive conductance states exhibit identical current levels, indicating forgetting of previously written states and mimicking the forgetting curve. Finally, advanced synaptic functions, i.e., excitatory postsynaptic current, paired-pulse facilitation, pulse-dependent plasticity, and a transition from short- to long-term memory driven by post-tetanic potentiation, are demonstrated. In conclusion, operating on the principle of purely electronic RS, these novel organic semiconductor MT mesh devices provide an attractive combination of large dynamic range, access to multiple conductance states, linear and symmetric conductance tuning, and biorealistic synaptic emulation.

EL05.11.28

Light-Induced Electric Field Assisted Self-Driven Perovskite Photodetector for Fluorescence Detection in Biomedical Application

Md Fahim Al Fattah, Asif Abdullah Khan and Dayan Ban; University of Waterloo, Canada

The exceptional photo conversion efficiency of solution-processed metal halide perovskite (MHP) materials which can rarely be observed in conventional semiconductors, has led to their applications in many optoelectronic devices and sensors. Despite significant advancements in perovskite-based devices, these materials are gaining substantial attention as promising candidates for fluorescence-based sensors in biological marker detection and quantification. Herein, a self-driven CsPbBr2I-based photodetector for fluorescence detection is reported elucidating a controlled charge carrier dynamics under the light-matter interaction. The light-induced doping phenomenon, resulting from the migration of optically activated ions, generates a built-in electric field that enables device operation without external power. However, the uncontrolled migration of those ions increases the dark current and reduces the stability of the output current. To address this, we fabricate a vertically stacked FTO/PEDOT: PSS/$CsPbBr_2I$/PCBM/Ag photodetector with a non-symmetrical electrode design to trigger controlled ion migration upon light illumination thereby improving the device performance and output stability. The photodetector, driven by electric field due to directional light-induced polarization, achieves an ultra-low dark current (~298 pA), a high on/off ratio (~10^5), a responsivity of 202 mA/W, a large bandwidth of 3.1 KHz, a linear dynamic range (LDR) of 81.11 dB, and a rapid response time (190 μs/100 μs) at 0 V, surpassing the performance of many similar state-of-the-art materials. These insights are valuable for practical applications, particularly in fluorescence-based biomarker detection, where the ability to detect weak signals is essential. As a proof of concept, we integrate the $CsPbBr_2I$-based photodetector with a microfluidic chip to detect varying concentrations of 525 nm quantum dot-conjugated beads. The device demonstrates exceptional sensitivity, with the ability to detect fluorescence signals from quantum dot solutions as low as ~22.63 nM within a microfluidic channel, highlighting its potential for future biological sensing applications.

Designer 2D Materials and Machine-Learning Assisted Characterization Shengxi Huang; Rice University, United States

2D materials offer enormous opportunities to build designer structures with widely tunable properties. The precise atomic engineering and quick characterization approach are critical to advance the application of designer 2D materials. This talk will introduce new optical features of designer 2D materials [1-5], including dipole-induced mechanical behavior, phonon interference, and single photon emission. The engineering of 2D materials presents unique opportunities for optoelectronic devices and quantum information platforms. When designing optoelectronic devices of 2D materials, spectroscopic permittivity of 2D material is a key parameter. While ellipsometry has been used to measure permittivity, it requires simple device structure, non-trivial parameter fitting, and special setup. This talk will also present a new machine-learning assisted approach to measure permittivity of 2D materials embedded in complex device structures without model fitting, which can facilitate a quick, accurate, and in-situ characterization of 2D and other thin film materials [6].

Probing Hyperbolic and Surface Phonon-Polaritons in 2D Materials Using Raman Spectroscopy Alaric Bergeron[1], Clément Gradziel[1], Richard Leonelli[2] and Sebastien Francoeur[1]; [1]Polytechnique Montréal, Canada; [2]Université de Montréal, Canada

The hyperbolic dispersion relation of phonon-polaritons (PhPols) in anisotropic van der Waals materials provides high-momentum states, directional propagation, subdiffractional confinement, large optical density of states, and enhanced light-matter interactions. In this work, we used Raman spectroscopy in the convenient backscattering configuration to probe PhPol in GaSe, a 2D material presenting two hyperbolic regions separated by a double reststrahlen band. By varying the incidence angle, complete dispersion relations are revealed. Raman spectra simulations confirm the observation of one surface and two extraordinary guided polaritons and match the evolution of PhPol frequencies as a function of vertical confinement. GaSe appears to provide relatively low propagation losses and supports confinement factors matching or exceeding those reported for other 2D materials, such h-BN and MoO3. Resonant excitation close to the 1s exciton singularly exalts the scattering efficiency of PhPols, providing enhanced scattering signals and means to probe the coupling of PhPols to other solid-state excitations. Almost universally available in 2D material research labs, backscattering Raman spectroscopy is a complementary technique for the study of phPol and may accelerate the development of a wider variety of polaritonic materials and devices.

High-Throughput Photoluminescence Characterization of Transition Metal Dichalcogenides Juri G. Crimmann[1], Moritz N. Junker[1], Yannik M. Glauser[1], Nolan Lassaline[1,2], Gabriel Nagamine[1] and David J. Norris[1]; [1]ETH Zürich, Switzerland; [2]Technical University of Denmark, Denmark

Transition metal dichalcogenides (TMDs) are two-dimensional layered semiconductors that are exploited in optoelectronic devices such as light-emitting diodes, photodetectors, and photovoltaic cells. Fabricating these devices requires finding high-quality TMD monolayers with favorable optical properties. Flakes are often investigated via photoluminescence (PL) characterization, giving access to information about the optical band gap and the defect density of a crystal. However, such measurements are time-consuming, limiting studies to a small number of flakes. Here, we report a fully automated PL characterization method for TMDs. We present a study of more than 2400 monolayers and bilayers of WSe_2, $MoSe_2$, and MoS_2. We investigate geometric and PL properties with a previously unattainable number of flakes, revealing significant variations of PL intensity across the monolayers. Additionally, investigated flakes show a strong correlation between PL intensity and the size of the crystal, which is attributed to reduced PL at the edges of monolayer TMDs. We anticipate that our methodology will aid the growth of high-quality TMDs, enhancing their performance for optoelectronic devices.

2:30 PM EL06.01.04

Characterization of Engineering Defects in 2D-MoS_2 Layers by Oxygen Plasma Treatment Using Nanoscale TERS and KPFM Imaging Sanju Gupta[1,2]; [1]The Pennsylvania State University, United States; [2]Gdansk University of Technology, Poland

Transition metal dichalcogenides (TMDCs), such as molybdenum disulfide (MoS_2), exhibit interesting and technologically relevant optoelectronic characteristics owing to the strong dependence of the bandgap on dimensionality. Previous scientific investigations have tended to focus on electronic transport properties and device demonstrations that tend to employ electron-beam lithography for patterning [1, 2]. However, modulating the physical properties of two-dimensional 2D-MoS_2 induced by oxygen plasma and defect engineering at the nanoscale is actively pursued [1]. In this work, exfoliated atomically thin layers of two-dimensional 2D-MoS_2 treated with oxygen plasma for 0, 10, 20, 40, and 60 s are investigated using Kelvin Probe Force Microscopy (KPFM) and Tip-Enhanced Optical Spectroscopy (TEOS) imaging in addition to micro-Raman and photoluminescence spectroscopy. Under oxygen plasma, defects (mono- and di-sulfur vacancies) and chemical oxidation are predominant from 0s (native defects) up to 40s, while etching takes over beyond 40 s, for mono- (1L), bi- (2L), and tri- (3L) layer MoS_2 with optimal defect density for four- (4L) or more layers. While Raman spectra exhibited lattice distortion (broadening of phonon bands) and surface oxidation by the presence of sub-stoichiometric molytrioxide MoO_3 (*i.e.,* MoO_{3-x} or MoS_xO_{2-x}), the quenching of PL and increased spectral weight of trions are observed with treatment time. The localized nanodomains (~20 nm) and aggregated vacancies nanovoids, intermixed MoS_2/MoO_{3-x} alloy, and trions are identified in near-field Raman spectra. The Kelvin probe force microscopy revealed the work function (WF) increase from 4.98 eV to 5.56 eV, corroborating the existence of MoO_{3-x} phase which enables doping and Fermi level shift. We also emphasize the unique interaction between the gold and MoO_{3-x} facilitating Mo^{6+} cation reduction to lower oxidation state (*i.e.*, Mo^{4+}) yielding intermediate oxidation states responsible for lowering WF (*ca.* 6.3 eV for stoichiometric MoO_3). Strong correlations among the work function, vibrational, and optical responses help in establishing a phase diagram and changing the landscape of nanoscale defects. The defects that confine charged defects constitute well-defined atomic-scale quantum systems explored as single photon emitters and spin qubits and heterogeneous electrocatalysis, applicable to other 2D

material systems. Supported by NSF-MRI, USA. [1] S. Gupta, A. Johnston, S. Khondaker, J. Appl. Phys. **131**, 164303 (2022); [2] S. Gupta, A. Johnston, S. Khondaker, J. Electron. Mater. **52**, 1331-1346 (2023).

Light-Driven Actuation Enabled by 2D Transition Metal Carbides Haozhe Wang; Duke University, United States

2D transitional metal carbides (MXene) have attracted attention for its unique properties such as adjustable electrical conductivity, high mechanical stability, and versatile responsiveness, offering a huge potential for advancing soft robotics and sensing. However, the performance of the MXene-based soft actuator is limited by uncontrollable surface terminations (-OH, -F, etc) induced in the synthesis process. Modifying these surface functional groups allows for customizing Ti2C3Tx to possess desired properties.

In this work, we propose an innovative approach to engineer the surface termination of Ti2C3Tx using plasma treatment. The Ti2C3Tx flakes were exposed to different plasma conditions, with the resulting change in surface termination characterized by X-ray Photoelectron Spectroscopy (XPS). The morphology of Ti2C3Tx is evaluated using Scanning Electron Microscopy (SEM) and Atomic Force Microscopy (AFM). Furthermore, we fabricated Ti2C3Tx /cellulose actuators using Ti2C3Tx with controlled surface terminations. In addition, cellulose in the nanocrystal, nanofiber, and microfiber phases are utilized and compared to obtain the best actuation performance. We observe that our Ti2C3Tx /cellulose actuator demonstrates strong responses to light and moisture, which can be applied in soft robotics and sensing applications. The mechanism of controlled surface terminations contributing to the multi-responsive actuator will also be discussed.

3:45 PM EL06.01.06
Solution-Phase Sample-Averaged Single-Particle Spectroscopy of Quantum Emitters with Femtosecond Resolution Jiaojian Shi and Aaron Lindenberg; Stanford University, United States

The development of many quantum optical technologies depends on the availability of single quantum emitters with near-perfect coherence. Systematic improvement is limited by a lack of understanding of the microscopic energy flow at the single-emitter level and ultrafast timescales. Here [1] we utilize a combination of fluorescence correlation spectroscopy and ultrafast spectroscopy to capture the sample-averaged dynamics of defects with single-particle sensitivity. We employ this approach to study heterogeneous emitters in two-dimensional hexagonal boron nitride. From milliseconds to nanoseconds, the translational, shelving, rotational and antibunching features are disentangled in time, which quantifies the normalized two-photon emission quantum yield. Leveraging the femtosecond resolution of this technique, we visualize electron–phonon coupling and discover the acceleration of polaronic formation on multi-electron excitation. Corroborated with theory, this translates to the photon fidelity characterization of cascaded emission efficiency and decoherence time. Our work provides a framework for ultrafast spectroscopy in heterogeneous emitters, opening new avenues of extreme-scale characterization for quantum applications.

4:00 PM EL06.01.07
Structural Detwinning of Multiferroic Domains in NiI_2 Isabella Kaye Torres; Massachusetts Institute of Technology, United States

Multiferroic materials have attracted a lot of interest for potential nano electric device applications. The strong coupling between ferroelectric and magnetic orders provides new opportunities for ultrafast and energy efficient information processing. Less explored, however, is the coupling between these orders and the crystal lattice. Here we demonstrate structural detwinning of multiferroic domains in bulk NiI_2, a van der Waals type-II multiferroic material. NiI_2 has a triangular lattice structure with a helical spin spiral and ferroelectric dipole coupled to a monoclinic distortion. We used a piezoelectric to apply mechanical strain and align the spin spiral along different directions within our sample. We used cross-polarized imaging and linear dichroism (LD) to visualize how the magnetic domains within the crystal change in response to strain. Ultimately, we detected magnetic domains and that grew in size with strain, demonstrating our ability to strain tune this quantum material. These observations establish NiI_2 as a strongly tunable multiferroic system with potential for future device development.

4:15 PM EL06.01.08

Tailoring Optical Response of 2D Photonic Materials via Nanoscale Strain Gradients Abhishek Mukherjee, Morgan Blevins and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

We present an experimental and computational study of engineering in-situ strain in two-dimensional materials aiming to unlock and enhance their fundamental magnetic, electronic, and optical properties. The materials under study include semiconducting metal thio(seleno)phosphates, which have been synthesized by vapor transport techniques reported in previous literature [1] and exhibit a wealth of promising nonlinear optoelectronic and magnetic properties, including bulk photovoltaic effect, second harmonic generation, and (anti)ferromagnetic response [1]. These single crystalline materials complete the multi-spectral library of 2D photonic materials as they possess bandgaps between 1.6 and 4 eV, which provide the opportunity to fill the void between narrow band gap materials such as TMDs and wide band gap hBN.

Our prior work has shown that accidental structural defects in these materials can enhance and modulate photoluminescence from spatially localized areas via a combined effect of strain and optical confinement [2]. Here, we describe the process of tailored engineering of the in-situ strain fields with large, localized strain gradients via a custom-built robotic transfer setup that is loaded with micron-scale PDMS stamps. The setup picks up and transfers nanocrystalline flakes onto substrates with pre-engineered nano-pillars and gratings, which impart strong localized strain gradients to the materials. We have developed a protocol of strain gradient mapping with Raman spectroscopy, which is used to reveal the limits and advantages of different strain-engineering strategies. Strain-induced linear and nonlinear optical responses are characterized by imaging ellipsometry, atomic force microscopy, photoluminescence spectroscopy [2], and second harmonic generation experiments, revealing opportunities for engineering strain-enhanced optical responses.

This research has been supported by the MIT Lincoln Laboratory Advanced Concepts Committee Award (ACC-777), along with a Draper Fellowship to Morgan Blevins, as well as the Siebel Scholarship and MIT MathWorks Fellowship to Abhishek Mukherjee.

4:30 PM EL06.01.09

Modulating Thermoelectricity in Bilayer Graphene Nanoribbons Via Light Irradiation

Cynthia I. Osuala[1], Tanu Choudhary[2], Raju K. Biswas[2], Sudin Ganguly[3], Chunlei Qu[1] and Santanu K. Maiti[4]; [1]Stevens Institute of Technology, United States; [2]M. S. Ramaiah University of Applied Sciences, India; [3]University of Science and Technology Meghalaya, India; [4]Physics and Applied Mathematics Unit, Indian Statistical Institute, India

Thermoelectric materials which convert thermal energy into electrical energy and vice versa, hold significant promise for sustainable energy technologies and waste heat recovery [1-2]. The efficiency of these materials is quantified by the dimensionless figure of merit ZT, which depends on the Seebeck coefficient, electrical conductivity, and thermal conductivity. Materials with a ZT < 1 are usually deemed inefficient for real-world uses whereas those with a ZT > 1 are seen as having strong thermoelectric performance. The goal generally is to reach a ZT > 2 for commercially feasible solutions. This has spurred significant research efforts into enhancing thermoelectric efficiency through new materials and structural innovations, as achieving high ZT can lead to better performance in power generation technologies [3-5].

We will present our investigation on utilizing bilayer graphene (BLG) for thermoelectric applications by irradiating it with light to reduce thermal conductivity while preserving its excellent electrical properties. We will utilize ultrasoft pseudopotentials in the local density approximation using the Perdew, Burke, and Ernzerhof (PBE) [6] functional to obtain the structural and phonon transport properties of the AA- and AB-stacked bilayer graphene. The van der Waals interactions, which play a crucial role in bilayer graphene, were accounted for using the Grimme D3 method [7]. By exposing BLG to light, we induce anisotropy and modify the electron and phonon interactions within the material. We provides a detailed analysis of the electron and phonon spectra of thermoelectric quantities, atomic vibration modes, phonon group velocity, and Gr{\"u}neisen parameters. This approach opens up new possibilities for optimizing the performance of thermoelectric devices using bilayer graphene.

Demonstration of Designer Strain Distributions in Two-Dimensional Semiconductors Eric Herrmann, Lottie Murray, Igor Evangelista, Anderson Janotti, Matthew Doty and Xi Wang; University of Delaware, United States

Strain engineering of two-dimensional (2D) semiconductors has recently revealed exciting nanophotonic effects such as localized bandgap tuning, exciton funneling, and the creation of site-specific single photon emitters. While there has been significant progress in the theoretical understanding of nanoscale strain engineering over recent years, experimental progress is hindered by the presence of unintended strain in solid-state devices, blurring the relationship between the local strain environment and direct material response. Existing studies have mainly investigated the strain-induced nanophotonic effects of 2D semiconductors on isolated nanostructures such as nanopillars and nanotips. Here, we introduce an additional degree of freedom to strain engineering to investigate complex strain distributions by transferring 2D materials flakes onto nanostructures patterned in close proximity, enabling the study of a variety of strain distributions, such as uniaxial, biaxial, and triaxial strain within a single flake. The bright emission from thick flakes makes gallium selenide a fantastic material for understanding the relationship between local strain and optical response. Our findings reveal that finite strain distributions and resulting bandgap shifts occur in regions of gallium selenide suspended between closely spaced nanostructures, which is in agreement with strain distributions simulated using finite element analysis. Furthermore, by rotating nanopillar units within the same pattern, we enable studying strain effects as a function of alignment to the crystallographic directions. By carefully designing the strain distribution, we show that the energy, intensity, and localization of gallium selenide emission can be controlled. In addition, we demonstrate Raman shifts and emission shifts by strain engineering in tungsten disulfide. This research paves the way for designer strain distributions and tailorable nanophotonic behavior in two-dimensional materials.

Emerging Magnetoelectric Responses in Quantum Materials Tony Low; University of Minnesota, United States

In this talk, I will discuss emerging magnetoelectric responses in quantum materials, such as materials with broken inversion or time reversal symmetry, and twisted atomic bilayers. I will emphasize on magnetoelectric responses which has a quantum origin, and their experimental signatures on optical experiments through concrete materials systems. Some fundamental questions related to magnetoelectric responses are; can mgnetoelectric coefficients be significantly larger than that observed in conventional chiral molecules, can magnetoelectic reponses be tunable, amplified magnetoelectric responses through electrical bias, among others.

9:00 AM *EL06.02.03
Ferroelectric Switching of Light-Matter Interaction in Rhombohedral-Stacked MoS_2 Ziliang Ye; The University of British Columbia, Canada

The tunability in the stacking of layered materials with van der Waals bonding provides a new and powerful approach to engineer their physical properties. Sliding ferroelectricity is one such example where an electric field drives one layer of materials to move relative to the other due to an out-of-plane electrical polarization arising from the interlayer coupling. As a result, sliding ferroelectricity can occur in traditionally non-ferroelectric materials and it has been observed in artificially stacked boron nitrides and transition metal dichalcogenides. In this talk, I will show that such a hysteric phenomenon can also be observed in chemically synthesized rhombohedral-stacked molybdenum disulfide (3R-MoS_2) with pre-existing domain walls. I will first discuss our studies on domain characterization using photocurrent and scanning probe microscopy. I will then show that these polarization domains and their ferroelectric switching can be probed using optical spectroscopy. We find the switching pathway strongly depends on the local pinning centers and screening effects. Due to their strong interaction with light and the ferroelectric properties, rhombohedral-stacked TMDs can be built into nonvolatile optical memories with high performances.

9:30 AM EL06.02.04
s-SNOM for Addressing Optical Phenomena in 2D Materials at Nanoscale Artem Danilov, Tobias Gokus and Andreas Huber; Attocube Systems AG, United States

The combination of the atomic force microscopy with optical channels breaks the diffraction limitation for the spatial resolution, enabling optical analysis at nanoscale. Scattering-type near-field optical microscopy employs a tiny metallic probe with typical size of ~10-20 nm to interact with the underlying matter via far-field light confinement. One of the direct applications of the technology enables direct electric field sensing, resolved in both amplitude (intensity) and phase (field direction). That paves the way to the set of approaches, suitable for 2D materials characterization. s-SNOM can be used to detect light propagation at the interfaces, including propagating or localized polaritons. Furthermore, polariton interferometry is a great method for measuring dispersion of 2D materials. Employment of fs-pulsed light sources allows tracking of ultrafast event such as charge-carrier dissipation or relaxation processes in matter. Combination of various approaches providing reflectivity, absorption and photoluminescence and i.e. electric modes (KPFM, c-AFM, etc.) enables correlation nanoscopy, delivering wide picture of the phenomena at nanoscale.
In this talk, I will be introducing the basics of the technology and will highlight typical examples of applications, recent trends and developments.

9:45 AM EL06.02.05
Infrared Dielectric Anisotropy in Rhenium Diselenide ($ReSe_2$), an Excitonic van der Waals Material
Ramachandra Bangari[1], Siddharth Nandanwar[1,2] and Thomas G. Folland[1]; [1]The University of Iowa, United States; [2]Boston College, United States

Polaritons, hybrid light-matter excitations that arise from the strong coupling between photons and various excitations in materials, such as excitons, plasmons, and phonons, have garnered significant attention in the field of nanophotonics. Recent studies have demonstrated that van der Waals materials with monoclinic and triclinic crystal structures, such as β-Ga_2O_3 (bGO), can support a new type of polariton called hyperbolic shear polariton with anisotropic propagation along the material surface [1]. These low-symmetry materials show promise for applications in directional light propagation, polarization and phase control of light, and polarization-sensitive photodetectors.

In this study, we investigate Rhenium diselenide ($ReSe_2$), a two-dimensional (2D) van der Waals material with reduced in-plane symmetry, using infrared spectroscopy to determine its optical constants. $ReSe_2$, a member of the group VII transition metal dichalcogenides (TMDCs), exhibits distinct anisotropic characteristics that set it apart from more commonly studied hexagonal TMDCs like MoS_2 or WS_2. Previous literature has reported polarization-sensitive photoluminescence [2] of $ReSe_2$ in the infrared, arising from excitonic oscillators, which aligns with our findings.

Our research employs temperature dependent polarized FTIR (Fourier Transform Infrared) microscopy and numerical analysis to probe the birefringence and excitonic behavior in $ReSe_2$. This technique, like spectroscopic ellipsometry, allows us to extract in-plane anisotropy in the dielectric function due to the excitonic oscillators observed in the near-infrared region (850nm-950nm). We utilize the transfer matrix method [3] to computationally fit the reflectivity calculated from a dielectric function model comprising directional Lorentzian oscillators to the experimental data, enabling us to optimize the optical constants. Our results show that the non-orthogonal oscillators give rise to a non-diagonalizable dielectric tensor, influencing the optical response in the infrared spectrum. Understanding these optical parameters is crucial for modeling polaritons in $ReSe_2$ and exploring its potential for hosting novel types of polaritons. Our work contributes to the growing knowledge of anisotropic 2D materials and their prospective applications in next-generation optoelectronic devices.

10:00 AM BREAK

10:30 AM *EL06.02.06
Sliding vdW Polytypes Moshe Ben Shalom; Tel Aviv University, Israel

Electric field control of structural transitions is typically impractical due to the large energy re-quired for breaking solid bonds. Recently, however, structural switching between different lattice orientations of layered materials was demonstrated owing to relatively weak van der Waals (vdW) attraction between successive layers. In response to external electric fields, the layers slide along vdW interfaces to switch between meta-stable configurations with distinct properties. These so-called 2D vdW polytypes exhibit substantial interlayer band hybridizations and diverse electronic, optical, and magnetic responses that switch via super-lubricant sliding of incommensurate boundary strips.
The talk outlines the many possible vdW polytypes in mono and binary compounds, their typical stacking energies, orbital inter-layer overlaps, and discrete symmetries. The distinct response of each polytype, its internal charge redistribution, electric polarization, and underlying band structure are further discussed with emphasis on our recent reports of interfacial ferroelectricity [1], ladder-like cumulative polarization [2,3], doping-dependent polarization in elemental graphitic polytypes [4], and the microscopic switching dynamics between polytypes. Lastly, I will describe our efforts to extend this conceptual "Slide-Tronics" switching mechanism to practical devices.

11:00 AM EL06.02.07
Deciphering Edge Effects in Exfoliated Transition Metal Dichalcogenide Nanoribbons Ashley P. Saunders[1], Andrey Krayev[2], Victoria Chen[1], Amalya C. Johnson[1], Amy McKeown-Green[1], Eric Pop[1] and Fang Liu[1]; [1]Stanford University, United States; [2]Horiba Scientific, United States

Transition metal dichalcogenide nanoribbons are predicted to have distinct morphology-dependent optical, electronic, and magnetic properties when compared to their monolayer counterparts. However, their method of preparation may drastically change their properties based on edge configuration and the presence of adsorbates or dangling bonds. We employed a gold-assisted mechanical exfoliation technique to obtain MoS_2 and WSe_2 nanoribbons with one pristine zig-zag edge and one torn edge. Then we compare the ribbon edges and the body to expose the influence of nanoribbon edge density on electrical transport characteristics in fabricated field-effect transistors, the edge termination-induced differential doping across exfoliated nanoribbons (electrostatic force microscopy), and the impact of edge structure on the band gap (tip-enhanced Raman spectroscopy).

11:15 AM EL06.02.08

Proximity-Induced "Magic" Raman Bands in TERS Spectra of MoS_2 and WS_2 Deposited on the 1L h-BN-Capped Gold Pavel Valencia Acuna[1], Andrey Krayev[2], Ju-Hyun Jung[3], Cheol-Joo Kim[3], Andrew J. Mannix[4], Eleonora Isotta[5] and Patrick El-Khoury[1]; [1]Pacific Northwest National Laboratory, United States; [2]Horiba Scientific, United States; [3]Pohang University of Science and Technology, Korea (the Republic of); [4]Stanford University, United States; [5]Northwestern University, United States

Over the last decade the tip enhanced Raman scattering (TERS) imaging has become an important nanoscale spectroscopic technique capable of identifying structural peculiarities and defects in 2D semiconductors and their vertical and lateral heterostructures with routine spatial resolution of 10-20nm in ambient. Particularly advantageous implementation of sample geometry for TERS imaging is the so-called gap mode when thin sample is sandwiched between a plasmonic tip and plasmonic substrate. At the same time, the direct contact of 2D semiconductors with metallic substrate makes observation of tip enhanced photoluminescence (TEPL) very difficult if possible at all due to non-radiative decay of excitons in adjacent metal.

To resolve the above problem we suggested to use the monolayer h-BN – capped gold substrates as an ideal platform for the gap mode TERS and TEPL imaging, that on the one hand, should preserve strong gap mode enhancement of Raman signal due to small thickness (0.3 nm) of the dielectric h-BN layer, and on the other hand preserve strong TEPL response due to de-coupling of 2D semiconductors from the metallic substrate. Data collected on mono- and a few-layer-thick crystals of MoS_2 and WS_2 show both the TERS and TEPL response, confirming the validity of the proposed approach.

In addition to the enhancement of both the PL and Raman signal, in the course of assessment of TERS/TEPL response of mono- and a few-layer-thick crystals of MoS_2 and WS_2 deposited on 1L h-BN-capped gold we observed in TERS spectra, completely unexpectedly, appearance of Raman bands at about 796 cm^{-1} and 76 cm^{-1} which are not normally observed in regular Raman spectra of h-BN or WS_2/MoS_2. We can safely state that these "magic" bands belong to h-BN as they appear at the same spectral position in TERS spectra of both the monolayer MoS_2 and WS_2 deposited on the monolayer h-BN capped gold, moreover, the 796 cm^{-1} band often was the strongest band observed in TERS spectra, even stronger than A' mode from WS_2 or MoS_2. Presence of the transition metal dichalcogenide (TMD) monolayer is mandatory for the appearance of these "magic" bands as they are absent outside of the monolayer TMDs in these samples. Literature search showed that similar (but not identical) phenomenon was observed earlier in h-BN encapsulated WSe_2 [1,2], $MoSe_2$[2] and WS_2[3]. There have been several significant differences between our data and the earlier reported one: in our case we have not been able to observe the "magic bands" in $MoSe_2$ and WSe_2 @ 1L h-BN@Au, while WS_2 monolayers deposited on the same substrate as WSe_2, showed expected response. More importantly, the excitation laser wavelength dependence in our case was completely different from what was reported earlier: in WS_2-based samples we observed strong "magic" bands with excitation at 830 nm, 785nm, 594nm, but not 633nm, the wavelength closest to the A exciton in this material. This excitation profile is remarkably reminiscent of the excitation profile of the monolayer WS_2 in intimate contact with silver where we observed strong dip of the intensity of main A' mode in TERS spectra at 633nm excitation wavelength.

We will argue that intricate interaction between the tip-substrate gap plasmon, TMD excitons and most probably, normally mid-IR-active phonons in h-BN is responsible for the appearance of observed "magic" bands. We'll briefly discuss the next steps in investigation of this fascinating phenomenon such as the use of $MoS_{2x}Se_{2(1-x)}$ alloys and MoSSe/MoSeS Janus monolayers on 1L h-BN-capped gold or silver.

Density Functional Theory Investigation of the Physical Properties of Hydrogenated Borophene Nanosheets

Arpita Varadwaj[1], Takahiro Kondo[2], Yasunobu Ando[3], Iwao Matsuda[4] and Masato Kotsugi[1]; [1]Tokyo University of Science, Japan; [2]University of Tsukuba, Japan; [3]Tokyo Institute of Technology, Japan; [4]The University of Tokyo, Japan

Two-dimensional materials such as graphene, borophene, hydrogen boride, and hexagonal boron nitride exhibit extraordinary chemical stability and structural flexibility required for high-speed modern technologies [1-2] in many different research fields viz. spintronics, thermoelectronics, magnetism, hydrogen storage, lithium batteries, sensors, and detectors [3-4]. In this study, we focus on hydrogenated borophenes (sometimes referred to as hydrogen borides (HBs)), which can be readily synthesized by cation-exchange methods [5-6]. We have performed density functional theory to investigate the physical chemistry of some free standing 6,6 and 5,7 HB nanosheets with the empirical formula B_xH_x.

We used Atomic Simulation Environment (ASE) tool to create the 6,6 and 5,7 HB geometries and the VASP code for DFT calculations at the PBE level of theory. The results suggest that the orthorhombic *Cmmm* geometry (B_4H_4) is energetically favorable over the triclinic *Pm* geometry (B_2H_2) of the 6,6 HB (energy per atom formula unit: -4.8 eV vs. -4.3 eV), and are dynamically stable. The XAS spectrum (simulated using supercell core hole method) gave B-K edge peaks approximately at 181, 185, 192, 194 and 198 eV for 6,6 HB, in which, orthorhombic crystal lattice was used. The origin of the first peak is due to the transition from B's 1s orbital to the π* antibonding orbital, and the remaining peaks are due to transitions from B's 1s to the σ* antibonding orbitals. A blue shift about 4 eV for each peak position was observed while changing and lattice symmetry to triclinic.

For 5,7 HB nanosheets, we considered two different hydrogenation patterns, comprising 5,7-α1 and 5,7-α2 phases. As found for 6,6 HB, our calculations suggested that the orthorhombic *Pbam* geometry of 5,7 HB (5,7-α2) is nearly isoenergetic to the monoclinic $P_{21/c}$ geometry (5,7-α1) (energy per atom formula unit: -4.92 eV vs. -4.90 eV), which are dynamically stable. The computed XAS spectrum of 5,7-α1 HB sheet gave B-K edge peaks approximately at 180, 185, 187, 188, 190,193 and 195 eV. These results demonstrate that there are indeed some small changes to peak positions compared to that observed for 6,6 HB, which can be understood as a result of electronic structure changes. A detail of the geometric, electronic, vibrational, charge density topology, optical and XAS spectral aspects of the studied HB nanosheets will be discussed in this presentation.

Hybrid Interface Between Monolayer TMDCs and Covalent Organic Framework Yuchen Kan[1], Parag Deotare[1,2], Nicholas Glavin[3], Dayanni Bhagwandin[3] and Brian Everhart[3]; [1]University of Michigan, United States; [2]University of Michigan–Ann Arbor, United States; [3]Air Force Research Laboratory, United States

The field of Covalent Organic Frameworks (COFs) has rapidly evolved over the past two decades, with numerous studies focusing on exploring the structural diversity, properties, and applications of these porous organic materials. COFs offer several advantages such as ordered structure, high chemical stability, and tunable optical and electrical properties. These advantages can be favorably utilized if combined with inorganic semiconductors with complementary properties. In particular, the ordered nature of COFs provides a unique knob (axes orientation dependence) to control the charge transfer process at the hybrid interface.
In this work, we investigate hybrid heterointerfaces between several imine-based COFs including 1,3,5-tris (4-aminophenyl) benzene - benzaldehyde (TAPB-PDA) COF and thiophene doped TAPB-PDA with four TMDC monolayers: tungsten diselenide (WSe_2), molybdenum diselenide ($MoSe_2$), tungsten disulfide (WS_2), and molybdenum disulfide (MoS_2). Optical spectroscopy reveals formation of a charge transfer state at the heterointerface of TAPB-PDA and WSe_2 well below the bandgap of either individual material system. This suggests a type-II bandgap alignment resulting in a charge transfer exciton at the hybrid interface. The results from our investigation on orientation dependence formation dynamics of the charge transfer exciton along with UPS, PXRD, UV-Vis, CVs of the hybrid interface will be presented. Hybrid states generated at the interface between crystalline COFs and 2D materials represents an exciting opportunity to tune optoelectronic properties for a variety of applications from energy conversion to beyond-CMOS devices.

SESSION EL06.03: Excitons and Exciton Polaritons in 2D Materials

Self-Hybridized Exciton-Polariton Photovoltaics Adam Alfieri, Tobia Ruth, Cheryl Lim, Jason Lynch and Deep M. Jariwala; University of Pennsylvania, United States

Emerging excitonic semiconductors are attractive for next generation photovoltaics (PVs) with low cost, weight, and materials consumption. However, the exciton diffusion required for photocurrent generation is generally a source of inefficiency due to the localized nature of excitons. In contrast, the strong coupling of excitons to cavity photons produces hybrid light-matter states called exciton-polaritons, which are delocalized and have low effective mass due to the photonic component. We show that strong coupling of excitons to cavity photons in a bulk WS_2 absorber layer, serving as both the optical cavity and excitonic material, can enhance the external quantum efficiency (by a factor of >10) and power conversion efficiency (by a factor of ~3) of photovoltaics. We use varying WS_2 thickness to change the cavity energy and show that enhanced efficiency is due in part to enhanced exciton transport enabled by strong coupling. Remarkably, the enhanced transport occurs for on- and off-resonant excitation, underscoring the importance and practicality of the self-hybridized system, which can simultaneously enable broadband absorption and polariton-enhanced transport. This result offers a path towards efficient excitonic optoelectronics and energy conversion devices.

Excitons in $NiPS_3$—A Computational and Experimental Study Miles R. Johnson, Harry A. Atwater and Marco Bernardi; California Institute of Technology, United States

In recent years, the study of $NiPS_3$ and other members of the transition metal phosphorus trichalcogenide class of materials (MPX_3) has accelerated significantly. As a class of antiferromagnetic van der waals materials, they provide a unique platform to study magnetism and spin-related phenomena in the 2-D limit. In particular, in NiPS3 an exciton with remarkably thin linewidth was recently observed in the photoluminescence and absorption, and moreover the appearance of this exciton seems to be correlated with the magnetic ordering of the material. While there have been a variety of papers on this exciton since its initial observation, there is still no consensus as to its origin, and it is thus unclear how one might utilize this exciton in novel technologies or to study novel physics. Here I will present my work on studying this exciton, and generally NiPS3, both computationally and experimentally. I will present my experimental results verifying and characterizing the exciton through temperature-dependent photoluminescence and reflectance measurements. I will also discuss my computational results, mainly utilizing density functional theory (DFT) and the bethe salpeter equation (BSE), highlighting the effects of certain approximations such as the inclusion of a hubbard U parameter (or lack thereof). My experimental results are in close agreement with previous observations of the exciton, and I find encouraging overlap between experiment and my BSE results, mainly in the predicted absorption curves and exciton radiative lifetime.

Electromechanics of Excitons in 2D Materials Mo Li, Adina Ripin, Ruoming Peng, Xiaowei Zhang, Srivatsa Chakravarthi, Minhao He, Xiaodong Xu, Kai-Mei Fu and Ting Cao; University of Washington, United States

Quantum emitters based on excitons in 2D materials and their heterostructures have great potential for quantum photonics applications. Methods of electrical and mechanical controlling excitons and their quantum emission are highly desirable. This talk will discuss electromechanical methods, including acoustic waves and strain engineering, to control, transport, and modulate excitons and quantum emitters. We show that, in 2D systems, excitons can be transported by acoustic waves beyond the diffusion limit to induce non-local effects, and the internal phonon states are heralded by single-photon emissions from strain-engineered 2D quantum emitters.
Biography - Mo Li
Dr. Mo Li is a Professor in the UW Department of Electrical & Computer Engineering and the UW Physics Department. Prior to joining UW in 2018, he was a faculty member in the Department of Electrical and Computer Engineering at the University of Minnesota, Twin Cities, since 2010. From 2007 to 2010, he was a postdoctoral associate in the Department of Electrical Engineering at Yale University. He received his Ph.D. degree in Applied Physics from Caltech in 2007, B.S. degree in Physics from the University of Science and Technology of China (USTC) in 2001.

Exciton-Activated Phonon Magnetic Moment in Monolayer MoS_2 Wencan Jin[1], Chunli Tang[1], Gaihua Ye[2], Cynthia Nnokwe[2], Mengqi Fang[3], Li Xiang[4], Masoud Mahjouri-Samani[1], Dmitry Smirnov[4], Eui-Hyeok Yang[3], Tingting Wang[5], Lifa Zhang[5] and Rui He[2]; [1]Auburn University, United States; [2]Texas Tech University, United States; [3]Stevens Institute of Technology, United States; [4]National High Magnetic Field Laboratory, United States; [5]Nanjing Normal University, China

Optical excitation of chiral phonons plays a vital role in studying the phonon-driven magnetic phenomena in solids. Transition metal dichalcogenides host chiral phonons at high symmetry points of the Brillouin zone, providing an ideal platform to explore the interplay between chiral phonons and valley degree of freedom. In this talk, I will present helicity-resolved magneto-Raman studies of monolayer MoS_2, in which a doubly degenerate-point chiral phonon mode is found at $\sim$270cm^{-1}. Our wavelength- and temperature-dependent measurements show that this chiral phonon is activated through the resonant excitation of A exciton. Under an out-of-plane magnetic field, the chiral phonon exhibits giant Zeeman splitting, which corresponds to an effective magnetic moment of $\sim 2.5\mu_B$. I will conclude by discussing the ingredients that may be responsible for the coupling between exciton and chiral phonon. Our study provides important insights into lifting the chiral phonon degeneracy in an achiral nonmagnetic material, paving a route to excite and control chiral phonons.

Exciton Dynamics and Time-Resolved Fluorescence in Nanocavity-Integrated Monolayers of Transition-Metal Dichalcogenides Kaijun Shen[1], Kewei Sun[2], Maxim F. Gelin[2] and Yang Zhao[1]; [1]Nanyang Technological University, Singapore; [2]Hangzhou Dianzi University, China

We have developed an ab initio-based, fully quantum, numerically accurate methodology for the simulation of the exciton dynamics and time- and frequency-resolved fluorescence spectra of the cavity-controlled two-dimensional materials at finite temperatures and applied this methodology to the single-layer WSe2 system. Specifically, the multiple Davydov D2 Ansatz has been employed in combination with the method of thermofield dynamics for the finite-temperature extension of accurate time-dependent variation. This allowed us to establish dynamical and spectroscopic signatures of the polaronic and polaritonic effects as well as uncover their characteristic time scales in the relevant range of temperatures. Our study reveals the pivotal role of multidimensional conical intersections in controlling the many-body dynamics of highly intertwined excitonic, phononic, and photonic modes.

Quantum Many-Body Light-Matter Interaction in 2D Materials Farhan Rana; Cornell University, United States

The strong light-matter interaction and strong Coulomb interaction in 2D materials, in particular in transition metal dichalcogenides (TMDs), give rise to a rich set of many-body highly correlated quantum states of light and matter. The most prominent of these states are excitons, trions, bi-excitons and their respective polaritons. The optical emission and absorption spectra of doped 2D TMDs shows two prominent peaks that have been traditionally labeled as the exciton and the trion peak. Until very recently, and for over several past decades, a trion was considered to be a charged bound state of two electrons and one hole (or two holes and one electron). This concept of a trion could neither explain the variation of the trion linewidth and binding energy with the doping density nor the experimental observation of polaritons involving trions. Thus, a revision in the concept of a trion was required. In this talk, we will discuss the modern picture of excitons and trions, and their polaritons, in doped

2D materials that has emerged in the last several years [1-3]. In an electron doped 2D material, an exciton is not a good eigenstate of the Hamiltonian. A two-body exciton gets coupled with four-body excitations consisting of two electrons in the conduction band, one hole in the valence band and one hole in the conduction band (what is also called the Fermi hole) as a result of the Coulomb interaction between the exciton and the electron density. The four-body trion states have no direct optical matrix elements with the material ground state. The contribution to the material optical conductivity from these four-body trion states results almost entirely from their Coulomb coupling to the exciton states [1]. Neither the exciton and nor the four-body trion are good eigenstates of the Hamiltonian in doped 2D materials. Supersposition states of excitons and four-body trions [1], also called exciton-polaron states [2-3], are good eigenstates. The exciton-polaron states resemble the Fermi-polaron states observed in cold atomic gases [4]. The exciton-trion superposition states can quantitatively explain all the prominent features experimentally observed in the optical absorption spectra of 2D materials, including the observation of two prominent absorption peaks and the variation of their energy splittings, spectral strengths, and spectral linewidths with the doping density. The strong light-matter coupling between photons and excitons inside an optical microcavity and the strong Coulomb coupling between the four-body trions and the excitons result in robust exciton-trion-polaritons (or exciton-polaron-polaritons) that are highly correlated states of light and matter [5-6]. We present experimental results on exciton-trion-polaritons states and their energy dispersion [6]. These polariton states display three energy bands and their experimentally measured energy-momentum dispersion is well described by the theory described here. The talk will also present the practical applications of these unusual polariton states in novel devices such as highly efficient light modulators and switches. Going further in the hierarchy of many body states, biexcitons and charged biexcitons have also been experimentally observed in 2D materials. We will show that in an exciton gas, neither the excitons nor the biexcitons are good eigenstates but exciton-biexciton superposition states, to the first level of approximation in the exciton density, are good eigenstates and correspond to the excitations observed in experiments. Finally, we will show that the phenomenology of charged biexciton states is similar to that of the charged exciton states.

Self-Hybridized Exciton-Polaritons in the Blue and UV Regimes Deep M. Jariwala, Bongjun Choi, Wangleong Chen and Bonnie Chen; University of Pennsylvania, United States

The formation of hybrid quasiparticles known as exciton-polaritons (EPs) through the hybridization of excitons with cavity photons has been extensively studied across various semiconductor materials. Two-dimensional (2D) layered excitonic materials such as transition metal dichalcogenides (TMDs) and 2D perovskite exhibit strong coupling of excitons and photons due to their high exciton binding energy and large refractive index. Self-hybridization, hybridization of excitons and photon modes without the need for an external cavity, has been recently observed in layered 2D excitonic materials, enabling simpler design for exciton-polaritonic applications. EPs in the blue and UV regime hold great promise for fundamental science and applications such as polaritonic lasing. However, there is a lack of understanding in this regime due to the scarcity of layered 2D materials with large bandgap. Here, we report the self-hybridized EPs in the blue and UV regime from the layered material called mithrene (AgSePh, $E_g \sim 2.7$eV) which is one of the metal-organic chalcogenate (MOC) compounds. The simple open cavity design, where mithrene serves as the photonic cavity, enables self-hybridized EPs with large Rabi splitting ($2g > 600$ meV) due to its strong exciton oscillation strength and large refractive index ($n \sim 2.8$). The mithrene shows clear anti-crossing behavior in the reflectance spectrum with good agreement with the theoretical calculation. Furthermore, we investigate the self-hybridized EPs in the UV regime with another MOC compound called thiorene (AgSPh, E_g ~ 3.4eV) and hexagonal boron nitride (hBN, E_g ~ 5.9eV), a wide bandgap layered material. Thiorene and hBN exhibit a large refractive index around exciton resonance energy, which is favorable for self-hybridization. These properties lead to clear anti-crossing behavior in the reflectance spectrum, strongly indicating the formation of EPs. Our results extend the range of self-hybridized EPs into the UV regime in various layered materials.

4:15 PM EL06.03.08

Core/Shell Quantum Dot-Like Excitonic Emissions of Strain-Localized Emitters at Atomically Thin Semiconductor-Metal Interface Kiyoung Jo[1,2], Christopher E. Stevens[3], Bongjun Choi[1], Patrick El-Khoury[2], Joshua R. Hendrickson[3] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Pacific Northwest National Laboratory, United States; [3]Air Force Research Laboratory, United States

Scanning probe techniques have significantly advanced our understanding of the electronic and optical properties of nanoscale materials, including organic single molecules and inorganic low-dimensional nanomaterials such as quantum dots, nanowires, and two-dimensional semiconductors. These methods enable the exploration of localized emitters confined to nanoscale areas, which are crucial for highly efficient optoelectronics and quantum information technologies. Among various nanoscale emitters, strain-localized excitons in transition metal dichalcogenides have shown potential as single-photon sources, yet the impact of charge transfer on excitonic emission is not fully understood.

Here, we report distinct excitonic emission behaviors of strain-localized emitters in monolayer WSe_2 on different types of semiconductor-metal junctions, i.e. Schottky and Ohmic interfaces, achieved by varying the annealing temperature. In Schottky interfaces, we observe two excitonic emissions: one at the core (1.45 eV) and another at the shell (1.57 eV) of the nanobubble, which are distinct from the neutral exciton of WSe_2 (1.63 eV). Using techniques such as tip-enhanced photoluminescence, Kelvin probe force microscopy, piezoelectric force microscopy, and Föppl–von Kármán calculations, we attribute the core and shell emissions to the piezoelectric potential due to the strong polarity of the Schottky interface and the localized strain field, respectively. Conversely, nanobubbles on Ohmic contacts show only strain-localized excitons (1.56 eV), indicating that the strong polarity of the interface plays a crucial role in forming core/shell-like emissions.

Our approach offers reliable and electronically controllable core/shell-like excitonic emitters from two-dimensional materials for future applications in nano and quantum photonics.

4:30 PM EL06.03.09

Long Range Valley Pseudospin Transport via Bloch Surface Wave Polariton in Monolayer Tungsten Disulfide

Zhengyang Lyu, Haonan Zhao, Claire Arneson, Bin Liu, Stephen R. Forrest and Parag Deotare; University of Michigan, United States

Monolayer transition metal dichalcogenide (TMD) has attracted much attention due to its unique spin-valley locking property. The valley degree of freedom acts as a pseudospin and can be differentiated by opposite circularly polarized light, and the energy degeneracy can be lifted by the Zeeman effect, which makes it possible to spatially separate pseudospins during excited state transport for applications such as quantum information processing. However, the exciton diffusion length of monolayer TMDs is limited to hundreds of nanometers to a few micrometers, making it difficult for significant spatial separation of the spin states. In contrast to excitons, Bloch surface wave polaritons (BSWPs) have been found to propagate nearly 100 μm[1]. In this work, we demonstrate spatial pseudospin (K and K’ valleys) separation under an external magnetic field by strong coupling of excitons in monolayer tungsten disulfide (WS_2) films to BSWP at ~4K. The propagation of K and K’ valley pseudospins is inseparable without the presence of an external magnetic field, while under 7T, spatial population separation up to 10 μm is observed for different valley pseudospin species. The difference in propagation between pseudospin valley exciton-polaritons is most pronounced at wavelengths close to the anti-crossing region, where the BSWP has a higher exciton content. This implies that the exciton content of the BSWPs determines the propagation behavior. Thus, the long range pseudospin transport enabled by BSWPs and the degeneracy lifted by an external magnetic field both contribute to the net spatial separation of different valley pseudospin species. These results not only contribute towards our understanding of the governing physics of BSWP transport, but also provide a pathway for realizing on-chip quantum communication and information processing.

Monolayer Indium Selenide—An Indirect Bandgap Material Exhibits Efficient Brightening of Dark Excitons

Naomi T. Paylaga[1,2], Chang-Ti Chou[3], Chia-Chun Lin[1,2], Takashi Taniguchi[4], Kenji Watanabe[4], Raman Sankar[1], Yang-hao Chan[1], Shao-Yu Chen[3] and Wei-Hua Wang[1,3]; [1]Academia Sinica, Taiwan; [2]National Central University, Taiwan; [3]National Taiwan University, Taiwan; [4]National Institute for Materials Science, Japan

Tightly bound excitons in two-dimensional (2D) semiconductors have attracted intensive attention from the fundamental exciton science to emerging photonic and optoelectronic applications. Bright excitons exhibit great oscillator strengths, but their ultrashort radiative lifetimes on the subpicosecond timescale hinder potential optoelectronic and catalytic applications that require a long exciton lifetime. In contrast, dark excitons, such as spatial- and momentum-indirect excitons, have a higher population density and a longer lifetime of approximate nanoseconds; nevertheless, these excitons are optically inaccessible due to their weak coupling to light. Therefore, exploring mechanisms that can effectively brighten the dark exciton is crucial for extending the functionality of indirect gap materials. We demonstrate pronounced photoluminescence (PL) observed from monolayer (ML) indium selenide (InSe) [1], a two-dimensional indirect semiconductor exhibiting a sombrero-shaped valence band [2]. Prior studies on the optical properties of ML InSe have reported either weak emissions or none from the lowest excitonic state, identified as the A exciton, [2,3], leaving the excitonic phenomena in ML InSe unexplored. By observing the distinct PL from our high-quality ML InSe samples, indicating the occurrence of the brightening of the momentum-indirect dark excitons. This brightening phenomenon is attributed to the acoustic phonon-assisted radiative recombination, facilitated by strong-exciton-acoustic coupling, and in combination with the extended wavefunction in the momentum space. Furthermore, our systematic study of the PL dependence on InSe layers, temperature, and excitation power validates the application of the carrier localization model [4] to account for the asymmetric line shape of the A exciton emission. Our work shows that monolayer indium selenide is a favourable 2D material for further investigations of dark exciton phenomenon and its role in optoelectronic devices of the future.

SESSION EL06.04: Optoelectronics, Meta-Optics and Polaritons in 2D Materials I
Session Chairs: Ho Wai (Howard) Lee and Haozhe Wang
Wednesday Morning, December 4, 2024
Sheraton, Second Floor, Independence East

8:30 AM EL06.04.01
2D van der Waals Photonic Bipolar Junction Transistors for Integrated Sensing Nodes of IoTs Zhengrui Zhu[1], Liwei Liu[1], Shaozhi Deng[2] and Ningsheng Xu[1]; [1]Fudan University, China; [2]Sun Yat-sen University, China

The exponential growth of the Internet of Things (IoTs) has led to the widespread deployment of millions of sensors, which are critical to the sensing capabilities of the sensing layer. However, sensing devices and chips often offer limited functionality, and the devices that provide their power take up too much space.
The emergence of two-dimensional (2D) semiconductor technology and its integrated devices provides an opportunity for the IoTs. 2D semiconductors have atomically sharp interfaces, which greatly increase the surface mobility of carriers. The rich band structures of 2D semiconductors enable photoelectric detection in ultra-wide bands from ultraviolet to terahertz. In addition, 2D semiconductors can simply achieve heterogeneous structures of a variety of complex structures through the van der Waals stacking method, which makes it possible to achieve complex multi-function integration and function tuning through the innovation of multiple device structures.
Bipolar junction transistor (BJT) is one of the earliest semiconductors solid-state transistors. BJTs are widely used in analog signal amplification, digital signal processing and photoelectric detection, because of their high current amplification ability and high photoelectric response. It's one of the most important microelectronic and optoelectronic devices. However, 2D BJTs are still poorly studied, especially in the field of photoelectric detection, where they have significant advantages. In this presentation, we will introduce the latest developments in integrated 2D optoelectronics technology. Moreover, we will introduce our latest research progress in the field of multi-functional integrated 2D-vdW optoelectronic BJT. This includes, but not limited to, photovoltaic energy supply, low-power photoelectric detection, and events recognition. And we will introduce its novel photoelectric properties, which are different from 3D semiconductors, which have the potential to surpass traditional silicon-based BJT. For example, wavelength sensitivity and pan-spectral detection capability. Finally, we will look at the application potential of integrated 2D optoelectronics in integrated systems and the IoTs.

8:45 AM *EL06.04.02
Optical Sensing in High Dimensions Thomas Mueller; Technische Universität Wien, Austria

Optical sensors measure the physical properties of incident light, such as the power, polarization state, or spectrum. Recently, the development of integrated sensing solutions using miniaturized devices together with dedicated machine learning algorithms has accelerated rapidly, and optical sensor research has become a highly interdisciplinary field encompassing device and materials engineering, condensed matter physics, and machine learning. Physical properties of light and the corresponding sensor output signals can be viewed as points in two high-dimensional vector spaces, and the sensing process can be understood as a mapping of one vector space to the other. This mapping can be linear or nonlinear, with an artificial neural network being the method of choice in the latter case. Based on this framework, we present examples in which a reconfigurable optical sensor can directly detect spectral and spatial features of incident light, enabled by the reconfigurability of the device and the implementation of machine learning algorithms for information encoding and decoding. Photosensors for image classification, spectral mixture analysis, autoencoding, and compressed sensing will be discussed. In all these devices, the computation is performed at the lowest possible level of the sensor system hierarchy – the physical level of photon detection – and does not require any external processing of the measurement data.

9:15 AM *EL06.04.03

2D Semiconductor Optoelectronics—Advances, Challenges and Opportunities Ali Javey; University of California, Berkeley, United States

In this talk, I will present recent advancements on understanding and controlling the radiative and non-radiative recombination rates in various 2D semiconductor systems. I will discuss the mechanisms by which non-radiative recombination can be fully suppressed in TMDC monolayers, resulting in near-unity photoluminescence quantum yield at room temperature despite the presence of large defect densities. I will discuss an AC carrier injection mechanism to enable bright light emitting devices using monolayers, overcoming the problem of Schottky contacts. Finally, I will discuss potential applications for black phosphorous (BP) thin films for midwave-IR photo detection and emission. Specifically, the BP based devices are shown to exhibit higher detectivity and luminescence efficiencies over state-of-the-art III-V and II-VI devices in mid-IR, owing to the lower Auger recombination rates and surface recombination velocity.

Graphene and Bandgap-Tunable 2D Semiconductor van der Waals Heterostructures—Their Fabrication, Characterization and Application for THz Detection Aoi Hamada[1,1], Chao Tang[1,2], Koichi Tamura[1,1,3], Akira Satou[1] and Taiichi Otsuji[1]; [1]Tohoku University, Japan; [2]Frontier Research Institute for Interdisciplinary, Tohoku University, Japan; [3]Research Fellow of Japan Society for the Promotion of Science, Japan

Terahertz (THz) waves lying between radio waves and light waves hold significant potential for applications in high-capacity, high-speed wireless communication and non-destructive testing. However, the development of effective THz sources and detectors is challenging, a problem known as the 'terahertz gap.' Graphene, with its unique linear Dirac dispersion and superior optoelectronic and plasmonic properties, emerges as a promising candidate for THz detection. Furthermore, graphene-based van der Waals heterostructures with different 2D materials opens up new possibilities for highly sensitive THz detection. In our previous study, we have theoretically revealed an excellent responsivity of 1,000 A/W in THz detection by exploiting an exceptional bolometric effect arising from the quantum barrier in a graphene-black phosphorus (b-P) heterostructure [1]. This bolometric effect does not associate with a classical mechanism in which the hot electrons transfer their heats via optical phonon emission suffering from very slow response speed, but with a totally new mechanism in which the hot electrons are thermionically emitted to the metal cool reservoir over the heterobarrier between the graphene and b-P, resulting in ultrafast response while preserving a high responsivity [2]. The experimental process involved fabricating the graphene/b-P heterostructure using mechanical exfoliation and hot-transfer methods, followed by electron beam (EB) lithography and EB metal evaporation to form ohmic contacts and antenna pads. The nonlinear electrical properties of the heterostructure reveal an asymmetric energy band alignment between the graphene and b-P layers. Additionally, the variation in electrical properties as a function of the number of layers can be attributed to the strong quantum confinement effect in the b-P layer. The experimental results in detail will be presented in the real session. This research advances our understanding of new THz response mechanisms in 2D material structures and paves the way for future ultrafast and sensitive THz detection using graphene heterostructures.

Boosting Bulk Photovoltaic Effect in 3R-MoS2 by Edge Semimetal Contact Li Lain-Jong[1] and Shuang Qiao[2]; [1]The University of Hong Kong, Hong Kong; [2]Hebei University, China

Bulk photovoltaic effect (BPVE) has traditionally been observed in oxide materials with non-centrosymmetric structures. However, these materials exhibited cell efficiencies too low for practical use. In recent years, larger BPVE coefficients have been reported in two-dimensional (2D) layers and stacks with asymmetry-induced spontaneous polarization. We now report a significant breakthrough in enhancing the BPVE in 3R-MoS_2 by utilizing edge contact (EC) geometry with bismuth semimetal electrodes. EC induces a pronounced tensile strain in the 3R-MoS_2 and allows complete access to the in-plane polarization from the underlying layers exposed to light. This approach results in over a 100-fold increase in BPVE-generated photocurrent. Specifically, the EC device demonstrated a significantly larger BPVE compared to the top-conatced device, with noticeable improvements in both I_{sc} and V_{oc}, surpassing previously reported values. Additionally, by creating a 3R-MoS_2/WSe_2 heterojunction, we show that BPVE can be constructively coupled with the conventional photovoltaic effect (PVE) in the designed devices, marking a significant advancement toward practical applications.

MEms-Based Generic Actuation platform (MEGA) for Twisted Optical 2D Materials Haoning Tang; Harvard University, United States

Twistoptics, the study of how the twist angle between layers of nanophotonic material affects optical properties, offers a solution with its multidimensional reconfigurability and wide range of tunability in optical properties. We introduce a MEMS-based Generic Actuation platform for 2DM (MEGA2D), a microelectromechanical systems (MEMS)-based platform, offering a universal, scalable, and highly integrated solution for manipulating IDoFs in 2DM heterostructures. This platform promises to expand the horizons of 2DM research in condensed-matter physics, optics, and beyond. In this study, we have explored the nonlinear twistoptical properties of hexagonal boron nitride (h-BN) heterostructure, demonstrating a novel approach to manipulating second order nonlinearity through microelectromechanical systems.

Polaritonic Metasurfaces Andrea Alu; The City University of New York, United States

In this talk, I will discuss our recent progress in the area of polaritonics, and its role in advancing the field of metamaterials and metasurfaces. Tailored material resonances, based on excitons, phonons, magnons and electronic transitions, can be strongly coupled to light in engineered metastructures, unveiling new degrees of freedom for the control of light-matter interactions at the quantum limit and enhancing optical nonlinearities. In particular, I will discuss our recent progress on engineered surfaces and metasurfaces strongly coupled to 2D materials, and the resulting control of polaritons in the classical and quantum limit.

11:45 AM EL06.04.08

Synthesis of 2D Dirac Semimetals and Their Applications on Fast and Sensitive THz Detection Chao Tang[1], Koichi Tamura[1], Aoi Hamada[1], Hiroyoshi Kudo[1], Shinnosuke Uchigasaki[1], Yuma Takida[2], Hiroaki Minamide[2], Tsung-Tse Lin[1,2], Akira Satou[1] and Taiichi Otsuji[1]; [1]Tohoku University, Japan; [2]RIKEN, Japan

In this study, we report the preparation and application of fast and sensitive terahertz (THz) detection using 2D Dirac semimetals, including graphene and Bi2Se3. Graphene thin films were prepared via the thermal deposition epitaxial (TDE) method, involving chemical-mechanical polishing (CMP) and decomposition of the hexagonal carbon surface of a silicon carbide (SiC) substrate, followed by cooling to room temperature. Bi2Se3 crystals were grown using the vapor pressure controlled liquid phase growth (VPC-LPG) method, which included sealing bismuth and selenium raw materials in a double-sided quartz tube, heating the growth and vapor-control sections independently to control selenium vapor pressure, and dissolving residual bismuth with dilute hydrochloric acid to collect the crystals. Characterization of the samples using x-ray diffraction (XRD), Raman spectroscopy, and transmission electron microscopy (TEM) confirmed the high quality of the several layer graphene and beta-polytype Bi2Se3 crystals. For THz detection, rectennas based on these Dirac semimetals were fabricated using mechanical exfoliation, dry-transfer processes, and electron beam (EB) metal evaporation for side contact and antenna pad formation, followed by EB lithography. THz detection utilized a 0.95-THz injection-seeded THz parametric generator (is-TPG) as the light source, with anode and cathode electrodes connected via a bias tee using a ground-signal-ground RF probe. When a 500-mW-peak is-TPG radiation was directed at the rectenna, the Bi2Se3 rectenna at a working bias of 10 V exhibited a THz photovoltage peak of 20 mV with a 200-ps full width at half maximum (FWHM), yielding a responsivity of 40 mV/W under a 50-Ω load (equivalent to 40 V/W under a 5-kΩ load) and an ultrafast response time of 100 ps (10 Gbps) at room temperature. In comparison, the graphene rectenna detected a peak photovoltage of 2.5 mV at an external electric field of 0.25 V/nm, translating to a 5 mV/W responsivity under the same conditions, with a response speed reaching 180 ps due to superior carrier mobility. Notably, the Bi2Se3 rectenna demonstrated a responsivity of 20 mV/W even without any bias, unlike the graphene rectenna, which requires bias for detection. This difference is attributed to the asymmetric Dirac dispersion in Bi2Se3, allowing detection without bias, whereas the symmetric Dirac dispersion in graphene leads to equal electron and hole masses, causing recombination and no responsivity at zero bias. In conclusion, we have achieved fast and sensitive THz detection using rectenna detectors based on 2D Dirac semimetals. This research paves the way for passive THz detection and next-generation high-speed THz wireless communication using 2D materials.

Exploiting and Controlling Lattice Symmetry for Infrared Nanophotonics and Ultrafast Thermal Transport

Joshua D. Caldwell[1,2]; [1]Vanderbilt University, United States; [2]Sensorium Technological Laboratories, United States

The field of nanophotonics is based on the ability to confine light to sub-diffractional dimensions. In the infrared, this requires compression of the wavelength to length scales well below that of the free-space values. While traditional dielectric materials do not exhibit indices of refraction high enough in non-dispersive media to realize such compression, the implementation of polaritons, quasi-particles comprised of oscillating charges and photons, enable such opportunities. Two predominant forms of polaritons, the plasmon and phonon polariton, which are derived from light coupled with free carriers or polar optic phonons, respectively, are broadly applied in the mid- to long-wave infrared. However, the short scattering lifetimes of free-carriers results in high losses and broad linewidths for the former, while the fast dispersion and narrow band of operation for the latter result in significant limitations for both forms. Through strong coupling strategies once can overcome some of these limitations by imparting benefits of both, as well as realizing emergent properties not existent in either individual material. Within anisotropic materials, these optical modes can be induced to propagate with different wavevectors along different axes, or even be restricted to propagate only along a single direction. Here, we discuss the influence of strong coupling and crystalline anisotropy in dictating the polaritonic dispersion, including recent observations from our group highlighting highly directional so-called hyperbolic shear polaritons in low-symmetry monoclinic and triclinic crystals, strong-coupling between optical modes for infrared emitters and laser concepts, as well as the ability to control the wavelength and propagation direction of these modes using free-carrier injection and twist-optic concepts. Further, we highlight how phonon polaritons can be employed as ultrafast and efficient carriers of thermal energy, providing alternative dissipation pathways for heat.

2:15 PM EL06.05.02
Hyperbolic Phonon-Polariton Electroluminescence in 2D van der Waals Heterostructures Qiushi Guo; The City University of New York, United States

Phonon-polaritons are electromagnetic waves resulting from the coherent coupling of photons with optical phonons in polar dielectrics. Due to their exceptional ability to confine electric fields to deep subwavelength scales with low loss, they are uniquely poised to enable a suite of applications beyond the reach of conventional photonics, such as sub-diffraction imaging and near-field energy transfer. The conventional approach to exciting phonon-polaritons through optical methods, however, necessitates costly mid-infrared and terahertz coherent light sources along with near-field scanning probes, and generally leads to low excitation efficiency due to the substantial momentum mismatch between phonon-polaritons and free-space photons. Here, we demonstrate that under proper conditions, phonon-polaritons can be excited all-electrically by flowing charge carriers. Specifically, in hexagonal boron nitride (hBN)/graphene heterostructures, by electrically driving charge carriers in ultra-high-mobility graphene out of equilibrium, we observe bright electroluminescence of hBN's hyperbolic phonon-polaritons (HPhPs) at mid-IR frequencies. The HPhP electroluminescence shows a temperature and carrier density dependence distinct from black-body or super-Planckian thermal emission. Moreover, the carrier density dependence of HPhP electroluminescence spectra reveals that HPhP electroluminescence can arise from both inter-band transition and intra-band Cherenkov radiation of charge carriers in graphene. The HPhP electroluminescence offers fundamentally new avenues for realizing electrically-pumped, tunable mid-IR and THz phonon-polariton lasers, and efficient cooling of electronic devices.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

3:30 PM EL06.05.03
Nanolight Guiding and Manipulation in Phonon-Polaritonic Heterostructures Youning Gong; Shenzhen University, China

Phonon polaritons (PhPs) are light-matter hybrid quasiparticles originating from the coupling between electromagnetic waves and lattice vibrations in polar crystals, specifically within the mid-infrared to terahertz spectral range. The highly dispersive nature of PhPs enables the compression of electromagnetic fields into a deeply subwavelength scale, unlocking unprecedented possibilities for manipulating light at the nanoscale.
In phonon-polaritonic materials with strong crystallographic anisotropy, PhPs manifest a highly anisotropic dispersion relationship, wherein hyperbolicity denotes an extreme scenario, characterized by open hyperbolic isofrequency contours in the momentum-frequency space. The hyperbolic response occurs when the permittivity of a material not only differs along the orthogonal axes but also exhibits opposite signs. One of the most typical and extensively studied material demonstrating this effect is α-phase molybdenum trioxide (α-MoO3), a biaxial van der Waals polar crystal that supports in-plane and out-of-plane hyperbolic PhPs[1,2]. However, the hyperbolic dispersion with a single pair of symmetric branches inherently confines PhPs to propagate only within specific spatial directions, which hinders the capability to flexibly manipulate the flow of light.
In this paper, we report an exotic propagation state of PhPs with multi-branch in-plane hyperbolic dispersion in a phonon-polaritonic heterostructure composed of an α-MoO3 slab being stacked on a 4H-silicon carbide (4H-SiC) substrate. Using the real-space near-field nanoimaging, we demonstrated multi-directional polariton propagation with distinct concave wavefronts along the mutually orthogonal crystal directions of α-MoO3, which stems from two pairs of hyperbolic dispersion branches with different dispersive responses. The existence of multiple hyperbolic dispersion branches suggests a higher concentration of optical branches with enhanced local density of states in a specific region, potentially offering a new degree of freedom to manipulate nanolight. Moreover, the dispersion branches along the orthogonal crystal directions of α-MoO3 exhibit distinct dispersive responses, allowing them to be independently manipulated, thus potentially enabling the multi-channel energy transfer. Furthermore, the dispersion of polaritons along the [100] crystal direction of α-MoO3 evolves into a flat band as the frequency decreases, yielding broadband polariton canalization in the low-frequency region. These findings indicate that this phonon-polaritonic heterostructure is a promising platform for photonic applications such as multi-channel communication and broadband super-resolution imaging.

Layered Materials as Building Blocks for Higher Dimensional Classical and Quantum Optoelectronics Infrastructure

Ritesh Agarwal; University of Pennsylvania, United States

Classical and quantum computing devices need to ferry vast amounts of data and optical interconnects provide a promising approach allowing faster speeds and larger bandwidths. Critical interconnect components are light sources, waveguides and detectors. Currently, the information is encoded in intensity and frequency but other degrees of freedom (DOFs) such as photon spin and spatial orbital angular momentum modes (OAM) should be utilized to enhance the capacity of optical links. Therefore, new photonic materials and devices that can produce, transmit and detect light with complex polarization and spatial modes are needed. This is non-trivial as most materials are insensitive to chiral light. The development of on-chip chiral photonic devices requires fundamental investigations and manipulation of momentum space geometry, topology and optical nonlinearity in materials and their coupling to the environment to engineer specific interactions to control and detect the vectorial states of light. We will discuss some recent developments towards the development of on-chip devices that produce different SAM-OAM states and photodetectors utilizing layered materials that are uniquely sensitive to SAM-OAM modes. The direct transduction of photocurrents mapped to various SAM-OAM coupled states is engineered via nonlocal light-matter interactions that cannot be described within the electric-dipole approximation and requires a theoretical description accounting for the topology of electronic bands and light. We will then describe our efforts to utilize super-moire structures with lengthscales comparable to optical wavelengths to engineer responses with large optical nonlinearities couped to higher-order quantum geometric terms to understand and fabricate nonlinear photodetectors. Either by protecting or breaking certain symmetries in materials, prospects of designing new quantum photonic materials and devices will be discussed that can enable the next generation of classical and quantum photonic devices that can encode, manipulate, transmit and sense information encoded in different SAM-OAM modes of light.

4:15 PM EL06.05.05

Engineering THz Phonon and Charge Transfer in van Der Waals Heterostructures Yoseob Yoon; Northeastern University, United States

One promising way to engineer novel material properties is to create a heterostructure by interfacing different layered materials, where the interlayer coupling gives rise to emergent properties absent in the individual units. Various designs of van der Waals heterostructures as well as the use of ultrafast laser pulses allow us to achieve desired optical, electronic, and mechanical properties. In the first part, I will showcase how atomically thin graphene transducers and WSe_2 sensing layers can be assembled to enable the generation and detection of ultrafast nanomechanical motion at unprecedented frequencies up to 3 THz [1], previously hindered by the challenges of achieving the required material control at sub-nanometer precision. Using our newly developed platform, we fabricated a high-quality-factor THz phononic cavity using hexagonal boron nitride (hBN) stacks and revealed the interlayer force constants at nanoscale interfaces. Our results open novel routes for thermal engineering and serve as a building block for THz phononic metamaterials, such as ultrabroadband acoustic filters and modulators. In the second part, I will discuss the use of an hBN spacer to control ultrafast charge motion across layers in various $MoSe_2$/hBN/WSe_2 heterostructures [2]. The spacer effectively modulates interlayer charge transfer timescales from tens of femtoseconds to over a nanosecond, while maintaining high transfer efficiency. Such control of charge transfer motion not only allows the generation of tunable THz electric fields but also a design of strongly correlated materials with unconventional properties.

4:30 PM *EL06.05.06

Graphene-Based Calorimetric Single-Photon Detection Kin Chung Fong; Northeastern University, United States

High-sensitivity detectors for electromagnetic waves are essential in wide ranges of applications, such as astronomy, radar systems, quantum computing, and quantum communication. Depending on the spectrum of interest, detectors based on different material platforms, detection mechanisms, and coupling methods are developed over the years. However, detecting single photons remains a very challenging experiment especially at low frequencies because of the low photon energy. In this talk, we will present how to take advantage of the giant thermal response of graphene electrons for photon detection. Interestingly, when our graphene bolometer achieves a record-high sensitivity of 10-19 W/Hz1/2, this sensitivity is limited, no longer by extrinsic factors but, by the statistical thermal fluctuation intrinsic to the graphene electrons as a canonical ensemble at 0.2 K [1]. Using the graphene-based Josephson junction, we demonstrate the single-photon detection in the infrared regime by observing the photon shot noise [2]. More recently, we are able to demonstrate single-photon detection by sensing the internal energy of individual photons, a new paradigm known as single-photon calorimetry. As an outlook, we will discuss how we can apply this new technologies to a wider electromagnetic spectrum, from near to far infrared, as well as to resolve spatial mode of a single photon [3].

Electronic and Optical Properties of Novel 2D/Layered Materials by Parameter Quantum-Mechanical Ground and Excited State Methods Maurizia Palummo; Università degli Studi di Roma Tor Vergata, Italy

The use of emerging two-dimensional and layered materials in technological applications presupposes a detailed knowledge of their chemical and physical properties. In this context ab-initio theoretical methods and simulations are playing a fundamental role.

Here I aim to show how the use of parameter-free atomistic simulations can contribute to improve the microscopic understanding of the opto-electronic properties of novel 2D materials and to predict new ones. I will show how ab-initio DFT and post-DFT (GW and BSE) calculations, based on Many-Body Perturbation Theory (MBPT), provide a very useful scheme to study i) the giant electronic band-gaps renormalization ii) the strong light-matter interaction iii) the presence of strongly bound excitons, iv) the exciton radiative lifetimes v) the influence of electron-phonon interaction on the electronic and optical spectra, vi) how doping and/or molecular functionalization can tune their opto-electronic properties.

Among the families of 2D materials discovered after graphene, I will focus on those of particular interest for opto-electronic applications such Transition Metal Dichalcogenides (TMDs), 2D carbon based kagome materials, 2D/layered halide perovskites and a recently proposed $MoSi_2X_4$ family.

2D Atomic and Molecular Sheets Beyond Graphene—Optical Properties, Optoelectronics and Quantum Optics Ido Kaminer[1], Tomer Bucher[1], Harel Nahari[1], Hanan Herzig Sheinfux[2], Ron Ruimy[1], Arthur Niedermayr[1], Raphael Dahan[1], Qinghui Yan[1], Yuval Adiv[1], Michael Yannai[1], Jialin Chen[1], Yaniv Kurman[1], Sang Tae Park[3], Daniel Masiel[3], Eli Janzen[4], James Edgar[4], Fabrizio Carbone[5], Guy Bartal[1], Shai Tsesses[1], Frank Koppens[2] and Giovanni Maria Vanacore[6]; [1]Technion-Israel Institute of Technology, Israel; [2]ICFO–The Institute of Photonic Sciences, Spain; [3]Integrated Dynamic Electron Solutions, Inc., United States; [4]Kansas State University, United States; [5]École Polytechnique Fédérale de Lausanne, Swaziland; [6]University of Milano-Bicocca, Italy

Accessing the low-energy non-equilibrium dynamics of materials and their polaritons with simultaneous high spatial and temporal resolution has been a bold frontier of electron microscopy in recent years. One of the main challenges lies in the ability to retrieve extremely weak signals while simultaneously disentangling amplitude and phase information. Here, we present Free-Electron Ramsey Imaging (FERI), a microscopy approach based on light-induced electron modulation that enables coherent amplification of optical near-fields in electron imaging. We provide simultaneous time-, space-, and phase-resolved measurements of a micro-drum made from a hexagonal boron nitride membrane, visualizing the sub-cycle dynamics of 2D polariton wavepackets therein. The phase-resolved measurement reveals vortex–anti-vortex singularities on the polariton wavefronts, together with an intriguing phenomenon of a traveling wave mimicking the amplitude profile of a standing wave. Our experiments show a 20-fold coherent amplification of the near-field signal compared to conventional electron near-field imaging, resolving peak field intensities in the order of ~W/cm^2, corresponding to field amplitudes of a few kV/m. As a result, our work paves the way for spatio-temporal electron microscopy of biological specimens and quantum materials, exciting yet delicate samples that are currently difficult to investigate.

Highly Nonlinear Excitons in 2D Semiconductors You Zhou; University of Maryland, United States

Achieving strong nonlinear optical responses is of crucial fundamental and technological importance. In this talk, I will discuss the demonstration of giant optical nonlinearities in atomically thin semiconductors by exploiting the interaction between excitons and carriers in trilayer tungsten diselenide. By modulating the electric field and electrostatic doping, we observe the formation of Fermi polarons, which exhibit strong nonlinear optical behavior. The resonance of such optical excitations can shift as much as ~10 meV under moderate laser excitation. Additionally, an asymmetry in nonlinearity between electron and hole doping was observed, influenced by the applied electric field. I will discuss how these findings position atomically thin heterostructures as versatile platforms for nonlinear optical applications in both classical and quantum optoelectronics.

10:45 AM *EL06.06.06
Quantum Cascade Laser-Driven High Harmonic Emission in Dirac Materials for THz Compact Emitters in the Reststrahlenband Alessandra Di Gaspare; Consiglio Nazionale delle Ricerche, Italy

High Harmonic generation, a nonlinear optical process resulting from a strong interaction between light and matter, is a key technology for optics, as it allows the conversion of optical signals to higher frequencies. Atomic layered bi-dimensional materials, and primarily graphene, offer a huge potential for the exploitation of high-harmonic generation effects, at the terahertz (THz) frequencies, owing to their intrinsically large and electrically tunable non-linear optical response, albeit, so far, only at frequencies < 2 THz, and with high-power ultrafast table-top lasers or accelerator-based structures. Here, we demonstrate, for the first time, THG in graphene in the 9.6 - 10.1 THz, i.e. in the *Reststrahlenband*, by means of either optical or electrical pumping in two distinctive architectures.

In the first scheme, we engineered an integrated circular split ring resonator (CSRR) array, comprising a micrometric-size Dirac Material (single layer graphene or BiSe Topological Insulators) embedded in its gap. We optically pump the resonator array with a high power (2.5 W) 3.2 THz quantum cascade laser (QCL). Owning to the intense mode confinement and electric field enhancement in the CSRR gap, we demonstrated THG with a conversion efficiency of ~2.2 x10^{-5}, retrieved only when the polarization axis of the QCL is oriented parallel to the CSRR dipolar mode, and when nonlinear material is comprised in the resonator gap.

In the second configuration, we devised the first QCL operating in the Reststrahlenband, exploiting the same physical effect. We integrated a nonlinear plasmonic grating, realized by a simple metal/2D nonlinear film ribbon array, on a metallic 2nd order distributed feedback grating (DFB), both patterned on the top surface of a double metal top emitting THz QCL, whose active region was specifically designed to deliver a large power output (> 2W) at 3.3 THz. The intense QCL intracavity power drives the harmonic emission at 10.1 THz, allowing the first demonstration of a compact, electrically pumped, optical source in a spectral range (<45 μm), inaccessible so far. The integration of a gate contact coupled with the non-linear film, enables the modulation of the frequency of the devised QCL and the Fermi level of the 2D film itself, to enhance the efficiency of the THG effect.

11:15 AM *EL06.06.07
Quasi-Phase-Matched Up- and Down-Conversion in Periodically Poled Layered Semiconductors Chiara Trovatello; Columbia University, United States

Nonlinear optics lies at the heart of classical and quantum light generation. The invention of periodic poling revolutionized nonlinear optics and its commercial applications by enabling robust quasi-phase-matching in crystals such as lithium niobate[1]. However, reaching useful frequency conversion efficiencies requires macroscopic dimensions, effectively limiting on-chip integration with ultracompact footprints.

Here we realize **periodically poled transition metal dichalcogenides (PPTMDs)**, using 3R-MoS_2. Due to its large nonlinearity, we achieve macroscopic frequency conversion efficiency (0.01%-0.1%) over a microscopic thickness of only 3μm (just three poling periods), *i.e.*, 10^8 times more efficient than a monolayer TMD. For comparison, at least 10-100× longer path lengths are needed to achieve similar conversion efficiencies in existing crystals.

Further, we report the generation of **entangled photon pairs at telecom wavelengths** via quasi-phase-matched spontaneous parametric down-conversion (SPDC) at the key 1550 nm telecom wavelength, reaching a maximum coincidence-to-accidental-ratio (CAR) of 354 ± 32, outperforming any existing van der Waals-based SPDC source.

This work opens the new and unexplored field of **phase-matched nonlinear optics with microscopic van der Waals crystals**. As on-chip integrable, programmable, microscopic, entangled photon sources, PPTMDs hold potential for new applications that require simple, ultracompact technologies for integrated quantum circuitry and sensing.

High Purity Single Photon Emission from *In Situ* Carbon Doped hBN Thin Films Arka Chatterjee, Abhijit Biswas, Pulickel Ajayan and Shengxi Huang; Rice University, United States

Single photon emitters in two-dimensional layered hexagonal boron nitride are emerging as a promising platform for next-generation quantum technologies. However, control of defects, scalability, purity, and stability are key parameters that play a crucial role in their development. Here, we present a novel technique for generating pure defects in hBN thin films by incorporating carbon as a dopant using the pulsed laser deposition (PLD) method. The technique yields room-temperature polarized, stable, and bright single-photon emitters. Second-order photon correlation measurements further indicate a $g^2(0)$ value of 0.015±0.002, one of the lowest reported for room temperature quantum emitters and the lowest among any room temperature hBN quantum emitters, suggesting an impressively high purity of 98.5% for room-temperature single photon sources. Furthermore, detailed optical characterizations have been performed to study the nature of the emission. The results demonstrate a unique way to create carbon-related defects in hBN over a large-scale opening a new platform for quantum state engineering.

Exploring the Optical Properties of Two-Dimensional Silicon Carbide Sakineh Chabi, Nishan Shrestha and Luis Payan; The University of New Mexico, United States

Two-dimensional silicon carbide (2D SiC) exhibits intriguing optical properties stemming from its direct wide band gap feature, unique band structure, atomic thickness and quantum confinement effects. These properties include strong light-matter interactions, enhanced photoluminescence and high optical nonlinearity, positioning 2D SiC as a promising material for applications in optoelectronics, photonics, and quantum technologies. Moreover, 2D SiC holds potential as a solid-state platform capable of both hosting and transporting quantum information between emitters. Stacked SiC nanosheets or heterostructures combining 2D SiC with other 2D materials such as graphene present yet additional intriguing possibilities. However, realizing the full potential of 2D SiC in practical applications requires extensive experimental investigation, as many of these properties are yet to be investigated. In this presentation, I will discuss our latest advancements in understanding and exploiting the optical properties of 2D SiC. Specifically, I will focus on experimental investigations (such as mid-infrared s-SNOM characterizations) aimed at validating its photonic capabilities and exploring its potential role in future technologies.

Tailoring Light-Matter Interactions in 2D Materials with Atomic Defects and Interfaces Gabriele Grosso[1,2]; [1]CUNY Advanced Science Research Center, United States; [2]The City College of New York, United States

Artificial atomic structures in 2D materials enable the customization of the optical spectrum and the formation of quantum emitters, with applications ranging from optoelectronics to scalable quantum photonics. In the first part of this presentation, we discuss our investigation into defect-based quantum emitters in hexagonal boron nitride (hBN). We present our recent observation of elementary excitations that underlie quantum emission through a delocalized recombination process and the formation of coulomb pairs with large dipole moments [1]. In the second part of the talk, we explore light-matter interactions at phase interfaces in transition metal dichalcogenides (TMDs). Our findings indicate the possibility to generate additional optical resonances beyond standard excitons in TMD monolayers by combining metallic and semiconducting phases [2].

3:30 PM EL06.07.04
Impact of Uniaxial Strain on Deterministically Generated Optical Defects in van der Waals Materials Aqiq Ishraq[1], Eric Herrmann[1], Shahidul Asif[1], Muhammad Hassan Shaikh[1], Collin Maurtua[1], Kenji Watanabe[2], Takashi Taniguchi[2], Xi Wang[1] and Chitraleema Chakraborty[1]; [1]University of Delaware, United States; [2]National Institute for Materials Science, Japan

Over the past decade, there has been significant interest in employing 2D materials (van der Waals materials) as platforms for quantum emitters with distinct quantum characteristics like single photon emission, strong spin-orbit coupling, spin polarization, and valley polarization. These emitters hold promise for diverse applications in quantum technologies such as quantum information, and quantum sensing. Unlike bulk materials, 2D materials offer exceptional flexibility, potentially enabling devices to conform to various shapes, while housing ‘surface emitters' with enhanced resolution. Hexagonal boron nitride (h-BN) is one such promising 2D material with a wide band gap that can house various color centers and deep defects with in-gap states. In this work, site-controlled optical defects are deterministically introduced inside h-BN by utilizing a commercial plasma-focused ion beam (FIB) device to selectively expose the surface of a few tens of nm thick h-BN with variable fluence. The type of defect generated via this technique is identified as the boron vacancy complex (VB$^-$). This defect complex has been shown to be spin-active with a triplet ground state, which means it can directly compete with the very well-studied nitrogen-vacancy center (NV$^-$) in diamond for quantum sensing applications while offering the advantage of having near-surface emitters. Despite significant progress made in this field, there are still challenges that limit the effectiveness of these emitters. Unlike the NV$^-$ centers in diamond, the VB$^-$ defect is considerably dimmer with a lower optically detected magnetic resonance (ODMR) contrast, making it very challenging to isolate a single VB$^-$ defect. Although VB$^-$ ensembles have been effectively used as prototypes for quantum sensors, a large density of defects offers limited resolution and sensitivity. Despite FIB bombardment being effective in creating large defect ensembles in h-BN, precise control over the density of the defects formed is difficult to achieve since the minimum dosage that can applied by the device is finite and we can exert limited control over the formation threshold of the defects with irradiation alone. To overcome this limitation and potentially create low-density, spatially localized defects, we introduce directional strain on the h-BN crystal by transferring the h-BN flake on top of specialized nanopillars on a silicon substrate prior to irradiation. In our preliminary results, we observed localized strain-dependent photoluminescence intensity enhancement from the irradiated defects. It can be hypothesized that this observation is a consequence of several effects such as reduced defect formation energy and the induced emitter lifetime shortening due to the localized strain. Our results leads to the understanding of the impact of engineered static uniaxial strain and irradiation dose on the formation, defect density, and optical dipole orientation of room-temperature optical defects in h-BN.

Manipulating Optical and Magnetic Symmetry in a Nanophotonic Interface with 2D Semiconductors

Alexander High; The University of Chicago, United States

We will present two experimental studies that leverage the optically-addressable valley degree of freedom in transition metal dichalcogenide monolayers (TMDs) to locally manipulate the symmetry of optical and magnetic processes. First, I will discuss our realization of an electrically-tunable chiral nanophotonic interface with a TMD (1). We demonstrate a non-invasive method to fabricate high-performance optical waveguides directly on the surface of low disorder, boron nitride-encapsulated tungsten diselenide (WSe_2). The underlying excitonic states in the WSe_2 enable scattering into the waveguide that can be electrically switched between directionally-biased and balanced. We also demonstrate that the optical modes of the waveguide can act as a local source for diffusive, spin-polarized excitonic fluxes. Second, I will discuss our observation that ferromagnetic order in electrostatically-doped TMDs – which arises due to interactions between conduction band electrons - can be stabilized and controlled at zero magnetic field by local optical pumping (2). We show that a diffraction-limited, circularly-polarized optical pump can break symmetry between oppositely-polarized magnetic states and stabilize long-range magnetic order, with carrier polarization exceeding 80% over an 8 μm x 5 μm extent. The local control of optical and magnetic symmetry in TMDs can unlock new spin and optical technologies and provide versatile tools in the study of correlated phases in two-dimensional electron gases.
Additionally, I will provide a brief overview of our recent development of thin film diamond that hosts spin- and optically-coherent quantum states (3). We envision these films as a versatile platform for hybrid quantum devices.

Consistent Creation of Bright, Stable and Monochromatic Room Temperature Quantum Emitters in Hexagonal Boron Nitride Muchuan Hua[1], Wei-Ying Chen[1], Hanyu Hou[1,2], Venkata Surya Chaitanya Kolluru[1], Thomas E. Gage[1], Haihua Liu[1], Jian-Min Zuo[2], Maria K. Chan[1], Benjamin T. Diroll[1] and Jianguo Wen[1]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Urbana-Champaign, United States

Quantum emitters (QE), also known as single photon emitters, are essential components of measurement-based quantum information science systems. The practical usage of QEs requires perfect purity, indistinguishability and high creation efficiency of single photons. Hexagonal boron nitride (hBN) has been found to be possible host for QEs and been extensively studied for QE creation as its large electronic band gap and optical phonon energy, in principle, allowing it to host room temperature QEs with excellent monochromaticity. Although significant efforts have been made to realize deterministic QE creation in hBN, most of the reported approaches resulted in QEs with broad emission wavelength distribution and inconsistent optical properties. In this presentation, the authors report a deterministic creation of QEs by applying masked-carbon-ion implantation on freestanding hBN flakes, where almost identical room temperature QEs (emission center wavelength = 590.7 ± 2.7 nm) were produced consistently with perfect monochromaticity (full width half maximum = 7.1 ±1.7 nm) and excellent brightness (maximum emission rate approaching 1MHz). The QEs created by our method also showed exceptional stability against optical excitation, where they survived 1 MW/cm^2 (532nm) laser excitation for hours with no observable degradation in emission rate. Our method provides a reliable platform for characterization and fabrication research, helping to reveal the origins of the QEs in hBN and favoring the practical application, especially the industrial-scale production of quantum technology.

Electrically Tunable Quantum Control for Interlayer Exciton Superlattices with Metasurface Nanoelectrodes
Qitong Li, Helen Yao, Xueqi Chen, Mark L. Brongersma and Tony F. Heinz; Stanford University, United States

Atomically-thin transition metal dichalcogenide (TMDC) monolayers have attracted significant and broad interest in the last decade. They provide a clean two-dimensional system for the investigation of low-energy optical excitations because of the enhanced quantum effects due to the reduction of the available states in the system. Specifically, an interlayer exciton state can be formed when stacking two different types of TMDC monolayers into a heterobilayer with the type-II band alignment, where electrons and holes are separated in two different layers. As compared with their intralayer counterpart, interlayer excitons feature electrically tunable energy levels by a linear Stark effect and display much longer lifetimes since their recombination rate is limited by quantum tunneling.

By leveraging the state-of-the-art nanofabrication technology, we explore that, instead of relying on the passive built-in potential in moiré heterobilayers, we can create extrinsic but dynamically tunable electrostatic potential distributions for interlayer excitons [1] using the metasurface nanoelectrodes. Specifically, when applying an external bias between the top and bottom electrodes, the topography of the metasurface electrode can be imprinted into the potential of the interlayer exciton state via the non-uniform vertical electric-field distribution across the heterobilayer plane. This opens up opportunities to spatially control the energy of interlayer excitons down to the nanometer scale. For instance, our simulations show that an electrode with patterned nano-holes (diameter ~ 25 nm) can trap interlayer excitons in quantum wells with the radius of the center of mass wave function down to 3 nm. The depth of the quantum wells can also be scaled with the applied external vertical electric field up to ~ 50 meV.

To verify the above-described concept, a misaligned $MoSe_2/WSe_2$ heterobilayer (twist angle ~ 8°) encapsulated with thin hBN flakes (< 10 nm) is transferred onto a 285 nm thick SiO_2/Si substrate, where a periodic grating-like structure (period p = 100 nm, trench width w = 50 nm, trench depth d = 50 nm) is patterned on the top surface. A graphite top electrode is also applied for the critical non-uniform vertical electric field generation. Cryogenic photoluminescence measurements confirm the validity of this concept by observing the trapped interlayer exciton state spectroscopically with the potential depth electrically tuned continuously from 0 to ~ 20 meV. Related power-, position-, and temperature-dependent measurements have been conducted to reveal the properties and interactions of the confined interlayer excitons.

Such prominent confinement leads to considerable exciton-exciton on-site interaction [2] where its Hamiltonian can be described using a Bose-Hubbard model. With that, we can explore the possible collective behavior of interlayer excitons by gradually tuning the depth of the quantum wells, which can be experimentally characterized by an electrically tunable interlayer exciton diffusivity.

Novel 2D COFs Derived from Stabilized Acenes as Organic Semiconductors Qian Liu and Glen Miller; University of New Hampshire, United States

Two-dimensional covalent organic frameworks (2D COFs) exhibit periodically stacked π-columns and extended conjugation within their layers, promoting robust intralayer electronic interactions and effective interlayer π-delocalization. These electronic interactions provide pathways for charge carrier mobility (holes and electrons) along both the vertical π columns and within the 2D layers. Consequently, 2D COFs represent promising constructs for the design of semiconducting materials with excellent electronic properties. This presentation will describe the synthesis and characterization of 2D COFs using rationally selected π-conjugated units (acene derivatives). Experimental results will be integrated with theoretical (DFT) calculations. We actively seek collaborations in the field of organic electronics, including organic field-effect transistors (OFETs), organic photovoltaics (OPVs), organic photodetectors (OPDs), memory devices, and sensors, before, during, and after the meeting.

Dynamic Tuning of MoS_2 Photoluminescence via Thickness Modulation of CrSBr in van der Waals Heterostructures

Satyam Sahu[1,2], Vaibhav Varade[3], Oleksandr Volochanskyi[1,4], Luka Pirker[1], Rahul Kesarwani[1,3], Otakar Frank[1], Kseniia Mosina[5], Zdenek Sofer[5], Martin Kalbáč[1], Jana Vejpravová[3] and Matěj Velický[1]; [1]J. Heyrovsky Institute of Physical Chemistry, Czechia; [2]Faculty of Mathematics and Physics, Charles University, Czechia; [3]Charles University, Czechia; [4]Faculty of Chemical Engineering, University of Chemistry and Technology in Prague, Czechia; [5]University of Chemistry and Technology, Prague, Czechia

Single-layer (1L) semiconducting transition metal dichalcogenides (TMDs) are known for their exceptional excitonic photoluminescence (PL), which can be enhanced through various methods such as defect engineering and environmental modifications. However, integrating TMDs into van der Waals heterostructures often results in a significant quenching of PL due to an increased rate of nonradiative recombination processes. In this study, we demonstrate an enhancement in the PL of 1L-MoS_2 when combined with the recently discovered magnetic semiconductor CrSBr. By examining the effect of CrSBr thickness on the PL of MoS_2, we discovered that CrSBr layers up to 18 nm thick enhance the PL of MoS_2, while thicker layers cause quenching. This behavior is potentially due to n- to p-type doping transition of MoS_2 upon contact with CrSBr. Additionally, we showcase the optoelectronic applications of this heterostructure, including photodetectors, memristors, and LEDs. These findings highlight a novel strategy for optimizing PL in TMDs through interlayer doping in van der Waals heterostructures.

How Does Sodium Polyphosphate Used to Prevent Ti3C2Tx Degradation in Water Impact Electronic Properties of Thin Films?

Tom Kohen[1], Andrew M. Fitzgerald[1], Laura Londono Fandino[1], Michael Zajac[1,2], Dawei Liu[1], Tianqi Jin[1], Mary Qin Hassig[3], Kateryna Kushnir[1], Joshua R. Uzarski[4], Michel W. Barsoum[3], Ronald L. Grimm[1], Jeannine Coburn[1] and Lyubov V. Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Rhode Island College, United States; [3]Drexel University, United States; [4]U.S. Army, United States

Titanium carbide, Ti3C2Tx, where Tx stands for surface terminations -OH, -F, and -O, is the first discovered member of 2D MXene family[1]. Its hydrophilic nature enables fabrication of high-quality thin films from Ti3C2Tx aqueous suspensions. High conductivity of resulting films makes them attractive for flexible electronics, electromagnetic shielding, and THz devices[1-3]. However, degradation of Ti3C2Tx in aqueous environments due to oxidation and hydrolysis presents a challenge. Capping MXene flake edges and defects with sodium polyphosphate improves chemical stability in solution[4,5]. Here, we investigate the effect of sodium polyphosphate on the electronic properties of thin films using a four-point probe measurement of DC conductivity and time-domain THz spectroscopy measurement of complex frequency-resolved conductivity[2,6]. We find that polyphosphates can improve MXene conductivity, possibly acting as bridges that facilitate inter-flake transport and passivating defects that act as carrier traps.
Approved for public release PR2024-1144.

EL06.08.04

Imagining a World Full of Organic Semiconductor Molecules and 2D Electronic Materials Deprived of Aromatic Stabilization Glen Miller, Qian Liu, Nayanthara Krishnan and Yingling Lai; University of New Hampshire, United States

Acenes are composed of linearly fused, fully conjugated six-membered rings in which only one of the rings may possess an aromatic sextet with the associated benzenoid stabilization. This interesting structural feature imparts quinoidal character and highly interesting electronic properties to large acenes, properties that most other polycyclic aromatic hydrocarbons lack including unusually small HOMO-LUMO gaps and high charge carrier mobilities. In this presentation, the synthesis and characterization of functionalized, soluble, photooxidatively resistant acenes and their associated 2D nanosheets and 2D nanoribbons will be described.

Once the connection between structures that are largely devoid of benzenoid stabilization and interesting electronic properties is made, the next logical step is to study molecules and 2D materials that are largely if not completely devoid of benzenoid stabilization. We have begun imagining, designing, synthesizing and characterizing highly conjugated polycyclic molecules and 2D materials that are deprived of benzenoid stabilization. Instead, they possess either quinoidal, non-aromatic pi-systems or formally anti-aromatic pi-systems. Within the anti-aromatic polycyclic molecules and 2D materials exists an energetic driving force to delocalize pi-electron density in order to remove localized regions of unfavorable anti-aromaticity. In order to stabilize said structures such that they can be prepared and studied, special substituent effects are employed.

This presentation will describe our progress to date. Experimental results will be combined with theoretical (DFT) calculations. Characterizations of molecules and 2D materials will include optical and electronic measurements.

Collaborations with dreamers working on optoelectronic devices of all kinds including organic photovoltaics (OPVs), organic light emitting devices (OLEDs), organic semi-metals, sensors, UV-vis and NIR camouflage and dark matter detection are actively sought before, during and after the meeting. Imagine all the electrons, moving freely throughout a 2D sheet. You may say we are dreamers, but we’re not the only ones. We hope that some day you'll join us, and the world beyond graphene will live as one.

EL06.08.05

Ultraresponsive, Self-Driven Broadband (UVC-NIR) Photodetector Based on Localized Surface Plasmon Enhanced $MoS_2/GaSe/Ga_2O_3$ Heterostructures Urvashi Varshney[1,2] and Govind Gupta[1,2]; [1]Council of Scientific & Industrial Research–National Physical Laboratory, India; [2]Academy of Scientific & Innovative Research (AcSIR), Ghaziabad-201002, India, India

Innovation in photodetector technology is reported by developing a novel $MoS_2/GaSe/Ga_2O_3$ heterostructure on Si substrate, capable of detecting a broad spectral range from UVC to NIR. The heterostructure device was designed via sputtered deposition of MoS_2 and Ga_2O_3 films and GaSe via chemical vapor deposition. MoS_2 offers high electron mobility and direct bandgap, GaSe provides high optical absorption and good carrier mobility, while Ga_2O_3 features a wide bandgap and excellent UV detection capabilities. Integrating these materials within the heterostructure addresses the growing demand for broadband photodetection. The fabricated device exhibited ultrahigh responsivity of 14.7 A/W with a response speed of ~ 20 ms under self-driven condition (zero applied bias) for an optical illumination of 266 nm. The device also demonstrate a maximum responsivity of 3.2 A/W and 4.3 A/W under 532 nm and 1064 nm light illuminations at zero applied bias. Further, the functionalization of the heterostructure surface with mono-dispersed Au-nanoparticles (5nm) led to the generation of hot charge carriers through the excitation and decay of surface plasmons. The fabricated surface functionalized heterostructure photodetector exhibits a remarkable 3500% enhancement in responsivity, attributed to localized surface plasmon resonance (LSPR) effects that augment light absorption and carrier generation within the heterostructure. This study paves the way for developing MoS_2/GaSe/Ga_2O_3-based broadband photodetectors for developing high-performance, self-driven optoelectronic devices.

EL06.08.06

Symmetry Breaking and Charge Density Wave Instabilities in Ultra-Thin Two-Dimensional Chalcogenides

Divya Rawat, Aksa Thomas and Ajay Soni; Indian Institute of Technology Mandi, India

Two-dimensional materials have shown complete paradigm shift for the understanding of physical and electronic properties because of reduced dimensionality, symmetry breaking and quantum confinement effects. The reduced quantum size strongly affects the electron correlations, which are important to understand the many body physics of electron-electron and electron-phonon interactions. [1,2] Charge density wave is a low temperature strongly correlated ordered phase that arises from periodic modulation of atomic lattice accompanying with the modulations on the electronic charge density.[3] Charge density wave is exclaimed to be driven from Peierls distortion, where electronic instabilities are results from Fermi-surface nesting.[4] However, in the cases of several layered two-dimensional materials, $NbSe_2$, VSe_2, TaS_2, $TaSe_2$, nesting alone is insufficient to explain the charge density wave. For instance, strong electron-phonon coupling plays a major important role than Fermi-surface nesting. Charge density wave is mostly understood for bulk, but for atomically thin materials, where the confinement effects dominate, the onset of charge density wave is unclear. Our low temperature optical study on the thin flakes of 2H-TaS_2 suggest that the charge density wave can persist even in the ultra-thin layer (~ 3 nm) and transition temperature (T_{ICDW}) well above ~ 200 K, which is quite high as compared to bulk 2H-TaS_2 (~ 76 K).[5] The understanding of electron-phonon coupling, structural instabilities, tuning of charge density wave transition temperature with reduced dimension can be inferred using low temperature Raman spectroscopy and charge transport measurements.

Spectrally-Resolved Polarization-Resolved Multiphoton Luminescence and Second Harmonic Imaging of Multi-Layer 2D Materials

Arik Ahmed[1], John Fix[2], Sheikh Parvez[2], Alexey Lipatov[3], Nicholas J. Borys[2] and Steve Smith[1]; [1]South Dakota School of Mines & Technology, United States; [2]Montana State University, United States; [3]South Dakota School of Mines & Technology, United States

Low-dimensional materials, especially two-dimensional (2D) materials, can have significantly enhanced nonlinear optical coefficients. In particular, the second-order nonlinear polarizability $\chi^{(2)}$, an important materials parameter for the generation of entangled photon pairs via parametric downconversion, can be notably enhanced in monolayer materials. The relationship between this nonlinear susceptibility and multi-layer stacking, orientation and material defects can be revealed by spectroscopic, polarization-resolved imaging. A spectrally-resolved multi-photon luminescence (MPL) and second harmonic generation (SHG) imaging system, based on a closed loop piezoelectric stage, a transmission grating and an EMCCD is used to examine the nonlinear optical properties of low-dimensional materials. From the spectrally-resolved multiphoton emission, we form ratiometric images of select spectral bands, reducing sensitivity to variations in intensity caused by scattering or attenuation of the excitation beam. We visualize the spectrally-resolved MPL and SHG in multi-layer two-dimensional (2D) materials WSe_2 and In_2Se_3. In WSe_2, we observe the correlation between the symmetry-induced suppression of SHG for even-numbered layers, where inversion symmetry is established, and the presence of edge and localized defect states on the finite-sized 2D flakes, revealed by variations in MPL. We observe an order-of magnitude enhancement in $\chi^{(2)}$ for 3R vs. 2H stacked In_2Se_3. The polarization-resolved SHG in the single and multi-layer 2D material identifies the symmetry and orientation of the layers. The application of the methods to determine $\chi^{(2)}$ in other low-dimensional materials is also described.

EL06.08.08

Self-Assembled Moiré Superstructure of $Ti_3C_2T_x$ MXene Andrea Cabero del Hierro[1], Kuanysh Zhussupbekov[1,1], Samuel Berman[1], Dahnan Spurling[1], Ainur Zhussupbekova[1,1], Stefano Ippolito[2], David O'Regan[1,1], Yury Gogotsi[2], Valeria Nicolosi[1,1] and Igor Shvets[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Drexel University, United States

The atomically reconstructed moiré superlattice and its impact on the microscopic electronic structure remains absent. In this investigation, we meticulously inspect and compare the self-assembled moiré superlattices of MXene. Employing a combination of experimental scanning tunneling microscopy/spectroscopy and ab initio simulations, we investigated three distinct self-assembled moiré patterns characterized by wavelengths approximately around 2.32 nm, 2.17 nm, and 1.12 nm. Our results illuminate a non-monotonic behavior in the moiré potential concerning moiré periods on the conductance band side. This research not only contributes to a detailed comprehension of MXene's moiré phenomena but also establishes a fresh foundation for further exploration into unique correlated phases.

EL06.08.09

Chemical Sensing Using MoS_2 Field Effect Transistor Combined with Monochromatized Light Tsuyoshi Takaoka[1], Haotian Liu[1], Gaku Kosuge[1], Kazuki Kurosawa[1], Sushen C. Devsharma[1], Atsushi Ando[2] and Tadahiro Komeda[1]; [1]Tohoku University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

There is a great demand for miniaturized sensors, which enable the on-chip integration of sensors, and analyses/processes can be applied for their operation under in vivo conditions. For such an application, the field-effect transistor (FET) sensor using atomically thin channel can be a promising candidate. Due to the large area-to-volume ratio of the thin channel layer, the atomic-layer FET can exhibit higher sensitivity for the adsorption of an atom/molecule on its channel. For these sensor devices, the adsorption of a molecule on their channel is detected by the measurement of the drain current change, which is caused by the charge transfer or the polarization of the molecule. However, this technique has no significant chemical sensitivity for the adsorbate.

Thus, to realize a sensor with chemical sensitivity, methods to make the chemical property of the target molecule manifest in the FET property have to be developed. Accordingly, spectroscopic measurement of the FET property upon the injection of monochromatized light onto the channel is required. We fabricated a field-effect transistor (FET) consisting of several atomic layers of MoS_2, and observed the change in electrical properties when monochromatic light was irradiated onto the surface of the Cu-phthalocyanine(CuPc) and Cu-naphthalocyanine molecules (CuNPc) adsorbed on the surface.

A MoS_2-FET was used, which was created by transferring MoS_2 to the surface of a silicon (gate) with an oxide film formed thereon using a peeling method and evaporating Au/Ti electrodes (source, drain) on both ends. A tungsten halogen lamp was used as the light source for the light irradiation device, and the light from the light source was monochromatized using a monochromator and then irradiated onto the sample surface. After evaporating molecules onto the MoS_2-FET, it was set in the light irradiation device, and the drain current during light irradiation was measured.

After measuring the Id-Vg plot (source-drain current (Id) versus voltage (Vg) applied to the gate electrode) of the pristine surface of a MoS_2-FET, the surface was irradiated with monochromatic light pulsed using a chopper, and the change in Id versus time was measured. A photo-response spectrum can be obtained by plotting the increase in Id in response to light irradiation versus the wavelength of the irradiated light. After depositing CuPc and CuNPc molecules on this MoS_2 surface, the photo-response spectrum was measured. We compare the results of the pristine channel and the CuPc-molecule deposited channels (2 Å and 10 Å in thickness). The maximum photo-current of the molecule deposited channel is 3.5 time higher than that of the pristine channel. If we trace the plot from the longer wavelength side of the incident light, we see the Id shows a rapid increase at 680 nm. It shows two split maxima at 650 nm and 605 nm. From the maxima, the drain current gradually decreases in the short-wavelength direction. On the other hand the plot for the sample after 2Å CuPc deposition shows a gradual increase starting from 780 nm and shows split maxima similar to the pristine case, and an apparent peak appears at the energy ~710 nm. For the pristine channel, we used three Gaussian curves. The ones centered at 605 and 650 nm are split maxima and are visible in the raw experimental plot. When 2 Å of CuPc is deposited on the channel, we see the spectrum of the longer wavelength side grows higher in intensity and we employ an additional peak centered at 710 nm to obtain a good fitting. When the coverage is increased to 10 Å, we see further enhancement of the 710 nm peak. From the results above, the 710 nm peak corresponds to the excitation of electron in HOMO orbital to the LUMO orbital of the system composed of CuPc molecule and MoS_2 surface. In addition, the comparison between photocurrent spectra for CuPc and those for CuNPc is also discussed.

Vanadium-Based Doping Concentration Modulation in CVD-Grown MoS_2 for Vertical UV-Vis Photodiodes

Muhammad Suleman, Minwook Kim and Seo Yongho; Sejong University, Korea (the Republic of)

2D molybdenum Disulfide has been used extensively as a semiconductor in recent years. Typically, MoS_2 demonstrates an n-type behavior as there are sulfur vacancies that are present in the material. However, the large-scale synthesis of p-type MoS_2 and other 2D materials can still be challenging. Various methods can be used for doping the pristine MoS_2 to provide p-type behavior and one of these methods is substitutional doping. In this work we have achieved p-Type behavior in CVD grown MoS_2 through a similar method. Moreover, the existence of doping atoms was confirmed by using XPS (X-ray photoelectron spectroscopy), EDX (Energy dispersive X-ray) and TEM (Transmission Electron Microscopy). With variation in the doping concentration, the electrical transport properties of MoS_2 are modulated to show ambipolar and p-Type behavior. The p-type MoS_2 is then used to fabricate a photodiode which shows promising performance over different wavelengths from UV light to visible light. This proposed method for the synthesis of p-Type MoS_2 can have a lot of potential applications ranging from photodiodes, photodetectors, optoelectronics, field effect transistors, synaptic transistors, advanced materials heterostructures and energy harvesting.

Manipulating Valley Polarization in Two-Dimensional Transition-Metal Dichalcogenides Suman Kalyan Pal, Bhuvan Upadhyay and Ashish Soni; Indian Institute of Technology Mandi, India

Two-dimensional (2D) transition metal dichalcogenides (TMDs) exhibit unique spin-valley locking properties, holding significant promise for the development of valleytronic devices [1, 2]. Due to their valley-dependent optical selection rules, interactions between light and valleys have garnered attention in these systems, as electrical generation of valley magnetization can be easily achieved [3]. Manipulating and controlling the valley degree of freedom in TMDs is crucial for advancing valley-based electronics and optoelectronics. In this presentation, I will discuss the enhanced room temperature valley polarization in monolayer (ML) MoS_2 achieved through substitutional doping. Our helicity-resolved transient absorption spectroscopic study demonstrated prolonged valley polarization in alloyed MoS_2, which can be explained by modifications in the exciton ground state owing to additional levels introduced near the conduction or valence band edges via substitutional doping [4]. Furthermore, we observed that the degree of valley polarization in ML MoS_2 varies with substrate materials. Both substrate-induced strain and defects introduced during the transfer of the MoS_2 layer influence the dynamics of valley polarization.

Optoelectronic Properties of SnSe Nanoflakes Prepared by Selective Wet-Chemical Etching Chiu-Yen Wang; National Taiwan University of Science and Technology, Taiwan

Single crystalline SnSe nanoflakes were prepared from Sn-Se eutectic bulk by selective wet-chemical etching with H_3PO_4 solution. The thickness and lateral sizes of 24hr etched SnSe nanoflakes were less than 100 nm and tens of micrometers, respectively. Near-infrared (NIR) absorption spectrum was used to determine the direct and indirect bandgaps of the as-prepared SnSe nanoflakes at 1.24 eV and 0.95 eV, respectively. Selective wet-chemical etching of SnSe nanoflakes was an efficient process that can be conducted on a large scale to obtain two-dimensional nanomaterials. The NIR absorption spectrum and photoresponse at NIR (850 nm) show that the as-prepared SnSe nanoflakes can be used as NIR photodetectors. The NIR absorption spectrum and photoresponse at NIR (850 nm) show that the as-prepared SnSe nanoflakes can be used as NIR photodetectors.

EL06.08.13

In-Depth Analysis of 2D Materials Using Angle-Resolved Polarized Raman Spectroscopy Jacek B. Jasinski, Mohammed Irziqat, Hiruni Weerahennedige, Dinushika C. Vithanage, Kazi Jannatul Tasnim, Md Rajib Khan Musa, Ming Yu and Gamini Sumanasekera; University of Louisville, United States

Raman spectroscopy is a non-destructive analytical technique used to characterize the composition, structure, and properties of various materials. By utilizing the polarization of incident and scattered light in angle-resolved polarized Raman spectroscopy (ARPRS), it is possible to analyze material properties as a function of crystallographic orientation. Recently, ARPRS has emerged as a versatile technique for the in-depth characterization of 2D materials, particularly those with low symmetry. Here, we will present examples from our ongoing research, demonstrating the use of ARPRS in addressing significant issues in several 2D material systems.

The first example highlights our recent ARPRS study of black arsenic-phosphorus (b-As_xP_{1-x}) alloys [1]. These 2D materials have an orthorhombic honeycomb puckered crystal structure similar to black phosphorus (BP) but exhibit enhanced properties and environmental stability. ARPRS measurements in this study enable the clear identification of all As-P vibrational modes, particularly the in-plane modes, which are challenging to resolve using regular Raman spectroscopy.

The second example demonstrates the use of ARPRS to analyze Fe_3GeTe_2, one of the most promising 2D magnetic materials. Fe_3GeTe_2 exhibits strong magnetic anisotropy, high-temperature ferromagnetic ordering even at monolayer thickness, and high environmental stability. ARPRS analysis provides compelling evidence for the unambiguous attribution of the A^1_g and E^2_{2g} vibrational modes to specific peaks observed in the Raman spectrum of Fe_3GeTe_2, thereby resolving existing confusion in the literature.

Finally, the third example discusses our recent ARPRS study of CVD-grown Cr_2Se_3. The results suggest that under certain growth conditions, the computationally predicted triclinic phase can be formed.

These examples collectively demonstrate the capabilities of ARPRS in advancing our understanding of the properties and behaviors of 2D materials. By providing detailed insights into their structure, this technique will continue to play a significant role in the advanced characterization and fundamental research of these systems.

Atomic Layer Etching Technique for 2D Titanium Carbide Soft Robotics Dhamelyz Silva Quinones and Haozhe Wang; Duke University, United States

Due to its exceptional properties, transition metal carbide (Ti2C3Tx) has drawn significant interest, particularly for its tunable electrical conductivity, robust mechanical stability, and adaptable responsiveness. These features make it highly promising for soft robotics and sensing technology developments. Nevertheless, the effectiveness of TMC-based soft actuators is often compromised by uncontrollable surface terminations, such as hydroxyl (-OH) and fluoride (-F) which are introduced during the synthesis process. By altering these surface functional groups, Ti2C3Tx can be engineered to exhibit specific, desired characteristics, enhancing its suitability for particular applications.
This study introduces an innovative methodology to manipulate the surface termination of Ti2C3Tx through plasma atomic layer etching (ALE) treatment, which is a precise method to remove thin layers of materials, atom by atom, using alternating chemical reactions in plasma. Various plasma ALE conditions were applied to Ti2C3Tx flakes, with resultant alterations in surface termination analyzed via X-ray Photoelectron Spectroscopy (XPS). Additionally, changes in structure were evaluated using X-ray Diffraction (XRD) and Raman Spectroscopy. Furthermore, Ti2C3Tx/cellulose/plasma (TMC-CNF-P) actuators were fabricated utilizing Ti2C3Tx with controlled surface terminations. Remarkably, the TMC-CNF-P actuator exhibited robust responses to Near-Infrared (NIR) light, showcasing potential applications in soft robotics and sensing. The mechanism of controlled surface terminations contributing to the multi-responsive actuator will also be discussed.

EL06.08.15

Telecom Band Photodiodes Using Full Vertical MoS_2/PbS/$MoTe_2$ Heterostructures Hojun Choi, Seong Hyeon Kim and Hyun-Soo Ra; Kyungpook National University, Korea (the Republic of)

The significance of fast sensing in the telecom band has been expected to keep growing due to the increasing demand for long-distance data transmission driven by advancements in AI technology. In commercial photodetectors, Ge and InGaAs are mainly used in telecom band (1260 nm ~ 1625 nm) detection. Its drawback is the complex and costly epitaxial process. In contrast, 2D transition metal dichalcogenides (TMDs) are synthesized via chemical vapor deposition (CVD)[1] and quantum dots (QDs) are fabricated through solution-based processes[2], both offering the potential for scalable and cost-effective production. Furthermore, QDs exhibit absorption in the C-band region (1530 nm ~ 1565 nm), which is beyond the coverage of 2D materials.[3] Additionally, by replacing it with the short ligand, tetrabutylammonium iodide (TBAI)[4], we significantly strengthened the interactions within the 2D-0D heterostructure and improved carrier properties. So we report first full vertical high-speed 2D-0D hybrid photodiode operating in the telecom band. To demonstrate a high speed 2D-0D photodiode, we adopt a MoS_2/PbS/$MoTe_2$ heterostructure, which can be directly related to fast charge transport via full vertical short channel.[5] This novel structure effectively minimize the carrier pathway, leading to a significant reduction in resistance and consequently reducing time constant. Therefore it achieves a fast response speed (<5 ms). We propose that our newly designed structure addresses the synergy of both 2D TMDs materials and quantum dots (QDs), and we anticipate that this approach will enable the development of devices capable of competing with sensors currently used in industry.

EL06.08.16

Fast-Response Avalanche Photodiode Using Multi p-n Junctions Uiyeon Kim, Sang Min Jang, Ja Yun Choi and Hyun-Soo Ra; Kyungpook National University, Korea (the Republic of)

Photodiodes are widely used across various industries and play a critical role especially in autonomous vehicles, defense and security systems. In these fields, the fast response time in photodiode is directly linked to safety issues, thus, accurate and efficient light detection is required. Conventional silicon photodiodes (Silicon PDs) have limitation in detection, only for visible light, due to their bandgap. To overcome this limited detection range, compound semiconductors like germanium (Ge) and indium gallium arsenide (InGaAs) have been studied. However, compound semiconductors require complex epitaxial growth on different substrates respectively, due to their lattice mismatch, resulting high-fabrication costs. Here, we propose a novel near-infrared (NIR) avalanche photodiode (APD) design using a 2D material, $MoTe_2$, as the channel material. In comparison with Ge and InGaAs, our device has benefits on time and cost, avoiding the need for complex epitaxial processes while maintaining high performance. Bandgap (0.88 eV)[1] of $MoTe_2$ covers detection range to NIR[2, 3]. Moreover, $MoTe_2$, which has ambipolar characteristic[4], enables precise p-n junction control by tuning the Fermi level through electrostatic doping. By adopting our previous work: multi-p-n junction structure[5], our device can increase Avalanche Bullets (ABs) which are photo charge carriers that can induce avalanche multiplication. An increased number of ABs can significantly improve the probability of impact ionization in the $MoTe_2$ lattice, greatly enhancing current-rising speed to the saturation region when light is applied. The photodiode with our multi p-n junctions structure can be a road map for improving fast response time compared to existing PDs, and is expected to be a solution for safety issues on current and upcoming-autonomous technologies.

EL06.08.17

Full Vertical 2D TMDs/Graphene vdW Heterostructure NIR Photodetector for Fast Response SeongYong Kim, JaeJun Jo and Hyun-Soo Ra; Kyungpook National University, Korea (the Republic of)

In the era of big data, where data volumes are increasing exponentially, data processing speed directly influences the efficiency of large-scale data transmission. It is also crucial for sensors receiving the information to have fast response times. Currently, most industrial Near Infrared Photodetectors (NIR PDs) rely on compound semiconductors like InGaAs and GaAs, which present cost challenges due to complex and expensive processes. As an alternative, 2D Transition Metal Dichalcogenides (TMDs), which are somewhat tolerant of lattice mismatch and relatively low-cost, have been extensively studied. Conventional TMDs-based PDs have been reported to exhibit lateral[1] and semi-vertical[2] structures. However, these PDs demonstrate relatively slower response times[2,3] due to long carrier pathways, leading to increased parasitic resistance. To address this, we propose a novel full-vertical 2D TMDs/graphene van der Waals heterostructure for fast response. As the thickness of $MoTe_2$ increases, more $MoTe_2$ interacts with photons, improving the photoresponse. On the other hand, thicker $MoTe_2$ extends the carrier pathways, which directly affects the response time. Therefore, we have investigated the trade-off between photoresponse and response time by adjusting the thickness of $MoTe_2$. By optimizing this structure, we can minimize the carrier transport pathways, which apply the maximum electric field efficiently. As a result, we achieved a device with both fast response times and high photoresponse. We anticipate that this innovative design will inspire further research into 2D material-based photodetectors.

Growth of SnSe Thin Films for Bulk Photovoltaic Effect Studies Marshall B. Frye, Jonathan R. Chin, Jeremy Knight, Victoria Pozzi and Lauren M. Garten; Georgia Institute of Technology, United States

Upon approaching the monolayer limit, SnSe transforms from a centrosymmetric *Pnma* phase to a polar *Pmn*2_1 phase for an odd number of layers. Layer selective polarity makes SnSe an ideal material to study the impact of structural anisotropy on charge separation and transport such as the bulk photovoltaic effect (BPE). The BPE is a proposed mechanism of charge separation in polar materials which allows for above-bandgap V_{OC}. There are reports of BPE devices exceeding the Shockley-Queisser limit, but the fundamental limits and underlying mechanisms are not yet established. By directly controlling the polar-nonpolar transition without any confounding independent variables (e.g., temperature), SnSe provides a route to systematically study the BPE mechanisms in 2D materials. However, current methods of SnSe thin film growth, such as mechanical or liquid phase exfoliation, result in films with lateral sizes too small for device fabrication and random crystallographic orientations. Thus, the growth of oriented films with controlled layering is critical to study the BPE in SnSe.

In this study, we explore the phase stability and optical properties of molecular beam epitaxy (MBE) grown SnSe thin films. Thin films of (2 0 0) oriented SnSe were grown by MBE on cleaved (1 0 0) MgO substrates at a deposition temperature of 290 ± 5 °C. No secondary phases or orientations were measured by x-ray diffraction or Raman spectroscopy. The deposition timing was varied to grow films from 5-100 nm thick. We employ UV-vis spectroscopy and photoluminescence to reveal that the bandgap of MBE-grown SnSe increases from 1.4 eV for 100 nm films to 1.9 eV for 5 nm films and the bandgaps are found to be direct for all measured film thicknesses. This is in contrast with previous findings of an indirect bandgap ranging from 0.9-1.4 eV for SnSe thin flakes grown by liquid phase exfoliation (LPE).[3] Further polarized Raman spectroscopy and photoluminescence spectra with different light polarization directions relative to the polar axes of the films provide further insight into the optical anisotropy of SnSe. By understanding the optical response of SnSe as a function of layering and crystallographic orientation we are taking the first steps towards understanding the mechanisms of BPE in these 2D materials.

Enhanced Growth Study of h-GaTe Animesh S. Nanaware; University at Albany, State University of New York, United States

Since its inception 2-D materials, the scientific community has been keen on effectively synthesizing them for their applications. Their wide applications range from energy storage devices, flexible electronics, topological insulators for possible future quantum devices, optoelectronics applications etc. The most convincing class of 2-D materials for these applications would be chalcogenides which have inherent structural and optical anisotropy favorable in one crystal direction. Gallium Telluride (*GaTe*) is a favorable material in the family because of its direct bandgap and a distinctive phase *hexagonal-gallium telluride* (*h-GaTe*). Traditionally *h-GaTe* is fabricated by mechanical exfoliation, liquid-phase exfoliation [1], and chemical vapor deposition [2][3][4]. Growth of *h-GaTe* is challenging, and it is conventionally grown at higher temperatures and at atmospheric pressure, however, for an enhanced growth we developed a novel technique which varied different parameters as pressure, substrates, substrate-source distance, temperature, growth time and the flow rate our custom CVD chamber. To verify the quality of the film we used techniques like EDS analysis, AFM, UV-VIS-SE, TEM, PLS, XPS, and AES. My future studies will be focused on successful growth followed by a device fabrication based on *h-GaTe* for next generation state of the art polarization sensitive *h-GaTe* photodetectors. I will be discussing in detail about the fabrication, results from the tests and what will be done in the future to improve quality of the *h-GaTe* film and the potential device.

Novel 2D Nanosheets and 2D Nanoribbons Derived from Stabilized Acenes Qian Liu and Glen Miller; University of New Hampshire, United States

Acenes are composed of linearly fused, fully conjugated six-membered rings. Large acenes possess interesting electronic properties including small HOMO-LUMO gaps and relatively high charge carrier mobilities. Unsubstituted acenes composed of 5 (pentacene) or more rings show poor solubility and are generally not amenable to further solution-phase chemistry including condensation reactions to create 2D nanosheets or nanoribbons. The incorporation of select substituents, however, dramatically improves acene solubility while slowing photooxidation in solutions exposed to light and air. In this presentation, the synthesis and characterization of functionalized, soluble, photooxidatively resistant acenes and their associated 2D nanosheets and nanoribbons will be described. Experimental results will be combined with theoretical (DFT) calculations. Characterizations of molecules and 2D materials will include optical and electronic measurements. Collaborations involving optoelectronic devices of all kinds including organic photovoltaics (OPVs), organic light emitting devices (OLEDs), organic semi-metals, sensors, UV-vis and NIR camouflage and dark matter detection are actively sought before, during and after the meeting.

2D Integrated Solids and Hybrid Bilayer Crystals Jiwoong Park; The University of Chicago, United States

Two dimensional (2D) electron transport has been one of the most important topics in science and technology for decades. 2D van der Waals (vdW) crystals offer new methods for building fully integrated 3D solids that confine and contral electron transport in all three dimensions with nanoscale precision. In this talk, I will start with the large-scale processes for generating 2D crystalline semiconductor films and superlattices that could be used to fabricate 2D integrated solids. Then we will discuss exciting new directions, where we combine large scale 2D molecular crystals with vdW monolayers to form 1-nm thick hybrid bilayer crystals with unprecedented properties. First, they generate interlayer potentials and anisotropic hybridized excitons that are tuned by the molecular building blocks. Second, they display conductor-to-insulator transition deep inside of the conduction band caused by the massive interlayer charge transfer aided by molecule to ion coupling.

10:45 AM EL06.09.05

0D and 2D SnS Monolayers with Enhanced Optoelectronic Properties Abdus Salam Sarkar[1,2]; [1]Stevens Institute of Technology, United States; [2]Foundation For Research and Technology Hellas, Greece

Recent advances in atomically thin zero- and two- dimensional (2D) anisotropic group IV_A-VI metal monochalcogenides (MMCs) and their fascinating intrinsic properties and potential applications are hampered due to an ongoing challenge of monolayer isolation. [1-3] Among the most promising MMCs, tin (II) sulfide (SnS) is an earth-abundant layered material with tunable bandgap and anisotropic physical properties, which render it extraordinary for electronics and optoelectronics. To date, however, the successful isolation of atomically thin SnS single layers at large quantities has been challenging due to the presence of strong interlayer interactions, attributed to the lone-pair electrons of sulfur. Here, a novel liquid phase exfoliation approach and chemical scissoring method is reported, which enables the overcome of such strong interlayer binding energy.[4-6] Specifically, it demonstrates that the synergistic action of external thermal energy with the ultrasound energy-induced hydrodynamic force in solution gives rise to the systematic isolation of highly crystalline SnS monolayers (1L-SnS) and its quantum dots. It is shown that the exfoliated 1L-SnS crystals exhibit high carrier mobility and deep-UV spectral photodetection, featuring a fast carrier response time of 400 ms. At the same time, monolayer-based SnS transistor devices fabricated from solution present a high on/off ratio, and remarkable stability upon prolonged operation in ambient conditions. Moreover, the isolated SnS quantum dots revealed the excitation dependent emission properties. Finally, the second- and third- order nonlinear absorption and refraction of SnS quantum dots (QDs) will be presented.[7]

11:00 AM EL06.09.06

Evolution of the Bandgap in WS_2, from Monolayers to Multilayers, with Different Film Fabrication Methods Xu He[1], Jinpeng Tian[1], Wenjing Wu[2], Shengxi Huang[2], Saien Xie[1,3] and Antoine Kahn[1]; [1]Princeton University, United States; [2]Rice University, United States; [3]Princeton Materials Institute, United States

The appeal of transition metal dichalcogenides (TMD) stems from their 2D character as well as the versatility enabled by the tuning of the electronic bandgap by adjusting composition and layer number. While theoretical investigations have predicted the evolution of the gap in TMDs, including WS_2 [1], with a common consensus that it increases as the number of layers decreases, no systematic experimental work has been done to study how the gap changes with the number of layers. Furthermore, the effects of the preparation methods on the electronic properties of the TMD films are still unknown. In this study, we explore the optoelectronic properties of mechanically transferred monolayer, bilayer, trilayer, and quadrilayer WS_2 in ABAB stacking and compare them with directly deposited CVD-grown high-quality and large-scale (1 cm^2) monolayers and multilayer (> 10 layers). The transferred layers are obtained by exfoliation from a WS_2 single crystal [2]. Using ultraviolet and inverse photoelectron spectroscopies (UPS/IPES), we determine Fermi level position, conduction band minimum (CBM), valence band maximum (VBM), and thus the electronic bandgap (E_G) of the materials as a function of the number of layers. We find that the bandgap of the mechanically transferred and stacked WS_2 decreases from 2.43 eV for monolayer, to 2.19 eV for bilayer, to ~1.97 eV for trilayer and quadrilayer, signaling a bulk transition at trilayer from the experimental perspective. The 0.45 eV bandgap reduction comes mainly from a CBM shift away from E_{vac} by 0.37 eV, as well as a VBM shift toward E_{vac} by 0.08 eV. We further compare the electronic properties of the transferred monolayer and multilayers with the CVD-grown samples. The bandgap of the CVD-grown monolayer WS_2 is found to be 2.56 eV, slightly larger than the bandgap of the mechanically transferred monolayer. This is consistent with the optical bandgap (E_{opt}) trend measured by UV-Vis absorption and photoluminescence (PL) emission. The difference becomes more negligible with multi-layer films: the bandgap for CVD-grown multilayer is 1.90 eV, consistent with the bandgap of mechanically transferred WS_2 (≥ 3 layers). By combining UPS/IPES with UV-Vis measurements, we also determine the exciton binding energy (E_B) for monolayer WS_2, which is 0.55 eV for the CVD-grown monolayer and 0.43 eV for the mechanically transferred monolayer. This series of experiments helps incorporate WS_2 in devices such as LEDs and photovoltaics with a more comprehensive band alignment in practice. The resilience of WS_2 in different fabrication methods, as demonstrated in comparable optoelectrical properties of layers either mechanically transferred or CVD-grown, will be important to help scale up the use of WS_2 in other applications.

A New Era of Wireless Ultra Large Scale Integration with Sub-1nm Millimeter Wave and Light Wave CMOS—Performance Advantages and Technologies James Pan[1,2]; [1]American Enterprise and License Company, United States; [2]Northrop Grumman, United States

Traditionally CMOS is not a light emitting device, nor is it a microwave device. Similar to laser, LED, and microwave diodes, millimetre wave photonic CMOS is a light emitting as well as microwave generating device. The process of including MOSFET, laser, photon sensors, and microwave diodes as one integral transistor is 100% compatible with any existing CMOS process flows, and the microwave optoelectronic CMOS actually outperforms the separated, individual components, due to higher quantum efficiency, and the internal positive feedback loops.

The trillions of micro metal wires in an ULSI chip produce a large amount of heat and RC delays. Most of these micro metal wires must be eliminated with the millimetre wave photonic CMOS in order to achieve very high frequency for far beyond 5G RF mobile processors.

In order for the CMOS based circuits to communicate with microwaves and light waves instead of a large amount of long micro metal wires, it is necessary to modulate, multiplex, or polarize the microwaves and light waves generated from the CMOS. In this report we will discuss the following:

(1) How to design Powered Optical Waveguides: extending and using the drain region of a Photonic Microwave CMOS as part of the photonic waveguide increase the output drive current, improves CMOS switching speed and efficiency of transmitting light waves and microwaves. Layout designers need to fill the unused spaces in a circuit with Photonic Microwave CMOS drain regions. For traditional CMOS, FINFETs or All Around Gate FETs, extending the CMOS drain region does not improve CMOS speed.

(2) Avalanche Breakdown Microwave Photonic CMOS: ultra-low resistance IMPATT and BARITT microwave diodes in the photonic CMOS drain region generate a large amount of microwaves with the Photonic Avalanche Effects. We will illustrate how to modulate and multiplex the avalanche microwave generation with applying coordinated gate and drain RF signals.

(3) Tunnel Microwave Photonic CMOS: Tunnel Laser and Tunnel Microwave diodes in the CMOS drain region efficiently produce microwaves and light waves. The RF signals driving the Tunnel Diodes are different from the Avalanche Breakdown Microwave Diodes - we will illustrate how to achieve microwave and light wave communications with specially designed RF signals and antennas.

(4) On the receiving end, the CMOS in the destination needs to receive only the specified RF signals. The optical waveguide and microwave antennas must include the filtering design so only specially processed light waves and microwaves may arrive and enter the CMOS circuit in the specified destination.

(5) Optoelectronic Millimeter wave CMOS with GaAs, InP, SiGe (microwave), GaN for Tunnel, IMPATT, BARITT microwave and light wave generations will be discussed.

SESSION EL06.10: Quantum Defect, Quantum Emitters and Quantum Sensors in 2D Materials II

Achieving High Purity Quantum Emission in WSe_2 Wenjing Wu[1], Song Liu[2], James Hone[2], Junichiro Kono[1] and Shengxi Huang[1]; [1]Rice University, United States; [2]Columbia University, United States

Single photons are pivotal ingredients of quantum communication, enabling quantum key distribution and the interconnection of quantum networks. On the other hand, such quantum applications poses a demand on the purity of single photons. Two-dimensional (2D) materials, with their exceptional light-matter interaction properties and readiness to integrate with photonic structures on-chip, have emerged as a promising platform for next-generation optoelectronics and quantum information. In particular, single photon emission has been realized in a number of 2D materials. On the other hand, achieving a high purity single-photon source on 2D materials remains a pressing challenge. In this work, we developed effective approaches enhance single-photon purity from 2D transition metal dichalcogenides (TMDs) by suppressing parasitic radiative decay processes. By judiciously engineering the morphology of 2D WSe_2 and dichroism of light, we successfully mitigated broad defect-bound excitonic emission in WSe_2, significantly improving the purity of single photon emission to over 98%, one of the highest reported in 2D TMDs.

1:45 PM *EL06.10.02
Learning a van der Waals Qubit for Quantum Sensing and Noise Spectroscopy Souvik Biswas; Stanford University, United States

Quantum sensors are an important emerging technology with wide wide-ranging use and the precision to outperform classical sensors for certain applications. While nitrogen-vacancy (NV) centers in diamond have demonstrated remarkable promise, van der Waals materials are emerging as prime candidates for next-generation quantum sensing. These materials are particularly attractive due to their atomically thin nature, defect-free surfaces, and potential for integration into hybrid systems. Among them, negatively charged boron vacancies in hexagonal boron nitride (hBN) have garnered significant attention. Much like NV centers, the spin states of boron vacancies can be optically read out with high-fidelity via fluorescence under green light excitation.

In this work, we demonstrate that using isotopically modified hBN (B^{10}, N^{15}) we "learn" the qubit Hamiltonian through comprehensive tomography via external vector magnet control. This approach reveals microscopic details of orientation-dependent electron-nuclear hyperfine interactions, which can significantly alter the Optically Detected Magnetic Resonance (ODMR) spectrum as well as the qubit's decoherence profile. Leveraging this external control, we demonstrate that the qubit can be configured to act as either a purely magnetic sensor or an electric/strain sensor.

By employing dynamical decoupling sequences, we extend the coherence time of the boron vacancy center to nearly 0.1 milliseconds–the longest reported for any 2D material to date–and estimate the resulting sensitivity in quantum sensing applications. Furthermore, we perform noise spectroscopy to gain insights into the origin of qubit decoherence in both magnetic and electric regimes, aiming to identify feasible improvements for future experiments.

Collectively, our findings underscore the potential of hBN-based spin qubits for advanced quantum sensing applications. These results not only highlight the current capabilities of hBN qubits but also pave the way for future research aimed at optimizing their performance in quantum sensors.

2:15 PM EL06.10.03
Single-Ion Spectroscopy of h-BN Point Defect Fluorescence in Liquid Environments Yecun Wu[1], Kun Xu[1], Hori P. Sarker[2], Takashi Taniguchi[3], Kenji Watanabe[3], Frank Abild-Pedersen[2], Arun Majumdar[1], Yan-Kai Tzeng[2] and Steven Chu[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]National Institute for Materials Science, Japan

Understanding individual ions in solutions is essential for advancing our knowledge of complex chemical systems. However, tracking and detecting ions at the single-ion level in liquid environments remains a challenge. We introduce a strategy for visualization and differentiation of different ions in liquid environment via point defects in hexagonal boron nitride (h-BN) as the ion sensor. Ions interacting with the optically active point defects in h-BN alter emission properties, allowing us to capture these changes and visualize single ions. Using Li^+ in organic electrolytes as a model, we observed a spectral shift of over 10 nm upon Li^+ addition, and an over 50 nm red shift with applied electric fields due to reactions between Li^+ and h-BN point defects. Frequency domain analysis further revealed the rapid dynamics of ion migration and the slow electrochemical reactions. We further spectroscopically differentiated various ions (H^+, Li^+, Na^+, K^+, Zn^{2+}, Al^{3+}) in aqueous solution. Each ion, with its distinct electron cloud configuration, interacts distinctively with the electron clouds of h-BN defects, resulting in specific and identifiable spectroscopic signatures. This ion sensing platform enables the direct visualization and differentiation of individual ions in a liquid environment, offering insights into chemical reactions at the single-ion level. This capability presents potential applications in various fields involving ions in liquids, including but not limited to biology, battery technology, and environmental science.

3:00 PM EL06.10.04

Influence of Dopant-Defect Coupling on Electronic Properties of Vanadium-Doped Tungsten Disulfide Monolayers Shreya Mathela[1], Zhuohang Yu[1], Zachary Ward[2], Alexander J. Sredenschek[1], Kyle T. Munson[1], Humberto Terrones[2], Mauricio Terrones[1] and John B. Asbury[1]; [1]The Pennsylvania State University, United States; [2]Rensselaer Polytechnic Institute, United States

Substitutional doping of metal sites is a promising approach to tune the optical, electronic, and magnetic properties of transition metal dichalcogenides (TMDs). However, confinement in the two-dimensional basal planes of TMDs can cause strong interactions and coupling of substitutional dopant atoms with intrinsic defects, which can modify their doping and defect chemistries. We explore these interactions using temperature-dependent photoluminescence (PL) spectroscopy and atomic scale scanning transmission electron microscopy of p-type vanadium dopant atoms with sulfur vacancy defects in WS_2 monolayers synthesized via atmospheric pressure chemical vapor deposition. Doping WS_2 with less than 0.2 atom% vanadium reduces the density of electrons emitted into conduction band states from sulfur vacancy defects, reduces the optical signatures of negative trions, and enhances the PL quantum yield of the material. At significantly greater concentrations, vanadium dopants interact with and modify the electronic states associated with intrinsic defects, leading to quenched PL and mid-gap states with energies that depend sensitively on vanadium concentration. Our findings layout a framework for controlled synthesis and doping of p-type TMDs with tunable optical and electronic properties for applications in catalysis, dilute magnetic semiconductors, and quantum photonic devices among others.

3:15 PM EL06.10.05

Origin of Optically Active Color-Centers in Two-Dimensional Lead Iodide Perovskites Studied by Photoemission Marie Krecmarova[1], Jesús Rodríguez-Romero[2], Iván Mora-Seró[2], Juan P. Martínez-Pastor[1], Maria C. Asensio[3] and Juan F. Sanchez[1]; [1]Universitat de València, Spain; [2]Universitat Jaume I, Spain; [3]ICMM-CSIC Materials Science Institute of Madrid, Spain

Two-dimensional perovskites have attracted considerable attention for potential applications in photonics and optoelectronics on the nanoscale due to their outstanding electrical and non-linear optical properties [1]. In particular, they are appealing since their optical emission properties can be controlled by their n value, which labels the number of inorganic monolayers building the quantum well structure (from n = 1, 2, 3 to bulk) [2,3]. We have been able to detect the presence of very narrow and spatially localized optical transitions in n=2 two-dimensional Lead Halide perovskites by micro-photoluminescence and time-decay measurements. These discrete optical transitions are characterized by sub meV linewidths (around 120 m eV) and long decay times (5-8 ns) [4]. In this communication, we show that the combined use of x-Ray photoemission and DFT calculations succeed to reveal the chemical origin of electronic states responsible of these discrete optical transitions. In particular, our results pint out that the association of Phenethylammonium with Methylammonium cations into n=2 2D Ruddlesden-Popper perovskites, $(PEA)_2(MA)_{n-1}Pb_nI_{3n+1}$, promote the formation of donor-acceptor pairs corresponding to the displacement of lead atoms and their replacement by methylammonium. Ionized donor-Acceptor Pair recombination is identified as the most likely physical source of the observed discrete optical transitions.

High-Throughput First-Principles Discovery of Quantum Defects in Monolayer WS Weiru Chen[1], Yihuang Xiong[1], Wei Chen[2], John C. Thomas[3], Sinead M. Griffin[3], Archana Raja[3], Gian-Marco Rignanese[2], Alexander Weber-Bargioni[3] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Université Catholique de Louvain, Belgium; [3]Lawrence Berkeley National Laboratory, United States

The availability for reliable quantum defects is crucial towards the realization of quantum information science applications. Two-dimensional (2D) materials, particularly transition metal dichalcogenides (TMDs) like tungsten disulfide (WS_2), emerge as a promising platform to host such quantum defects owing to their intrinsic quantum confinement nature, long expected spin coherence time and strong spin-orbit coupling (SOC). We will present a study using high-throughput first-principles screening on monolayer WS_2 to build a database of over 1000 charged defects. We will discuss the guideline which we employ to search for the defects with promising characteristics. For those promising candidates, we compute their corresponding excited states and predict their optical properties through electron-phonon coupling using the zero phonon line (ZPL) and ΔQ. Our work will show the discovery of reliable quantum defects in WS_2 can be accelerated using high-throughput screening and sheds light towards future experimental synthesizing and studying quantum defects in WS_2.

3:45 PM EL06.10.07

A Novel Screened Exchange Potential Approach Michael Lorke; Universität Duisburg-Essen, Germany

Density functional theory is the workhorse of theoretical materials investigations. Due to the shortcoming of (semi-)local exchange correlation potentials, hybrid functionals have been established for practical calculations to describe surfaces, molecular adsorption, and defects. These functionals operate by mixing between semi-local and Hartree-Fock exchange semi-emprically. However, their parameters have to be optimized for every material separately. To treat materials with a more physics driven approach and without the need of parameter optimization is possible with many-body approaches like GW, but at an immense increase in computational costs and without the access to total energies and hence geometry optimization.

We have introduced an exchange correlation potential[1] for semiconductor materials, that is based on physical properties of the underlying microscopic screening. We demonstrate that it reprocuduces the low temperature band gap of several materials. Moreover it respects the required linearity condition of the total energy with the fractional occupation number, as expressed by the generalized Koopman’s theorem. We show that this novel functional can be used as a kernel in linear response TDDFT to reproduce excitonic effects in optical spectra.

We will also discuss how to genereralize such a functional to anisotropic systems like surfaces and 2D materials.

The presence of interfaces modifies the screening behavior in layered systems in a way, which cannot be described by HSE or any other screened exact exchange functional, which are based on assumptions of isotropy. Defect calculations for 2D systems (or for slab models in general), using hybrids or the sX functional, all suffer from these problems and we could show in Ref. [2] that for some systems such as monolayer hBN, the assumption of isotropy of the screening is bound to fail. Since GW calculations must be based ona priori defect geometries obtained by LDA, GGA, or a hybrid functional, at present there is no method available to achieve the same accuracy in mono- and few-layer systems or their heterostructures as for the bulk. We aim at including the effects of the interface into the model dielectric function of our new screened exact exchange functional and we will present first results of this approach.

Charge Localization and Overscreening in Two-Dimensional Ion-Coupled Hybrid Bilayer Crystals Mengyu Gao and Jiwoong Park; The University of Chicago, United States

Recent advances in moiré lattices with tunable interlayer potentials have enabled observation and control of collective electronic phenomena. However, developing large-scale applications based on them remains difficult because of the extreme sample and experimental requirements, which originate from the relatively weak localization potential. Here, we report large-scale fabrication of hybrid bilayer transistors with strongly localized states that exhibit metal-insulator transistion under room temperature with tunable charge densities. Our transistors use four-atom-thick crystalline films synthesized with perylene molecular crystal atop MoS_2 monolayer, simultaneously hosting localized and delocalized electronic states. Upon electron doping by ionic gating, their electrical conductivity increases to a high peak value before dropping by two orders of magnitude; this coincides with a massive charge transfer from the delocalized to localized states reaching a high density up to 3×10^{13} per centimeter square. Our experiments show that this strong localization of injected carriers leads to an overscreening effect, which is driven by the drastic reduction of the Coulomb repulsion through the ion-pair formation. The different transconductance regimes in our bilayer transistors further enable an ambipolar operation within a single band, and we apply this to produce a complementary transistor device without substitutional doping. Our study reveals an uncharted working regime of two-dimensional hybrid crystals engineered with charge localization, unlocking the potential of strong Coulomb correlations for practical electronics applications.

Diamond-Spin Resonant Metasurfaces for Magnetic Field Imaging Laura Kim[1,2]; [1]University of Florida, United States; [2]University of California, Los Angeles, United States

Atom-sized quantum sensors constructed from a spin-based qubit system can provide unparalleled sensitivity along with atomic resolution. Among solid-state quantum systems, nitrogen vacancy (NV) centers in diamond stand out with coherence times exceeding one second even at room temperature. These color centers are capable of optically measuring magnetic field, temperature, and electric field, making them a versatile platform for sensing and imaging applications. However, the central challenge lies in suboptimal optical readout restricted by an inefficient spin-photon interface. In this presentation, I will explore resonant nanophotonic strategies that can achieve near-unity optical spin readout fidelity for absorption-based readout. I will discuss various sensing modalities achieved with resonant photonic structures, tailored to applications that require distinct resolvable lateral dimensions and volume-normalized sensitivity. Our research demonstrates that diamond metasurfaces hosing NV ensembles serve as an effective imaging surface for mapping local magnetic field, electric field, and temperature via free-space illumination. They coherently encode information about the local magnetic field (and also other quantities like electric field and temperature) on spin-dependent phase and amplitude changes of near-telecom light, that is suitable for advanced signal processing and computational imaging techniques that rely on phase information. I will first introduce a plasmonic metasurface supporting the Rayleigh-Wood anomaly mode. Subsequently, I will discuss an all-dielectric dual-resonance metasurface. The studied metasurface consists of dimer clusters arranged in a 2D array, coupling with both visible and IR optically active transitions of NV centers – the triplet and singlet state transitions, respectively. We introduce sharp Fano resonances through symmetry breaking, making the mode accessible with free space illumination while maintaining a quality factor exceeding 10^4. I will explore the effects of resonantly enhanced spin-photon interactions on the steady-state NV dynamics for both IR emission and absorption readout schemes. Furthermore, I will discuss design criteria to consider at different operating temperatures, addressing the challenges of operating in bad-emitter versus bad-cavity regimes. I will also show that we can improve spatial imaging resolution by maximizing the lateral localization of the mode with a slow-light effect. Spin-coupled resonant nanophotonic devices are projected to particularly benefit applications that require high readout fidelities from spins in a confined volume. The projected performance makes the studied quantum imaging metasurface appealing for the most demanding applications such as imaging through scattering tissues and spatially resolved chemical NMR detection.

2:00 PM EL07.01.02
Organic Electroluminescent Metasurfaces Jiwoo Oh and Chih-Jen Shih; ETH Zürich, Switzerland

Organic materials have been used in optoelectronic devices such as light emitting diodes (LEDs) and solar cells due to their great tunability and flexibility. The patterning of organic materials has been challenging, especially when pushing the feature size down to the sub-micron level, as organic materials are incompatible with conventional lithography-based patterning techniques. Here we present the scalable fabrication of nano organic LED (nano-OLED) devices that achieve an array density of up to 100,000 pixels per inch (ppi) with sub-micron-sized pixels. Direct nanopatterning of organic emissive material was realized through 'nanostencil lithography.' Nanostencil lithography is a resistless patterning technique where a free-standing thin silicon nitride membrane is utilized as a shadow mask, on which sub-micron-sized pores are located. We optimized the device fabrication process by evaporating hole transport and emission layer through nanostencil shadow mask, whereas other layers in the OLED stack were deposited as bulk film. The average external quantum efficiencies (EQEs) extracted from a nano-OLED device record up to 10%. As array periodicity and feature size lie in subwavelength scale, individual pixels of a nano-OLED device act as electroluminescent meta-atoms forming metasurfaces that convert electric energy directly into modulated light. The diffractive coupling between the light-emitting nanopixels enables control over far-field emission properties. We have examined a variety of periodic arrays such as 1D gratings, 2D square and hexagonal arrays, and circularly symmetric bullseye arrays to investigate if the emission directionality or polarizability can be modulated.

2:15 PM EL07.01.03
Spin-Momentum Locked Thermal Metasurfaces Mingze He, Lin Jing, Sander Mann, Shixiong Yin, Yanjun Gao, Adam Overvig and Andrea Alu; The City University of New York, United States

Incandescence, i.e., thermal emission, is the most ubiquitous form of light source, characterized by incoherent, broadband and unpolarized emission. Despite this, it remains widely used, especially in the mid-infrared spectrum, for its low cost and easy access. However, for many applications it is vital to control and select polarization, wavelength, temporal and spatial coherence and/or wavefront of emission. A stack of optical components, e.g., band pass filters, pinholes, polarizers, waveplates and refractive lenses may be used to tailor and control the features of thermal light, but at the cost of efficiency, footprint and setup complexity. Recently, we have been demonstrating that nonlocality engineering may offer a powerful approach to engineer spatially and temporally the coherence of thermal emission, offering powerful opportunities for thermal emission manipulation. In particular, quasi-bound states in the continuum (q-BIC) can be employed in thermal emission engineering, enabling high Q-factors and narrow emission angles. Moreover, the polarization states of these q-BIC thermal states can be arbitrarily defined by manipulating the scattering matrix. However, controlling the wavefront of thermal emission remains challenging, particularly when a specific polarization state of interest is required. One of the underlying reasons is that the wavefront control requires engineering local geometrical phases, and the spatial and temporal coherence must be maintained across these different phases. It is challenging to realize such a task in a single-layer metasurface, as these tuning knobs are frequently correlated.
Here, we introduce and demonstrate spin-momentum locked wavefront engineering of thermal emission in an aperiodic metasurface platform. We leverage deliberate local perturbations of BIC thermal states, in a way that the non-local properties (spatial and temporal coherence) are preserved even when the local features (geometrical phase) are manipulated. The high Q-factor of the q-BIC enables temporal coherence, while spatial

coherence is upheld through the modal dispersion of the unperturbed periodic structure. The resulting thermal emission is spin-momentum locked, i.e., opposite handednesses have reversed dispersion because of the single-layer geometry of choice. We use this platform to demonstrate beam steering of thermal emission by introducing linear phase gradients of geometric phase, and confirm that the non-local properties are preserved. Then, we explore advanced local phase control to demonstrate a cylindrical lens design, where the unit cells along one of the axes are completely aperiodic. Because of spin-momentum locking, the left-handed polarization is focused as in a convex lens geometry, while the opposite handedness diverges as in a concave lens. Additionally, different wavelengths of emission are all focused on the same focal plane, yet at different positions, mimicking a rainbow pattern with highly coherent focused light. In summary, our platform and the experimental demonstrations showcase a locally controlled non-local metasurface for spin-momentum locked thermal emission, which exemplifies exciting opportunities for thermal emission engineering and low-cost distributed thermal sources.

2:30 PM EL07.01.04

Thermally Activated Delayed Fluorescence Organic Light-Emitting Diode Lifetime is Extended by the Purcell Effect Sritoma Paul, Haonan Zhao and Stephen R. Forrest; University of Michigan–Ann Arbor, United States

Organic light emitting diodes (OLEDs) have emerged as a promising display technology for smartphones, monitors, televisions and wearable electronics. One open question is to obtain both high efficiency emission and long operational lifetime in the deep blue spectrum. The lifetime bottleneck arises from bimolecular annihilation involving the long-lived triplet state.[1] The high energies delivered in these processes result in molecular fragmentation and the creation of defect sites that act as luminance quenchers. Recent studies have shown evidence that the Purcell effect can reduce the triplet density in Ir-based blue phosphorescent OLEDs, and hence the probability of destructive annihilation events.[2] In this work, we extend the study of the Purcell effect to blue thermally activated delayed fluorescence (TADF) OLED transient decay and operational lifetime. We observe an exciton radiative decay lifetime 0.7 times in the structure with optical cavity effect compared to a conventional structure. Temperature-dependent delayed emission lifetime characterization reveals the cavity affects both singlet and triplet excitons. We demonstrate more than 1.5 times increase in device operational lifetime of the plasmon-exciton-polariton enhanced Purcell device compared to the control. This work establishes the generality of Purcell effect in decreasing the triplet density and extending operational stability of OLEDs across a variety of emission processes.

2:45 PM EL07.01.05

Quantitative Optical Properties of Sustainable Bio-Pigment Xanthommatin, Host Polymers and Biomaterials for Sensing Metasurfaces and Cavities—Nanophotonic Refraction, Absorption and Scattering Richard M. Osgood, Ihsan Uluturk, Jin Ho Kim, Michael Leuenberger, Andrew Peters and Peter Stenhouse; U.S. Army, United States

New optical biomaterials such as bio-pigments and biominerals enable very interesting properties, such as bright structural color and iridescence, dependency of perceived color on viewing angle. For example, isoxanthopterin nanoparticles in reflectors within shrimp eyes cause significant photonic backscattering that optimizes the sensitivity and spectral coverage of shrimp eyes.[1] The bio-pigment Xanthommatin has been found to create color in cephalopod chromatophore organs, has demonstrated natural and artificial photon scattering when encased in natural and artificial granules present in the chromatophores, has demonstrated good properties as a sustainable, natural ingredient for cosmetics [2], and can, because it is a small molecule, be combined with a variety of non-toxic polymer hosts. However, the latter add nanostructures complicating optical analysis, and so far, a quantitative determination of the indices of refraction of Xanthommatin (Xa) across a broad wavelength range has eluded researchers. Xanthommatin (Xa) is also robust for a pigment and can withstand unusual amounts of UV radiation [2].

We have fabricated Xa-bearing polymer films of PVA and found the PVA films to be too porous and rough for high-quality optical analysis. Instead, we use a polymer film platform of ethyl cellulose (EC), a sustainable material which, when fabricated using a specific protocol determined in our laboratory, can be made into a reasonably good optical material with indices of refraction determined by broadband (380 nm – 3300 nm) ellipsometry including depolarization analysis. As an alternative good optical quality polymer film platform, we also try SU-8 resist, which is less sustainable than EC. We also analyze the optical indices of a biomineral (goethite), which is both sustainable and robust against environmental conditions, in an EC matrix. We synthesized goethite (a-FeOOH), using a mixture of iron nitrate and tetramethylammonium hydroxide with an initial pH around 13. The reactant has a pure yellowish color and forms spinel rods having 10-30 nm diameters and lengths in the range of 100-300 nm as determined by Scanning Electron Microscopy (SEM). We have created nanophotonic devices – Fabry-Perot cavities and 1-D and 2-D metasurfaces with photonic crystal properties – using Xa and goethite, and have carried out sensing experiments in environments rich with glucose liquid, ethanol vapor, and humidity. The 1-D metasurface experienced overall signal attenuation and perhaps a small peak shift. This peak shift was modeled and the wavelength shift per refractive unit change at the surface estimated, for detecting such molecules. We comment further on their optical performance, detection bandwidth, and other capabilities for sensing molecules such as sensitivity and selectivity in future nanophotonic devices.

Prof. Richard M. Osgood, Jr., who passed away unexpectedly this past fall, was a leader in optical materials and optical devices and, while he did not work extensively in the biomaterials field, was a proponent of researching sustainable materials like biomaterials and some polymers. The perspective of Osgood's past efforts, related to this research, will be briefly mentioned.

Electrically Tunable Phase Singularities in Excitonic Two-Dimensional Heterostructures for Active Metasurfaces Melissa Li, Lior Michaeli and Harry A. Atwater; California Institute of Technology, United States

We report on gate-tunable excitons in monolayer transition metal dichalcogenides (TMDCs) heterostructures to actively control the spectral position of their phase singularities. Previous analysis on passive metasurfaces revealed that the full-2π phase control of scattered light is associated with a branch cut crossing the real frequency axis on the complex frequency plane. Here, we show how we can dynamically tune the branch cut crossing with moderate voltage values of ±5 V by leveraging the tunability of TMDC exciton resonances. We use the complex frequency plane trajectories to design a metasurface that demonstrates full-2π phase modulation with uniform reflectance, enabling dynamic beam deflection with near-unity diffraction efficiency, and to explore in-plane coupling effects. Our results pave the way for exploiting exciton resonances for designing nanophotonic systems to explore actively tunable topological phenomena.

3:45 PM EL07.02.02

Fourier Crystal for Polaritonic Dispersion Engineering Sergey Menabde[1], Yongjun Lim[2], Kirill Voronin[3], Jacob Heiden[1], Alexey Nikitin[3], Seungwoo Lee[2,2,4] and Min Seok Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Donostia International Physics Center, Spain; [4]Korea Institute of Science and Technology, Korea (the Republic of)

Polaritonic crystals – periodic structures where the hybrid light–matter waves called polaritons can form Bloch states – promise a deeply subdiffractional nanolight manipulation and enhanced light-matter interaction. In particular, polaritons in van der Waals materials boast extreme field confinement and long lifetimes allowing for the exploitation of wave phenomena at the nanoscale. However, despite the advantages in terms of strong field confinement and momentum tunability, these high-momentum modes suffer from a combination of the inherent material-mediated losses and the severe scattering losses at sharp edges and surface defects. Consequently, the realization of polaritonic crystals with pronounced wave phenomena is a non-trivial task.

Two approaches have been demonstrated so far to create a polaritonic crystal: patterning the polaritonic waveguide and patterning the dielectric substrate, where conventional nanofabrication methods result in sharp material edges. Using this approach, researchers demonstrated 2D polaritonic crystals for hyperbolic phonon-polaritons (HPhP) in hexagonal boron nitride (hBN) and alpha-phase molybdenum trioxide (α-MoO$_3$) that support collective Bloch modes. However, hBN and α-MoO$_3$ slabs of finite thickness support a practically infinite number of polaritonic modes due to their hyperbolic nature. Therefore, a severe scattering of propagating polaritons at the sharp patterned edges leads to an excitation of multiple higher-order modes, so that the band structure of such polaritonic crystals is filled with mode branches, hindering the band engineering and manifestation of polaritonic bandgaps for individual modes.

We suggest a new concept of polaritonic Fourier crystal for mid-IR HPhP in hBN based on the continuously varying metallic Fourier surface which bypasses the aforementioned limitations of conventional patterning methods. We employ a holographic inscription method to fabricate a wafer-scale Fourier surface which is then covered with gold, acting as a substrate for a pristine polaritonic material. The proximity of the 2D polaritonic waveguide to a highly conductive metal leads to a coupling of the polariton to its mirror image and formation of an “image polariton”. Since the momentum of image polariton depends on the distance between the mirror and the waveguide, polaritons in the Fourier crystal experience a harmonic modulation of their wavevector. Most importantly, due to the stronger field confinement in the hBN layer, higher-order modes experience lesser modulation depth, while the intermode scattering is minimized due to the adiabatically varying geometry of the structure.

In our device with a 106 nm-thick hBN, the momentum of the fundamental HPhP mode decreases by approximately 50% as the air gap between hBN and gold expands from 0 to 70 nm. At the same time, more confined higher-order modes are increasingly less sensitive to the variation of the gap size and thus experience much weaker modulation (less than 25%). Besides, these high-momentum modes are expected to be damped in the absence of coupling mechanisms such as scattering at sharp material edges. Indeed, our near-field experiments and full-wave numerical simulations demonstrate that the polaritonic Fourier crystal predominantly supports the fundamental Bloch mode in the hBN slab. Furthermore, we show that the momentum modulation of the fundamental mode would lead to a manifestation of a wide polaritonic bandgap for this mode even in a relatively lossy naturally abundant hBN crystal used in our experiments.

Heterogeneous HEA Plasmonics for Superior and Low-Cost Photocatalytic Hydrogen Evolution Ta-Jen Yen; National Tsing Hua University, Taiwan

Plasmonic nanoparticles (PNP) can hybridize with atomically thin transition metal dichalcogenides (TMD), to dramatically intensify the weak light–matter interaction of those functional semiconductors. Herein, such a heterogeneous system has been designed in the form of gold or high-entropy alloy (HEA) nanoparticles, as well as silicon nanowires (SiNW) and molybdenum disulfide (MoS_2) nanofilms (PNP/SiNW/MoS_2), which exhibits excellent photocatalytic hydrogen evolution reactions (PC-HER). The resonance frequency of the 0D-PNP, the antireflection frequency of 1D-SiNW and the absorption frequency of 2D-MoS_2, match with the visible range simultaneously, for effectively harvesting the free solar energy. In addition, to enable superior efficiency and low cost of PC-HER, there present the following synergetic mechanisms. First, PNP not only show strong electromagnetic enhancement, but also offer photochemical to be a powerful co-catalyst. Next, the SiNW substrate exhibits high antireflection of 95% within the visible light absorption. Besides, an optimal MoS_2 structure that is a hybrid of both 1T and 2H phases was prepared by using reproducible and facile pyrolysis. Moreover, a p–n junction formed at the MoS_2/SiNW interface, facilitates charge separation to further boost the efficiency. In the end, our Au and HEA heterogeneous plasmonics demonstrate exceptional H_2 hydrogen generation rates of 246 and 477.5 mmol g^{-1} h^{-1}, respectively.

4:30 PM EL07.02.04

Active Metasurface Based on TiO_2/BTO Heterostructure Kerolos M. Yousef[1], Zhongpeng Sun[1], Michael Domm[1], Agham Posadas[2], Marcus Ossiander[1,3], Maryna L. Meretska[1,4], Moaz Waqar[5], Xiaoqing Pan[5,5], Alex Demkov[2] and Federico Capasso[1]; [1]Harvard University, United States; [2]The University of Texas at Austin, United States; [3]Graz University of Technology, Austria; [4]Karlsruhe Institute of Technology, Germany; [5]University of California, Irvine, United States

Metasurfaces have significantly advanced in recent years, offering exceptional control over the amplitude, phase, polarization, and spectral properties of electromagnetic waves. However, passive metasurfaces cannot be adjusted post-fabrication, driving the quest for reconfigurable metasurfaces with enhanced tunability. Barium titanate (BTO), known for its high electro-optic Pockels coefficient, faces challenges in thin-film form due to costly growth processes and limited thickness at the desired crystal orientation. In this work, we developed an active heterostructure comprising a 2D titanium dioxide (TiO_2) metasurface with interdigitated electrodes atop a high-quality a-oriented BTO layer. The BTO, with a thickness of 300 nm, was deposited using RF sputtering. The metasurface and interdigitated electrodes were fabricated with high precision using atomic layer deposition (ALD) and lift-off process, respectively. Our experimental results demonstrate guided mode resonances (GMR) confined within the BTO thin film, producing a high-quality factor dip in transmission mode around 1.56 μm. We further illustrate the active tunability of the metasurface through two mechanisms: the angle of incidence and electric bias. By changing the angle of incidence, we achieved resonance splitting and continuous shifting at a high rate. Additionally, the precise spectral position of this resonance is modulated via the electro-optic Pockels effect at low voltage, tuning the transmission of the metasurface around a wavelength of 1.56 μm. Our successful demonstration of a tunable metasurface based on TiO_2/BTO heterostructures suggests a promising path toward low-cost, large-scale free-space optical modulators. This work bridges the gap between the unique properties of metasurfaces and their active tunability, with potential applications in sensing, adaptive displays, spatial light modulators for advanced imaging, free-space communication, and beam steering.

4:45 PM EL07.02.05

Solid-Phase DNA Synthesis Using High-Quality Factor Metasurfaces Punnag Padhy, Varun Dolia, Sahil Dagli, Hamish M. Carr Delgado, Sajjad Abdollahramezani, Babatunde Ogunlade, Kai Chang, Halleh B. Balch, Michael A. Jensen, Yirui Zhang, Ronald W. Davis and Jennifer A. Dionne; Stanford University, United States

Solid-phase synthesis is the de-facto route for the synthesis of long-chained polymeric biomolecules like oligonucleotides (DNA and RNA), oligopeptides, and oligosaccharides [1,2]. Photolithographic microarrays have revolutionized solid-phase synthesis technologies by combining advances in chip scale device integration, microelectromechanical systems, and microfluidic reagent handling to enable the low-cost, high-throughput and massively parallel synthesis of these oligomers. In this approach, time multiplexed projection of an incident beam of light onto millions of reaction sites on a planar synthesis substrate using digital micromirror devices (DMDs) drives light-activated site-selective synthesis of a corresponding number of unique sequences. However, these moving mechanical mirrors along with their finite size effects result in misalignment of optical beam projections with the designated synthesis spots. The resultant deletion and substitution errors limit the yield and purity of synthesis products. Efforts to mitigate these issues by spacing the synthesis spots further apart and making them larger to generate surplus redundant copies of the same strand to aid in post synthetic error correction curtail the density and diversity of synthesis.

High-Q metasurfaces consisting of arrays of dielectric nanoantennas [3-5] have the potential to address the limitations of the photolithographic microarrays. Their geometry and orientation dependent wavelength and polarization response can be exploited to uniquely excite synthesis sites without resorting to moving mechanical components. The narrow spectral linewidth in high-Q metasurfaces prevents spatial and spectral crosstalk between nanoantennas, allowing for a large number of unique resonant wavelengths over a spectral range for maximum sequence diversity that are densely packed on the synthesis substrate.

Here, we present the fabrication and characterization of wavelength and polarization sensitive silicon nanoantennas for long and diverse DNA synthesis. Both in simulations and experiments, we integrate absorbing gold nanostructures for resonant photothermal heating. These resonant nanoheaters have high Q-factors ranging from 300 to 500 (simulated Q-factors around 1000). As a proof-of-concept, using infrared imaging, we demonstrate the optical switching between the 20 nanoantennas by tuning the incident wavelength and polarization without resorting to error prone mechanical deflection of the incident beam. We then demonstrate the transduction of the resonant optical switching to site-selective photothermal heating by characterizing the on and off-resonant dependence of temperature on the driving optical power. This photothermal switching will be exploited to drive thermolytic deblocking reactions only at the resonant nanoheater sites. This will be confirmed through the coupling of fluorescently labeled nucleotides only to the deblocked sites catalyzed by the enzyme terminal deoxynucleotidyl transferase. This switching mechanism will be used to demonstrate multistep synthesis reactions as well as the synthesis of diverse oligo sequences across different sites. In the absence of mechanical deflection of the excitation beam, our approach can exceed synthesis efficiencies and densities of current platforms to synthesize DNA oligomers longer than 300 nucleotides at densities exceeding 10M/cm^2. This will open up new avenues to genetically engineer complex biological functions in synthetic biology. Furthermore, the general operating principles discussed here can be extended for the high-throughput and massively parallel synthesis of long chained polymeric biomolecules.

5:00 PM EL07.02.06

Decoding Antibody Repertoires—Large-Scale Profiling Enabled by Highly Multiplexed Metasurfaces and Digitized Acoustic Bioprinting Sajjad Abdollahramezani[1], Darrell Omo-Lamai[1], Fareeha Safir[2], Parivash Moradifar[1], Sahil Dagli[1], Varun Dolia[1], Jack Hu[2], Kai Chang[1], Hamish M. Carr Delgado[1], Burtus T. Khuri-Yakub[1] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Pumpkeenseed, United States

The human adaptive immune system can generate over a quintillion unique immunoglobulin antibodies, which are crucial for combating infections, regulating immunity, and serving as the foundation for various immunotherapies. Although the recent breakthrough of AlphaFold has significantly accelerated the in silico discovery and design of antibody therapeutics, empirical assays that provide experimental insights into antibody-antigen interactions have not kept pace. Conventional bioanalytical techniques for probing antibody binding to target molecules (antigens or peptides) typically screen only a few hundred samples simultaneously due to the constraints imposed by the multiplexing capacities of surface-plasmon-resonance spectroscopy and microfluidics. These methods may also introduce potential bias in the selection process, failing to recover all target-specific binders present in phage display libraries.

Here, we present a scalable multiplexed assay utilizing ultra-densely pixelated metasurfaces and digitized acoustic bioprinting enabling large-scale antibody profiling. Our high-throughput metasurface antibody screening (HT-MAbS), incorporating over 10 million sensors per cm^2, capitalize on the ultrasharp resonance modes driven by the physics of the quasi-bound state in the continuum (qBIC). With quality factors exceeding 2000 in physiological buffers and subwavelength mode volume, this array of nanoresonators provides a sensing figure of merit of approximately 400. Our nozzle-free acoustic bioprinting system deposits picoliter droplets of antigens at rates up to 25,000 droplets per second with micrometer precision, allowing highly customizable surface functionalization. Our hyperspectral imaging technique captures two-dimensional spatially resolved images of thousands of nanosensors across contiguous spectral bands, revealing subtle differentiation of spectral signatures associated with a few tens of linked biomolecules.

We characterize the binding properties and epitope landscapes of antibodies targeting two potential "Disease X" antigens: the SARS-CoV-2 receptor binding domain and avian Influenza hemagglutinin. This characterization includes quantitative analyses of specificity, kinetic binding rates, and equilibrium affinity constants. The antibody panels tested include neutralizing antibodies against SARS-CoV-2 and Influenza A&B subtypes, alongside therapeutic antibodies such as Herceptin and Cetuximab, serving as specificity controls. By visualizing the epitope binning results using dendrograms and heatmaps, we assess the diversity and redundancy of a panel of monoclonal antibodies targeting various functional epitopes on the H5N1 strain of avian influenza A. Our HT-MAbS, with a femtomolar detection limit, demonstrates a linear dynamic range in the concentration range from picomolar to micromolar, and unlocks binding kinetics within a 30-minute timeframe. This high-throughput, sample-efficient, and spectrometer-free assay platform can significantly accelerate biotherapeutic discovery by enabling efficient screening of millions of protein-protein interactions on a single miniaturized chip.

5:15 PM EL07.02.07

Point-of-Care Plasmonic Immunoassay for Early Detection of Heart Failure Deniz Acil, Daria Semeniak, Ashutosh Chilkoti and Maiken H. Mikkelsen; Duke University, United States

In the last decade, there has been a growing demand for sensitive yet affordable point-of-care diagnostic tools that would allow for fast and accurate detection of disease biomarkers. There have been various strategies to improve fluorescent assays performance using nanostructures, but many are not technologically ready to be viable candidates for point-of-care testing (POCT) [1]. Here, we discuss our recent work on the use of a plasmonic enhancement in a POCT microarray immunoassay platform that is compatible with multiplexed detection of biomarkers in both well plate and microfluidic formats [2].

This presentation will cover the development of a plasmonically enhanced POCT immunoassay for heart failure, focusing on key design aspects such as optimizing the assay for multiplexed detection of three heart failure biomarkers (NT-proBNP, NGAL, and Galectin-3), and ensuring compatibility with POCT use. Our plasmonically enhanced immunoassay platform utilizes a fluorescent sandwich antibody assay paired with a custom smartphone-based detector for fast and user-friendly assay quantification. Integration of nanogap plasmonic cavities results in fluorescence brightness enhancement of several hundred-fold and a significant improvement of assay sensitivity. Our plasmonic immunoassay design represents a significant technological leap towards achieving true low-cost, high sensitivity point-of-care testing.

Metasurface Micro-lightsails—From Radiation Pressure Optomechanics to Interstellar Travel Harry A. Atwater; California Institute of Technology, United States

Nanophotonic design principles can enable self-stabilizing optical manipulation, levitation and propulsion of ultralight microscopic and macroscopic-sized (i.e., micron, *mm*, *cm*, or even meter-scale) metasurface ‘lightsails’ via radiation pressure from a high power density pump laser source. Here we report on new simulations and measurements to test the stringent criteria for metasurface lightsail design, dynamical and opto-mechanical stability, and thermal management. We discuss the optomechanical stability of micro-lightsails in the linear and nonlinear regime, as well as first experimental radiation pressure characterization of small silicon nitride (<1 mm) microscale lightsails. We will also present results from multiphysics simulations that identify key issues for lightsail stability, and will give a vision for the design of large-scale lightsail spacecraft.

11:00 AM EL07.03.02
Ultrafast All-Optical Light Manipulation with a Local High-Q Metasurface Claudio U. Hail, Lior Michaeli and Harry A. Atwater; California Institute of Technology, United States

Local modulations in refractive index due to ultrafast nonlinear effects present a promising route for realizing space-time-varying optical materials. However, the typically small changes in refractive index prohibit their application for spatial wavefront patterning. Here, we report on space-time light modulation using local ultrafast all-optical modulation of the refractive index in a dielectric, higher-order Mie resonant metasurface. This is enabled by extreme local field enhancement stimulating increased Kerr nonlinearity and free carrier effects in the nanostructure. The metasurface consists of amorphous silicon nanoparticles exhibiting a spectrally overlapped electric dipole and electric octupole mode, and allows for local wavefront manipulation. First, we investigate the time-dependent transmission modulation of the metasurface by resonantly pumping the metasurface at a wavelength of 1305 nm with an intense pulsed illumination at normal incidence (100 fs pulse length, 1 kHz, fluence up to $F = 2.3$ mJ/cm^2) and analyzing the spectrum of the transmitted light. We observe strong pump self-modulation evidenced by a red shift of the resonance at low power ($F < 24$ μJ/cm^2) due to the optical Kerr effect, and a pronounced blue shift of up to 3.1 nm at higher power originating from free carrier effects. Next, we experimentally demonstrate space-time diffraction of a wavefront by spatially patterning a transient ultrafast grating using two pump beams incident on the metasurface at angles $\theta = \pm 6°$ and measure the diffraction of the pump on the grating. Finally, we present results from time-dependent degenerate pump-probe experiments of the space-time light modulation.

11:15 AM EL07.03.03

Enhancing Optical Chirality via UV-Resonant Hafnium Oxide Metasurfaces for Enantioselectivity Remi S. Dado, Priyanuj Bordoloi, Sajjad Abdollahramezani, Parivash Moradifar and Jennifer A. Dionne; Stanford University, United States

The chirality, or ‘handedness’, of molecules frequently determines their efficacy and safety, with enantiomers displaying disparate biomedical and chemical behavior. However, the high costs associated with enantiomeric separation or asymmetric synthesis lead pharmaceutical, agrochemical, and industrial markets to predominantly supply racemic mixtures containing off-target enantiomers. More facile methods for chiral separation and synthesis could alleviate this disadvantage, especially in synthetic amino acid and chiral polymer production. To this end, spin-polarized electrons have emerged as powerful symmetry breaking agents in radical-mediated electro and photochemical reactions, but the broad application of electron spin as a chiral reagent is currently limited by insufficient spin polarization and injection. Metasurface enhancement of chiral light-matter interactions can amplify circular dichroism signal,[1] which is associated with spin polarization.[2] In parallel, ferromagnetic materials support highly polarized spin injection.[2] Integration of metasurface enhanced chiral light-matter interactions and magnetic properties represent a path to enantiomeric excess in radical-mediated photochemical reactions through chirality induced spin selectivity.[1,2] Here, we present a new ferromagnetic metasurface platform capable of enhancing near-field optical chirality and ultimately facilitating enantioselective synthesis.

We design, fabricate and characterize UV-resonant nanodisk arrays of hafnium oxide, a lossless, high refractive index dielectric in the 200-700 nm wavelength regime. Reports of hafnia’s defect-induced ferromagnetism allow it to simultaneously enhance local density of optical chirality, C, and support spin polarization and coherence. We design hafnia metasurfaces with disk heights of 100 nm and radii ranging from 50-100 nm in order to achieve UV resonances overlapped with the absorption peaks of α-aminonitriles, valuable targets for amino acid production. By manipulating the geometric parameters of these nanodisk arrays, we can spectrally align the magnetic and electric dipolar modes, resulting in Kerker-like conditions to maintain incident light's circular polarization. Full field electromagnetic simulations indicate that these structures enhance C by at least a factor of 100, averaged over the top volume of the metasurface compared to free-space, leading to an equivalent boost in spin-selective injection. We fabricate these hafnia metasurfaces using RF magnetron sputtering, electron beam lithography, and inductively coupled plasma reactive ion etching. Vacuum annealing and reactive sputtering conditions are varied to generate oxygen vacancies in the hafnia, inducing ferromagnetic character. We conduct UV transmission measurements verifying the metasurface’s resonance frequencies and evaluate the varying hafnia samples’ perpendicular magnetic anisotropy and ferromagnetic character through polar magneto-optical Kerr effect experiments. Finally, we demonstrate integration with fluidics to enable a photochemical, radical-mediated Strecker-type synthesis of an α-aminonitrile precursor of phenylglycine. We discuss preliminary results towards enantioselective excess exceeding typical solution phase reactions for this non-proteinogenic amino acid and helical polymers. Our UV-resonant metasurfaces are positioned as versatile platforms for chiral chemical processes, expanding the possibilities for spintronic applications and novel photochemical synthesis methods.

11:30 AM *EL07.03.04
Nonlocality Engineering in Optical Metasurfaces Andrea Alu; The City University of New York, United States

In this talk, I will discuss our recent advances on metasurfaces that can efficiently manipulate the impinging wavefront based on highly delocalized modes, stemming from long-range resonant interactions and lattice phenomena. Different from conventional metasurface approaches, engineered nonlocality offers tailored spectral control, and at the same time can be tailored in space with large resolution using geometric phase concepts. Their response is ideal for wavefront shaping, imaging and signal processing applications, which may open new opportunities for wireless communication systems. We achieve their exotic features by combining quasi-bound states in the continuum with geometric phase variations in engineered metasurfaces, tailoring the supported eigenwaves in frequency, momentum, polarization, amplitude and phase. The resulting metasurfaces support responses selective to the impinging wave properties, effectively realizing ultrathin transparent films that highly reflect light only when illuminated by selected polarization, frequency and wavefront spatial distribution of choice. The demonstrated wavefront selectivity of these metasurfaces opens exciting opportunities for augmented reality, secure communications, emission management, modulators and enhanced wave-matter interactions. I will also discuss how their nonlocal features make them particularly relevant for reconfigurability.

1:30 PM *EL07.04.01
Advances in Metaoptics—From Snapshot Stokes Cameras to Mueller Matrix Metaimaging Federico Capasso; Harvard University, United States

Metasurfaces enable a new class of polarization components based on structural birefringence. The meta-atoms can be engineered to locally control the propagation phase and the geometric phase. Metasurfaces arranged in a grating in turn can be designed to implement in the far-field diffraction orders that represent specific polarization functionalities, designed using Matrix Fourier Optics, which are at the heart of new Stokes cameras with demonstrated greater performance than conventional ones, which suffer from either too many components, slow speed and other complexities. Our Stokes cameras involve a single metagrating, a focusing lens and the CMOS sensor, with advantages of detector limited speed, snapshot performance with all the Stokes parameters recorded at once, leading to superior imaging for a number of applications. When light scatters off an object, its polarization generally changes, a process described by the object's Mueller matrix. Mueller matrix imaging is a crucial technique in science and technology, used to image the spatially varying polarization response of an object and reveal information that traditional imaging cannot. We have conceptualized, implemented, and demonstrated a compact Mueller matrix imaging system. This system includes a metasurface for producing structured polarization illumination and another for polarization analysis, enabling it to capture all 16 components of an object's spatially varying Mueller matrix in a single shot. Our design, which avoids moving parts or bulky polarization optics, is expected to advance applications in real-time medical imaging, material characterization, machine vision, target detection, and other significant areas.

2:00 PM EL07.04.02

Tunable Metasurface on Multimode Optical Fiber Enabled by Wavefront Shaping Andrew J. Palmer[1,1], Yucheng Jin[1,1], Beyonce Hu[1,1], Andrew Da Lee[1,1], Yao-Wei Huang[2] and Ho Wai (Howard) Lee[1,1]; [1]University of California, Irvine, United States; [2]National Yang Ming Chiao Tung University, Taiwan

The study and design of optical metasurfaces has greatly matured over the last decade, enabling wavefront engineering with remarkable degrees of freedom via control over the intensity, phase, and polarization at a sub-wavelength scale. By integrating these nanostructures directly onto the optical fiber endface, the naturally diverging fiber output (determined by the refractive index of the core and cladding) can be modulated in a number of useful ways, including focusing[1], filtration[2], off-axis deflection[3], and complex beam shaping (e.g. vortex beam generation[4]). However, in these nanostructured fibers, the device is limited to a single functionality and the designed output properties are fixed in during fabrication, limiting the practical photonic applications.

Multimode fibers are well-poised to circumvent this issue, with the recent development of techniques to shape the output wavefront via careful control of the mode dispersion and mixing during propagation. However, the range of possible outputs is still restricted to linear combinations of the individual mode field patterns, confined to the fiber numerical aperture (NA)[5,6]. In this work, we exhibit the first integration of a spatially-varied metasurface on the multimode fiber endface, which, combined with structuring of the fiber output beam via control over the input, demonstrates tunable functionality in the form of beam steering to a continuous range of angles far beyond the fiber NA. Our initial demonstrations utilize arrays of many dielectric nanopillar phase gradient metasurfaces fabricated by nanoscale 3D printing or electron beam lithography, each with their own unique combination of gradient magnitude and direction, in order to deflect light from 0 to 70° off-axis depending on the targeted location of light concentration within the fiber output. This extreme and active optical functionality is desirable for a wide range of miniaturized fiber imaging applications, where probe size can be reduced to that of a single fiber itself (~100μm).

2:15 PM EL07.04.03
Inverse-Design Enabled Prototyping of Photonic Metalens for Simultaneous Beam Collimation and Color Mixing in Near-Eye LED Displays Zhuo Li, Jiechen Wang, Yue Cao and Pingfan Wu; Futurewei Technologies, United States

Digital displays (including LCD, OLED, and micro-LED displays) mix light from red, green, and blue sub pixels to generate images. In the state-of-art near-eye displays in AR/VR devices, such as Apple^{R} Vision Pro^{TM}, the whole pixel pitch has been reduced to 7.5 microns. Nevertheless, human ocular system can still percept the discretized pixels instead of smooth images, leading to the screen door effect. A direct approach to resolve it could be further increasing the pixel density, but the miniaturized pixel size may cause the divergence angle of emitted light too big to the light coupling optics. At the same time, considering the short illumination distance of typical near-eye displays, an appropriate coloring mixing is also critical to avoid strong color patterns. Hence, precisely engineered beam collimation and color mixing optics are critical to near-eye displays.

Here we proposed a prototyping design of a metalens to achieve simultaneous beam collimation and color mixing. The metalens is discretized into a series of design units, and the material distribution inside the metalens is the design parameter to be optimized. As the dimension of the deign parameters could be large, machine learning based optimization is employed. To achieve this, we employed the adjoint method to evaluate the optical performance of a given design by finite-difference time domain (FDTD) simulations and calculate its derivative with respect to the design parameters. Therefore, the metalens design can be iteratively improved via a gradient descent process.

Specifically, we designed the metalens covering an entire pixel pitch (with a cross section of 4.5 by 4.7 um), consisting of a set of R, G, and B subpixels (the illumination area of a single subpixel measures 1.05 by 3.3 um). The metalens was discretized into 90 * 47 *40 design units. We optimized the capability of the metalens to route vertically incident RGB plane wave sources into corresponding channels, as is described in Zhao, *et al.*, 2021, *Adv. Photonics Res.* It should also be noted that while most literatures discussing inverse-design of photonic devices employ finite-difference frequency-domain solvers, we demonstrated FDTD solvers can also solve similar problems and be more adaptive to multi-frequency cases. The metalens optimized in the above-mentioned manner, according to the reciprocity principle of optical system, will convert the RGB lights from their respective channels back into the same planewave-like profile, and thus achieving beam collimation.

Our preliminary results have demonstrated the feasibility of the design concept. The optimized metalens showed the capability of collimating lights from R, G, and B subpixels into a planewave-like profile with divergence angle ~ 5°, while the controlling setup without the metalens showed a divergence angle ~ 20°. The mechanism for the reduction in divergence angle could be explained by the optical/étendue invariant: the optimized metalens defuses the light for the subpixels and increase the cross section of the beam roughly by 6 times, therefore the divergence angle is reduced. The increased cross sections of beams from RGB channels overlap with each other, and naturally achieves color mixing. At the same time, compared to a control setup without the metalens, the optical efficiency is evaluated to be 66%, 78%, and 69% for RGB lights, respectively.

In summary, we demonstrated a design of metalens for beam collimation and color mixing in near-eye LED displays. The design principle of the metalens combines the reciprocity principle of linear optical systems and the adjoint method for optimization, which can be executed in FDTD solvers. We have proved the feasibility of the design concept by simulation results, which indicate a light collimation effect. Future endeavors will focus on further improving the color mixing uniformity, improving the viewing angle tolerance, and integrating the fabrication constrains into the optimization process.

Multiplexed and Continuous Monitoring of Metabolites Using High-Q Metasurfaces and Modular DNA Aptamer Probes Yuanwei Li, Varun Dolia, Darrell Omo-Lamai, Sajjad Abdollahramezani, Parivash Moradifar and Jennifer A. Dionne; Stanford University, United States

Chronic stress is a burgeoning global health issue, impacting nearly one-third of the population with severe consequences including cardiovascular diseases, autoimmune diseases, and certain cancers. The metabolites adenosine, dopamine, oestradiol, and cortisol are critical biomarkers for monitoring stress due to their known roles in physiological and psychological stress responses. Current methodologies, including mass spectrometry and fluorometric assays for detecting stress-related biomarkers, however, are limited by their need for laboratory settings, lengthy processing times, or lack of sensitivity, especially in complex biological matrices like sweat. Furthermore, existing technologies often do not support the simultaneous detection of multiple biomarkers, essential for comprehensive stress assessment. There is a pressing need for a more accessible, accurate, and rapid technology to enable continuous monitoring of stress-related metabolite biomarkers, to facilitate immediate and personalized therapeutic interventions.

Here, we demonstrate sensitive, multiplexed, and continuous monitoring of these metabolites by integrating high-quality (high-Q) dielectric metasurfaces with spherical nucleic acid (SNA) reagents. Specifically, we design DNA sequences (aptamers) that undergo a structural change upon target metabolite binding. A split portion of this aptamer is bound as a single strand to the SNA nanoparticle core (typically ~30 nm diameter gold). Another portion of this split aptamer is bound to our resonant silicon nanophotonic antennas, termed VINPix1, which can have quality factors in the thousands to tens of thousands. Upon the presence of target analytes, the DNA sequences on the metasurfaces and the SNAs interact with the target analyte molecules, resulting in the formation of a secondary DNA structure. This interaction effectively localizes the analytes and SNAs on the dielectric metasurfaces and creates localized electromagnetic hotspots, leading to significant optical scattering intensity changes. Concurrently, the SNAs' attachment to the high-Q metasurfaces results in a visible color change of the metasurfaces, providing a visual signature of the biomarkers’ presence. We demonstrate the detection of clinically relevant, picomolar concentrations of adenosine, dopamine, oestradiol, and cortisol in artificial sweat. Our method establishes a quantitative correlation between the concentration of target molecules and the observed resonance shifts. Moreover, the dense array of VINPix, combined with regenerative chip surfaces, and the application of microfluidic techniques and photochemistry, allows for the simultaneous and continuous detection of thousands of sensors targeting various metabolites. By facilitating continuous, non-invasive monitoring of stress biomarkers, this project could substantially improve individual health management and could lead to a reduction in the incidence and severity of stress-related health conditions.

Metasurfaces for NIR to DUV Imaging and Their Scalable Manufacturing with Engineered Optical Materials

Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Here, we demonstrate metasurface-integrated imaging applications for NIR to DUV frequencies. They include achromatic NIR meta-endoscope, high-contrast NIR meta-camera, neural 360° visible structured light imaging, UV-DUV metalenses. Then, to show their scalability and manufacutrability, we will also discuss low-cost, scalable manufacturing of optical metasurfaces with three approaches: 1) increasing a refractive index of resin with dielectric particle embedding for single-step nanoimprinting, 2) suppressing optical losses of hydrogenated amorphous silicon (a-Si:H) to apply complementary-metal-oxide-semiconductor technologies, and 3) high-index atomic layer deposited (ALD) structural resin. We demonstrate the effectiveness of these materials in creating optical metasurfaces operating at different wavelengths in the infrared, visible, and ultraviolet spectra. Firstly, we achieve high efficiencies of up to 90.6%, 47%, and 60% with a-Si, TiO_2, and ZrO_2 PER at wavelengths of 940, 532, and 325 nm, respectively. Furthermore, we obtain a measured efficiency of 30% at a wavelength of 248 nm using ZrO_2 PER metasurfaces. Secondly, by adjusting the deposition conditions of plasma-enhanced chemical vapor deposition, we engineer the bandgap of a-Si:H to enable low-loss operation, with minimum extinction coefficients as low as 0.082 at 450 nm. Using low-loss a-Si:H, we demonstrate efficient beam-steering metasurfaces with measured efficiencies of 42%, 65%, and 75% at 450, 532, and 635 nm, respectively, marking the first Si-typed metasurfaces working at the full visible. Finally, we manufacture highly efficient metalenses using hybrid ALD structural resin with deep-ultraviolet lithography at visible wavelengths. Their measured efficiencies approach 60.9%, 77.8%, and 64.8% at 450, 532 and 635 nm, making them suitable for ultrathin virtual reality devices. Our approaches using PER, low-loss a-Si:H, and hybrid ALD structural resin enables the low-cost, large-area manufacturing of efficient optical metasurfaces across different wavelengths, facilitating the commercialization of metasurface-based photonic devices.

Advancing Nanophotonics with Tailorable Materials—From Tunability to Novel Phenomena Alexandra Boltasseva; Purdue University, United States

The recent advent of tailorable photonic materials such as plasmonic ceramics including transition metal nitrides (TMNs), MXenes, Weyl semimetals and transparent conducting oxides (TCOs) is currently driving the development of new concepts and devices for IT, communication, sustainable energy and quantum technologies. In addition to great tailorability of their optical properties, strong plasmonic behavior, optical nonlinearities, these materials offer pathways to uncovering new optical and quantum phenomena ranging from epsilon-near-zero behavior to transdimensional photonics and strongly correlated systems. In this talk, we explore novel applications of TMNs (titanium nitride, zirconium nitride) and TCOs for flat optics, all-optical switching, high-harmonic-based XUV generation as well as for demonstrating new physical effects in atomically thin, transdimensional plasmonic films related to strong light confinement and metal-to-insulator transition. Our work paves the way to novel phenomena and device design with ultrafast tunable and tailorable optical materials.

Phase Change Materials for Nanophotonics and Metamaterials—Multiphysics Approach Dmitry N. Chigrin[1,2]; [1]RWTH Aachen University, Germany; [2]DWI–Leibniz Institute for Interactive Materials, Germany

Phase change materials undergo a rapid and reversible phase transition, resulting in a significant change of their physical properties. These materials have the potential to revolutionize technology, with applications ranging from neuromorphic devices and efficient high-frequency electronics to (re)programmable optical metamaterials and integrated photonics. Nevertheless, the process of analysing and optimising material properties is a lengthy and iterative empirical one. The integration of computational methods into the design of materials offers a promising avenue for streamlining and optimising the design process, which could ultimately result in a reduction in the time and cost associated with achieving desired material properties. The implementation of computational techniques for materials design significantly reduces the resource and time requirements, thereby promoting advanced product development in a wide range of fields. This presentation presents progress towards a unified description of complex nanophotonic devices based on phase change materials. A self-consistent analysis of electromagnetic, heat transfer, carrier transport and phase transition models is required for this description. The potential applications of such a multiphysics approach in the realms of metamaterials and nanophotonics are explored and discussed.

4:30 PM EL07.05.03
Reconfigurable Plasmonics Enabled by Low-Loss Phase Change Materials Maria Losurdo[1], Yael Gutierrez-Vela[2], Gonzalo Santos[2], Capucine Laprais[3], Naida El Habra[1], Shirly Espinoza[4], Fernando Moreno[2] and Sebastien Cueff[3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Universidad de Cantabria, Spain; [3]Université de Lyon, France; [4]The Extreme Light Infrastructure, Czechia

The dynamic modulation of the optical response of plasmonic systems and devices by optical, mechanical and electrical stimuli is crucial for advancing nanophotonic applications such as optical switches, modulators, reconfigurable antennas, LIDAR system, surface-enhanced spectroscopies and photonic integrated circuits. In this contribution, we present an innovative approach to achieving tunable plasmonic properties by integrating phase-change materials (PCMs) with plasmonic systems. Specifically, we explore the dynamic plasmonic response of of low-loss PCMs of group III (Ga, In) and group-V (Sb) chalcogenides such as GaS, In2S3, Sb2Se3 and S2S3 also coupled with gold (Au) and gallium (Ga) plasmonic gratings and nanoparticle (NPs). We present active systems spanning from prtiodic gratings, to hybrid core-shell phase-change plasmonic NPs, to disk-shaped metasurfaces with PCM sandwiched between plasmonic elements and dielectrics. We show their active responsible tunable in a broad range from UV-VIS to IR. In these active heterostructures, the optical response of the plasmonic, traditionally fixed by design parameters during fabrication, can now be spectrally tuned through the reversible phase transitions of the incorporated PCM layer. We successfully demonstrate the reversible and tunable plasmonic response of the fabricated active heterostructures through controlled low-energy (in the nJ-fJ range) thermal, laser and electrically (low-voltage induced reversible amorphous-to-crystalline (and viceversa) phase change of the PCM. Engineered applications of those dynamics plasmonic structures in optical switches, light modulators, broadband plasmonically enhanced photodetectors and switchable scattering directionality nanoantennas will be demonstrated.

Arbitrary Control over Reflectance with Freeform Phase-Change Metasurfaces Xiaomeng Zhang, Jackson Bentley, Christina Boyd, Richard Haglund and Jason G. Valentine; Vanderbilt University, United States

Active optical control has long been a pursuit in optical engineering, where external stimuli offer tunability of the properties of optical components post-fabrication. While well-established reconfigurable optical components, such as deformable mirrors and spatial light modulators, have been widely used in various fields, they usually suffer from a large pixel pitch and an increased system size, leading to a small field of view and large driving voltages. Active metasurfaces, which integrate active materials with metasurfaces, could give rise to active optical components of the next generation, featuring compactness, high spatial resolution, and low power consumption. Over the past decade, despite the integration of various active materials in metasurfaces, common issues such as small tuning range and functionality degradation have limited the dynamic optical performance of active metasurfaces due to the vast design complexity caused by the presence and interplay of different optical states. As a result, arbitrary control over the reflectance of the phase-change metasurface has yet to be achieved.

We introduce a freeform phase-change metasurface platform by integrating freeform Si nanostructures onto a vanadium dioxide (VO2) layer to realize arbitrary reflectance control at both the semiconducting and metallic states of VO2. The remarkably increased tuning capability and elimination of crosstalk are achieved by embracing the unprecedented design space and resonant diversity enabled by the freeform nanostructures, which are inverse-designed by a generic global optimization approach consisting of a generative neural network and the adjoint method. This inverse design method also considers performance robustness, ensuring desirable dynamic functionalities with feasible nanostructures and moderate computational cost. The ability of arbitrary reflectance control of the inverse-designed metasurface is then experimentally demonstrated with two exemplified dynamic functionalities: switchable independent grayscale nanoprinting and reconfigurable varifocal focusing. Our work provides a generic avenue for active metasurfaces to fully unleash the dynamic benefits of the active material through leveraging diverse resonances offered by inverse-designed freeform nanostructures, facilitating intriguing active optical applications in optical display, imaging, and light detection and ranging.

Redox-Tunable Conducting Polymer Plasmonics and Metasurfaces Magnus P. Jonsson and Mohammad Shaad Ansari; Linköping University, Sweden

We recently introduced conducting polymers as a new type of redox-tunable plasmonic materials,[1] opening for chemically and electrically controlled nanooptics and metasurfaces.[2-3] I will present the background to this emerging area of nanooptics and discuss recent results. As example of unique opportunitues enabled by conducting polymers, I will show how aligning the polymer chains by straining can induce redox-tunable in-plane hyperbolic permittivity and broadband chirooptics.[4, 5] I will also discuss requirements, possibilities and limitations in extending this research area to materials beyond PEDOT-based systems.[6]

Electrically Tunable Epsilon-Near-Zero Properties and Anisotropy in Conjugated Polymers Weitung Yang, Aleksei Anopchenko, Jack Wright and Ho Wai (Howard) Lee; University of California, Irvine, United States

Epsilon near zero (ENZ) materials have been extensively studied in recent years due to their unique optical properties arising from extreme light matter interaction within them [1-2]. Controllable ENZ properties realized in polymer materials drawn particular interest because of their advantages such as dynamic tunability, ease of fabrication, and naturally hyperbolic dispersion [3]. The oxidation states of the conducting polymer can also be tuned between the metallic and dielectric states, depending on the applied voltage [4]. This, combined with its polymeric flexibility, makes it a promising material for metasurface applications. In this work, we demonstrate that high electrical conductivity, anisotropy, and a tunable ENZ wavelength in the visible regime can be achieved in conducting polymer PEDOT:PSS (poly(3,4-ethylenedioxythiophene) polystyrene sulfonate) by varying the sulfuric acid treatment recipe (e.g. controllable ENZ wavelength from 700 nm to 1600 nm). Furthermore, the ENZ wavelength in visible regime can be controlled in electrochemical devices made of PEDOT:PSS. This electrical tunability of ENZ wavelength and anisotropy in the visible spectrum is unique for ENZ materials and enables gate control of ENZ effects and the topological state of iso-frequency surface. We prepare our samples by spin coating of PEDOT:PSS solution. The conductivity and degree of anisotropy is controlled by adding DMSO (dimethyl sulfoxide) into the solution and using post-deposition acid treatment. We observed that the thin films exhibit uniaxially anisotropy with its in-plane direction having ENZ properties, while the out-of-plane direction remains dielectric after the acid treatment. The ellipsometry characterization of the material can be perfectly describe using an anisotropic Drude-Lorentz model. Electrochemical devices are assembled with solid polymer electrolyte and transparent conducting oxide as electrodes. The reflection spectrum of the device in the visible range exhibits a 60% change in reflectivity upon application of a voltage. This change is due to the gate control of the polymer's redox state, making it either dielectric or metallic. The optical behavior of the device was simulated using commercial software, highlighting the potential for designing hyperbolic metasurfaces for various applications and controlling the topological state of iso-frequency surfaces using external fields.

5:30 PM EL07.05.07

Multiband Electro-Optic Modulator Employing a Lithium Niobate Racetrack Resonator Integrated with Two Pulley Couplers Hyeon Hwang[1], Min-Kyo Seo[1], Hansuek Lee[1], Mohamad Reza Nurrahman[1], Hyungjun Heo[2], Kiyoung Ko[1], Kiwon Moon[3], Jung Jin Ju[3], Sang-Wook Han[2] and Hojoong Jung[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Electronics and Telecommunications Research Institute, Korea (the Republic of)

Integrated optical modulators (IOMs) have attracted attention in various applications, including optical interconnects, sensors, spectroscopic devices, and quantum photonic circuits. The visible to near-infrared wavelength IOMs exhibit potential for the manipulation of the ion or neutral atom qubits, while the telecommunication wavelength IOMs play a crucial role for the development of quantum photonic circuits and long distance communication. It has thus been relevant to address and bridge the elements operating in multiple spectral bands with a single IOM. In this study, we present a multiband electro-optic (EO) modulator employing a lithium niobate (LN) micro-resonator integrated with two pulley couplers. Our device offers high modulation extinction ratios over multiple spectral bands at 775, 980, and 1550 nm wavelengths. The EO modulator consists of a high-quality-factor racetrack micro-resonator and two pulley couplers. While the first coupler divides the incident light into two paths along the resonator and the bus waveguide, the second coupler recombines the traveling light. In the two-coupler integration method, the external coupling strength is tunable sinusoidal way depending on the relative phase difference of the two paths, respectively. When the four times of the coupling strength at the one-coupler (κ_{one}) exceeds the intrinsic loss of the resonator (κ_{int}), the high-extinction EO modulation traversing from the under, through the critical to the overcoupling states is allowed. We should note that the multiband operation originates from the synergy of several essential ingredients, including the wide transparent window of LN, the high quality factor of the racetrack resonator, the aforementioned advantage of the two-coupler integration method, and the broadband performance of the pulley coupler. In particular, we designed the pulley coupler by adjusting the structural parameters such as the gap size, waveguide width, and interaction angle to support sufficiently high coupling strength even at short wavelengths. Both the theoretical and experimental results confirm that the condition of $4\kappa_{one} > \kappa_{int}$, which is required for high-extinction EO modulation, is satisfied in all the targeted wavelength bands. The applied voltage-dependent transmission spectra were precisely characterized in the multiple bands using an experimental set-up consisting of three different external-cavity diode lasers and Mach-Zehnder interferometers. The experimental results for representative resonant modes in each spectral band demonstrate that the EO transition from the under-, the critical- to the over-coupling condition was realized. The extinction ratio at the critical-coupling condition reached 12 dB at the wavelength of 775.2 nm, 10 dB at 969.7 nm, and 21 dB at 1539.5 nm. The effective half-wave voltage was evaluated from the EO

evolution of the transmittance at the critical-coupling frequency: approximately 1.0, 3.7, and 2.7 V at the wavelengths of 1539.5, 969.7, and 775.2 nm. The length of the EO modulation part of our device was 2.5 mm, and then the half-wave voltage-length product was evaluated as 0.25, 0.93, and 0.68 V×cm. This value in the telecommunication band is an order of magnitude lower than those obtained in typical MZI-based IOMs, owing to the high quality factor of the LN racetrack micro-resonator. In summary, our multiband IOM based on the thin-film LN micro-resonator and the two-pulley coupled platform represents the widest operating spectral range in a single device to our knowledge, and is ready to extend to midinfrared wavelengths, where LN is still highly transparent. The multiband EO modulator holds promise for low-cost, high-density integration in optical communications and quantum information processing.

5:45 PM EL07.05.08

Growth of Self-Aligned Oxide Photonic Devices on Silicon Dhiman Biswas[1], Melissa I. Ayala Artola[1], Sumit Goswami[1], Pralay Paul[1], Casey P. Kerr[1], Sreehari Puthan Purayil[1], Benjamin Summers[1], Horst Hahn[2,3,4], Alisa Javadi[1], Bin Bin Weng[1], Dhruv Fomra[5], H. J. Lezec[5] and T. Venky Venkatesan[1,5]; [1]The University of Oklahoma, United States; [2]Karlsruhe Institute of Technology, Germany; [3]Center of Optimal Materials for Emerging Technologies (COMET)-University of Oklahoma, United States; [4]School of Sustainable Chemical, Biological and Materials Engineering, The University of Oklahoma, United States; [5]National Institute of Standards and Technology, United States

Functional oxides play a significant role in the emergence and growth of novel plasmonic and quantum photonics devices. The ability to precisely engineer micro/nano structures with smooth surfaces of these oxides is a critically important technical enabler for device applications. However, using reactive ion etching (RIE) tools, to pattern oxides remains a formidable challenge as many of the cations do not form volatile species easily. At the University of Oklahoma, we have developed a reproducible technique for epitaxial growth of yttria-stabilized zirconia (YSZ) on silicon substrates with native oxides on their surface with a rocking curve full width at half maximum (FWHM) of 0.68 degrees on silicon (100) [1]. This establishes a solid foundation for the epitaxial growth of diverse functional oxide materials, including dielectric, ferroelectric, magnetic, conducting, and electro-optic materials, over large areas (up to 4 inches).

To circumvent the problem of patterning these oxide films with smooth and vertical side walls, we have used the highly directional nature of pulsed laser deposition (PLD), which allows for self-aligned growth of functional oxide materials on pre-patterned silicon wafers. Reactive ion etching (RIE) of silicon [2] is utilized to achieve the required device dimensions. PLD deposition of oxides onto the patterned substrates gave non-conformal growth with negligible deposition on the sidewalls. High temperature deposition gave rougher surfaces than room temperature due to crystallization induced non uniformities. Furthermore, the non-conformality of the deposition may depend on the sidewall undercut and nature of the oxide. By combining electron beam lithography and RIE with PLD, we demonstrate the capability to fabricate high aspect ratio optoelectronic device structures and will report on their performance. This technology facilitates the seamless integration of state-of-the-art silicon electronics with oxides for optoelectronic devices.

Improving Photoelectric Conversion with Broadband Perovskite Metasurface Ruwen Peng and Mu Wang; Nanjing University, China

The miniaturization and integration of optoelectronic devices require progressive size reduction of active layers, resulting in less optical absorption and lower quantum efficiency. In this work, we demonstrate that introducing a metasurface made of hybrid organic-inorganic perovskite (HOIP) can significantly enhance broadband absorption and improve photon-to-electron conversion, which roots from exciting Mie resonances together with suppressing optical transmission. Based on the HOIP metasurface, a broadband photodetector has been fabricated, where photocurrent boosts more than ten times in the frequency ranging from ultraviolet to visible. The device response time is less than 5.1 μs at wavelengths 380, 532, and 710 nm, and the relevant 3dB bandwidth is over 0.26 MHz. Moreover, this photodetector has been applied as a signal receiver for transmitting 2D color images in broadband optical communication. These results accentuate the practical applications of HOIP metasurfaces in novel optoelectronic devices for broadband optical communication.

8:15 AM *EL07.06.02
Advanced Materials for Ultra-High-Temperature Photonic Devices Marina S. Leite; University of California, Davis, United States

Optical materials that can withstand high temperature environments have been recently sought after for applications ranging from thermophotovoltaics (TPV) to color filters. Yet, the limited material options used to date in these applications substantially restrict the temperature to which they can be exposed, or constraint overall device performance (e.g. far from ideal spectral control). In this talk I will present our recent progress towards identifying and testing materials that are suitable for high-temperature photonics. First, I will provide an overview of our materials' screening approach with >2,800 material combinations with melting point >2,000 °C to identify optical emitters that enable TPV with power conversion efficiency >50% . Second, we analyze the performance of SiC/AlN option, where we found this material combination to be stable up to 1,200 °C in air and 1,500 °C in inert environments, using in situ high-temperature optical measurements. Third, I will show how primary colors can be achieved by using refractory metals and their oxides, including a detailed characterization of their optical response. The material screening approach implemented here could be expanded to additional high-temperature photonic devices, such as thermal regulation ones, and barrier coatings for extreme environmental conditions.

8:45 AM EL07.06.03
Nanoscale Imaging of Hot-Electrons Using Electron-Scanning Thermal Microscopy Rituparna Mohanty, Mohammad S. Tekmedash and Amin Reihani; Rutgers, The State University of New Jersey, United States

Hot-carrier generation and transport under highly non-equilibrium conditions are pivotal for the operation of advanced clean energy technologies such as plasmonic photocatalysis and photovoltaics, as well as operation of high-frequency electronic and optoelectronic devices. This study aims to probe the spatial distribution of hot carrier generation, transport, and dissipation in nanoscale systems. We demonstrate a novel Electron-Scanning Thermal Microscopy (E-SThM) technique capable of mapping the electron temperature field with nanometric spatial resolution and sub-kelvin temperature resolution on conductive or semiconductor surfaces. The principle of E-SThM is as follows. A custom-fabricated scanning thermal probe is employed, where the probe tip is coated with a thin platinum (Pt) electrode, followed by deposition of an ultrathin (<5 nm-thickness) layer of aluminum oxide (Al_2O_3), to form a fixed tunneling barrier. Upon contact with a conductive surface, the E-SThM tip establishes a metal-insulator-metal tunneling junction with a fixed insulator thickness. When a bias voltage is applied across the tip-sample junction, it induces a tunneling current through the thin insulating film. The tip tunneling current exhibits an energy distribution that is primarily concentrated near the Fermi levels of both the sample and the probe. This concentration results in a characteristic double peak in the energy distribution of the current. An increase in the electron temperature within the sample leads to a broadening of the Fermi-Dirac distribution, consequently increasing the tunneling current. A calibration involving lattice (phonon) temperature measurements allows us to extract the electron temperature map on the surface of the sample. To demonstrate this technique, we measured the hot-electron temperature distribution on plasmonic Ag nanoparticles under resonant optical excitation and show that localized hot-spots with high local electron temperature exist on the nanoparticles. The proposed technique can provide microscopic insights on the magnitude and spatial distribution of non-equilibrium electrons in nanoscale systems and will be specifically applied to address key fundamental questions in plasmonic photocatalysis.

9:00 AM EL07.06.04

Unraveling Coherence Effects of Coupled Resonant Thermal Emitters Komron J. Shayegan[1], Lior Michaeli[1], Arun Nagpal[1], George Rossman[1], Zongfu Yu[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of Wisconsin–Madison, United States

In this talk, we will discuss the interactions between resonant thermal emitters to realize complex coherence effects, such as thermal focusing. We will particularly examine three key regimes: response governed by local resonances, nearest-neighbor coupling, and collective modes. Using germanium nanorods on a gold backplane, we experimentally measure local resonances of individual germanium rods (600 nm tall) with varying widths that tune the peak resonances from 4 to 10 mm. With these resonant emitters, we construct finite-sized arrays that supports collective modes spanning the spectral range between the dipole and quadrupole resonances of the constituent resonators. Finally, we introduce defects into the arrays, which emit and scatter radiation at wavelengths within and beyond the local resonances of the constituent resonators of the finite array.
We will present simulations and (time-permitting) provide an analytical explanation of the contributions of each of these effects, with a focus on nearest-neighbor interactions versus collective modes for applications in thermal lensing.

Magnetoplasmonic Metasurfaces as a Tunable Platform for Near-Field Radiative Heat Transfer Raul Esquivel-Sirvent, Shunashi G. Castillo-Lopez and Alonso Marquez; Universidad Nacional Autónoma de México, Mexico

Magnetoplasmonic resonances combine the properties of magnetic and plasmonic materials, offering unique capabilities in manipulating electromagnetic waves at the nanoscale. These resonances arise from the interaction of plasmons—collective oscillations of free electrons in a material—with external magnetic fields, resulting in tunable optical properties. When applied to near-field heat transfer, magneto plasmonic resonances provide a versatile and adjustable platform that can significantly enhance and control the transfer of thermal energy at the nanoscale.
In this work, we present a theoretical calculation of the near-field heat transfer (NFRHT) modulation by an array of magnetoplasmonic spheres made of InAs on a Si substrate. Spoof plasmons can be generated in an array of nanospheres, and the dispersion relation will depend on the separation of the spheres and their size. This is, the

plasmon-polariton dispersion relation can be changed just by the geometry of the system (1). Furthermore, the application of an external magnetic field will excite magnetoplasmons (2) that can be tuned to hybridize with the spoof plasmons of the array of nanoparticles. This hybridization is then used to enhance or decrease the coherent near-field radiative heat transfer. (3). Finally, we will discuss how Near-field thermophotovoltaic devices can benefit from the enhanced and tunable heat transfer properties of magnetoplasmonic materials, improving their efficiency.
In summary, magnetoplasmonic resonances offer a promising platform for tunable near-field heat transfer. They have significant potential for advancing thermal management and energy harvesting technologies at the nanoscale. By exploiting the interplay between magnetic fields and plasmons, researchers can develop highly efficient and controllable thermal systems.

Quantifying Mid-IR Radiation from a Single Nano-Object—The Next Generation Thermal Engineering Using Phonon Polaritons Sunmi Shin; National University of Singapore, Singapore

Rigorous thermal control at nanoscales has become essential with the miniaturization of electronic devices. Thermal management in nano-devices has been challenged by the diffusive nature of heat conduction by classical heat carriers, e.g., phonons and electrons, due to their short mean-free-path. Furthermore, low-dimensional systems enlarge the boundary scattering of the heat carriers, which suppresses the thermal conductivity of specimens. It leads to substantial challenges in thermal management by making heat conduction diffusive owing to the incoherence of heat carriers. If one could engineer the transport of thermal energy, arguably the most ubiquitous form of energy, with similar degree of controllability as electrical and optical energy, a variety of energy transport and conversion technologies can be improved.

In this talk, I will introduce a thermo-photonic engineering approach to manipulate nanoscale heat transport by using surface phonon polaritons (SPhP), coupled energy carriers of optical phonons and mid-IR photons within the Reststrahlen band of polar dielectrics (e.g. SiO_2). In a recent decade, nonlinear heat transfer mediated by SPhPs has brought increased attention in various forms of heat transfer, including near- and far-field radiation and conduction. I will firstly discuss how the SPhP can be utilized to tailor thermal radiation properties, especially to achieve a coherent, near-monochromatic far-field thermal emission, which is a big departure from the incandescent behaviour in the classic textbook as described by the Planck's law. The key feature of the design is to utilize nanoscale emitters whose dimension is comparable to or smaller than the thermal wavelength, a regime when the Planckian energy distribution no longer holds (as Planck himself originally noted). I will show my experimental and theoretical work to quantify the far-field thermal radiation from these rationally-designed single nano-emitters. Anisotropic SiO_2 nanoribbons were designed to enable independent control of the incoherent and coherent behaviors by exploiting the large disparity in the skin depth and wavelength of surface phonon polaritons. A thermometry platform was devised to extract the thermal emissivity from such polar dielectric nanoemitters with nanowatt-level emitting power.

Furthermore, new approaches of exploring polaritonic heat conduction will be introduced. Theoretical predictions suggest that these distinctive heat carriers exhibit anomalously long propagation lengths over 100s μm. The theoretical prediction of the thermal conductivity has been achieved by assuming the infinite length of samples in which Rossland approximation is valid up to ~250 W/m-K of thermal conductivity in a 50 nm thick SiO_2 film due to the long propagation lengths. While the past theoretical models for heat conduction treated polaritons as phonons described by the kinetic theory with an abnormally long propagation length, the existing understandings failed to account for the radiative behaviours of SPhPs which involve evanescent waves confined along the surface, at the same time, vastly dispersed in empty surroundings. The exploit of polaritonic heat conduction and radiation shares the same origin of coupled energy of mid-IR photons and optical phonons within the Reststrahlen band in polar dielectric surfaces. However, the implications of SPhPs have been studied separately and limited to specific heat transfer mechanisms, leading to a discontinuous understanding of polaritonic heat transfer along the heat channel that converts radiation to conduction. I will introduce our experimental observations of quasi-ballistic heat conduction by SPhPs to exploit a new mode of heat conduction which is dispersive in radiative nature, yet directional guided along the surface.

9:45 AM EL07.06.07

Enhancing Efficiency and Directionality of Photon Upconversion Via Bound States in the Continuum Mengfei Wu[1,2], Kangning Yu[2], Liangliang Liang[2], Febiana Tjiptoharsono[1], Emmanuel Lassalle[1], Yuxiang Zhang[2], Dileep Kottilil[1], Ramon Paniagua Dominguez[1], Xiaogang Liu[2] and Arseniy Kuznetsov[1]; [1]Institute of Materials Research and Engineering, Singapore; [2]National University of Singapore, Singapore

Upconversion (UC) of infrared light into visible light has wide potential applications, such as bioimaging, 3D displays, and anti-counterfeiting. However, current UC efficiency is low, whether by organic-based triplet-triplet annihilation (TTA) or lanthanide-doped upconversion nanoparticles (UCNPs). Here, we utilize dielectric metasurfaces with high quality factors, specifically arrays of titanium dioxide (TiO_2) cylinders that support bound states in the continuum (BICs), to enhance the UC efficiency. For instance, a bilayer film of quantum dots and organics for TTA-UC is deposited on a TiO_2 array, which gives a quadrupole-based symmetry-protected BIC at the pump wavelength of 976 nm. Efficient coupling leads to nearly two orders of magnitude of increase in quantum dot absorption and hence the UC efficiency. In contrast, a layer of UCNPs is deposited on a TiO_2 array, which results in a Friedrich-Wintgen BIC at the emission wavelength of 654 nm. A highly directional beam is produced, albeit with a limited increase in the UC efficiency. Our work points to a design principle that maximizes absorption for efficiency enhancement and modifies emission for directionality control.

Extreme Space-Time Optics Vladimir Shalaev; Purdue University, United States

In the dynamic field of optics, extreme nonlinear and space-time subtopics stand out for their rapid evolution and broad applicability. Here, I discuss recent developments in extreme nonlinear optics, from harnessing extreme intensities through single-cycle optical modulation to pushing the boundaries of modulations induced by a single photon.

The road to Photonic Time Crystals: Transparent conducting oxides (TCOs) and other near zero index (NZI) materials demonstrate exceptional optical properties, particularly enhancing optical nonlinearities. Leveraging TCOs' rapid optical response from optically driven electronic transitions, they prove valuable for optical modulators and beyond. This study examines how a single-cycle pulse modulates a probe beam, paving the way for exploring photonic time crystals—an intriguing new phase of photonic matter.

In standard *spatial* photonic crystals (PCs), periodic modulations in material and optical properties lead to interesting optical behavior including frequency bandgaps, modification spontaneous emission, and nontrivial topologies. Importantly, PCs require sharp spatial interfaces. A photonic time crystal (PTC) is a spatially-homogeneous medium that changes periodically in time leading to predicted bandgaps in momentum and lasing in the bandgap. As in the spatial case, there must be sharp temporal changes placing stringent requirements on implementation in the optical domain. Our results demonstrate that TCOs unexpectedly have an ultrafast relaxation time accompanying the ultrafast rise-time making them ideal candidates for PTCs.

All-optical Modulation with Single-photon Intensities: The manipulation of light by light lies at the core of numerous photonic applications spanning telecommunication, microscopy, computing, and quantum optics. However, achieving such effects at a single photon level, where one photon significantly influences another macroscopic beam, remains a formidable challenge. Demonstrations of nonlinearity at a single photon level have been realized in optical/photonic cavities strongly linked to atoms, quantum dots, and other types of single-photon emitters. Progress in achieving single-photon nonlinearities has been demonstrated with polaritons. However, achieving high-speed single-photon all-optical modulation at room temperatures and for a broad range of wavelengths remains a challenging problem.

Here, we use electron avalanche multiplication process to modulate a beam of light by another beam with a single-photon intensities. The single photon produces a cascade up to millions of new electrons into a conduction band of silicon, that is typically detected electrically. We show the detection these changes through another probe laser beam at a near-infrared (NIR) wavelength and successfully demonstrated the modulation of the telecom light using an 810-nm light pulse with an average photon count of approximately 0.0005-0.1 per pulse. Our approach has a high efficiency operation across a broad wavelength range (from 400nm to 1000nm for silicon SPAD) at room temperature. We believe that our approach has great potential for achieving strong optical nonlinearity at the single-photon level and at THz rates, which could significantly advance the field of photonics and enable a variety of applications at the single-photon level.

10:45 AM EL07.07.02

Matte Surfaces with Broadband Transparency Enabled by Highly Asymmetric Diffusion of White Light Mu Wang, Ruwen Peng and Yun Lai; Nanjing University, China

The long-standing paradox between matte appearance and transparency has deprived traditional matte materials of optical transparency. Here, we present a solution to this centuries-old optical conundrum by harnessing the potential of disordered optical metasurfaces. Through the construction of a random array of meta-atoms tailored in asymmetric backgrounds, we have created transparent matte surfaces that maintain clear transparency regardless of the strength of disordered light scattering or their matte appearances. This remarkable property originates in the achievement of highly asymmetric light diffusion, exhibiting substantial diffusion in reflection and negligible diffusion in transmission across the entire visible spectrum. By fabricating macroscopic samples of such metasurfaces through industrial lithography, we have experimentally demonstrated transparent windows

camouflaged as traditional matte materials, as well as transparent displays with high clarity, full color, and one-way visibility. Our work introduces an unprecedented frontier of transparent matte materials in optics, offering unprecedented opportunities and applications.

11:00 AM EL07.07.03
Switchable Terahertz Beam Steering with Nearly 100% Ordinary Transmission Zhixiang Huang[1], Jie Ji[2], Ke Ma[1], Eric Herrmann[1], Riad Yahiaoui[3], Fei Ding[4], Peter U. Jepson[5], Thomas A. Searles[3], Binbin Zhou[5], Zizwe Chase[3] and Xi Wang[1]; [1]University of Delaware, United States; [2]Technische Universiteit Eindhoven, Netherlands; [3]University of Illinois at Chicago, United States; [4]University of Southern Denmark, Denmark; [5]Technical University of Denmark, Denmark

We present a reconfigurable metasurface demonstrating transmission manipulation over a broadband terahertz (THz) wavelength range. This metasurface realizes controllable THz beam deflection utilizing only one layer of patterned vanadium dioxide (VO_2) film, known for its phase-transition properties. When the metasurface is at the OFF state, it has little distortion to the wavefront of incident light, exhibiting nearly 100% ordinary transmission. The simulation and experimental results show highly efficient THz beam steering when the metasurface is turned ON.

To realize the terahertz beam steering, we utilize two gap-split ring resonators as the unit cells of the metasurface and implement VO_2 on a sapphire substrate as the activation material. The metasurface is geometrically optimized to within the frequency range of 0.2 – 1 THz, where anomalous diffraction occurs in the transmitted beam, with polarization orthogonal to that of the incident beam. Eight resonators exhibit nearly identical transmission amplitudes and a π/4 phase increment, effectively covering the entire 2π phase range.

Fabrication is carried out in the University of Delaware Nanofabrication Facilities. About 120 nm thick of VO_2 thin film on the sapphire substrate is deposited using pulsed laser deposition and patterned by standard photolithography and inductively coupled plasma reactive ion etching. The as-deposited VO_2 thin film exhibits higher than 4 orders of magnitude resistance change across its phase transition.

THz time-domain spectroscopy, combined with a rotation stage, was used to characterize the fabricated metasurface. The state of the metasurface was controlled thermally. When the metasurface is in an ‘OFF’ state, the transmission intensity closely matches that of a bare sapphire substrate. When the metasurface is in an ‘ON’ state, it shows a large deflection consistent with the simulation results. For example, at three distinct frequencies: 0.4, 0.6, and 0.8 THz, the corresponding deflection angles are 69°, 39°, and 27°, respectively, aligning closely with the simulated angles of 69.52°, 38.65°, and 27.93°. The efficiency of beam steering is comparable with that of an identical metasurface sample fabricated of gold.

11:15 AM EL07.07.04
High-Q-Factor Chiral Metasurfaces for Spin Angular Momentum-Encoded Photon-Pair Generation Rajas G. Apte, Feng Pan and Jennifer A. Dionne; Stanford University, United States

Photonic quantum states that involve entanglement of multiple degrees of freedom (e.g. energy, momentum, and polarization) underpin devices and systems for quantum communication, sensing, and metrology. Spin angular momentum (SAM) of light is an important degree of freedom that can be entangled at the same time along with photon energy. SAM-encoded entangled photons, i.e. circularly polarized photon pairs, encode and transmit quantum information more efficiently and amplify sensitivity in quantum metrology. Among a wide variety of approaches for photon-pair generation, spontaneous parametric downconversion (SPDC) stands out because of room-temperature operation, the ease of photon pair extraction and entangling several degrees of freedom, and strong coherent emission. Conventionally, nonlinear crystals that are used to realize the down-conversion require the stringent phase matching and significant volume footprint for light-matter interaction, challenging current efforts in on-chip quantum light sources. Despite some successful demonstrations of SPDC in ultrathin films of nonlinear materials by relaxing the phase-matching condition, the photon-pair generation rates are modest due to weak parametric amplification of the vacuum field and free of SAM encoding. Engineering high-quality-factor chiral photonic modes in miniaturized SPDC-based sources is an exciting route to strongly enhance chiral light-matter interactions and thus the down-conversion process for high chiral photon-pair generation rates.

Here, we present a high-Q-factor chiral metasurface to generate photon pairs encoded with SAM. Our chiral metasurface is composed of periodically arranged AlGaAs nano-discs, which have a large second-order nonlinear coefficient (100 pm/V). In our design, the nano-discs are cut in the diagonal direction to break both in-plane inversion and mirror symmetries, forming a nonlocal chiral quasi-bound state in the continuum. Through numerical simulations, a high-Q chiroptical resonance is observed at 1452 nm, with Q's exceeding 7200, when the nano-disc has a radius of 280 nm and height of 350 nm. This high-Q resonance is designed for coinciding with both signal and idler photon energies so that signal and idler emissions are strongly enhanced. Our simulations demonstrate a strong electric field enhancement (E/E0: 600), which largely boosts the reverse classical nonlinear process of sum-frequency generation. Our calculations give rise to a significantly high photon-pair generation rate of up to 106 Hz at 1452 nm using the quantum-classical correspondence, four orders of magnitude higher than Mie-type resonant AlGaAs nano-antennas. We further examine the power-dependence of photon-pair generation rate and engineer dual chiral q-BIC modes in the metasurface for realizing signal and idler emission at different resonant wavelengths. Moreover, the generation rate is tunable with the Q-factor by engineering the symmetry perturbation strength. This SAM-encoded quantum light source holds promise for advancing chiral quantum optics, quantum sensing, and communication.

11:30 AM EL07.07.05

Mie Resonators Made of Time-Varying Materials for Dynamic Control of Electromagnetic Radiation

Mohammad Mojtaba Sadafi, Achiles F. Da Mota and Hossein Mosallaei; Northeastern University, United States

Dielectric nanostructures are known to support optical resonances with high quality factors, making them ideal candidates for various advanced light-matter interaction applications. The interaction of light with dielectric particles is often described using generalized Lorenz-Mie theory, where electromagnetic fields are expanded in terms of the eigenfunctions of the vector Helmholtz equation, also known as electromagnetic multipoles. Depending on the shape, size, and refractive index of the particles, they can support different Mie resonances, including dipolar, quadrupolar, and higher-order modes. The interplay of these resonances can be engineered to enable applications such as unidirectional light scattering, nonradiating optical modes, levitating optical forces, and asymmetric imaging. Despite these remarkable achievements, traditional approaches mainly rely on tuning the geometric properties of the particles to achieve desired functionalities, which limits the design of more intricate devices requiring strong spatial dispersion effects. Recently, the emergence of materials with time-varying permittivity has introduced an additional degree of freedom in the design paradigm, which can be exploited to achieve novel functionalities. In our study, we utilize time modulation to dynamically tune the scattering characteristics of optical resonators without relying on their inherent geometrical or dispersion properties. We demonstrate that resonators with time-varying characteristics can dynamically control both spatially coherent light, like plane waves, and incoherent light sources, such as quantum dots. Specifically, we control the interaction of the excited magnetic and electric dipolar modes within a single scatterer using time modulation and demonstrate that forward or backward unidirectional scattering can be obtained by satisfying the Kerker conditions on demand. Moreover, we propose a viable pathway for controlling incoherent quantum light sources using time-modulated dielectric resonators. Our results indicate that a precisely designed set of dielectric resonators can remarkably enhance the spontaneous emission rate of a quantum emitter, while the time-variation in the permittivity can be judiciously optimized to act as a closed feedback loop and compensate for the frequency detuning in the quantum emitter radiation. Finally, we illustrate that the interplay between the excited magnetic and electric multipole moments can be controlled through time modulation to direct the far-field radiation of the quantum emitter to the desired angles. This work not only paves the way for the development of more sophisticated nanophotonic devices but also holds potential for significant advancements in fields such as quantum computing, telecommunications, and advanced imaging technologies.

11:45 AM EL07.07.06
Inverse Design of Photonic Scattering Media with Multiscale Physics-Informed Neural Networks Roberto Riganti and Luca Dal Negro; Boston University, United States

There is an ever-increasing interest in utilizing deep learning (DL) and artificial intelligence (AI) approaches for engineering electromagnetic waves in complex media and inverse design functional optical materials. Emerging methods include training generative models of artificial neural networks (ANNs) to tackle inverse problems and estimate relevant material parameters. While traditional DL techniques have been effective in solving inverse design challenges, they remain fundamentally data-driven techniques that require extensive and time-consuming training procedures based on large datasets. To enhance these purely data-driven methods, it is important to incorporate the constraints that arise from the underlying physics of the problems within the physics-informed neural network (PINN) approach that has shown remarkable successes in the solution of complex scalar and vector problems with applications to parameter estimation, inverse scattering, and metamaterials design. Recently, the multiscale physics-informed neural network (MscalePINN) framework was introduced to overcome the implicit spectral bias of deep neural networks that quickly learn the low-frequency content of training datasets with good generalization error but struggle in the presence of high-frequency data. Here, we utilize the novel MscalePINNs approach to determine the effective dielectric permittivity of finite-size arrays of scattering nanocylinders and to inverse design photonic metamaterials. MscalePINNs convert the learning and approximation of high-frequency data to that of low-frequency ones, using different sub-networks that operate on down-shifted frequency contents, thus enabling accurate and efficient solutions. In this work, we show the applications of MscalePINNs to the high-frequency homogenization and inverse design of finite-size scattering arrays of dielectric nanocylinders in different aperiodic geometries that provide isotropic optical responses and control of focal fields at desired locations. Our work provides an efficient avenue for the design of inhomogeneous scattering media with effective properties that are important to implement low-loss mode transformation and control for on-chip imaging and integrated photonics devices in the near-infrared spectral range.

SESSION EL07.08: Honoring the Memory of Professor Osgood
Session Chairs: Ho Wai (Howard) Lee, Yu-Jung Lu and Richard Osgood
Tuesday Afternoon, December 3, 2024
Sheraton, Second Floor, Back Bay D

1:30 PM *EL07.08.01
Tunable Nonreciprocal Fano Resonance Transmission Richard M. Osgood[1], Golsa Mirbagheri[2], Nop Toemtrisna[2] and Jimmy Xu[2]; [1]U.S. Army, United States; [2]Brown University, United States

Plasmonic effects in metasurfaces have generated a great deal of interest in the materials and optics community and inspired many groundbreaking studies in the last quarter century, both in basic research and in pursuit of applications such as sensing of molecules, nonlinear optics for new light sources, and optoelectronics for electrical readout of optical (visible or infrared) signals. The effect of Extraordinary Optical Transmission (EOT) through a periodic arrays of holes in the metal films was discovered in 1998 [1] and is due to excitation of surface plasmon polaritons (SPPs) by the incident electromagnetic field. Another interesting metasurface effect under study is the Fano resonance in periodically patterned metal films due to coupled plasmonic modes. This can be understood as two oscillators with different linewidths; typically a ‘background’ process and a ‘resonance’ process, the latter with a much narrower resonance spectrum. The coupling between these two oscillators creates a resonance with an asymmetric line shape, so that photon scattering is almost suppressed at lower energies while it is enhanced at higher energies, off resonance.

In this presentation, we describe our study (currently submitted for publication) of a Fano-resonant metasurface with EOT that is, interestingly, nonreciprocal; e.g., transmission in the top-to-bottom direction is higher than in the bottom-to-top direction. The metasurface consists of a gold film of variable thickness (50-300 nm) atop a 3 mm-thick Cr adhesion layer on glass with a periodic array of holes (cylinders) in the Au film (1200 nm period, square array, and 600 nm diameter), and is modeled as consisting of two plasmonic oscillators representing SPPs in the metasurface on the top and bottom surfaces of the gold. The bottom oscillator is more highly damped than the top oscillator, due to the proximity of the Cr film, which has large ohmic losses. The interesting nonreciprocity in transmission is due to the fact that the top oscillator, at the top surface of the plasmonic Au (the Au-air interface), is damped less strongly than the plasmonic oscillator at the Au-Cr interface. As a result, the evanescent field from the wave, incident on the top of the metasurface, penetrates deeper into the metasurface and transmission is higher. The Fano resonance for the top-to-bottom transmission is calculated to be at 756 nm, while the Fano resonance for the bottom-to-top transmission is calculated to be broader and have a slightly redshifted resonance wavelength due to the proximity of the Cr.
For deeper holes, the plasmon modes of the top and bottom interfaces decouple due to the finite penetration depth of the plasmonic oscillation, and reciprocity is present due to the ohmic link between two weakly coupled oscillators. For shallower holes (~ 100 nm), the top-to-bottom coupling is strong enough to render the transmission nonreciprocal.

Prof. Richard M. Osgood, Jr., who passed away unexpectedly this past fall, was a leader in optical materials, optical devices, and in plasmonics. The perspective of Osgood’s past efforts, related to this research [2], will be briefly mentioned.

[1] Nature 391 667 1998. [2] Phys. Rev. Lett. 95 137404 2005.

2:00 PM *EL07.08.02
Integrated Optics to Metasurfaces—Impact and Legacy of Professor Richard Osgood, Jr. Alan Willner; University of Southern California, United States

The ability to accurately create fine features on optical materials has been crucially important for the advancement of the fields of plasmonics, nanophotonics, and metamaterials. For nearly half a century, the late Prof. Richard Osgood, Jr., was at the forefront of semiconductor materials processing. Indeed, he was a key impactful leader within MRS and critically helped enable the growth of multiple fields.

This presentation will first describe Prof. Osgood’s early work on defining narrow features in various material platforms. Such advances led to developments in waveguiding structures and then ultimately to highly novel nanostructures and metamaterials. His impact even extended to the software tools that became significant for the design of various waveguiding and wave-emitting structures.

Subsequently, this presentation will focus on specific current-day nanophotonic metastructure examples. One highlight will be photonic-integrated-circuits (PICs) for high-capacity free-space optical communication links.

Beyond using a single data-carrying beam, the aggregate free-space data transmission rate can be enhanced by using mode-division-multiplexing (MDM). In MDM systems, multiple data-carrying beams are simultaneously transmitted through the same medium, and each beam is “located” on a different orthogonal spatial mode from a modal basis set. These beams can be multiplexed at the transmitter, spatially co-propagate, and demultiplexed at the receiver – all with little inherent crosstalk. This presentation will describe the use of orbital-angular-momentum (OAM) modes, which are a subset of Laguerre Gaussian modes.

A specific type of metamaterial for mode-multiplexing communication systems is one that can generate a desired spatial mode for a given data-carrying beam. Potentially beneficial characteristics include: (a) broadband operation to enable wavelength multiplexing on top of mode multiplexing; (b) tunability in mode emission to enable advanced switching and routing functions; and (c) emitting multiple data beams simultaneously and co-axially to enable mode multiplexing.

One example of an integrated circuit that can emit a beam on a single spatial mode is a pixel-array-based metasurface. The metasurface is fed by a waveguide that carries a data-modulated beam, and the metasurface is designed so that a specific spatial mode is emitted normal to the surface depending on the direction from which the waveguide meets the metasurface. Importantly, this metasurface has been shown to enable the above desirable characteristics of broadband operation, tunable mode emission, and co-axial mode (de)multiplexing.

This presentation will describe this broadband optical metasurface-based integrated circuit. The pixel-array-based metasurface is a spatial mode converter, which converts the mode propagating in an optical waveguide into a different free-space mode that is emitted from the surface. This metasurface is fed by multiple different optical waveguides that each carry the same data-carrying wave but with a tunable temporal phase delay between each waveguide input into the metasurface. By tuning the phase differential between the waveguides, the emitted mode can be tuned. Moreover, if there is a coupler with multiple input ports and multiple output ports feeding the waveguides, then multiple tunable modes can be emitted simultaneously from the metasurface. Results for this structure will be shown, including modal purity, channel crosstalk, bandwidth, and tunability.

3:00 PM *EL07.08.03

A Tunneling Nanoswitch Based on Mechanically-Tunable Molecular Junctions Vladimir Bulovic; Massachusetts Institute of Technology, United States

We show that monolayers of molecules can be used as active, mechanically-tunable components in nanometer-scale electromechanical switches. Using molecules as controllable-length nanosprings, our nanoelectromechanical (NEM) switches overcome the typical challenges of high actuation voltages and slow switching speeds for previous NEM technologies. Our NEM switches are hierarchically assembled using a molecular spacer layer sandwiched between atomically smooth electrodes, which defines a nanometer-scale electrode gap and can be electrostatically compressed to repeatedly modulate the tunneling current. The molecular layer and the top electrode structure serve as two degrees of design freedom with which to independently tailor static and dynamic device characteristics, enabling simultaneous low turn-on voltages (sub-3 V) and short switching delays (2 ns). This molecular platform with inherent nanoscale modularity provides a versatile strategy for engineering diverse high-performance and energy-efficient electromechanical devices.

3:30 PM EL07.08.04
Enhanced Second-Harmonic Generation in Monolayer MoS_2 Induced by Excitation of Dual Bound States in the Continuum Nicolae C. Panoiu[1], Ji Tong Wang[1] and Jian Wei You[2]; [1]University College London, United Kingdom; [2]Southeast University, China

In recent years, dielectric metasurfaces have open up new avenues in nonlinear nanooptics through their remarkable functionality of dramatically increasing the frequency conversion efficiency of nonlinear optical interactions at the nanoscale. In this contribution, we propose a nonlinear, all-dielectric metasurface consisting of a square array of cruciform-shaped silicon unit blocks covered by a monolayer MoS_2, aiming to enhance the second-harmonic generation (SHG) in the MoS_2 monolayer. By carefully designing the nonlinear metasurface so that it supports optical bound states in the continuum (BICs) at the fundamental frequency and second harmonic, we demonstrate that one can achieve nearly 600 times increase of the SHG in the MoS_2 monolayer as compared to that of the same MoS_2 monolayer suspended in air. Further understanding of the physics of the metasurface-induced enhancement of nonlinear optical interactions is achieved using an eigenmode expansion method in conjunction with an analytical approach based on optical mode expansions at both the fundamental frequency and second harmonic. These theoretical tools have been employed to investigate the main characteristics of SHG and the results show a good agreement with the results obtained *via* full-wave numerical simulations. Finally, a versatile nonlinear homogenization approach has been employed to reveal and characterize the interplay between the BICs of the optical metasurface and the efficiency of the SHG process. This research suggests a particularly promising method to enhance nonlinear optical processes in two-dimensional materials, enabling the development of future advanced photonic nanodevices with new or improved functionalities.

***In Situ* Investigations of MIM Diode Behavior in the Presence of an Electromagnet** Guinevere Strack[1], Jin Ho Kim[2], Alkim Akyurtlu[1] and Richard M. Osgood[2]; [1]University of Massachusetts Lowell, United States; [2]U.S. Army, United States

The wireless transfer of electrical energy using a directed electromagnetic beam is a process called power beaming. These free-space laser power networks transmit electrical power using aircraft or satellites as receivers and relays of optical energy. A growing interest in power beaming is motivated by an increasing number of satellites. Power beaming can be enabled via a process called rectification, which can be implemented by integrating a metal–insulator–metal (MIM) diode with a resonating metasurface. The design of the metasurface depends on the target frequency and materials properties. MIM diodes are comprised of layered materials; for example, our previous work used niobium as the base metal later and niobium oxide as the dielectric. A thin (100 nm) layer of ferromagnetic material (Co capped with Au) was incorporated as the top patterned layer. Electron transport between the Nb and Co layers can result from tunneling through the dielectric layer or thermionic emission. Electrical characterization was performed to assess device performance. Considering that *I-V* curve characteristics are dependent on dielectric layer thicknesses, barrier heights, and the work function difference between Nb and Co, fabrication of a high-quality device is essential to the repeatability of MIM diode performance. Functionality of the dielectric layer separating the two metals requires homogeneity with very low roughness and no pinholes. We found that replacing magnetron sputter deposition with atomic layer deposition provided more control over layer growth and improved quality. This has been evidenced by minimal electrical shorting and a linear dependance between pad surface area and current. Another consideration is the quality of the substrate.

Low quality wafers contain defects and surface roughness, which can contribute to shorting between metal layers. The effect of a magnetic field on the electrical characteristics was studied by placing a small permanent magnet under the MIM diode.[1] Magnetic characterization of 100 nm Co films on polyimide substrate indicated that saturation magnetization could be reach with a relatively low magnetic field (250 to 350 Oe). This preliminary result indicated that *in situ* electrical changes in the presence of a small permanent magnet were feasible. We anticipate that placing a small permanent magnet near the rectenna could be a low power strategy to control rectenna performance. Additional investigations are required to fully understand the mechanism behind the magnetically induced changes in electrical performance. For example, placing the diodes between the poles of an electromagnet requires a unique experimental test fixture. Wafers were coated in layers of Nb and Nb_2O_5, respectively, and then strip lines were patterned across the length of the wafer with a pad for electrical connection on one side. The strip lines can be placed between the poles to maximize the exposure to the magnetic field. This experimental configuration enables the study of changes in electrical characteristics in the presence of a range of magnetic field strengths. We anticipate that this knowledge could be used to maximize device control or reconfigurability.

Thermomechanical Engineering of Photonic van der Waals Nanomaterials Maxim Shcherbakov; University of California, United States

Advances in optical and optoelectronic materials define many areas of technological progress, from microelectronics and communications to sensing and metrology. Here, we will overview recent accomplishments in applying thermomechanical engineering to photonic van der Waals materials. We will show how hot pressing can induce large permanent strains in few-layer tellurium nanoflakes, making it a direct-gap semiconductor with profound blue-light photoemission. In molybdenum trioxide, phonon polaritons dispersion can be tuned by tens of percent through oxygen deprivation, as directly measured using photon-induced force microscopy. Controllable thermomechanical modification of photonic nanomaterials is a powerful technique to expand the zoo of materials for on-chip optoelectronics.

4:30 PM *EL07.09.02
Dynamic Thermal Emission Steering with Active Metasurfaces Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Active control over various properties of thermal emission can be accomplished through elaborate engineering of optical states without altering the temperature of the object. This presentation introduces our study on the dynamic steering of thermal emission using a graphene-based metasurface device. We employ a laterally delocalized Fabry-Perot mode, whose phase condition can be actively tuned by adjusting the graphene's carrier density via electrostatic gating. We experimentally demonstrate that the device can steer thermal emission across a 16-degree range at a wavelength of 6.61 microns, while maintaining high emissivity.

5:00 PM EL07.09.03

Enhancing Spin Photocurrent in Scalable Monolayer MoS_2 Plasmonic Phototransistors Using Chiral Metasurfaces Shyr-Shyan Yeh[1,2], Chen-Yu Wang[1,2], Tzu-Yu Peng[1,2], Jia-Wern Chen[1,2], Kai Qi[3], Jui-Han Fu[3], Vincent Tung[3] and Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]The University of Tokyo, Japan

The broken inversion symmetry and valley-selection rule due to the different spin orientations within the split valence band of each K(K') valleys in monolayer MoS_2 (1L-MoS_2) justifies their potential applications for spintronic devices, valley-sensitive optoelectronic devices and quantum-based information processing. However, the ability to distinguish the degree of freedom between left/right circularly polarized (L/RCP) spin photocurrent is still a challenge due to the low photoresponsivity and lack of polarization sensitivity in 1L-MoS_2 at room temperature conditions. To counter these concerns, we propose a spin photocurrent sensitive plasmonic phototransistors with wafer-scaled 1L-MoS_2 integrated with gold chiral metasurfaces upon a hafnium nitride substrate. The geometry and handedness of the chiral metasurfaces were designed *via* finite-difference time-domain (FDTD) methods and the calculated absorption spectra signified that the left/right handed orientation of the gold chiral plasmonic metasurfaces dictates the selective absorption enhancement of L/RCP light (or vice versa) upon the 1L-MoS_2 surface. An additional plasmonic hafnium nitride material (deposited via RF-magnetron sputtering at 800°C) was introduced as a gate electrode with excellent metallic properties and strong local surface plasmon resonance attributes within the visible spectrum [1,2]. The inclusion of hafnium nitride plays a crucial role in amplifying the light-matter interaction upon the 1L-MoS_2 layer, where a 4-fold enhancement factor was observed from the photocurrent measurements (in comparison to pristine p^+-Si substrate). Spin photocurrent measurements at different wavelengths showed up to 30.02% change at 660 nm (on-resonance with MoS_2) and less than 10% change at 450 nm and 550 nm (off-resonance). Overall, these promising results reveal a clear distinguishable approach to manipulate and tailor the L/RCP spin photocurrent at room temperature conditions. Ultimately, we will discuss the potential applications of ultrathin plasmonic phototransistors with high spin-selective photoresponse.

5:15 PM EL07.09.04

Enabling High-Throughput Screening of Materials for Chiral-Induced Spin Selectivity (CISS) with 2D Material-Optical Metasurface Heterostructures Priyanuj Bordoloi[1], Feng Pan[1], Remi S. Dado[1], Jefferson Dixon[2], Sajjad Abdollahramezani[1], Punnag Padhy[1], Sahil Dagli[1] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Johns Hopkins University, United States

Chiral-induced spin selectivity (CISS) describes the preferential scattering of spin-polarized electrons through chiral media. CISS has brought a new approach to control spin transport and enable spin-selective chemical reactions. In particular, CISS removes the need for chiral catalysts to generate enantiomeric excess in chiral chemistry. However, spin-polarized currents are difficult to detect, and existing methods (e.g magnetic conducting atomic force microscopy) are not yet adequately high-throughput to efficiently screen CISS materials. Two-dimensional transition metal dichalcogenides (TMDC) present an exciting method for the optical readout of spin-polarized current. TMDC's unique valley degree of freedom couples the optical spin of emitted photons (i.e., circular polarization) to the valley pseudo-spin (i.e. electron spin) of the K' and K valleys in the Brillouin zone, presenting a bridge between the types of angular momentum of these quantum particles. This allows quantification of spin-polarization through the emitted photons' degree of circular polarization (DOP). However, valley coupling degrades severely at higher temperatures due to strong intervalley scattering, traditionally precluding TMDC's use in investigating spin-polarized electronic transport for CISS-enabled synthesis.

Here, we present a nanophotonic approach to enhance and control the emission properties of TMDCs at elevated temperatures using high-quality-factor (high-Q) spin metasurfaces. An integrated TMDC-metasurface system is tested to read the spin-polarization of the electrons through the enhanced DOP signals at from 4 K to room temperature from various CISS-supporting materials from ferromagnetic films (Co/Pt/Ni oxides, HfO2). Our metasurfaces consist of dielectric nanodisks arranged in a biperiodic lattice and support quasi-bound states in the continuum (q-BIC) resonances upon circularly polarized illumination. More importantly, these q-BIC resonances enhance the spin dissymmetry factor instead of Kuhn's dissymmetry factor. More specficially, our previous work utilizes metasurfaces that maximize the density of incident circularly polarized light (optical chirality) in the chiral basis to enhance TMDC photoemission, our current work uses the spin basis, allows more efficient coupling to the TMDCs, enhancing the spin-selectivity of the optical transition rate of K and K' valleys, and thereby minimizing the spin dephasing of metasurface-coupled TMDCs that dominate at elevated temperatures. These resonances can have Q-factors >1000, allowing large electric field confinement and contributing to valley-selective Purcell enhancement of the TMDCs. We use silicon nitride (SiN, n ~ 2) as our metasurface material because of its high refractive index and low ohmic loss properties around the excitation wavelength (760 nm) of A-exciton for a monolayer of molybdenum diselenide ($MoSe_2$). Our nanodisks have radii of ~ 150 nm and height ~ 200 nm, allowing large optical spin density on top of the metasurface. We then fabricate these SiN nanodisks on a quartz substrate (n ~ 1.45), providing a large permittivity contrast for better electric field confinement near the TMDC. An integrated TMDC-metasurface system is tested to readout the spin-polarization of the electrons through the enhanced DOP signals from 4 K to room temperature from various CISS-supporting materials from ferromagnetic films (Co/Pt/Ni oxides, HfO_2). Moreover, these experiments are repeated in various organic media (acetone, 2-propanol and toluene) to demonstrate the viability of using this platform in these environments for future work for measuring spin-polarized currents from CISS-enabled chiral molecules and macromolecules, such as α-helical oligopeptides, DNA, and helicenes. These experiments allow us to compare and standardize spin polarization measurements en-route to improved CISS-based molecular synthesis.

5:30 PM EL07.09.05
Strong Optical Chirality Leveraged by Vertically-Aligned 3D Helical Graphene Metasurfaces Zihao Lin, Carol Mikhael, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota Twin Cities, United States

Optical chirality in Terahertz (THz) range remains a large blank page due to materials limitations and their plasmon resonant frequency range. Graphene offers a promising avenue to address this challenge because its plasmon resonant frequency resides in THz range and can be well tunable. In this work, we developed a novel 3D graphene metasurface (vertically-aligned helical graphene). A thin layer photoresist, acting as an actuator, together with graphene, are both self-twisted and curved upward to 3D vertically-aligned direction simultaneously using a self-assembly approach. The chiral properties of the 3D graphene helix were carefully evaluated with simulation. In detail, the resonant frequency of the graphene helix in THz range can be well adjustable from 25 THz to less than 1 THz by changing the size. For a same size and handed helix, under the illumination of different polarized light, the chiral response demonstrates differently, as indicated by the circular dichroism (CD) and g-Factor, an absolute value from the different absorption of the light and a normalization value of CD, respectively. Moreover, the angle of the helix compared with the light versus the CD property are also carefully studied, with CD value of 0.003 and 0.07, and g-Factor of 0.12 and 1.4 when the helix lies down and perpendicular to the substrate, respectively. The simulation results verify and argument our hypothesis that extended the coupling distance between the helix and the light results in larger CD property, meaning a higher degree of optical chirality. This newly developed graphene metasurface and evaluated chirality property can be further used as a THz biosensor for medicine and chemical molecular detection.

5:45 PM EL07.09.06

Direct Patterning of Chiral Plasmonic Surfaces Using Circularly Polarized Light Ji-Young Kim[1], Connor McGlothin[2], Minjeong Cha[2], Zechariah Pfaffenberger[2], Emine Turali-Emre[2], Wonjin Choi[2], Julie Biteen[2] and Nicholas A. Kotov[2]; [1]Rensselaer Polytechnic Institute, United States; [2]University of Michigan–Ann Arbor, United States

Chiral plasmonic surfaces, which exhibit substantial optical rotation, play a crucial role in various scientific fields. However, their compatibility with diverse substrates is currently limited by complex and multi-step nanofabrication processes. More importantly, achieving diverse local chiroptical patterns on the same substrate while ensuring scalability remains unattainable using conventional synthesis methods. In this study, we present a breakthrough in substrate-tolerant direct-write patterning, demonstrating the fabrication of silver nanohelicoids with locally variable optical activity using circularly polarized light (CPL). Centimeter-scale chiral plasmonic surfaces can be produced within minutes using inexpensive medium-power lasers. The growth of nanohelicoids is governed by symmetry-broken site-selective deposition and self-assembly of silver nanoparticles (NPs). The ellipticity and wavelength of incident photons serve as parameters to dynamically control the handedness and size of the printed silver nanohelicoids, allowing on-the-fly modulation of nanohelicoid chirality during direct writing. This process offers straightforward pathways to create complex multifunctional metasurfaces with high polarization rotation and fine spatial resolution. Our computer-driven direct-write system extends its capabilities by printing local patterns with various optical activities over distances spanning four orders of magnitude. Importantly, direct-write printing by CPL involves no organic ligand materials, promising in chiroptical diagnostics by enhancing sensitivity to the dielectric environment and eliminating the charge transport dilemma of solution-processed nanomaterials. We conducted spectroscopic detection of chiral analytes based on the CD peak wavelength shift of the printed chiral silver pattern. CD spectra of the pattern exposed to pepsin gradually red-shift with increasing concentration, demonstrating a limit of detection below 100 pM. Enantiomer selectivity is also confirmed through different absolute wavelength shifts observed upon the absorption of L- and D-lysine. Processing simplicity, high polarization rotation, and fine spatial resolution of the light-driven printing of stand-up helicoids provide a rapid pathway to chiral plasmonic surfaces, accelerating the development of chiral photonics for health and information technologies.

Nanophotonic Metasurfaces to Enhance the External Radiative Efficiency of Organic Solar Cells Jinyu Chong and Deirdre O'Carroll; Rutgers, The State University of New Jersey, United States

Lightweight, low-cost organic photovoltaics (OPVs) are considered one of the next generations of solar cells. Metasurfaces possesses distinct advantages of ultrathin thickness and wide wavelength-response, which make them suitable for applications in OPVs to improve light harvesting and power conversion efficiency (PCE). Plasmonic metasurfaces, in particular, can interact in three ways with the OPV active layer to improve light-matter interactions: increased light scattering and surface plasmon polaritons can couple more incident sunlight into the plane of the active layer. Additionally, localized surface plasmon resonances can be used to improve light absorption cross-section (when resonant with active layer absorption) or create a Purcell effect (when resonant with active layer emission) that alters exciton decay rate (radiative and non-radiative). The latter is less well studied and the aim of this work is to understand the impact of plasmonic metasurfaces on engineering radiative decay in OPVs and the effect on external radiative efficiency (ERE) of OPVs.

ERE quantifies the radiative loss in a solar cell and is also related to the performance of the solar cell. The theoretical Shockley-Queisser limit assumes an ERE of 100%; however, in practice, ERE values are much lower than this upper limit. In the realm of high-efficiency solar cells, such as GaAs and silicon solar cells, the recorded ERE increases with improved PCE. For example, the highest reported ERE values are 1.6% for silicon solar cells and 35.7% for GaAs solar cells. However, the reported ERE values for OPVs are still very low ($<10^{-3}\%$). We hypothesize that improving the radiative efficiency inside the organic semiconductor active layer in OPVs, using plasmonic metasurfaces for example, improves the PCE of OPVs closer to the theoretical limit predicted by Shockley-Queisser.

The photoluminescence of OPV active layers (typically bulk-heterojunctions (BHJs)) is rarely studied due to its extremely weak signal intensity, and its signal is challenging to decouple from background noise and weak substrate fluorescence. In this work, we carry out a systematic study with various substrates, like quartz, planar silver, and hemispherical silver nanoparticle metasurfaces with ~75 nm diameter and ~155 nm diameter nanoparticles. For devices, the nanoparticle metasurfaces are incorporated between the transparent electrode and the BHJ active layer. OPV BHJ materials poly[(2,6-(4,8-bis(5-(2-ethylhexyl)thiophen-2-yl)-benzo[1,2-b:4,5-b']dithiophene))-alt-(5,5-(1',3'-di-2-thienyl-5',7'-bis(2-ethylhexyl)benzo[1',2'-c:4',5'-c']dithiophene-4,8-dione)] (PBDB-T) and 3,9-bis(2-methylene-(3-(1,1-dicyanomethylene)-indanone))-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[2,3-d:2',3'-d']-s-indaceno[1,2-b:5,6-b']dithiophene (ITIC) are selected to form the BHJ OPV active layer. Our preliminary results show improved photoluminescence quantum yield (PLQY) from the BHJ active layer on certain substrates. By optimizing the size and distribution of the metasurface, the BHJ shows different extents of PLQY enhancement. The PLQY data shows 18.4% for the BHJ on metasurfaces with average silver nanoparticle diameter of 155 nm, 23.3% for the BHJ on metasurfaces with smaller nanoparticles (~75 nm), and 13.7% for the BHJ on a planar silver. The metasurfaces with 75 nm diameter silver nanoparticles show the highest improved PLQY, attributed primarily to the Purcell effect. For larger silver nanoparticles (diameter of ~155 nm), the PLQY enhancement is partially suppressed mainly due to excessive metal-induced quenching of excited excitons and a weak Purcell Effect. We have demonstrated the capability to modify the radiative efficiency of organic semiconductors OPV active layers with silver nanoparticle metasurfaces. The performance of PBDB-T/ITIC OPV devices is also studied in both conventional and inverted device structures to verify the relationship of PCE to ERE with and without the plasmonic metasurfaces.

EL07.10.02

Control of Electrochromic Film Growth with Plasmonics Ashleigh K. Wilson, Asia Jones and Natalia Noginova; Norfolk State University, United States

Cyclic voltammetry measurements reveal significant changes in the electrochemical reaction kinetics under light illumination in both flat gold and nanostructured gold systems. When photoexcited, the electron transfer rate increases up to three-fold. This study is to explore further the extent of that impact on electrochemical growth of electrochromic polymer polyaniline (PANI) films. In the experiment, PANI thin films are deposited onto flat gold substrates using cyclic voltammetry method under illumination of the laser light (with the wavelength of 632 nm and 114 mW) focused on the center of the working electrode. Using various patterning methods including masks and interference patterns, we show that the film grows thicker at the exposed sites. This allows one to obtain patterned and profile modulated plasmonic structures with the electrochromic polymer films, which can then be utilized as electrically tunable meta-surfaces and plasmonic systems.

EL07.10.03

Enhancing Solar-Driven CO_2 Reduction Reactions Using Broadband Plasmonic Absorbers Thai H. Nguyen[1], Tzu-Yu Peng[1,2], Chen-Yu Wang[1,2], Jia-Wern Chen[1], Jeyavelan Muthu[2,3], Hsin-Hui Lin[4], Mario Hofmann[2], Wen-Hui (Sophia) Cheng[4] and Yu-Jung Lu[1]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]Institute of Atomic and Molecular Science, Academia Sinica, Taiwan; [4]National Cheng Kung University, Taiwan

Photosynthesis is an eco-friendly process that converts sunlight energy into chemical energy, creating fuels and essential intermediates. Drawing inspiration from nature, nanostructured photocatalysis has become a prominent method for photochemical CO_2 reduction reaction (CO_2RR), utilizing chemically modified nanoparticles and nanolithography techniques. Despite its potential, challenges such as reproducibility, high costs, and complexity hinder its broader application. In this work, we introduce a lithography-free plasmonic perfect absorber. This innovative approach features a sandwich structure with a variable-thickness TiO_2 gap layer (ranging from 0 to 15 nm) placed between gold nanoparticles (AuNPs) and Titanium Nitride (TiN). This structure is fabricated using mask-assisted e-beam evaporation, presenting a simpler, more cost-efficient alternative suitable for large-scale production. It exhibits dual-peak absorption, achieving 90% at wavelengths centered between 497-529 nm for the short wavelength peak and 628-644 nm for the long wavelength peak. The total absorption band spans an impressive 80% across 400-750 nm. FDTD calculations reveal a strong electromagnetic field within the TiO_2 layer, which enhances exciton generation. The gap plasmon resonance significantly boosts the photocatalytic efficiency for solar-driven CO_2RR,
reaching rates as high as ~2000 μmol/g*h—six times higher than previous benchmarks. This structure not only facilitates scalable and reproducible photocatalysis but also paves the way for innovative fabrication techniques. We will also discuss the detailed working mechanism of this approach.

EL07.10.04

Cu(II)-Mediative Oxidative Etching of Ag Nanostructures to Synthesize Monodispersed Ag Nanospheres for Uniform Plasmonic Cavities with InP/ZnSe/ZnS Quantum Dots Yoonhee Kim and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

Ag nanoparticles have garnered significant attention for their excellent plasmonic properties and potential use as plasmonic cavities, primarily because of their intrinsically low ohmic losses and optical properties in the visible range. These are particularly crucial in systems involving quantum dots that absorb light at low wavelengths, where the need for a high threshold energy of interband transitions necessitates the incorporation of Ag nanostructures. However, the synthesis of Ag nanoparticles still encounters challenges in achieving structural uniformity and monodispersity, along with chemical stability, consequentially inducing inconsistent and poorly reliable optical responses. Here, we present a two-step approach for synthesizing highly uniform spherical Ag nanoparticles involving depletion-induced flocculation and Cu(II)-mediated oxidative etching. We found that the selective flocculation of multitwinned Ag nanocrystals significantly enhances the uniformity of the resulting Ag nanostructures, leaving behind only single-crystalline and single-twinned nanostructures. Subsequent oxidative etching, in which cupric ions are directly involved in the reaction, was designed based on Pourbaix diagrams to proceed following thermodynamically favourable states and circumvent the generation of reactive chemical species such as H_2O_2. This leads to perfectly spherical shapes of final Ag nanoparticles with a synthetic yield of 99.5% and additionally reduces the overall reaction time. Furthermore, we explore the potential applications of these monodisperse Ag nanospheres as uniform plasmonic cavities. The fabricated Ag nanosphere films uniformly enhanced the photoluminescence of InP/ZnSe/ZnS quantum dots (QDs), showcasing their capabilities in exhibiting consistent plasmonic responses across a large area.

Particularly, less toxic InP/ZnSe/ZnS QDs have been successfully commercialised in display devices, although their low absorption characteristics still limit external quantum efficiency, which can be addressed by photonic cavities often used alongside plasmonic materials. Hence, we additionally developed a novel conjugation chemistry based on silanol-alcohol condensation reaction to construct uniform and consistent plasmonic cavities that stably create identical photonic environments to QDs. The QDs incorporated with such plasmonic cavities, Ag nanospheres, showed an unexpectedly high enhancement in photoluminescence. This was primarily attributed to increased internal quantum yields facilitated by the Purcell effect, which accelerates radiative decay rates. In this presentation, the optical interactions between the plasmonic cavity and QDs will be deeply analysed. These findings suggest that plasmonic cavities can significantly improve the performance and broaden the application scope of QD-based technologies, including display devices and other optoelectronic applications.

Am. Chem. Soc.* **2024**, *146*, 10591–10598.

EL07.10.05

Suppression of Radiative Heat Transfer Between Two Metasurfaces Mingze He[1], Lin Jing[1], Sander Mann[1], Timothy Palinski[2], Gregory Holdman[2], Kevin Plocher[2] and Andrea Alu[1]; [1]The City University of New York, United States; [2]Honeywell, United States

Heat can transfer between two objects through conduction, convection, and radiation. In many applications, efficient heat transfer is desirable, such as in the cooling systems for electronics, to ensure reliable operations. Conversely, it is imperative to suppress heat transfer in certain applications. While thermal conduction and convection can be easily controlled, the ubiquity of thermal radiation from materials at finite temperature poses challenges to engineering solutions aimed at suppressing radiative transfer. For instance, for a superconducting material working at ~2 K, its intrinsic radiation is minimal and any radiative heat transfer would have a significant impact, which is undesirable. For the suppression of radiative heat transfer, the most common approach is to coat a metal layer to reduce emissivity, thereby reducing heat exchange. Yet, adding another metal layer may interfere with the designed electronic functionalities. Alternatively, distributed Bragg reflectors (DBRs) and other photonic structures using dielectric materials have been employed to reduce emissivity compared to bulk systems. However, such designs are mostly limited to a narrow frequency range, as any photonic resonance that restrains emission at one frequency inevitably enables the emission in other frequencies. Therefore, it is beneficial to develop a system that could alleviate these bandwidth restrictions and effectively suppress the radiative heat transfer across a wide frequency range. However, there are fundamental constraints on the bandwidth of passive DBRs which prevent such functionality.
Here, we demonstrate optimal DBR design pairs that suppress heat transfer between two finite-sized planes over broad bandwidths. Rather than aiming at maximizing the continuous bandwidth of high reflectivity for each DBR, we achieve this feat by mis-aligning the peaks and dips of the DBR pair, making it mutually incompatible for heat transfer. Notably, we co-optimize the two-DBR response using an end-to-end inverse design algorithm. We

experimentally validate the effectiveness of the design by measuring angular-resolved emissivity and calculating the radiative heat transfer between the two slabs. Moreover, we extend the theory to near-field heat transfer in this scenario, and investigate the fundamental limit of this approach. In summary, our co-optimized metasurfaces effectively suppress radiative heat transfer over broad bandwidths, demonstrating their potential in thermal management across various applications, including cryogenic radiative insulation, energy harvesting, and cooling technologies.

EL07.10.06

Advancing Nanoscale Characterization with s-SNOM and Nano-FTIR for Plasmonics, Nanophotonics and Metasurfaces Artem Danilov, Tobias Gokus and Andreas Huber; Attocube Systems AG, United States

Employment of scattering-type scanning near-field optical microscopy (s-SNOM) and nanoscale Fourier transform infrared spectroscopy (nano-FTIR) provides significant benefits for the study of plasmonics, nanophotonics, and metasurfaces. These advanced optical methods enable high-resolution imaging and precise characterization at the nanoscale, crucial for various applications.
s-SNOM excels in mapping plasmonic fields with high spatial resolution, essential for developing highly sensitive biochemical sensors and improving photonic device designs. It allows researchers to visualize optical near-field distributions in plasmonic and photonic structures, which is critical for optimizing high-performance sensors, enhancing photodetectors, and increasing the efficiency of energy harvesting devices.
nano-FTIR offers unparalleled sensitivity for investigating the local absorption properties and chemical compositions of nanoscale photonic materials. This capability is particularly beneficial for studying carrier dynamics and energy transfer processes in plasmonic nanostructures, leading to more efficient solar cells and photodetectors. nano-FTIR also facilitates the examination of molecular interactions and chemical compositions, which is essential for the development of advanced energy harvesting and sensing technologies.
Together, s-SNOM and nano-FTIR provide detailed insights into the optical, electronic, and chemical properties of nanophotonic and plasmonic materials. These techniques enable the exploration of ultrafast dynamics in plasmonic nanosystems, providing crucial information on light-matter interactions at femtosecond timescales, important for developing next-generation ultrafast photonic devices. Additionally, they support the study of vibrational and electronic properties of 2D materials and metamaterials, aiding in the advancement of quantum photonic applications.
By offering high-resolution, nanoscale imaging and spectroscopy, s-SNOM and nano-FTIR drive innovation and enhance our understanding of plasmonic, nanophotonic, and metasurface materials and devices, enabling new applications across scientific and technological fields.

In this talk, I will explain the basics of the technology and highlight some recent examples of appications in fields of plasmonics, photonics and metasurfaces.

EL07.10.07

Photothermal Reflectance Spectroscopy for Precise Measurement of Single Nanoparticle Absorption Spectra Ki Soo Chang; Korea Basic Science Institute, Korea (the Republic of)

Single nanoparticle spectroscopy is essential in biology, medicine, and materials science. In biomedicine, it is particularly valuable for photothermal therapy, where metal nanoparticles generate heat under laser illumination to induce cancer cell necrosis. Effective photothermal therapy requires sufficient laser intensity to destroy cancer cells while minimizing damage to healthy cells. Thus, accurately identifying the surface plasmon resonance peaks of nanoparticles with varying sizes and shapes is crucial for optimizing heat generation with low laser intensity.
For nanoparticles smaller than 40 nm, optical absorption by the excitation source dominates over scattering,

causing localized temperature changes and refractive index variations in the surrounding medium. Photothermal microscopy, which monitors these refractive index changes, is a key tool for single nanoparticle absorption spectroscopy. However, existing photothermal microscopy methods depend heavily on precise optical alignment and are time-consuming due to single-point illumination and sample scanning.

To overcome these limitations, we developed a new photothermal spectroscopy method that combines a tunable continuous-wave pump laser with a wide-field photothermal reflectance microscope. This system simplifies the setup, reduces optical alignment dependence, and enables the simultaneous detection of multiple nanoparticles. We used dark-field microscopy to identify nanoparticles before photothermal imaging, achieving high sensitivity with a simple four-bucket method. Embedding gold nanorods (GNRs) in a PDMS layer improved the signal-to-noise ratio (SNR) by confining heat locally.

We confirmed the wavelength-dependent sensitivity of our method by observing photothermal reflectance signals of GNRs at various pump beam wavelengths. The absorption spectra of individual GNRs had narrower full-width at half-maximum (FWHM) compared to ensemble measurements, indicating precise measurement capability. The absorption peak positions varied with the refractive index of the surrounding medium and the aspect ratio of the GNRs, consistent with theoretical predictions.

This photothermal reflectance spectroscopy system offers a quick and straightforward way to measure the absorption spectra of multiple individual nanoparticles, providing precision comparable to conventional spectrophotometry without requiring precise optical alignment.

Additionally, we are conducting research to introduce a photothermal transmittance imaging method aimed at further enhancing the signal-to-noise ratio of photothermal spectra, and we would like to present the results of this research as well.

EL07.10.08

Multiple Rabi Splitting in Terahertz Nano-Slots Integrated with Organic-Inorganic Hybrid Perovskites Sujin Song and Jeeyoon Jeong; Kangwon National University, Korea (the Republic of)

In a strongly coupled light-matter hybrid system, increasing the coupling strength, thereby increasing the Rabi splitting, have profound impact on various nonlinear optical processes and quantum information processing applications. Among many photonic cavity structures, terahertz nano-slot antennas are found to be effective in squeezing the mode volume and increasing the coupling strength, thereby achieving Rabi splitting of record-high $0.48w_0$ in an optical phonon mode of an organic-inorganic hybrid perovskite $MAPbI_3$ at 1 THz. In this study, we find that the nano-slots strongly coupled to the 1 THz phonon also strongly couples with another phonon at 1.85 THz, creating a unique one-light-two-matter polaritonic system with multiple Rabi splitting. Such peculiar phenomenon arises due to an interplay between (1) strong dispersion of $MAPbI_3$ and (2) dependence of resonance frequency of the nano-slots to the background permittivity of the gap-filling $MAPbI_3$. Our findings may enable more efficient and complex nonlinear or quantum optical processes in strongly coupled system, such as spontaneous parametric downconversion and quantum gating, etc..

Ultrathin Nonreciprocal Thermal Absorbers Enabled by Anomalous Hall Effect and Fizeau Drag in Dirac and Weyl Semimetals Hannah Gold, Morgan Blevins, Simo Pajovic, Abhishek Mukherjee and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

Fundamental limits of thermal radiation are imposed by Kirchhoff's law, which assumes the electromagnetic reciprocity of a material or material system. Thus, breaking reciprocity can enable breaking barriers in thermal efficiency engineering[1]. We present 1D photonic crystals composed of Weyl and Dirac semimetal and dielectric layers, whose structures are optimized to maximize the nonreciprocity of infrared radiation absorptance and emittance in planar and compact designs. Two different mechanisms to enable nonreciprocal infrared absorbers are simulated and compared – the anomalous Hall effect in Weyl semimetals[2] and electric-current-induced Fizeau drag in either Dirac or Weyl semimetals[3]. To engineer an ultra-compact absorber structure that does not require gratings or prisms to couple light, we used a genetic algorithm (GA) to maximize nonreciprocity in the design globally, followed by the application of the numerical gradient ascent (GAGA) algorithm as a local optimization to further enhance the design[4]. The first absorber design takes advantage of the intrinsic nonreciprocity of time-reversal symmetry (TRS) breaking Weyl semimetals due to their pseudomagnetic field in momentum space. We then apply the GAGA methodology to design and optimize a flat absorber using inversion (I)-symmetry breaking Weyl and Dirac semimetals as active layers, in which tunable nonreciprocity is induced through an applied DC current bias. This momentum bias imparts plasmon Fizeau drag, the drag of an electrical current on propagating surface plasmon polaritons (SPPs). We use a semi-classical theory recently developed in our lab to model SPP transport along interfaces of 3D semimetals under Fizeau drag[3]. Lastly, in both designs the optimization algorithm accounts for both s- and p-polarized absorptance spectra in the mid- to far-IR to create a final design suitable for thermal applications, which maximizes the nonreciprocal absorptance of p-polarized light and simultaneously minimizes the parasitic, reciprocal absorptance of s-polarized light.

Development of the Plasmon-Driven Synthesis of Copper Nanoparticles Benjamin J. Adams and Joseph DuChene; University of Massachusetts Amherst, United States

Plasmonic nanoparticles are an attractive material for photocatalysis due to their unique optical and catalytic properties. Light-driven synthesis for silver and gold nanoparticles has emerged as a promising alternative to traditional synthetic approaches due to the environmentally friendly process and precise size and shape control. However, the controlled light-driven synthesis of copper nanoparticles remains a challenge due to constraints such as oxidation, pH, temperature, and stability. Our approach aims to explore the limitations of the copper system through the light-driven growth of copper nanoparticles. Oxidation challenges are combated with inert handling on a Schlenk line while UV-Vis, ICP-MS, and TEM are utilized to monitor the reaction progress. We show that this process is plasmon-driven as reaction rate is dependent on both photon power and wavelength. Future work will focus on exploring the shape control of this plasmon-driven synthesis of copper nanoparticles. Ultimately, we anticipate this plasmon-driven synthesis will enable a greater understanding of the fundamental limits of hot-carriers in photocatalysis.

EL07.10.11

Analytical Prediction of Plasmon-Induced Hot Carriers in Clustered Nanoparticles Pablo M. Uribe-Pizarro[1], Alan McGaughey[2] and Francisco V. Ramirez-Cuevas[1]; [1]Adolfo Ibañez University, Chile; [2]Carnegie Mellon University, United States

Plasmon-induced photochemistry is an emerging field that utilizes surface plasmons to activate and control chemical reactions at the nanoscale, presenting significant potential for enhancing photochemical efficiency and developing advanced photocatalytic and photoactive materials. Despite extensive experimental and theoretical studies, the fundamental physics underlying the interaction of plasmonic particles in photochemical processes remains elusive. In this study, we employ an analytical model based on plasmons hybridization to accurately predict electronic transitions in clustered metal nanoparticles. Our model provides a detailed understanding of how the spatial distribution of the electric field influences the energy transitions of hot carriers, surpassing traditional models that focus solely on electric field intensity. Due to its computational efficiency, our model facilitates the exploration of various configurations, aiming to establish design rules that optimize throughput for specific application. These insights significantly advance our comprehension of nanoparticle interactions and their impact on photochemical reactivity, solar energy harvesting and photodetection.

EL07.10.12

Angle-Resolved Polarimetry in Plasmonic Metamaterials via Charged Aerosol-Based Additive Manufacturing

Younghwan Yang[1], Wooik Jung[2], Changnyeong Hur[3], Hongyoon Kim[1], Jooyeon Shin[3], Junsuk Rho[1] and Mansoo Choi[3]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Hanbat National University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

The integration of localized surface plasmon resonance (LSPR) and quasi-bound states in the continuum (q-BIC) within a single plasmonic structure offers a promising avenue for advanced optical applications. In this study, we present a novel approach to fabricating three-dimensional (3D) plasmonic metamaterials that exhibit dual optical resonances using a π-shaped plasmonic structure. Our 3D plasmonic metamaterials are characterized by their ability to support both LSPR and q-BIC modes within the near-infrared (NIR) region. The dual optical modes are distinctly responsive to different polarizations of incident light: x-polarization-sensitive LSPR and transverse magnetic (TM) mode-sensitive q-BIC. This unique optical behavior enables simultaneous polarization detection and incident angle analysis, which we demonstrate by measuring our π-shaped structures using a commercial Fourier-transform infrared spectroscopy (FTIR) system. The experimental results confirm the high performance of our 3D plasmonic metamaterials in polarization and incident angle sensing. The LSPR mode is observed under x-polarized light, while the q-BIC mode is prominent under TM-mode illumination. These optical modes are highly sensitive to the angle of incident light and polarization, making them suitable for applications in optical alignment and imaging systems.

In terms of a manufacturing process, the π-shaped plasmonic structures are produced through a charged aerosol-based additive manufacturing technique that manipulates local electrostatic fields to control the deposition of charged metallic nanoaerosols. This technique allows for the direct printing of metallic nanostructures under ambient conditions without the need for postprocessing, such as metal coating steps, thereby preserving the functionality of the complex 3D geometries.

The successful fabrication and characterization of these π-shaped plasmonic structures highlight the potential of 3D aerosol nanoprinting in advancing the field of plasmonic metamaterials. This technique opens new possibilities for creating multifunctional materials with tailored optical properties, suitable for applications ranging from biosensing and imaging to advanced photonic devices. Our study demonstrates a significant step forward in the field of additive manufacturing, providing a versatile and efficient method for producing complex 3D plasmonic structures with enhanced optical functionalities.

EL07.10.13

Modeling Cutting-Edge Organic Hyperbolic Metamaterial for Super-Resolution Imaging via First-Principles Study

Suim Lim[1,2], Dong Hee Park[3], Bin Chan Joo[3], Yeon Ui Lee[3] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Sogang University, Korea (the Republic of); [3]Chungbuk National University, Korea (the Republic of)

Hyperbolic materials have attracted significant attention due to their unique optical properties including negative refraction[1], nanoscale light focusing, amplified scattering[2]. These properties enable super-resolution imaging, making hyperbolic materials highly valuable in advanced optical applications. Conventional hyperbolic metamaterials are composed of alternating metal-dielectric stacks, limiting their properties due to constraints in reducing the interlayer spacing. In contrast, recently discovered organic hyperbolic metamaterials (OHMs) overcome the limitation and exhibit excellent hyperbolic properties.[3] Moreover, OHMs show high biocompatibility and flexibility, making them promising candidates for various optoelectronic device applications. In this study, we propose for the first time that self-assembled polymeric films consisting of donor-acceptor (D-A) conjugated polymers can facilitate low-loss multi-band hyperbolic dispersion (HD) through first-principles calculations. We explore various copolymers composed of thiophene (D) and benzothiadiazole (A) units by determining their most stable molecular crystalline structures and calculating their frequency-dependent dielectric functions to evaluate their HD performance. Additionally, we investigate electronic structures, including band structures and partial density of states, to understand the influence of bridge or spacer unit incorporation on HD properties. As a result, we discover the multi-band HDs from candidate OHMs with a new record in theoretical figure-of-merit and find that tuning the building units of polymers or adjusting the film condition can change the wavelength range exhibiting HD. The potentials of candidate OHMs are also confirmed from the calculated volumetric confinement and propagation of high-k hyperbolic polaritons using finite-difference time-domain (FDTD) simulation. Consequently, this study provides novel insights into the molecular-scale design of low-loss OHMs for the target wavelength range.

EL07.10.14
Vertical and Deep Micro- and Nanofabrication Technique of SiO$_2$ Using HF Gas and Catalyst Yoshitaka Ono, Ko-hei Sano, Akira Ueno and Yasuo Hayashi; AGC Inc., Japan

Here, we report a new SiO$_2$ micro- and nanofabrication technique, advanced gas-phase chemical reaction for anisotropic catalyst etching (AGC-ACE) using a catalyst and HF gas. SiO$_2$ is used in optical components such as metalens owing to its high chemical durability and transparency. Reactive ion etching (RIE) is a typical SiO$_2$ nanofabrication technique used to fabricate optical components. Because SiO$_2$ has a lower selectivity ratio with the mask than Si, RIE has the drawbacks of tapered etching shapes and difficulty in deep etching. The taper etching has caused the silica glass metalens to deviate from the optical design. In addition, a phase difference of 2π has not been achieved because the height of the meta-atom cannot be increased (*Nano Lett.* 2019, **19**, 8673-8682). Therefore, if a vertical and deep nanofabrication technique for SiO$_2$ is realized, it will be possible to fabrication of optical components made of SiO$_2$ with higher performance.
Although the etching rate of SiO$_2$ with HF is very low in an anhydrous atmosphere, we have previously shown that the silanol groups on the SiO$_2$ surface catalyze the reaction (*J Am Ceram Soc.* 2023, **106**, 4052-4060). Therefore, we hypothesized that if a material containing OH groups was patterned on a SiO$_2$ substrate and treated with HF, selective SiO$_2$ etching could be achieved. As a result, we developed a novel microfabrication method for SiO$_2$ substrates by combining a polymer, such as a photoresist, with HF (*ACS Appl. Mater. Interfaces* 2024, **16**, 22657-22664). After patterning an i-line resist on an SiO$_2$ substrate, the hydroxyl (OH) groups in the resist acted as catalysts upon treatment with HF, selectively etching the resist-coated area. This technique is the opposite of the conventional RIE technique in that the area to be etched is the area where the resist is located. Additionally, highly

vertical processing is enabled because the catalyst will continue to retain its shape without being consumed. In fact, a trench structure with a width of 5 μm and a depth of 20 μm could be fabricated with a taper angle of <1 °. Another feature of this etching technique is that the etching depth is capable of much deeper than RIE. Deep holes with a diameter of 10 μm and a depth of 100 μm could be fabricated with this process. Furthermore, the etching depth and rate can be controlled by the processing time and HF concentration. The AGC-ACE etching rate at 20% HF was approximately 1 μm/min, several times faster than that of RIE, and is advantageous in terms of throughput. AGC-ACE enables the vertical and deep etching of SiO_2, which is not possible with conventional methods. SiO_2 pillar structures were fabricated by AGC-ACE for application in optical components, such as metalenses. The i-line resist was patterned into a 500 nm hole and treated with HF. High aspect ratio pillars with a diameter of 500 nm and a height of 25 μm (aspect ratio 50) were achieved, which is impossible with conventional techniques. Extending the HF processing time also produced a structure with an aspect ratio exceeding 100 with a height of 80 μm. Even with this high-aspect-ratio structure, the pillar diameters were nearly uniform. Further, density functional theory (DFT) calculations of the catalytic effect of the photoresist showed that polar functional groups, such as hydroxyl groups in the polymers, enhanced the dissociation of HF and activated F^-. This suggests that resins with carboxylic acid and amino groups may also act as catalysts. In fact, it has also been experimentally confirmed that AGC-ACE is possible in principle with electron beam resist and nanoimprint. AGC-ACE is expected to be applicable to many optical components, including highly functional visible-light metalenses that achieve an ideal phase difference. Now, we plan to create SiO_2 metalens using AGC-ACE.

EL07.10.15

Non-Monochromatic Plasmonic Behavior of Metal Nanoparticle/Dielectric Nanorod Composite Material

Jaeyeon Jo and Miyoung Kim; Seoul National University, Korea (the Republic of)

The integration of plasmonic metal nanoparticles with dielectric materials has been extensively studied due to the enhanced photovoltaic and photocatalytic properties these composites can achieve [1]. However, most research has focused on their functionality rather than on a fundamental understanding of the plasmonic behavior that forms the basis of this functionality. A thorough investigation of the plasmonic resonance energy and spatial distribution of plasmonic fields in these systems is crucial for developing advanced materials with optimized performance.

To address this, we utilized STEM-EELS, which has emerged as an unrivaled technique for exploring plasmonics at the nanoscale. Recent advancements in monochromator technology have enabled the exceptional spatial resolution of STEM-EELS to be applied in the visible spectrum, making it a highly active technique in plasmon research.

Here, we present the non-monochromatic plasmonic behavior of metal nanoparticles on dielectric nanorods, highlighting the different field distributions of two distinct plasmons. Numerical simulations using the well-known MNPBEM toolkit for plasmons [2], along with STEM-EELS measurements of silver nanoparticles on zinc oxide nanorods, were conducted as a proof of concept. The plasmon peak of the metal nanoparticle was split into two different plasmons due to the incorporation of a dielectric nanorod. These two plasmons exhibited different spatial distributions: one with lower energy located on the opposite side of the nanoparticle adjacent to the dielectric nanorod, and the other with higher energy near the nanorod. This splitting is thought to arise from symmetry-breaking in the surrounding dielectric environment induced by the addition of the nanorod. This is supported by simulation results where the dielectric environment was artificially inverted by switching the dielectric function of the vacuum area and the nanorod area, resulting in lower energy plasmons appearing near the nanorod.

This work demonstrates that the composite of metal nanoparticles and dielectric nanorods exhibits non-monochromatic plasmonic behavior due to the symmetry-breaking of the dielectric environment. It provides additional insights into the complex structure of metal/dielectric composite systems and offers hints for designing composites to enhance their functionality.

EL07.10.16

Simultaneous All-Polarized Elastic Wave Energy Harvesting and Attenuation with Chiral Mechanical Metamaterials

Jeonghoon Park[1], Geon Lee[1], Hyunhee Kwon[2], Miso Kim[2] and Junsuk Rho[1,1,1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

We present a novel approach to address the challenge of simultaneously attenuating elastic waves across all polarizations and harvesting energy from these waves. Our research introduces an innovative chiral mechanical metamaterial design with defect structures (CMMD), overcoming the limitations of existing mechanical metamaterials that typically excel in either wave attenuation or energy harvesting, but not both.
The CMMD demonstrates dual functionality by exploiting both complete bandgap and defect mode phenomena, enabling effective broadband wave attenuation and enhanced energy harvesting across the low-frequency spectrum. Through theoretical analysis and numerical simulations, we systematically develop a complete bandgap and strategically incorporated defect structures that induce modes for all wave polarizations within the bandgap region. Importantly, we design the defect structures with consideration to ensure they seamlessly integrate into the overall shape of the structure. Through numerical simulations, we confirm that our designed CMMD can acheive the desired vibration reduction and energy harvesting as intended. Experimental validation substantiates the CMMD's superior performance, demonstrating remarkable enhancements in electrical output power: up to 20.5 times for flexural waves and 511.4 times for longitudinal-torsional waves compared to defectless counterparts. These results underscore the CMMD's effectiveness in both attenuating and harvesting energy across various wave polarizations.
Our findings open new possibilities for multifaceted applications in fields such as vibration control, energy-efficient structures, and smart structures, highlighting the potential of thoughtfully designed chiral mechanical metamaterials in addressing complex engineering challenges.

EL07.10.17

Rotating Dielectric-Plasmonic Janus Particles via Electrostatic Voltages to Enable Optical Functionalities

Mohammad Mojtaba Sadafi, Achiles F. Da Mota and Hossein Mosallaei; Northeastern University, United States

Janus particles, characterized by their dual-sided physical properties, play a pivotal role in fields like optics, medicine, and chemistry. Their inherent asymmetry gives rise to unique light-scattering properties crucial for developing a one-way cloud. Our research focuses on a dense ensemble of optically asymmetric Janus particles, including spherical and matchstick-like hybrid dielectric-plasmonic structures, which effectively act as a synthesized bulk medium with anisotropic optical characteristics. Such synthetic material results in an asymmetric smoke, creating a clear or obscured vision based on the viewing direction. However, achieving the necessary light-scattering asymmetry hinges on the precise orientation of these particles within the cluster. Various approaches have been implemented for the mechanical manipulation of Janus particles, including electromagnetic fields, mechanical waves, and fluid flow. Despite the effectiveness of current methods, the precise alignment of particles within a random array remains a significant challenge and an active area of research. In our study, we propose using electrostatics as an accessible and reliable method to meticulously orient optically asymmetric Janus particles within a dense cloud. Our findings show that by precisely engineering the amplitude, direction, and polarization of external excitation, we can effectively manipulate the final orientation of the particles in the smoke. This approach offers a unique perspective by creating stable steady states in the

orientation space, enabling control over both the short- and long-term behaviors of the particles in the cluster. We demonstrate the effectiveness of our approach by applying it to a cluster of Janus particles, successfully realizing a one-way cloud to provide coded visibility. Our analysis confirms that our method can precisely align optically asymmetric particles, creating a cloud that manipulates vision based on the observation direction.
We introduce and develop a sophisticated multiphysics platform that combines electrostatics and rigid body dynamics to concurrently predict the particles' electrostatic and mechanical responses when subjected to electrostatic stimuli in an ionic medium. We use this platform to investigate the impacts of various deterministic and stochastic variables on the transient and steady-state responses of the particles. Our findings show that engineering stable steady states in the orientation space can effectively align the particles within the cluster, even amidst thermal fluctuations. Additionally, our study reveals the effects of translational and rotational Brownian motions on the performance of the one-way cloud and details how to mitigate these negative impacts by enhancing deterministic electrostatic excitation. This work offers a robust model for manipulating micro- and nanoparticles and facilitates future applications, including directional light-scattering, targeted drug delivery, self-assembly, and autonomous swimmers.

EL07.10.18

Near-Field Coupling Dynamics of Erbium Ions and Surface-Plasmon Polaritons in Plasmonic Metasurfaces

Jose Yitzhak Aaron Chacaliaza Ricaldi[1], Iago C. Pinto[2], Younès Messaddeq[2], Víctor Anthony García Rivera[2] and Euclydes Marega Junior[1]; [1]University of São Paulo, Brazil; [2]Université Laval, Canada

Light-matter interactions play a crucial role in numerous scientific and technological domains, including optics, photonics, optoelectronics, and sensing. In recent decades, there has been a burgeoning interest in leveraging plasmons to augment these interactions. Plasmons exhibit the remarkable ability to substantially amplify the local electromagnetic field, thereby significantly enhancing the intensity of light-matter interactions. Nevertheless, the efficacy of these interactions is frequently impeded by the limited absorption and scattering cross-sections of many materials. The advent of plasmonic nanostructures has provided a means to overcome these limitations by generating highly localized and intense electromagnetic fields. These fields can effectively bolster the interaction between light and matter, leading to novel applications in sensing, energy harvesting, nonlinear optics, and engineering light transport at the sub-wavelength scale. The ability to significantly enhance optical and electromagnetic field intensities around metallic nanostructures, which can alter the excitation and emission properties of locally excited quantum systems, is crucial for the development of next-generation photonic devices. In this work, thin films were fabricated using Er^{3+} doped germane-tellurite glass nanoparticles diluted in Polymethylmethacrylate (PMMA). The PMMA solution was deposited on gold plasmonic gratings, a 20x20 μm sequence of 100 nm wide slits separated by 1000 nm, fabricated using Focused Ion Beam lithography. Confocal optical microscopy and confocal lifetime fluorescence techniques were employed to investigate the coupling mechanisms between surface plasmon polaritons located on the metasurface and the rare-earth ions. It was observed that when Er^{3+} ions are positioned close to the surface, a strong coupling mechanism occurs due to the reduction in the radiative lifetime of the Er^{3+} emitter. This coupling is more evident in smaller nanoparticles, which are closer to the interface. The results demonstrate the potential for developing photonic devices using this platform.

Medium-Volume GaN Metasurface Manufacturing Using Nanoimprint Lithography Emily Kendrick[1,2], Emil Marinov[1], Aloke Jana[1] and Patrice Genevet[1]; [1]Colorado School of Mines, United States; [2]Harvey Mudd College, United States

In recent years, metasurfaces have emerged as a ubiquitous tool to control and manipulate the properties of electromagnetic waves by tuning the geometry and changing the composition of individual sub-wavelength unit cells. Their manufacturing, however, often requires methods that are expensive and difficult to scale such as Electron Beam Lithography (EBL) and deep UV lithography. The development of nanoimprint lithography (NIL), which provides in a table-top system the replication of nanoscale patterns, enables simple and accessible medium-volume metasurface manufacturing capabilities. NIL involves the replication of a nanopatterned master surface by stamping it into a UV- or thermally-curable material. In this work, a compact nanoimprinting (CNI) tool, supplied by NIL Technology, is characterized and proven as a viable manufacturing method for UV-NIL. NIL parameterization and testing for pattern replicability is presented, followed by an assessment of plasma deep reactive ion etching recipes for GaN metasurface manufacturing for visible wavelength applications, including imaging and sensing. Improving the manufacturability of metasurfaces using this NIL technique will allow for further testing of nanoscale optical components, as it facilitates the fabrication of many identical samples, which can be useful for the characterization of fabrication processes and studying reconfigurable metasurfaces

EL07.10.20

A Scalable, Nanocrystal-Based Process to Narrow the Gap in Plasmonic Nano-Dimer Metasurfaces Shobhita Kramadhati, Yun C. Choi and Cherie R. Kagan; University of Pennsylvania, United States

Plasmonic metasurfaces composed of nano-dimer repeat units with ultra-narrow gaps have been of particular interest over the years due to the strong electric field enhancement that is possible in these gaps. However, these nano-gap metasurfaces have largely been fabricated using expensive, conventional cleanroom techniques such as electron-beam lithography and evaporation of bulk metals, which limit the achievable nanostructures. We report a facile, bi-layer nanoimprint lithography (NIL)-based fabrication process which takes advantage of the solution processability and surface conformability of metallic colloidal nanocrystals (NCs) to control the critical dimension, i.e. the gap, achieving gold nano-dimer metasurfaces of varying gaps from the same master template. The fabrication process involves a novel combination of wet-etching of the bi-layer imprint resists and NC deposition and ligand exchange to systemically control the gap. Using a master template with 50 nm gaps and tuning the wet etch and NC concentration/ligand exchange parameters, we achieve large-area (>100 mm^2) metasurfaces with nano-gaps tailorable from 70 nm, larger than the the master template gaps, to as narrow as 20 nm, to the point of fusing the nanorods. The metasurfaces have a gap-size dependent spectral response in the near-infrared, with a narrower linewidth and an increased polarization dependence as the gap narrows, consistent with the higher electric field confinement in the gap. This fabrication process can be readily extended to a wider nano-dimer geometry and NC material library enabling nano-gap engineering with a single master template and the scalable manufacturing of large-area nanoimprinted metasurfaces for plasmonic sensing and flat optics applications.

EL07.10.21

Electron Confinement-Induced Plasmonic Breakdown in Metals Prasanna Das[1], Sourav Rudra[1], Dheemahi Rao[1], Souvik Banerjee[1], Ashalatha Indiradevi Kamalasanan Pillai[2], Magnus Garbrecht[2], Alexandra Boltasseva[3], Igor Bondarev[4], Vladimir M. Shalaev[3] and Bivas Saha[1]; [1]Jawaharlal Nehru Centre for Advanced Scientific Research, India; [2]The University of Sydney, Australia; [3]Purdue University, United States; [4]North Carolina Central University, United States

Plasmon resonance in metals represents the collective oscillation of the free electron gas density and enables enhanced light-matter interactions in nanoscale dimensions. Traditionally, the classical Drude model describes the plasmonic excitation, wherein the plasma frequency exhibits no spatial dispersion. Here, we show conclusive experimental evidence of the breakdown of the plasmon resonance and a consequent photonic metal-insulator transition in an ultrathin archetypal refractory plasmonic material, hafnium nitride (HfN). Epitaxial HfN thick films exhibit a low-loss and high-quality Drude-like plasmon resonance in the visible spectral range. However, as the film thickness is reduced to nanoscale dimensions, the Coulomb interaction among electrons increases due to the electron confinement, leading to the spatial dispersion of the plasma frequency. Importantly, with the further decrease in thickness, electrons lose their ability to shield the incident electric field, turning the medium into a dielectric. The breakdown of the plasmon resonance in epitaxial ultrathin metals could be useful for fundamental physics studies in transdimensional regimes and novel photonic device applications.

EL07.10.22

Structural Colors from Mie Magnetic Dipoles Engineered with Short Chains of TiO2 Nanoparticles Minji Kim[1], Hyuncheol Oh[2], Syazwani Mohd-Noor[1], Christy F. Landes[2,2], Stephan Link[2,2] and Jerome K. Hyun[1]; [1]Ewha Womans University, Korea (the Republic of); [2]University of Illinois at Urbana-Champaign, United States

We demonstrate notable structural color variations from a basic and compact configuration made from a chain of one, two, or three nanoparticles. Instead of relying on high-index materials like Si for strong modal confinement, we utilize TiO_2, which has an intermediate refractive index, to enhance modal coupling between the magnetic dipoles of each particle. This approach allows for selective engineering of the magnetic response, resulting in larger spectral changes compared to those with Si. Despite its lower refractive index, TiO_2 leads to higher scattering intensities than Si. We develop a quasistatic analytical model to describe dipolar modal coupling in a trimer and use it to uncover distinct magnetic field strengths in the outer or central particle based on the polarization of incident light. These results highlight new methods to control the magnetic field in particle chains and create vibrant structural colors with simple configurations.

EL07.10.23

Design and Synthesis of ZIF-8@Au Core-Shell Nanocubes for Quantitative Surface-Enhanced Raman Scattering Hyeon-Jeong Shin and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

Recently, Metal-organic frameworks (MOFs) combined with plasmonic metal nanoparticles have been extensively studied due to their synergistic effects. MOFs have emerged as crystalline materials of great interest, featuring a three-dimensional network structure composed of metal nodes and organic ligands. Significant research has been reported on plasmonic nanoparticle-MOF hybridized structures with diverse shapes, offering various possibilities for tailored applications. However, the detailed synthetic mechanism on metal-MOF surfaces has not been thoroughly investigated. In this study, we designed and synthesized, for the first time, the Zeolite-imidazole framework-8 (ZIF-8) core with gold nanoshell structures (ZIF-8@Au). Unlike conventional methods, where reducing gold precursor onto MOFs often results in uncontrollable variations in size and shape, our approach achieves precise and uniform gold nanoshell deposition onto the MOF framework. We elucidated the detailed synthetic mechanism using XPS and XRD data analysis by carefully modulating the reduction potential, optimal reaction time, and concentration of reactants and using suitable capping agents. <div>Furthermore, we investigated the plasmonic properties of ZIF-8@Au through Raman spectroscopy, leveraging the innate Raman-active 2-methylimidazole ligand without any Raman dye. By comparing the Raman spectra of compositions with the same materials (ZIF-8 and AuNPs) but different structures, we evaluated the Zn and Au interactions on the surface of these materials. Additionally, we systematically varied the thicknesses of the enhancement. We also conducted incident-laser polarization-dependent SERS analysis of ZIF-8@Au at the single-particle level, demonstrating the quantitative capabilities of SERS-based analytical techniques.</div>

Bio-Inspired Flat Optics for Directional 3D Light Detection and Ranging Patrice Genevet; Colorado School of Mines, United States

LiDAR, for Light Detection and Ranging, is a 3D imaging technology that uses a time-triggered pulsed laser source to illuminate the environment, and a photodetector to collect the returning time of pulses backscattered by objects of a scene. By measuring the round-trip time of the scattered light, also called the Time-of-Flight (ToF), it is possible to determine the distance of objects from the transmitter/receiver device. The ToF depth recovering technology can be coupled with a light scanning engine to provide a sequential emission of the laser pulse into different angular positions, enabling point-by-point measurement to recover full 3D information. Most commercial imaging LiDAR operate using this rather simple architecture to reach high performances in terms of depth of field, FoV and angular resolution. However, the frame rate of such architecture is inherently limited by the speed of the scanning device, which can additionally suffer from mechanical wear. Here, we propose integrating directional metalens array (MLA) on a time-gated sensor to perform 3D imaging. The design of the MLA is planar but inspired by the arthropod curved eyes. It is composed of an assembly of micro-scaled metalenses, each specifically designed to have a unique phase profile, so that the overall MLA can mimic the optical function of a curved dragonfly's eye. The realization of planar directional optical interface is facilitating vertical integration on the top of planar detection modules, enabling directional imaging measurements without the limitations inherent to conventional curved optical systems. We will present 2D directional imaging and 3D LiDAR scanning experiments with a wide FoV^2.
The objective here is to mimic the characteristics of the dragonfly eye, by subdividing a 120°×120° FoV, reducing as much as possible the size of the shadowed areas. To perform directional detection, the MLA is coupled to a matrix of detectors (Single photon avalanche (SPAD) array or a fast CCD camera). We align the MLA such that the center of each ML (on a is perfectly facing a separated active region of the detector (a single SPAD or a designated pixel for a CCD camera)). The MLA phase profile is fragmented such that the ith ML collects information associated to its own (θ_(opt,i),ϕ_(opt,i)) direction. Thus, the ith ML operation principle is to rectify the direction of the incident light coming from the ith direction and to focus the light exactly along the ith ML optical axis, that is to activate only the detector placed along the center of the ith ML. Light impinging on all the other lenses will certainly be focused but away from their axis, and as a result their focal spots would simply not overlap with the active regions of the other detectors of the matrix. However, the design of the MLA is carefully chosen to make sure that light coming from a different direction denoted as j ≠ i will be focused along the optical axis of the #jth detector, thus mimicking the spherical directional observation properties of the dragonfly's eyes on a planar sensor.

In conclusion, we have fabricated an MLA for directional detection, and we have integrated this detection module in a ToF LiDAR experiment. As a proof of concept, the MLA designed to focus directional light in a plane is positioned in front of a gated CCD, synchronously triggered by the pulse emission rate of the LiDAR illumination laser source (500kHz frequency). The activation of the detectors by the MLA is in good agreement with the designed system to achieve both spatial (direction) and temporal (depth) detection of illumination.

Utilizing Pancharatnam-Berry-Phase Metasurface for Advanced Control in Waveplates, Beam Splitter and Flat Luneburg Lenses YuPing Kuang and Ta-Jen Yen; National Tsing Hua University, Taiwan

We utilize metasurfaces to design, fabricate, and experimentally demonstrate a novel microwave device based on the Pancharatnam-Berry (PB) phase principle, marking the pioneering application of PB phase theory in Luneburg lens design. This innovative approach allows for the creation of versatile components such as half-wave plates, beam splitters, and Luneburg lenses. Simulation results indicate nearly 100% linear polarization conversion efficiency for the half-wave plate almost in the Ka frequency band, while actual measurements confirm efficiency exceeding 80% between 26 and 37 GHz. Leveraging half-wave plate meta-atoms, we integrate them with PB principles for beam splitters and Luneburg lenses, enabling precise reflection of incident waves at specific angles. This study validates the effectiveness of these metasurfaces through comprehensive simulation and measurement analyses across the Ka-band frequency spectrum, showcasing excellent reflection efficiency. These findings underscore the groundbreaking nature of applying the PB phase principle to Luneburg lens design, offering advanced performance in microwave applications and promising applications across various electromagnetic wave bands, potentially supplanting conventional optical lenses.

9:00 AM EL07.11.03
Barium Titanate-Based Active Transmissive Metasurfaces in the Visible Spectrum Prachi Thureja, Martin Thomaschewski, Julie Belleville and Harry A. Atwater; California Institute of Technology, United States

We report the design of an electro-optically tunable barium titanate (BTO)-based transmissive metasurface for subwavelength amplitude and phase modulation at a wavelength of 630 nm. To date, most active metasurfaces have focused on controlling the properties of light in reflection. However, in recent years, there has been considerable interest in developing dynamically tunable transmissive metasurfaces that integrate seamlessly into optical systems with minimal insertion losses. In particular, there has been an increased demand for visible frequency optical modulators that can be readily integrated into imaging and augmented reality systems. Liquid crystals (LCs) have been widely used for achieving dynamic control in transmission. However, LC-based modulators typically consist of large unit cells ranging from 2-4 μm, which strongly limit the field-of-view for visible frequency operation. Additionally, LC modulators are restricted to kHz modulation frequencies. Electro-optic materials relying on the Pockels effect provide a promising alternative for reconfigurable transmissive metasurfaces with high efficiencies and subwavelength unit cell control at visible frequencies.

Here, we propose the integration of barium titanate nanoblock resonators, which exhibit higher order Mie resonances, into transmissive metasurfaces. Barium titanate is a high-index birefringent material with a wide transmission range across the visible and near-infrared spectrum, from 0.4 to 5 μm. The non-centrosymmetric crystal structure of BTO gives rise to its strong Pockels coefficient, dominated by the values of $r_{42} = r_{51} = 1300$ pm/V in bulk crystals. Recently, significant progress has been made in the fabrication of BTO thin films, with electro-optic coefficients as high as $r_{42} = 942$ pm/V reported using molecular beam epitaxy [1]. We first derive the crystal orientation and incident light polarization with respect to the applied field which yield the strongest electro-optic response in BTO. We find that an in-plane electric field in a-axis oriented crystals produces the maximal refractive index change when the electrodes are oriented at 54° with respect to the in-plane optical axis (c-axis). Assuming experimentally realized Pockels coefficients, this configuration corresponds to a maximal index change of 0.1-0.2 at 630 nm with applied fields ranging between 0.2-0.5 MV/cm. Using this response, we design subwavelength nanoblock resonators on top of a silicon nitride membrane and low-index dielectric thin film. The resonator dimensions and the dielectric thickness are chosen to engineer an avoided crossing between two resonant modes, yielding maximal phase shift at high transmittance values. The resonators are individually addressed in one dimension through lateral ITO electrodes. The resulting metasurface exhibits transmittance values of over 50% for index changes of +/- 0.2 and an associated phase shift of more than 240°. Full-wave simulations of the metasurface are complemented by electrostatic simulations confirming the desired polarization of the optical mode with respect to the incident light polarization. In a next step, we alter the refractive indices between adjacent metasurface elements to mimic the effect of independent resonator biasing and engineer spatial phase gradients that steer the transmitted beam in desired directions. We discuss design choices to mitigate crosstalk between individual resonators and maximize beam directivity. Finally, we explore experimental pathways to realize the proposed BTO metasurface and analyze the impact of fabrication imperfections – such as sidewall angles, deviation from target crystal orientation, and electrode configuration – on the achieved performance.

Meta-Optics for Edge Computing Jason G. Valentine; Vanderbilt University, United States

With the proliferation of networked sensors and artificial intelligence, there is an increasing need for edge computing where data is processed at the sensor level to reduce bandwidth and latency while still preserving energy efficiency. In this talk, I will discuss how meta-optics can be used to implement computation for optical edge sensors, serving to off-load computationally expensive convolutional operations from the digital platform, reducing both latency and power consumption. I will discuss how meta-optics can augment, or replace, conventional imaging optics in achieving parallel optical processing across multiple independent channels for identifying, and classifying, both spatial and spectral features of objects.

SESSION EL07.12: Quantum Plasmonics
Session Chairs: Patrice Genevet and Yu-Jung Lu
Wednesday Morning, December 4, 2024
Sheraton, Second Floor, Back Bay D

10:15 AM *EL07.12.01
Quantum Nanoplasmonic Coherent Perfect Absorption Ortwin Hess; Trinity College Dublin, The University of Dublin, Ireland

Nanoplasmonics offers the unique ability to confine light to extremely sub-wavelength volumes and strongly enhance local optical fields via resonant surface plasmon modes, thereby constituting exceptional architectures for enhanced light-matter interaction and the exploration of extreme nano-optics for quantum dynamics. In particular, room-temperature strong coupling using single molecules and colloidal quantum dots in nanoplasmonic environments has been realized using ultrathin (~1 nm) nanoplasmonic cavities [1] and scanning probe tips [2]. While ultrafast plasmonic near-field evolution can be exploited to achieve high-speed quantum operations [3], including dynamic bi [4]- and tripartite [5] entanglement in quantum dots, it is in the light of fast-decaying cavity plasmon modes vital to explore pathways for improving the temporal robustness of strongly coupled plasmon-emitter states under ambient conditions, with the aim of realizing truly room-temperature-viable quantum nanophotonic devices.

Here, a novel strategy for selective preparation and, conceivably, 'immortalization' of selected plasmon-exciton polariton states by means of quantum nanoplasmonic coherent perfect absorption (qnCPA) is discussed. It is shown that under plasmonic nanowire-waveguide driving, the qnCPA regime can selectively lock a nanocavity-emitter system in either the upper or lower plasmon-emitter polariton. Furthermore, in this regime, the intrinsic losses of the nanocavity-emitter device can be precisely compensated for by means of the coherent and non-perturbing waveguide feeding at a suitable rate, effectively paving the way towards strongly coupled light-matter states that are robust against decoherence at room temperature. This contrasts sharply with the conventional belief that preserving an individual quantum state requires cryogenic cooling and strict isolation of the system from environmental influence. In fact, here, dynamic dissipation under ambient conditions is fully embraced, strategically harnessing its interplay with plasmon interference in a specific dressed state to establish the qnCPA regime itself. As a novel paradigm for quantum state preparation and preservation in plasmonic cavity quantum electrodynamics, qnCPA offers exciting prospects for room-temperature-viable quantum nanophotonic technologies.

Leveraging Plexcitons in Strongly Coupled Nanophotonic Systems for Quantum Optical Sensing Peng Zheng and Ishan Barman; Johns Hopkins University, United States

Unlocking the potential of quantum sensing promises a broad range of applications in physics, chemistry, and biomedicine. Yet, the extreme conditions that are often required to achieve quantum state control significantly restrict practical implementation of quantum sensing. In this talk, we introduce a novel strategy for quantum optical sensing by harnessing plexcitons that can be achieved under ambient conditions on strongly coupled nanophotonic systems. By utilizing the plexcitons generated through the strong coupling between excitonic particles and a plasmonic hyperbolic metasurface, we demonstrate that our model of quantum plexcitonic sensing performs at a level that is ~40 times more sensitive as compared to classical sensing in the weak-coupling regime. By introducing optical noise into our measurements, we further demonstrate quantum advantage over classical sensing, featuring better sensitivity, smaller sensitivity uncertainty, and higher resilience against optical noise.

11:00 AM EL07.12.03
Toward Scalable Telecom Single-Photon Emitters for Quantum Photonics Alex Kaloyeros and Spyros Galis; University at Albany, State University of New York, United States

The most efficient and scalable method for generating and detecting quantum information involves creating an integrated photonic platform that hosts a variety of compact on-chip quantum devices. Single-photon emitters (SPEs) associated with point defects and ions in semiconductors are considered vital resources for quantum photonic integrated circuit (PIC) applications. A key challenge in scaling SPEs from lab environments to long-distance fiber-based quantum networks is developing SPEs that operate in the telecom O to C wavelength range, which aligns with low propagation loss in fiber communication channels. However, the scalability of SPEs is hindered by limited material platforms, strict fabrication and operational temperature requirements (e.g., ≥77K, room temperature), and the random nature of current telecom SPE emitters, which complicate their fabrication and efficient coupling to other photonic devices and PIC chips. Furthermore, the absence of electrically driven SPEs in the telecom regime presents significant obstacles to developing telecom quantum LEDs (QLEDs). These critical scientific and technological challenges have yet to be addressed on a single platform, highlighting the complexity and importance of ongoing research to develop future scalable and compact quantum devices at telecom wavelengths. In this context, we present nanophotonic structures composed of arrays of silicon carbide (SiC) nanowires (NWs) and nanopillars (NPs) based on a novel and CMOS-compatible nanofabrication process. These structures enable the precise placement of erbium (Er^{3+}) ions with state-of-the-art accuracy of ~10 nm and allow for the engineering of the optical properties of Er^{3+} ions. The structures exhibit high ensemble Er^{3+} photoluminescence (PL) excitation and emission efficiency at ~1532 nm and an absorption cross-section (10^{-18} cm^{-2}), two orders of magnitude larger than typical values in rare-earth-doped quantum materials. Additionally, we demonstrate precise control over nanostructure geometry and implantation engineering toward single Er^{3+} isolation at high temperatures. Finally, the NWs facilitate polarized Er^{3+} emission, an essential property for efficient coupling to optical cavities in quantum photonics applications. To this end, we present preliminary plasmonic cavity designs for efficient Purcell enhancement of the 1532 nm Er-related emission. The observed characteristics of these fab-friendly nanophotonic structures offer a promising path to scalable nanophotonics and the creation of SPEs in the telecom optical wavelength band.

Exploring Regenerative Coupling in Phononic Crystals for Room Temperature Quantum Optomechanics
Lukas Weituschat[1], Irene Castro Fernández[1], Irene Colomar[1], Christopher Everly[2], Pablo A. Postigo[2] and Daniel Ramos[1]; [1]Consejo Superior de Investigaciones Científicas, Spain; [2]University of Rochester, United States

Quantum technologies have gained immense significance in recent years, revealing them as critical drivers of innovation [1]. These technologies make use of fundamental quantum phenomena like superposition and entanglement to surpass the capabilities of classical systems. Applications of these technologies span various fields, including quantum computing [2] for high-speed processing, quantum cryptography [3] for secure communication, and quantum sensing [4] for precise measurements. The coherence of quantum states is crucial, as it ensures the stability and accuracy of these technologies, often necessitating operation at very low temperatures to minimize thermal fluctuations that can degrade quantum information. Therefore, recent efforts aim to develop robust quantum systems that can operate at or near room temperature, which would significantly expand their practical applications.

We explore a novel approach to enhance the performance of mechanical resonators in quantum optomechanics by using regenerative coupling in phononic crystals (PnCs) [5]. By engineering the phononic bandgap and optimizing the geometrical parameters of the PnC, we have developed a system that significantly reduces mechanical energy dissipation. This involves coupling a nanomechanical oscillator with a defect mode in the surrounding PnC, thereby improving the mechanical quality factor by up to four orders of magnitude compared to conventional designs. This method, applicable to various resonator types, utilizes finite element method (FEM) simulations to fine-tune the system, achieving a high product of mechanical mode frequency and quality factor (f × Q), essential for maintaining quantum states at room temperature.

Our results demonstrate that the proposed system can achieve f × Q products exceeding 10^16 Hz, enabling mechanical decoherence times of up to 700 microseconds at room temperature. This is a significant improvement over traditional designs and suggests the potential for new applications in quantum memories, communication, and signal processing. We have also studied the robustness of the system against fabrication imperfections, ensuring practical feasibility. The regenerative coupling mechanism, which enhances the mechanical quality factor and reduces energy losses, offers a promising pathway for advancing room-temperature quantum technologies.

11:30 AM EL07.12.05

Ultrafast Telecom Single Photons from Colloidal Quantum Dots Siyuan Zhang[1], Andrew Traverso[1], Ekaterina Dolgopolova[2], Hiroyuki Kishida[1], Maksim Livshits[2], Chris Sheehan[2], Eric Bowes[2], Jennifer Hollingsworth[2] and Maiken H. Mikkelsen[1]; [1]Duke University, United States; [2]Los Alamos National Laboratory, United States

Quantum science has transitioned from laboratory experiments to real-world applications, such as secure long-distance communication and enhanced computational speed. The telecom industry has evolved to meet the increasing need for faster data transmission, particularly within the low-loss C-band (1530-1565 nm). Significant progress has been made in single-photon generation within the telecom O-band (1260-1360 nm) at both low and room temperatures across various material platforms. However, existing telecom sources are still limited by long radiative lifetimes, material instability, and the need for cryogenic conditions.
Our research addresses these challenges by using stable colloidal PbS/CdS quantum dots emitting at 1550 nm (C-band) or 1350 nm (O-band), embedded in a solution-synthesized nanoparticle-on-mirror cavity. These quantum dots experience extreme Purcell factors of several thousands, resulting in ultrafast emission lifetimes on the picosecond scale. The single-photon action of the nanocavity-coupled quantum dots is confirmed pulsed second-order autocorrelation measurements.
Future improvements in quantum dot synthesis, aimed at minimizing intrinsic linewidth and enhancing coherence, similar to advances seen in colloidal lead halide perovskite quantum dots, could further reduce bandwidth to its lifetime limit, paving the way for ideal on-demand and indistinguishable single-photon generation.

11:45 AM EL07.12.06

A Tale of Spin-Spin Entanglement—High-Quality-Factor Chiral Metasurfaces to Enhance Spin in Monolayer

Materials Feng Pan[1], Xin Li[2], Amalya C. Johnson[1], Scott Dhuey[3], Ashley P. Saunders[1], Mengxia Hu[2], Zi-Lan Deng[2], Fang Liu[1] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Jinan University, China; [3]Lawrence Berkeley National Laboratory, United States

Spin is one of the most fundamental properties of elementary particles (e.g. bosons and fermions). Spin coherence describes the preservation of the phase relationship among spins over time. For electrons, long spin coherence time is required not only to create efficient spin-based devices (e.g. spin transistors and memories) but also to perform quantum operations using spin qubits. Circularly polarized light (CPL) is light with spin angular momentum. In transition metal dichalcogenides (TMDC) monolayers, CPL can excite excitons that possess spin angular momentum matched to that of the CPL by selectively addressing either the K or K' valley in the TMDCs' Brillouin zone. The control and manipulation of such chiral light-matter interactions could enable future solid-state, optically addressable quantum information systems (QIS). Unfortunately, intervalley dephasing processes in TMDCs, such as strong intervalley scattering and phonon-assisted valley coupling, can detrimentally affect chiral light-matter interactions and lead to fast spin decoherence. These fast dephasing processes prevent TMDCs from being employed as room-temperature on-chip valley-selective devices for wide applications in valleytronics and QIS.
Here, we present a new design of high-quality-factor (Q-factor) metasurfaces with chiral “meta-atoms” that can strongly favor exciton transitions from a particular valley (K or K') in TMDCs and thus enhance valley-polarized emission regardless of excitation polarization, i.e., chiral Purcell effects. These high-Q chiral metasurfaces are achieved by engineering a chiral quasi-bound state in the continuum (qBIC) at ~770 nm that matches the A-exciton resonance of MoSe2 monolayers. Our fabricated crystalline Si metasurfaces on a glass substrate yield Q-factors of several hundred at the qBIC resonance. Both our steady-state and time-resolved photoluminescence spectral measurements reveal strong valley-polarized emission at elevated temperatures from 100 K to 294 K with a high degree of circular polarization approaching 50%. The angle-resolved PL measurements show that our chiral metasurfaces localize valley-polarized emission in the vicinity of the Γ-point, a signature of the chiral qBIC mode for directional emission control. This chiral light-matter coupling can be leveraged to create chiral electro-optic devices (e.g., chiral electroluminescent devices and chiral light detectors) and quantum light sources encoded with spin angular momentum.

Tailoring Nanomaterials for Ultrafast and Chiral Plasmonics Anastasiia Zaleska, Yuanyang Xie, Jingyi Wu, Alexey Krasavin, Anton Bykov and Anatoly Zayats; King's College London, United Kingdom

Ultrafast nonlinear and chiral photonic applications are often limited by the available choice of naturally occurring materials and their generally weak responses. Here, we will discuss novel plasmonic nanomaterials and hetero-nanostructures for tailoring hot-electron dynamics, plasmonic nonlinearities, ultrashort pulse manipulation and chiral response. Going beyond traditional field enhancement effects, we show how the introduction of additional hot-electron relaxation pathways, anisotropy and nonlocality allows to accelerate of decelerate temporal response of nonlinear optical effects in plasmonic nanostructures. Precise control of nanoparticle shapes allows to achieve strong chiral response by engineering electric and magnetic dipoles responsible for chirality. This results in a freedom of engineering scattering patterns and optical forces.

2:00 PM *EL07.13.02
Plasmonics in Ultrathin Metal Films Javier Garcia de Abajo[1,2]; [1]ICFO-The Institute of Photonic Sciences, Spain; [2]ICREA, Spain

We discuss atomically thin materials as a robust platform for manipulating light at the nanoscale thanks to a wide variety of polaritonic modes, ranging from plasmons in thin metals and doped graphene to excitons in transition metal dichalcogenides and phonons in ionic insulators. The electromagnetic behavior of these modes can be well understood in terms of effective surface conductivities, which capture their strong dependence on temperature and external static electric and magnetic fields. Recent advances have also been produced in the synthesis of thin noble-metal films, which open a new regime of nanometallic plasmonics. In this talk, we overview the general characteristics of the optical response of these materials, which can be understood in terms of simple theoretical models. We also discuss more sophisticated models, aiming at the exploration of genuinely quantum-mechanical effects. We further review recent advances in the control of ultrafast and nonlinear optical processes, as well as potential applications in light modulation and quantum-optics. The in/out coupling problem between external light and strongly confined polaritons remains a major challenge, for which we propose innovative solutions based on critical coupling between dipolar scatterers and planar interfaces. We further discuss a disruptive approach to the design of polaritonic materials relying on quantum phase effects, as well as a new mechanism of electron-positron pair production based on the scattering between gamma-rays and surface polaritons.

3:30 PM *EL07.14.01
Perfect Absorption of Hybridized Silicon Metasurface with Monolayer Graphene Junichi Takahara; Osaka University, Japan

Research on optoelectronics using two-dimensional nanomaterials such as graphene and transition metal dichalcogenide (TMDC) has made remarkable progress. Among them, single-layer graphene is expected to be applied to ultrafast optical modulators and photodetectors because of its high electron mobility and optical absorption over a wide wavelength range due to its Dirac-type band structure. However, the single atomic layer of graphene has a weak interaction with light, resulting in a low optical absorption coefficient of 2.3%. This is a drawback in device applications.
We have demonstrated theoretically that Perfect Absorption (PA) of a monolayer graphene can be realized in the near-infrared region by coupling the graphene in close proximity on a silicon (Si) hollow-cuboidal Mie-resonator [1]. In this device, we carefully tuned the size parameters of the resonator to meet the Degenerate Critical Coupling (DCC) condition between Toroidal Electric Dipole (TED) and Magnetic Dipole in the resonator [2,3]. TEDs have extremely low radiative loss compared to dipoles and are non-radiative, which is expected to open up new

avenues for loss control and Q-value enhancement. We found that the metasurface significantly enhances the interaction between light and monolayer graphene to achieve PA.

In this talk, I will review the basic principles of all-dielectric PA by DCC at first. Then, I will talk about our recent progress of experimental work to fabricate hybridized system of monolayer graphene transferred onto Si metasurface. Such devices can be further extended by simply replacing the graphene support with TMDC, including enhancement of exciton emission.

4:00 PM *EL07.14.02

One-Way Smoke—Janus Particle-Engineered Material for Unidirectional Imaging Achiles F. Da Mota[1,2], Mohammad Mojtaba Sadafi[2] and Hossein Mosallaei[2]; [1]Universidade de Brasilia, Brazil; [2]Northeastern University, United States

Janus particles, with their unique properties on each side, present a promising solution for directional scattering. By harnessing these properties, we can design Janus particles that interact with photons in a direction-dependent manner. This opens the possibility of creating a medium composed of Janus particles that can obscure an image from one side while maintaining clear vision from the other. In practical terms, we can develop a material of such engineered particles that functions like one-way smoke, a concept with significant potential applications in various fields, including surveillance, imaging, security, and nanophotonics.

We demonstrate that meticulous material design and optimization for controlling the scattering and absorption cross-sections are essential to accomplish this task. For obscuring the image from one side, the particle must direct photons from the illumination source towards that side, effectively blurring the image. To achieve this, we have optimized two sets of Janus nanoparticles: a silica-rod gold sphere matchstick for illumination from behind the medium and a half-coated silica sphere for illumination from the front. These Janus particles are highly asymmetric, with dielectric properties on one side and plasmonic properties on the other. When the matchstick particle is excited from the rod side (dielectric), the probability of a photon being forward scattered is 46 times higher than backscattered. This occurs because the rod guides the electromagnetic waves toward the gold sphere, enhancing the scattering effect. Near-field analysis supports this conclusion, showing high-field concentration on the plasmonic side, indicating significant light guidance and absorption. For the half-coated silica sphere, the particle primarily backscatters incident photons when illuminated from the gold-coated side due to localized plasmonic resonance. When illuminated from the silica side, the sphere acts as a lens, focusing light onto the gold cap and increasing absorption. The high-intensity electric field resulting from localized plasmonic resonance increases absorption when excited from the dielectric side while enhancing reflection from the gold side.

Due to their engineered asymmetric scattering properties, we can create smoke, an engineered medium of Janus particles, by suspending and aligning them in the air. Using this configuration, we have a random array of these particles, where we model the visualization throughout the media using a Monte Carlo-based approach, where the scattering properties of the high asymmetrical particles are exploited. In this medium, a target can be identified more than 50% of the time when seen from one side, while the target is not even detected more than 50% from the other side. In addition, we present a practical quasi-electrostatic approach to align the particles in free space, where we leverage the metallic parts of the Janus particles using an electrical field to manipulate the free charges of the metal. It generates a torque and controls the particle's position and orientation.

These findings highlight the potential of Janus particle-engineered material to enable asymmetric imaging with simultaneous concealment from one side and clear visualization from the other, and they also open up new possibilities for exploring engineered materials for nanophotonics. In conclusion, we present an unexplored application for Janus particles based on its highly asymmetric scattering properties, having dielectric properties on one side and plasmonic on the other. This research has significant implications for various fields, including surveillance, imaging, security, and nanophotonics.

4:30 PM EL07.14.03

Resonant Polarization Response in Phononic Moiré Metamaterials Raghunandan B Iyer, S. Maryam V. Esfidani, Ramachandra Bangari and Thomas G. Folland; The University of Iowa, United States

Extensive studies on twisted van der Waals materials have led to the emergence of twistronics as a new paradigm in materials design. However, electronic Moiré structures are constrained by various factors, including natural lattice dependencies, symmetry constraints, and mismatches in length scales. Recently, its optical analog, metasurface-based photonic Moiré structures with designed lattice misorientations have emerged as a promising platform for new optical phenomena [1, 2]. These structures can mirror the design space of electronic Moiré systems of two-dimensional (2D) materials, demonstrating photonic flat bands with low group velocity, optical chirality, and enhanced light-matter interactions. Further, integrating photonic moiré structures with 2D materials or nanostructured media could unlock new functionalities and applications. Our work aims to use grating-based photonic structures to achieve a generalized understanding of twist physics in photonic Moiré structures.

To do so, we probe twisted metamaterials via far-field polarized Fourier-transform infrared (FTIR) microscopy and finite element method (FEM) simulations. We utilize a silicon carbide (SiC) substrate with a photolithographically patterned single-layer metal grating formed by combining two gratings at different twist angles. This structure excites resonant surface phonon polariton modes with twisted properties. This structure is coated with dielectric ZnO coating, enhancing light-matter coupling with the surface phonon polariton and supporting guided mode resonances. Our FEM simulations indicate that this metasurface supports both surface phonon polaritons and guided-mode resonances, which are strongly dependent on twist angle and incoming polarization state. Optical measurements of the twisted photonic structures reveal a strong polarization-dependent response, uncovering a resonant cross-polarization effect highly dependent on lattice parameters and twist angle. This effect offers almost perfect polarization conversion from the metasurface, aligns with the Brillouin zone of the 2D twisted grating, and arises from guided wave coupling in the device. Both surface phonon polariton modes and guided wave resonances are consistent with the calculated grating vector parameters and dependent on the lattice period. Our investigation provides insights into twist photonic physics and opens pathways for developing novel devices with tunable and enhanced functionalities. In the long term, such metamaterials could be leveraged for the generation of chiral thermal light sources, chiral sensing, and energy harvesting.

Scalable Self-Assembly of All-Dielectric Nanoparticle Metamaterials Raul Barbosa, Gabriel Cossio, Edward Yu and Brian A. Korgel; The University of Texas at Austin, United States

We have developed an aerosolized jet spray method to rapidly generate ordered monolayers of colloidal particles over large areas. Particles made of materials with high refractive index with diameters ranging from 100 nm to 1 micrometer can be assembled to generate a range of all-dielectric metamaterials. The colloidal particles are deposited onto a liquid interface using an ultrasonic spray coater to achieve large area (200 cm^2) ordered monolayers in less than a minute. Dense hexagonal close-packed monolayers or bidisperse superlattice arrays can be formed and transferred without a loss in structural integrity to a wide variety of solid surfaces, including metal, polymer, and glass, as well as non-planar surfaces. This high-throughput deposition technique could be readily integrated into a commercial spray coat manufacturing process. We further developed a method for controlling the spacing between the high refractive index particles in the monolayers. Uniform polystyrene shells on the primary particles with thickness ranging from 3 to 250 nm can be grown on a range of particles, including those made of titanium dioxide (TiO_2), silica (SiO_2), and amorphous silicon (a-Si). With tight size control and adjusting the ratio between sizes of small and large particles, binary colloidal crystals composed of particles of different refractive index can be generated. By stacking monolayers, three-dimensional films of ordered particles can also be made. Monolayers composed of these high refractive index particles have the potential for application as antireflection coatings, optical metasurfaces, transparent electrodes, or as substrates for biomedical sensing.

Metasurface Based Phosphor-Converted Micro-LED Architecture—Creating Guided Modes for Enhanced Directionality Debapriya Pal and Femius Koenderink; AMOLF, Netherlands

Phosphor-converted LEDs produce white light using a blue 'pump' LED to illuminate a phosphor blend that emits longer wavelengths. This study focuses on the complex scenario of micro-LEDs, typically envisioned as high-resolution display pixels, which constrains the LED's lateral size and requires placement of the phosphor directly on the blue die (GaN), which is highly disadvantageous for light extraction. We have experimentally established that driving phosphors more efficiently in a micro-LED architecture benefits from promoting light emission into guided modes within the phosphor layer. Furthermore, using a plasmonic metasurface to outcouple the light to the far field leads to a threefold increase in brightness.

Micro-LEDs are the advanced display technologies for smart devices such as wearables and AR-VR displays. Blue InGaN/GaN multi-quantum well LEDs are power efficient and used for phosphor-converted micro-LEDs to produce the desired spectrum. High-resolution displays demand compactly packed pixels in chips with high pixel density. Micro-LEDs are individually addressable self-emissive pixels with lateral dimensions below approximately 50 microns. It's crucial to prevent any optical crosstalk between adjacent pixels in an array, limiting the lateral size and distance between the phosphor layer and the GaN die due to pump light spreading and scattering effects. As a result, most of the phosphor emission goes into the GaN layer, posing a significant challenge for light extraction. Common nanophotonic strategies, such as diffractive metasurfaces, enhance pump absorption and emission directivity since the phosphor is far from the blue-emitting GaN, avoiding phosphor emission disappearing into the LED. This work focuses on the more complex scenario of micro-LEDs for display pixels. In this context, the efficiency of phosphor light emission can be enhanced by channeling it into guided modes. A metasurface can achieve a threefold brightness increase by outcoupling the guided mode emission in the phosphor layer into the far field. While promoting emission into guided mode existence in the phosphor layer may diminish the coupling of blue pump photons from the GaN into the phosphor, the overall benefit lies in the directed emission enhancement.

We propose geometries in which the phosphor is concentrated in submicron-sized layers and separated from the blue die chip by either (a) a micron-sized dielectric spacer with a refractive index lower than that of the phosphor (low index normal dielectric spacer) or (b) by a 1D dielectric multilayer stack of materials of alternating refractive index (Bragg stack dielectric spacer). The proposed geometrical design aims to restore the waveguide mode characteristics of the phosphor layer, prevent undesired emission into the GaN die, and accelerate it into the guided modes of the phosphor through the Purcell effect. This geometry can be combined with plasmonic and dielectric metasurface to increase pump light absorption and extract the guided light into specific directions in a microLED architecture.

We present rigorous theoretical calculations based on the local density of optical states, LDOS, to design spacers that enhance emission into quasi-guided modes in phosphor. We perform experiments demonstrating the benefits of inserting a thin micron-sized low-index silica spacer combined with periodic metasurface to facilitate the outcoupling of guided mode emissions towards the far field using angle-resolved fluorescence (Fourier) microscopy. Notably, the emission is highly directional towards the air, resulting in a four-fold enhancement in the forward direction by using a micron-thick silica spacer in conjunction with a plasmonic particle array, as compared to a planar layer of the dye-doped polymer layer of similar thickness directly on top of GaN (blue die). These results provide concrete evidence of the effectiveness of our proposed spacer strategies in enhancing light emission in micro-LEDs.

Reconfigurable Nanophotonic Control via a Two-Level Plasmon-Mediated Optomechanical System Irene Castro Fernández[1], Manuel Marqués[2], Antonio Garcia-Martin[1] and Daniel Ramos[1]; [1]Consejo Superior de Investigaciones Científicas, Spain; [2]Universidad Autónoma de Madrid, Spain

In this study, we theoretically demonstrate the potential of a two-level optomechanical system, actuated by plasmon-mediated optical forces, to serve as a reconfigurable nanophotonic element. Our simulations involve a nanostructured, suspended gold membrane designed to facilitate the normal excitation of a Surface Plasmon Polariton (SPP) through an air nanohole array. When this membrane is positioned near a reflective substrate, mode splitting occurs, resulting in two stable mechanical states that can be accessed by adjusting the illuminating wavelength.

Recently, the active control of optical forces has garnered increasing interest from the scientific community, spanning fundamental physics [1] to diverse applications such as optical and plasmonic tweezers [2], optically reconfigurable nanophotonic devices, and the cooling or amplification of mechanical modes to achieve the fundamental ground state or enhance the sensitivity of inertial sensors [3]. In this work, we introduce a two-level optomechanical system that can be manipulated both statically and dynamically to serve as an optical bit in photonic nanoprocessors or as an optical switch. The modulation of optical forces is theoretically demonstrated through the mechanical excitation of a suspended membrane composed of an array of air nanoholes in a gold layer that supports SPP modes. This nanostructured membrane, suspended over a silicon substrate, forms a Fabry-Perot microcavity, facilitating strong coupling between cavity and plasmonic modes [4].

We employ finite element simulations to model the entire optomechanical device, including the coupled Fabry-Perot cavity. The optical force is determined by evaluating the asymmetries in the integral of the Maxwell stress tensor over a closed surface surrounding the suspended membrane. The influence of the SPP on the optical force is analyzed as a function of the cavity length. At a fixed wavelength, the force calculation reveals a double potential well, indicating two stable states separated by a central energy barrier. Mechanical actuation on the membrane can dynamically alter the cavity length through harmonic displacement. This oscillatory movement of the suspended membrane is modeled using a Duffing non-linear mechanical oscillator, with its amplitude modulated via optomechanical techniques (cooling or amplification). Thus, the stable final state of the dynamic system can be actively selected, paving the way for the development of an optomechanical switch.

Self-Growth of Silver Tree-Like Fractal Structures Under Illumination of White Light Ryusuke Kagawa and Nobuyuki Takeyasu; The Okayama University, Japan

Silver tree-like structures are grown in a solution with low surface tension when silver ions are rapidly reduced [1]. The overall size exceeds 10 μm although many nanostructures (~20 nm) exist at the tips. The geometry is fractal, in which self-similarities are found at different scales [2]. Therefore, the silver tree-like fractal structures (AgTFSs) can support a wide variety of surface plasmon modes, resulting in broadband optical responses from visible to, at least, near-infrared region. For instance, it has been reported that Raman signals are enhanced at 532, 633, and 785 nm on the AgTFSs in surface-enhanced Raman scattering (SERS) measurements of *para*-aminothiophenol (*p*-ATP) [3].
It has been reported that AgTFSs are grown under ultraviolet (UV) irradiation, where needle growing and branching are repeated at different scales [1,4]. At first, many silver nuclei are produced when L(+)-ascorbic acid and silver nitrate solutions are mixed. Further silver ion reduction is accelerated at the silver surface with the UV irradiation, where the reduction rate is faster than the diffusion rate of silver ions (diffusion-limited condition). The condition causes the growths of stems with side-branches (1st generation). The growth direction is different from the stems and side-branches by 60°. The side-branches are also grown with emitting leaves at the same angle, resulting in the 2rd generation, and the leaves may emit finer structures for the higher generation. The iteration of needle growth and branching at different scales leads to complex fractal structures, giving a variety of plasmonic properties.
Surface plasmons of the growing AgTFSs can be excited by irradiation of light from ultraviolet to visible light region. The excitations also depend on the polarization direction, which may affect the growth of AgTFSs. In this study, we discuss the growths of AgTFSs under irradiation of white light in visible regime. Nanostructures of various shapes are observed while repeating the formation of needles and branches at every moment during the growth process. A white light sauce gives the broadband and unpolarized light in visible regime, which can interact constantly and efficiently with all nanostructures such as seeds, needles and branches in the growth process from the moment that the silver nuclei are formed. The geometries of the AgTFSs may be affected by the interaction. In the case of laser illumination, surface plasmons may be excited only at the selected sites matched to the illumination conditions, such as the laser wavelength and polarization. For example of a ultraviolet laser irradiation, tips at

least 20-30 nm of nanostructures can interact with the light, which may affect the geometries of the tips of AgTFSs. AgTFSs were grown by mixing L(+)-Ascorbic acid and silver nitrate solution under halogen lump. The L(+)-Ascorbic acid solution was kept in a dark room for at least 24 hours to avoid the poor reproducibility of the AgTFS. The self-grown AgTFSs were observed with a scanning electron microscope (SEM) to confirm the shape and size. The shape is characterized by a fractal dimension (D_f) [2], which was analyzed by the box-counting method with SEM images of AgTFSs [3]. In the presentation, we will discuss the differences in size and shape of AgTFSs between with and without irradiation of a white light.

Plasmonic Superlattices of Gold Nanohexagon with Controllable Gap for Unnaturally High Index in Near Infrared Region

Dong-In Shin; Sungkyunkwan University, Korea (the Republic of)

The refractive index (RI) stands out as a crucial parameter in material science, playing a key role to determine the interaction between light and matter within a medium. Therefore, the precise manipulation and enhancement of the RI hold significant importance across a broad spectrum of applications, including optical and electronic devices as well as metamaterials. While the fabrication of high-index structures has conventionally involved the widespread use of e-beam lithography in the terahertz regime through a top-down approach, this method often requires high-cost equipment and intricate skills. Moreover, creating narrow nanogaps (<10 nm) between nanoparticles on a large scale, essential for strong light-matter interaction in the visible and infrared regions, is significantly challenging. In contrast, the self-assembly of colloidal nanostructures, a bottom-up approach, offers precise control over size, crystallinity, and shape uniformity. This approach presents a highly effective tool to design two-dimensional metamaterials with a high RI.

Plasmonic nanoparticles (NPs) display localized surface plasmon resonance (LSPR) on their surfaces by incident light, exhibiting distinctive optical characteristics that can serve as foundational components in various applications including optoelectronic devices, catalysts, and chemical or biological sensors. Nevertheless, the predominant focus in research has been on spherical gold (Au) and silver (Ag) nanoparticles, characterized by intrinsic properties strongly tied to the visible range (400-750 nm). To broaden the spectrum of localized surface plasmon resonance into the near-infrared range (0.78-3 μm), it is essential to tune the size and shape, including the aspect ratio, of these fundamental units. Specifically, for inducing plasmon resonance in the infrared region, the size of individual building blocks should range from approximately 200 nm to 750 nm, roughly one-fourth of the electromagnetic wavelength. To enhance plasmonic coupling between nanoparticles and minimize the diamagnetic response induced by displacement current simultaneously, it is preferable to adopt a plate-like shape in the design of building blocks. Structures made up of triangular, square, and hexagonal building blocks, featuring line-to-line contact rather than dot-to-dot contact, enhance plasmonic coupling. Among these shapes, triangular-plate particles introduce symmetry-breaking in plasmon modes due to the odd vertex count, while uniform synthesis of square-plate particles is significantly challenging due to the growth mechanism of gold nanoparticles. Conversely, hexagonal-plate particles offer the advantage of maintaining symmetry in plasmon modes and are comparatively easier to synthesize uniformly. Moreover, they can be ideally assembled to form a large area film with a uniform gap distance, facilitating strongly percolated plasmonic resonance between nanoparticles.

In this study, we intricately designed Au nanohexagon (AuNH) capable of generating plasmon-symmetric polarization through a bottom-up synthesis approach. Through the introduction of hetero-ligands onto the surface of nanohexagons, they can serve as fundamental building blocks, resulting in the formation of a self-assembled, large-area thin film of periodic arrays of Au nanohexagons with nanoscale gaps. The assembly of 2D Au nanohexagons superlattices demonstrated a notably high refractive index, reaching the highest-ever value of 10.04 in the near-infrared (NIR) region. Additionally, as a proof-of-concept, a solution-processable 2D plasmonic superlattice of AuNHs was employed to produce a distributed Bragg reflector (DBR), indicating its potential applications in areas such as sensors and photonic devices.

EL07.15.03

Measurement Techniques of Low Symmetry Polaritons in the Monoclinic Crystal Bismuth Triborate Through Infrared Spectroscopy Mohit Pradhan and Thomas G. Folland; The University of Iowa, United States

Low symmetry anisotropic material interaction with incident light results in highly directional propagation of polaritons that exhibit exotic properties. The light-matter coupling (polaritons) in anisotropic material can have hyperbolic light propagation, and at the lowest symmetry of the crystal axis, the sheer effect acts on the hyperbolic polaritons. Probing these remarkable effects from anisotropy has been challenging, relying on specialized free electron lasers. Our work has developed techniques and implemented novel tools to observe these hyperbolic/hyperbolic sheer polaritons in low symmetry anisotropic crystals in mid to far infrared regions.
We explore surface phonon polariton propagation (SPhPs) in low symmetry anisotropic material through two different developed techniques of Fourier transform infrared (FTIR) spectroscopy that allow us to measure crystal orientation-dependent optical properties. The techniques are applied to Bismuth Triborate (BiB_3O_6) crystals with (100) and (010) orientations. Primarily, we performed the infrared reflectance measurement of the samples; the measurement allowed us to study the anisotropic Reststrahlen bands of the material which further helped in understanding the phonon bands present in the material. From the phonon band structure, we could better determine where the polaritonic activity occurs while also exploring the differences in the phonon band structure of the two crystal samples. Lastly, we developed Otto-type prism coupling measurements using ZnSe prism to measure the polariton propagation. The approach utilizes evanescent fields produced from the incident light on the prism to propel SPhPs. With variations of incident beam angle and azimuthal crystal orientation angle, we were able to observe the polariton propagation of BiB_3O_6. Through the results of our study, BiB_3O_6 greatly demonstrates low symmetry polaritonic behavior that is influenced vastly by its incident crystal axis and is a great candidate for further studying the nature of polaritonic behavior of low symmetry materials.

EL07.15.04

Insights into the 1.53 μm Luminescence Enhancement in Er^{3+}-Doped Tellurite Glasses via Quantum Emitter and Plasmonic Coupling at Low Temperatures Gaston Lozano Calderón[1], Víctor Anthony García Rivera[2], Younès Messaddeq[2] and Euclydes Marega Junior[1]; [1]Universidade de São Paulo, Brazil; [2]Université Laval, Canada

In the literature, the influence of metallic nanoparticles on the luminescence performance of rare-earth ions in glasses at room temperature is extensively discussed. Nevertheless, the interaction with the localized surface plasmon resonance and quantum emitters, in this case, the rare-earth ions, needs to be covered in in-depth analysis, especially in temperature-dependent spectroscopy. In this research, Er^{3+}-doped tellurite glasses with and without embedded gold nanoparticles were fabricated to study the coupling between Er^{3+} ions and the localized surface plasmon at controlled temperature. Here, a large emission enhancement, which involves increments of the FWHM and emission intensities, was obtained for the sample with nanoparticles (TErAu) compared with the simple Er^{3+}-doped (TEr) at different temperatures (-180 to 25 °C). The increment of the band area of the TErAu with respect to the TEr sample is about 66% at room temperature. Regarding temperature-dependent spectroscopy, the enhancement was quantified by measuring the relative area increment, I_{rel}, of the 1.53 μm emission band under 980 nm excitation, i.e., the ratio between the band area at a given temperature T and 25 °C (T < 25 °C). The Irel comparing the bands at -180 and 25 °C of the TEr sample is 348%, whereas for the sample TErAu is 414%. The enhancement is a consequence of the strong coupling between the Er^{3+} and the plasmon, which is attributed to an increment of the localized plasmon mode volume at low temperatures. Such mode volume is analyzed considering the changes in temperature-dependent permittivity, thermal contraction, free-electrons density and computing calculations of the damping parameter. These findings provide new directions toward engineering the Er^{3+} emission performance with the presence of gold nanoparticles.

EL07.15.05
Wafer-Scale Characterization of High-Density Blue Micro-LED Arrays with an Optimized ITO Layer Hyeong-Ho Park, Young Su Choi, Sang Hyun Jung, Eun Jeong Youn and Eun-Kyung Chu; Korea Advanced Nano Fab Center, Korea (the Republic of)

Micro-light-emitting diode (Micro-LED) technology continues to attract strong interest due to the high resolutions, outstanding luminous efficiency, remarkable brightness, and impressive durability. These features make these types of diodes a most promising platform in high-end display applications such as mobile phones, wearable watches, and augmented reality (AR)/virtual reality (VR) displays, which require high luminance, high refresh rates, and high pixel-per-inch (PPI) values. Despite the advancements in micro-LED technologies, several issues hinder their widespread application. For example, the application of near-eye displays to industrial mass production requires comprehensive wafer-scale characterization of blue micro-LED arrays. To the best of our knowledge, wafer-scale characterization of the blue micro-LED arrays has not yet been reported in detail. In addition, we still need to improve the optimization of indium tin oxide (ITO) films. This is associated with high power consumption resulting from the high forward voltage (V_F), attributed to the weakened optical and electrical properties of the ITO films. These motivations drove us to undertake the four-inch wafer-scale characterization of high-performance blue micro-LED arrays with a resolution of 1692 PPI to realize micro-LED displays with a high-density resolution. This study presents the four-inch wafer-scale fabrication of blue micro-LED arrays on a sapphire substrate with a resolution of 1692 PPI, accomplished by optimizing the properties of e-beam-deposited ITO (E-ITO) and sputter-deposited ITO (S-ITO) as a current-spreading layer ultimately to realize high-performance micro-LED displays. The surface morphology of the S-ITO film was relatively smooth and dense, while that of the E-ITO films was rather rough. The roughness of the E-ITO films is approximately 7.72 times greater than that of the S-ITO films. Also, the measured resistivity of the S-ITO films is 4.86×10^{-4} ohm cm, much lower than that of the E-ITO films, at 5.96×10^{-3} ohm cm. Interestingly, although the S-ITO films exhibited a densely packed morphology and lower resistivity compared to the E-ITO films, the V_F values of a micro-LED created with the S-ITO films were higher than those of a micro-LED created with the E-ITO films. The V_F values of a single pixel with the optimized E-ITO layer from region 1 to region 5 on a four-inch wafer are 2.88, 2.81, 2.81, 2.82, and 2.79 V at 30 A/cm^2, respectively. Also, with four pixels, the corresponding V_F values of the five different regions are 2.89, 2.83, 2.83, 2.83, and 2.79 V at 30 A/cm^2. Surprisingly, the V_F variations of a single pixel and of four pixels with five different regions are only 3.13 % and 3.46 %, respectively. As the current density was increased from 30 to 1,500 A/cm^2, the blue shifts in the electroluminescence (EL) peaks wavelength were approximately 8.2, 7.5, 6.4, 8.2, and 6.3 nm from region 1 to region 5, respectively. In addition, the corresponding variations of the full width at half maximum (FWHM) values on a four-inch wafer were approximately 10.5, 9.9, 9.8, 8.9, and 11.2 nm, respectively. The values of V_F, the emission wavelength, and the FWHM are very low and show a narrow distribution on the four-inch wafer. Also, various emission images of passive matrix-type blue micro-LEDs utilizing the optimized E-ITO spreading layer at 583 pixels and 847 pixels simultaneously demonstrate good display uniformity and brightness. These observations highlight the immense potential of blue micro-LEDs for demanding display applications, showcasing their ability to meet rigorous criteria for superior image quality in practical applications.

EL07.15.06
Plasmonic 2D Quasicrystals with Different Orientational Order for Strong Light-Matter Interaction Marzia

Ferrera[1], Vincenzo Aglieri[1], Jacopo Stefano Pelli Cresi[1], Lyuye Lin[1], Elena Ghidorsi[1,2], Remo Proietti Zaccaria[1] and Andrea Toma[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy

Numerous systems, from biological structures to solid-state devices, are driven by light-matter interaction. In many cases, this interaction is rather weak and such that the electromagnetic radiation can be treated as an external perturbation to materials. However, under specific circumstances, the energy exchange rate between light and matter can become faster than any other relaxation process and the system can enter the strong coupling regime. Hybrid light-matter states, called polaritons, emerge with an energy separation, known as Rabi splitting, dependent on the coupling strength. Strong light-matter interaction can thus be used as a tool to fundamentally reshape the material properties, with significant implications on technologically-relevant processes in various fields, spanning from photocatalysis to optoelectronic and quantum technologies [1].
Within the polariton panorama, particular interest has been addressed towards polaritonic systems in which quantum emitters, such as dye molecules and low-dimensional semiconductors, are integrated with plasmonic architectures. Among the proposed plasmonic platforms, 2D periodic nanohole arrays supporting surface plasmon polariton Bloch waves (SPP-BWs), *i.e.* standing waves of propagating SPPs, were extensively used since they are characterized by a planar and open architecture which facilitates both the placement of the excitonic material and, in the hybrid system, the excitation and probing of polaritons. Moreover, their main resonance features can be finely tuned by acting on both the array symmetry (*i.e.* hole arrangement) and geometry (*i.e.* inter-hole distance and hole diameter) [2]. Additional degrees of freedom in the design of the plasmonic component can be offered by the exploitation of metasurfaces lacking periodic translational order. Quasicrystals (QCs), ordered structures with a long-range quasiperiodic translational order and a long-range orientational order, belong to this category. In the reciprocal space, they are indeed characterized by a high density of diffraction peaks, which provides a quasi-isotropic multi-k-vector system with highly tunable optical properties [3].
Here, we show that QCs can be used as a platform extension beyond crystal-like nanohole metasurfaces to be integrated with quantum emitters for the realization of strongly-coupled hybrid devices. Nanohole patterns characterized by diverse quasicrystalline configurations were milled through an optically-thick silver film and coupled to J-aggregates of TDBC dye. Steady-state transmittance spectroscopy was employed to investigate the radiative properties of the hybrid structure. The presence of the anti-crossing behavior, as one of the distinctive fingerprint of strong-coupling regime, was assed and investigated. Moreover, our results highlight that the exploitation of quasiperiodic arrays generated by different tilings allows to obtain plasmonic structures with distinctive symmetry-dependent resonance features and, thus, enables the realization of polaritonic systems with tailored properties. More in general, our findings may inspire further exploration towards novel heterostructures, where plasmonic 2D quasicrystals are combined with low-dimensional semiconductors, such as quantum dots or 2D materials.

This work is part of the REPLY project that received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program (grant agreement No 101002422).

Nonreciprocal Reflection of Mid-Infrared Light from Flat InAs Interfaces at Low Magnetic Fields Simo Pajovic[1], Yoichiro Tsurimaki[2], Xin Qian[3], Gang Chen[1] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States; [3]Huazhong University of Science & Technology, China

Lorentz reciprocity—which, broadly speaking, states that a source and a detector of electromagnetic radiation can be interchanged—assumes that the constitutive relations in Maxwell's equations are linear and that the permittivity and permeability tensors are time-invariant and symmetric. The latter assumption can be broken using magnetic fields to create antisymmetric off-diagonal components of the permittivity tensor, giving rise to a number of nonreciprocal, magnetooptic effects such as the Faraday effect [1]. Nonreciprocity enabled by magnetic fields is of particular interest for its applications to thermal radiation, as it can lead to highly directional emission and absorption and the breakdown of Kirchhoff's law of thermal radiation [2]. Candidate materials for these applications include highly-doped semiconductors such as InSb and InAs and magnetic Weyl semimetals [3], as they are predicted to support nonreciprocity in the mid- to far-infrared spectral range. Despite the promise of these materials, few experiments have been done to understand their capabilities under different conditions. We experimentally observed nonreciprocal reflection of mid-infrared light (~16 μm) from flat InAs interfaces at magnetic fields lower than 0.2 T, achieved using low-cost, off-the-shelf neodymium magnets. Using spectroscopic ellipsometry, we showed that the amplitude ratio Ψ and phase shift Δ of reflected light are nonreciprocal in the Voigt configuration (magnetic field direction perpendicular to the plane of incidence). Furthermore, we showed that it is possible to fit the permittivity tensor by measuring Ψ and Δ, without the need for time-consuming Mueller matrix measurements, using symmetries present in the Voigt configuration. Fourier-transform infrared spectroscopy (FTIR) measurements confirmed that the reflectance of p-polarized light is nonreciprocal. The reflectance contrast, defined as the difference in reflectance at opposite angles of incidence, increases with the magnetic field magnitude for p-polarized light and is zero for s-polarized light, as expected. We observed this phenomenon at magnetic fields as low as 0.07 T, without the need for couplers such as gratings or prisms. Our work is a step toward practical implementation of nonreciprocal thermal emitters and absorbers and could enable other applications such as remote magnetic field sensors. This work is supported by ARO MURI (Grant No. W911NF-19-1-0279) via U. Michigan. S. P. gratefully acknowledges support from the NSF GRFP under Grant No. 2141064.

Exploiting Multiple Scattering Materials and Techniques for Data Encryption and Storage

Mohammadrasoul Taghavi and Edwin A. Marengo; Northeastern University, United States

Securing sensitive information such as passwords and biometric data, as well as ensuring real-time identification and validation, is of paramount importance across various sectors, including banking and homeland security. Traditional holography has leveraged the hologram's dependence on illumination as an encryption key; and recent advancements—such as using orbital angular momentum (OAM), space light modulators (SLMs), and programmable metasurfaces—have expanded the key space and enhanced security. Additionally, employing complex, multiple scattering media has become a practical strategy for creating resilient ciphertexts. This method scrambles information-carrying waveforms via intricate, multipath channels, making decryption difficult without detailed knowledge of the medium or decryption models. Current methods that utilize media with complex scattering responses that blend the propagated signal are susceptible to eavesdropping by various interceptive attacks. Some existing methods also use machine-learning-based computational techniques for encryption, increasing the computational burden and requiring additional steps. Moreover, storing the algorithm and data on a server makes them vulnerable to hacker attacks. Herein, we introduce several techniques and algorithms to improve the functionality of multiple-scattering-based approaches for image and data encryption. We explore the use of dual scattering media in the encryption and decryption process, where the information is embedded in the differential signal corresponding to the two media. The utilized scattering media, which we refer to as keys, are random distributions of clusters of nanoscatterers, such as dielectric and plasmonic nanoparticles or nanoantennas in a background medium, with each key having a unique distribution of scatterers. Nevertheless, we explore potential candidates for use as scattering media, including novel metamaterials. We analyze the security benefits they offer and compare the performance of these different materials. We also discuss the advantages of using the differential sensing technique over previously utilized single scattering medium encryption methods and its resistance to brute-force interceptor attempts. Furthermore, we introduce another method where, in the case of using the correct keys, the output image becomes null or of low amplitude, which can be used for verification and barcode storage applications. We also present our simulation platform, which enables the calculation of the scattered field after it passes through a scattering material that may consist of thousands of scatterers. In contrast to earlier works that emphasized analog encryption followed by digital decryption, our approach highlights the complementary method of conducting encryption either analogically or digitally, paired with real-time analog decryption using appropriate scattering media. Finally, our proposed innovations provide a robust framework for real-time secure information processing.

Unveiling Plasmonic Dynamics in Hierarchical Gold Superparticles Pietro Castronovo[1], Cristian Gonzalez[2], Shengsong Yang[2], Daniele Catone[3], Alessandra Paladini[3], Patrick Okeeffe[3], Christopher B. Murray[2], Emanuele Marino[1], Fabrizio Messina[1] and Alice Sciortino[1]; [1]Università degli Studi di Palermo, Italy; [2]University of Pennsylvania, United States; [3]Consiglio Nazionale delle Ricerche, Italy

Plasmonic nanoparticles are attracting much interest in the recent literature [1-3]. Their optical properties have been intensively studied [4-5] by different experimental and theoretical techniques. Recently, superparticles obtained by the hierarchical assemblies of colloidal nanoparticles have shown great promise in transitioning materials from the nanoscale to the mesoscale, building artificial materials with new properties stemming from the crosstalk between constituent nanoparticles. [6] While significant advances have been made in the self-assembly of semiconductor nanoparticles [6-7] the fundamental photophysics which governs their optical response remains largely unclear. In particular, little information is available on the dynamics of photoexcited superparticles made from the ordered assembly of plasmonic nanoparticles.

We synthesized superparticles (SPs) with a size of about 200-300 nm via by the self-assembly of different size gold nanoparticles (AuNps) by an oil-in-water emulsion template technique. After the synthesis of the SPs the length of the ligands between the nanoparticles has been changed by a ligand exchange protocol, in order to control the distance between individual AuNPs within the SPs, as a handle to control the properties of the final product. The plasmonic properties of the resulting SPs have been studied by femtosecond transient absorption spectroscopy and microscopy in order to reveal the difference between the isolated plasmonic nanoparticles and the SPs and the effects of different assembly conditions.

The absorption profile of SPs results broader than a colloidal suspension of isolated nanoparticles suggesting that their optical properties are regulated by the interactions between the single constituents rather than a simple sum of isolated AuNPs contributions. Moreover, femtosecond transient absorption (FTA) measurements reveal interesting differences between the relaxation dynamics of bare gold nanocrystals and that to the gold superparticles. In particular, both the spectral position and kinetics of the negative peak of the FTA signal of the superparticles depends on the mutual distance between the nanoparticles. In particular, the timescale typically associated to the electron-phonon scattering decreases as a function of length of the ligands. The results provide new insight on the fundamental electronic dynamics of plasmonic superparticles and pave the way to their applications in nanotechnology.

Enhancing Light-Matter Interaction in Molybdenum Disulfide Monolayers Using Plasmonic Nanostructures

Matheus Fernandes S. Lemes[1], Ana Clara S. Pimenta[1], Gaston L. Calderón[1], Marcelo de Assumpcao P. da Silva[1], Guilherme Migliato Marega[2], Richardo Chiesa[2], Andras Kiss[2], Alessandra Ames[3], Márcio D. Teodoro[3] and Euclydes Marega Junior[1]; [1]University of São Paolo, Brazil; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]Universidade Federal de São Carlos, Brazil

Two-dimensional transition metal dichalcogenides (2D TMDs) have attracted considerable attention due to their distinctive properties and potential applications in electronics and optoelectronics. Despite their promise, the light absorption efficiency of these materials is hindered by their atomically thin nature, necessitating innovative strategies to enhance and manipulate light-matter interactions. One promising approach involves the use of plasmonic nanostructures, which can amplify and modulate the electromagnetic field in their vicinity, thus enhancing light-matter interactions in 2D TMDs. Molybdenum disulfide monolayer is an example of a 2D TMD compound, considered one of this family's most stable layered materials [1]. It is an inorganic semiconductor with a direct bandgap and high photoluminescence emission, where the optical response is primarily determined by excitonic transitions [1]. In addition, the molybdenum disulfide monolayer exhibits only three first-order Raman active modes [3], being that Second-order bands can also be observed, depending on the excitation energy [4]. In this study, we investigate the vibrational and optical properties of molybdenum disulfide monolayer deposited on gold grating. The grating is composed of long sub-wavelength slits with a width of 100 nm, separated by a periodicity of 1000 nm. We examined the molybdenum disulfide monolayer on both supported and suspended regions inside the grating. Our results show that the molybdenum disulfide monolayer exhibits greater biaxial tensile strain in the regions supported compared to the uniaxial tensile strain observed in the suspended regions within the slits. Furthermore, we find that electron doping in the molybdenum disulfide monolayer within the slits varies with the polarization of the incident radiation. This polarization effect is not observed in the monolayer in direct contact with the Au substrate. This polarization dependence is interpreted in terms of plasmon-induced hot electron injection. It is supported by numerical simulations that indicated localized surface plasmons within the slits for this electric field configuration. Photoluminescence measurements further reveal a polarization-dependent ratio of Trion to A exciton intensity, corroborating the proposed plasmon-induced doping mechanism. These findings contribute to a deeper understanding of the underlying physics in hybrid molybdenum disulfide monolayer on Au nanostructures, offering insights that could advance fundamental plasmonic research and foster future technological applications.

Volumetric Photonic Crystal Scintillators Sachin Vaidya[1], Marius Jürgensen[2,3], Charles Roques-Carmes[1,3], Simo Pajovic[1], Shaul Katznelson[4], Jonathan Gales[2], Joshua Chen[1], Steven Kooi[1], Ido Kaminer[4], Mikael Rechtsman[2] and Marin Soljačić[1]; [1]Massachusetts Institute of Technology, United States; [2]The Pennsylvania State University, United States; [3]Stanford University, United States; [4]Technion–Israel Institute of Technology, Israel

Scintillators are materials that convert high-energy particles, such as X-rays, free electrons, or gamma rays, into optical photons through a complex cascade of processes. These materials are central to various modern imaging technologies, including diagnostic medical imaging and non-destructive testing. Integrating nanophotonics with scintillators represents a promising direction poised to advance several technologies by directly controlling and tailoring the light emission process. For instance, utilizing the Purcell effect can increase the rate of spontaneous emission, yielding significantly brighter scintillators (see: Kurman et al., arXiv:2302.01300 (2023)). This enhancement would directly translate to reduced X-ray dosage in medical settings, thereby decreasing the risk of radiation exposure to patients. Previous approaches have incorporated surface patterns in relatively thin scintillators to enhance the out-coupling of emission (see: Roques-Carmes, Rivera et al., Science 375 (6583), eabm9293 (2022)). Here, we demonstrate the fabrication and characterization of bulk-patterned (volumetric), two-dimensional photonic crystal scintillators that exhibit significant emission enhancement while being several hundred microns thick. Notably, we find that this enhancement results from a combination of bulk and surface effects, arising from the wavelength-scale periodicity of the photonic crystal embedded within the scintillating material

EL07.15.12

Dynamic, Tunable and Multi-Functional Liquid Crystalline Geometric Phase Optics Michael J. Carter[1], Nelson Tabiryan[2], Nicholas Godman[1], Michael Mcconney[1], Jonathan Slagle[1] and Timothy J. Bunning[1]; [1]Air Force Research Laboratory, United States; [2]Beam Engineering for Advanced Measurements Co., United States

Artificial materials composed of engineered subwavelength structures with a designer optical response, known as metamaterials, have a rich scientific history. Initial experimental work in this field was limited primarily to longer wavelengths (e.g., radiofrequencies) due to fabrication challenges associated with producing 3D nanostructured materials [1]. Advances in foundry-based planar nanofabrication techniques in combination with novel design approaches has given rise to a rich and vast field of research concerning 2D nanostructured surfaces, known as metasurfaces [1–3]. Over the past few decades research concerning metasurfaces has spanned from studies of fundamental light-matter interactions with dielectric and plasmonic nanostructures [4,5], to demonstrations of planar optical components capable of focusing, beam deflection and holography [1–3,6,7]. Even more recently the field has expanded to include demonstrations of non-linear metasurfaces with exceptional effective non-linear properties [8] and multi-functional metasurfaces capable of simultaneous control of the different degrees of freedom of light [9]. Despite these extensive efforts, several fundamental research challenges remain concerning optical metasurfaces, including the low efficiency of optical metasurfaces, particularly those that target broadband, achromatic optical functionalities and challenges producing high-efficiency dynamic metasurfaces which can be modulated in a repeatable and fast-manner [1,7,10].

An alternative and potentially complimentary approach towards the design and fabrication of artificial 2D and 3D optical materials with engineered optical response involves spatial patterning of the optical birefringence axis in a liquid crystal (LC) material, which modulate the phase of light leveraging the well-known geometric phase. This class of 2D or 3D patterned optical material are known as geo-phase materials and LC-based implementations can achieve ultra-high optical efficiencies [11] due to reliance on molecular scale self-assembly, which alleviates traditional losses in conventional optical metasurfaces (e.g., scattering and absorption). Another benefit of LC-based geo-phase materials is the intrinsic tunability and active nature of LCs. In this talk we will present recent work on LC based geo-phase optics, including demonstrations of dynamic, tunable optical functionality and of polarization insensitive, broadband optical functionality based on multilayered structures where the optical birefringence pattern is controlled in three-dimensions [12]. Finally, we will discuss tradeoffs between LC geo-phase optics and conventional metasurfaces and highlight, when possible, potential means for these two different approaches towards the design and fabrication of artificial optical materials to be used complimentarily.

New Amphiphilic Complexes with Luminescent Rare Earth Ions Jaycie A. Jenkins, Chantel Johnson, Ashleigh K. Wilson, Chi Yang, John N. Munga, Ezekiel Mills and Natalia Noginova; Norfolk State University, United States

Organic compounds containing luminous rare earth ions are of interest for numerous nanophotonic and plasmonic applications, including nanoscale lasers, biosensors and optical magnetism studies. We synthetize amphiphilic complexes with various rare earth ions (Eu3+, Nd3+, and Yb3+) and DPT ligands, and show that they are suitable for monolayer or multilayer deposition with the Langmuir-Blodgett (LB) technique. These materials are very promising for plasmonic applications and studies. In particular, optical studies of Eu3+ complexes reveal that ultra-thin LB monolayers are highly luminescent even when deposited directly on plasmonic metal, which is ascribed to the collective effects in the closely packed emitters' layer. These new complexes allow one a better opportunity to control and enhance magnetic dipole emission with a plasmonic environment. Using plasmonic cavities and nanomesh structures, we demonstrate significant enhancements of magnetic-to-electric branching ratio up to the order of magnitude.

Tunable Periodicity in Metal Nanogratings for Optimized Plasmon-Enhanced Upconversion Luminescence in Er^{3+}/Yb^{3+} Co-Doped GPG Glasses Jessica F. dos Santos[1], Vinícius B. Marcos[1], Otávio d. Silva[2], Luciana R. Kassab[3], Victor Rivera[4] and Euclydes Marega Junior[1]; [1]University of São Paolo, Brazil; [2]Universidade Estadual do Piauí, Brazil; [3]Faculdade de Tecnologia São Paulo, Brazil; [4]Université Laval, Canada

Surface plasmonics provide a powerful means to manipulate light at the nanoscale, offering innovative techniques to control the excitation and emission properties of quantum systems. Confining electromagnetic fields in extremely small volumes is essential for advancements in fields such as nanophotonics, biosensing, biotechnology, medical imaging, and more. The unique appeal of metallic nanostructures in plasmonics stems from their fascinating linear and nonlinear optical properties, which are significantly affected by parameters like shape, depth, and periodicity. Understanding and leveraging these factors enable precise tuning of optical responses, enhancing the performance and functionality of nanophotonic devices. This study analyzes the influence of the shape and periodicity of Au-plasmonic nanostructures on the enhancement of upconversion emission from Er^{3+} (1.0 wt%) and Yb^{3+} (3.0 wt%) ions. Circular and square grating nanostructures with periodicities ranging from 200 to 1000 nm were fabricated on GeO_2-PbO-Ga_2O_3 glasses (GPG: Er^{3+}/Yb^{3+}) using focused ion beam (FIB) lithography on a gold film. Plasmon-enhanced upconversion was studied using a combination of a confocal microscope and a motorized microscope setup. Upconversion emissions in the green (~550 nm) and red (~655 nm) spectra were observed for all samples when excited with a λ_{ex}= 980 nm in the near-infrared. The strongest upconversion emissions were noted in nanostructures with smaller periodicities. The excitation of Er^{3+} ions leads to emissions facilitated by plasmonic nanostructures, attributed to extraordinary optical transmission from the periodic nanostructures. To explain this behavior, we propose an energy transfer mechanism $Yb^{3+} \rightarrow Er^{3+}$ followed by a resonant coupling between Er^{3+} and surface plasmon polariton. This coupling modifies the local field, improving the emission intensity of Er^{3+}. These findings can be very useful for nanophotonic device applications employing a transparent medium with optical gain.

EL07.15.15

Room-Temperature Plasmonic Lasers with Quasi-2D Perovskite Gain Medium Yen-Yu Wang[1], Xing-Hao Lee[1,2], Chiung-Han Chen[2], Linchyn Yuan[1,2], Tzu-Yu Peng[1,2], Jia-Wern Chen[1], Chu-Chen Chueh[2] and Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Room-temperature lasers are pivotal for advancing optical communication and quantum technologies but face significant challenges, such as material instability and high lasing thresholds. To overcome these issues, we exploit the unique properties of quasi-2D perovskites and high-Q plasmonic nanostructures for both enhancing the optical gain and coupling strength. Our study introduces a stable, wavelength-tunable room-temperature single-mode laser, utilizing $PEA_2Cs_{n-1}Pb_nBr_3n_{+1}$ quasi-2D perovskites (n=5, λ_{PL} = 518 nm) coupled with a waveguide-hybridized surface lattice resonance (SLR) mode composed of aluminum nanoparticle arrays. This configuration leverages the enhanced light-matter interaction of the SLR cavity, tailored *via finite-difference* time-domain (FDTD) simulations. Additionally, amplified spontaneous emission (ASE) from trap states in the quasi-2D perovskite significantly boosts optical gain in the system. The results confirm the laser's performance and operational stability in an atmospheric environment; the gain medium maintained stable emission intensity up to 1.8×10^6 excitation pulses. By adjusting the periodicity of the surface lattice resonance (SLR) nanostructures, we achieved a tunable lasing wavelength across a 20 nm spectral range. Our findings establish a low-cost, energy-efficient approach for scalable plasmonic lasing. This advancement not only broadens the understanding of plasmonic systems but also unlocks potential in next-generation photonic applications such as sensing, optical communication, and computation. Finally, we will discuss the detailed working mechanisms of the room-temperature nanolasers.

EL07.15.16

High-Performance p-WSe2/p-Si Isotype Heterojunction Photodetector with Ultra High Detectivity and Responsivity Beomsu Jo[1], Ramu Singiri[1], Myung Gwan Hahm[2] and Young Lae Kim[1]; [1]Gangneung-Wonju National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

A p-p isotype heterojunction photodetector was fabricated using a p-type Si substrate and p-type monolayer WSe2 synthesized via chemical vapor deposition (CVD). The heterojunction of WSe2 and Si results in the accumulation of electrons on WSe2 and holes on the Si side, thereby creating an internal electric field. And combination of both materials, which are p-type, results in a notable reduction in recombination in the depletion region, thereby markedly enhancing the photodetection capabilities. The photodetector is capable of detecting light in the wavelength range of 400 to 1550 nm, with a high responsivity of 568 A/W at 532 nm and an external quantum efficiency (EQE) of 1.331 x 10^5 %. Furthermore, the device exhibits a high On/Off ratio of 2.811 x 10^4 and an ultra-high detectivity of 2.075 x 10^15 Jones, due to a minimized dark current of 5 nA. Furthermore, the internal electric field generated by the heterojunction contributes to excellent photovoltaic behavior at open circuit voltage (Voc), rendering it highly suitable for Internet of Things (IoT) and wearable devices. The promising results of these p-WSe2/p-Si heterojunction devices indicate significant potential for next-generation photodetectors.

EL07.15.17

Generating Multiplicative Encoding Space of Optical Physically Unclonable Function Based on Spatial Frequency Limiting Jeong Jin Kim, Min Seong Kim and Gil Ju Lee; Pusan National University, Korea (the Republic of)

Conventional security systems are facing new threats from advanced hacking tools, machine learning, and even the emergence of quantum computing. In this context, physically unclonable functions (PUFs) have emerged as a highly unpredictable encryption primitive due to inherent randomness. Specifically, optical PUFs harness light-matter interactions, providing advantages such as higher entropy, easy modulation, and various functionalities, making them a promising option for next-generation authentication and communication systems.

When using the simplest authentication system using optical PUF, the system is divided into three main parts: light emitter (*i.e.*, input referred to as the challenge), the photonic medium (*i.e.,* PUF tag), and the image sensor (*i.e.*, output referred to as the response). At this point, increasing the number of challenge-response pairs (CRPs) is equivalent to increasing the number of possible encryption keys generated from a single PUF. Furthermore, the extensive CRP space can be partitioned into smaller segments or concatenated to create larger keys with greater encoding capacity, depending on the encryption purpose (*e.g.*, the smaller for one-time passwords and the larger for high-resolution images XOR encryption). To support the potential PUF-based platform, retaining the extensive CRP space is crucial. Unfortunately, recently reported optical PUF systems tend to rely solely on digital micro-mirror devices (DMDs) to increase the number of CRPs. However, such excessive dependency is undesirable for achieving a highly extensive CRP space, and the quantitative feasibility of expanding with DMDs has not been thoroughly analyzed.

Herein, we propose an integrated system that employs optical elements to effectively expand the CRP space of optical PUF without DMDs. First of all, PUF tags are fabricated by a stochastic wet etching process. A Cr-mask deposited quartz substrate is dipped into BOE and stochastic generation of pinholes occurs on the mask. Then, BOE penetrates the mask through the pinholes and forms hemispherical pits on the quartz substrate. After removing the remaining Cr mask, the PUF tags with millions of micro-pits (*i.e.*, 2D-optical scatterer) on its surface are obtained. When illuminated by a coherent light source, numerous pit pairs generate interferometric fringe patterns, and their superposition produces highly unpredictable speckle images for encryption keys.

With the fabricated PUF tags, the authentication system can largely expand CRP space by utilizing the following three components. First, a tunable laser modulates wavelengths of probing light for spectral expansion of CRP space. Due to changes in refraction extent at the scattering pits, distinct speckle images are obtained. Second, a mirror modulates the incident angle of probing light toward the PUF tag for angular expansion. The illuminated area is shifted and different scattering regions engage in interference. Third, the aperture in front of the PUF tag filters the spatial frequency of the speckle. The farther two pits apart, the denser fringe patterns(*i.e.*, high spatial frequency and small speckle size) are observed, whereas closer pits generate sparser patterns(*i.e.*, low spatial frequency and large speckle size). In short, by adjusting the size of the aperture, fixing and selecting the size of speckles in the response image is feasible.

We anticipate this methodology will serve as a key cornerstone for developing future security platforms based on PUFs. The operations of each component can be combined multiplicatively, allowing for the acquisition of over 200 speckle images for encryption keys from a single tag. Smaller speckles are used for trivial purposes such as the everyday use of IoT devices, and larger speckles can be tailored to be partitioned or concatenated to achieve intensive security levels from one-time passwords to confidential long encryption keys, introducing hierarchical authentication.

Nitride Nanopatterning for Optoelectronic Advancements Sudarshana Patra, Carter Herbert, Lane Nichols, Uttam Manna and Mahua Biswas; Illinois State University, United States

Nanopatterning of inorganic materials is an emerging field with a wide range of applications such as optoelectronics, photonics, energy, and biomedical engineering. Group III nitride materials particularly Gallium Nitride (GaN) and Aluminum Nitride (AlN), are noteworthy due to their exceptionally wide bandgaps, enabling emissions across the ultraviolet (UV) and visible spectrum. Nitride-based planar structures are commonly used for blue LEDs and recently nanostructures have gained attention for growth on low-cost dissimilar substrates, better light extraction properties, and carrier confinement. Nitride material growth is challenging due to high-temperature requirements and lattice mismatch with conventional substrates. We used Sequential Infiltration Synthesis (SIS) to develop nanopatterns of AlN, allowing for scalable and well-ordered growth of patterned nanomaterials. We have used polystyrene-b-polymethylmethacrylate (PS-b-PMMA) self-assembled nanostructures as a guiding pattern. We analyzed the nitride patterns using Scanning electron microscopy and Fourier transform infrared spectroscopy. Nanopatterning nitride materials with SIS could lead to new, cost-effective substrate-independent nitride-based optoelectronic device applications.

EL07.15.19

Facile Enhancement of Upconversion Luminescence by Localized Surface Plasmon Resonance(LSPR) Effect with Metal Nanoparticles Sung Woo Jang and Won Bin Im; Hanyang University, Korea (the Republic of)

Upconversion material that convert infrared light into visible and ultraviolet photon are capable of a broad range application such as deep tissue bio-imaging, security labelling and anti-counterfeit, etc. Lanthanide-doped sodium yttrium fluoride ($NaYF_4$) upconversion nanoparticles (UCNP) are one of the most efficient UCNPs. However, the practical application of upconverting materials is limited owing to their extremely weak and narrow band absorption. Moreover, it is still a great challenge to short-wave infrared photon (such as 1550 nm) to visible since photon should be 3-pumped for visible region emission which hamper itself to a wide variety of applications. To solve this problem, we applied the localized surface plasmon resonance (LSPR) effect of indium tin oxide (ITO) NPs to enhance the 1550 nm absorbance of $NaYF_4:Er^{3+}$ NPs. We have synthesized core-shell $NaYF_4:Er^{3+}@NaYF_4$ NPs with particles size distribution of 15 nm via co-precipitation synthesis method. Synthesized 7 nm particle sized ITO NPs (Sn 10 mol% doped) exhibit intense LSPR effect in the range of 1400 to 1800 nm that perfectly overlap with 1550 nm excitation of Er^{3+} ions. We characterized upconversion efficiency of $NaYF_4:Er^{3+}@NaYF_4$ UCNPs with ITO NPs mixture solution with 1550 nm laser (10 $mWcm^{-1}$).

EL07.15.20

Free-Space Mid-Infrared Complex Modulation by Dual-Channel Graphene Nanoribbon Metasurface <u>Jiwon Kang</u>, Sangjun Han, Junhyung Kim, Seung Eun Lee and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The mid-infrared (MIR) region offers numerous advantages, such as the atmospheric window (8~13 µm), unique molecular fingerprinting, and thermal emission. However, the development of the devices operating in the MIR is hindered by the unexplored optical characteristics of many materials, with much research efforts focusing instead on the visible and near-infrared regions contributing to displays and telecommunications technologies. Recently, numerous papers regarding molecular sensing techniques and thermal emitters have been presented, harnessing molecular vibrations and quasiparticle resonances [1]. Despite their impressive demonstrations and functionalities, a lack of high-degree light modulation capabilities still limits the level of light-matter interaction, resulting in medium efficiencies. Free-space MIR wavefront shaping, with a high amplitude modulation and a wide coverage of phase, could address these challenges.

Graphene, the most renowned 2D material, possesses remarkable thermal, electrical, and mechanical properties. Graphene nanoribbons (GNRs), created by patterning graphene into nanoscale strips, enable enhanced light confinement with optimized configurations [2]. Furthermore, electrostatic doping can modulate the carrier density in GNRs, tailoring the Fermi level (E_F) and the intensity of graphene plasmons. While GNRs offer versatility in nanophotonic fields, the complexity of sophisticated fabrication requirements stunts the widespread application of GNRs-based optical modulators.

Here, we present an active metasurface using dual-channel GNRs for MIR complex modulation. The graphene plasmon (~λ_0/100) in GNRs is much smaller than that of MIR wavelengths, leading us to adopt a multiscale coupling architecture to maximize optical confinement. The optimized structural parameters of metallic scatters on the GNR monolayer improve the optical coupling efficiency between graphene plasmons and free-space photons via intermediate quasiparticle resonances. Owing to their subwavelength structure, we were able to design the nanophotonic structure with near-uniform amplitude and wide phase coverage using a surface admittance model. When the effective surface admittance (Y_{sur}) matches the substrate admittance (Y_{sub}), the center of the trajectory of the reconstructed reflection coefficient ($\underline{r}$) with regards to E_F becomes the origin of r-space. Additionally, we employed a genetic algorithm to optimize six structural parameters—w_{Au}, w_{Gr}, t_{Au}, t_{Ti}, t_{SiO2}, and *gap*—achieving phase modulation over 2π with independent amplitude modulation. The separated voltage control of the dual-channel GNRs below the ion-gel modulates the E_F in each channel, providing high-speed tunability in r-space.

In this study, we have presented optimization of the free-space MIR complex modulation with dual-channel GNRs with the surface admittance model and genetic algorithms and our attempt to experimentally demonstrate it. The independently poled array of graphene nanostrips and gold top electrodes will offer wide coverage and enhanced functionality for next-generation optical modulators. The fabrication process, involving focused ion beam (FIB) and e-beam lithography (EBL), facilitates creating of the nanoscale structure with high reproducibility. The showcased MIR complex modulation platform also can be expanded to MIR beam splitters and directive thermal emitters, potentially paving the way for real-world applications including medical imaging and quantum communications.

Modular Assembly of Metamaterial Using Light Gradient Forces Apurba Paul, Alexander Volk, Mohammad Hokmabadi, Eveline Rigo, Ryan Roeder and Gregory Timp; University of Notre Dame, United States

This work studies the feasibility of assembling metamaterials using the light gradient force in a Standing Wave Optical Trap (SWOT). When a tightly focused laser beam is reflected from its focal plane, the intensity gradient produced in the standing wave pattern creates a 1D array of traps. When the 1D array is time-shared across a 2D lattice, it creates a 3D array of traps. Traps like these formed in a microfluidic device were subsequently populated with commercially available monodispersed dielectric and metallic nanoparticles (NPs). Hundreds of NPs can be manipulated concurrently into a complex heterogeneous voxel this way The NPs were then anchored in position by photopolymerizing a hydrogel scaffold to create a voxel. Voxels formed this way can be stitched together using step-and-repeat method to produce metamaterials of any size, shape and constituency although imperfectly. To be practical for handling, the matrix can be stiffened by vitrifying the hydrogel scaffold using Tetraethyl Orthosilicate. The NP size and position in the array was estimated using fluorescent confocal microscopy along with iterative deconvolution. The results show that the mean separation of NPs along the optical axis is 322 nm, for 860 nm trapping laser, which is in line with the separation between successive antinodes of the standing wave in the water ($\lambda_{\mathrm{trap}}/2n_{\mathrm{water}}$). Compared to a Gaussian beam, a pseudo-Bessel beam produced a larger and more regular array along the optical axis due to its longer focal length and shorter healing distance. The minimum registration error within a voxel (σ = 55 nm) was limited by the Brownian motion, while the minimum error between the voxels (σ = 88 nm) was likely affected by Brownian motion and repeatability of the microscope stage. Finally, the optical performance of the metamaterials was tested using dark-field, cross-polarized reflection spectroscopy, and compared with the finite element simulations accomplished with COMSOL. The cross-polarized spectra showed evidence of a resonance peak. Interestingly, whereas the line-shape from an array of polystyrene NPs was symmetric, an array of rutile NPs was not, which may be indicative of Fano resonance. So, despite the structural defects, reflection spectroscopy revealed a resonance.

Phase Mask Metasurfaces for High-Resolution Scintillation-Based Imaging Joshua Chen, Simo Pajovic, Will Michaels, Sachin Vaidya, Seou Choi, Louis Martin, Juejun Hu, Charles Roques-Carmes and Marin Soljačić; Massachusetts Institute of Technology, United States

Scintillators are materials that convert high energy particles such as X-rays and free electrons to visible or near-visible light. Scintillators are often used as detectors for X-rays due to their cost-effectiveness, and have important applications in medical imaging such as CT scans and gamma cameras for medical diagnostics. An effective scintillation-based detection system would allow for a higher signal-to-noise ratio, better contrast, and higher spatial resolution, which can also allow for lower X-ray dosages. This is important because immunocompromised individuals cannot safely undergo imaging due to the high X-ray dosages currently required in some X-ray imaging modalities, such as computed tomography (CT). As a result, clinicians cannot obtain potentially life-saving imaging data.

An important limitation in the process of scintillation is that there is some randomness due to diffraction and disorder. Due to the finite thickness of a scintillator, scintillator imaging inevitably leads to defocus and decreased resolution as generated photons propagate. The primary solution involves utilizing a thinner scintillator, though this leads to a direct trade-off with signal intensity.

In this work, we demonstrate visible-wavelength transparent metasurfaces that address the issue of defocus and resolution deterioration in scintillators. We use a silicon nitride on fused silica platform and adopt the approach of wavefront coding to extend the depth of field of an imaging system across the thickness of the scintillator. In wavefront coding, extended depth of field is achieved by altering the system’s point spread function to be made insensitive to defocus aberrations, which in this work is achieved by the metasurface. Combined with post-measurement image processing, high resolution can be obtained across all scintillator depths. This effect is achieved while preserving scintillator thickness.

We have recently shown a 3.5x resolution enhancement in Micro-CT simulations, with optimized systems approaching 10x resolution improvement or more.

8:15 AM EL07.16.01
Employing Complex Analysis to Engineer Finite Photonic Crystals Rodrick Kuate Defo; Syracuse University, United States

We perform topology optimization for photonic crystal structures by minimizing the integrated photonic local density of states weighted by a window function having the form of a generalization of the Lorentzian[1]. In two dimensions, we find phase transitions for the TM polarization as a function of the number of poles in the window function, with the phase following the ultimate transition agreeing with known crystal structures. Our method has advantages over conventional approaches involving the computation of photonic bandstructures in that it allows for arbitrary crystal symmetry and can treat finite structures. This work has potential applications in the design of mirrors, waveguides, and cavities, and in the discovery of novel photonic crystals in three dimensions.

Tunable Plasmonic Infrared Absorbers/Emitters for Energy and Health Applications Po-Chun Hsu; The University of Chicago, United States

Plasmonic materials are excellent absorbers through several powerful mechanisms, such as localized surface plasmon, surface plasmon polariton, Berreman mode, and gap surface plasmon. The strong light-matter interaction has powerful leverage to achieve desirable optical properties via nanosized materials, enabling crucial advancements for various applications. This talk will discuss two recent examples: **(i)** Mid-infrared electrochemically active multispectral thermal meta-emitter. Electrochemistry enables large refractive index contrast because of the drastic chemical transformation. Metasurface designs allow us to obtain the desirable optical functionality for thermoregulation and building energy efficiency purposes. We used asymmetrical Fabry-Perot and gap surface plasmon resonance to realize broadband and visibly transparent dynamic thermal emitters. **(ii)** Near-infrared laser lithotripsy for kidney stone treatment. Kidney stone disease is a severe health condition that can be as painful as childbirth. Laser lithotripsy uses a ureteroscope to channel high-power Ho:YAG laser (2100 nm) or thulium fiber (1940 nm) laser into the ureter or kidney lumen to break down kidney stones. Nevertheless, in some cases, when urologists increase the laser power too much to break down hard stones, the laser could also easily damage the surrounding tissue by direct or indirect heating. Our research shows that injecting NIR-absorbing nanoparticles during the lithotripsy procedure can enhance the optical-to-mechanical energy conversion, therefore achieving more stone damage without excessive temperature rise or thermal injury. This nanofluid approach can significantly shorten the operation time and lower the patients' burden.

9:00 AM EL07.16.03

Thermal Emission Stabilization Due to Plasmon Effect Jaime Jaramillo, Janet A. Elias and Jorge L. Cervantes; Universidad de Guanajuato, Mexico

By melt-quenching technique, sixteen samples of lithium diborate glass doped with Er^{3+}, Yb^{3+}, Dy^{3+} and containing Ag and Cu nanoparticles were synthetized. X-ray diffraction patterns of samples reveal their amorphous structure. Physical properties such as density, molar volume and boron-boron separation of amorphous materials are shown. UV–Vis-IR absorption spectra of all samples were recorded and display the characteristic bands of the used rare earths; all absorption bands present an enhancement with increasing metallic nanoparticles concentration. The estimated optical energy band gap of the samples was obtained using the Tauc plot method. Emission spectra of doped samples were collected in the temperature range from 30 to 180 °C. The results of emission under temperature indicate that the addition of metallic nanoparticles (Ag and Cu) in glass matrices are responsible for emission stabilization duet to Plasmon Effect in samples when the temperature is increased creating a glass material for photonics and thermal sciences.

9:15 AM EL07.16.04

Isotope Effect on Radiative Thermal Transport Lanyi Xie and Bai Song; Peking University, China

Isotope effects on heat conduction and convection have been known for decades. However, whether thermal radiation can be isotopically engineered remains an open question. Here, we first predict up to 4-orders-of-magnitude variation of radiative heat flow with varying isotopic compositions for parallel polar dielectric plates at room temperature. We reveal this as an isotope mass effect which induce phonon line shift and broadening that in turn affect phonon-mediated resonant absorption both in the near and far field. In contrast, the isotope effect is negligible for metals and doped semiconductors which largely depend on free carriers. We also discuss the role of temperature with regard to surface mode excitation. Our work can inject momentum into the isotope physics and provide new pathways to control the nanoscale thermal transport.

9:30 AM EL07.16.05

Imaging Photonic Modes of a TiO_2 Nanorod Metasurface via Photoelectron Emission Microscopy Andrew R. Kim[1], Chloe F. Doiron[1], Fernando J. Vega[1], Alex M. Boehm[1], Joseph P. Klesko[1], Igal Brener[1,2], Raktim Sarma[1,2], Alex W. Cerjan[1,2] and Taisuke Ohta[1]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States

Metasurfaces, photonic crystals, etc. are deployed in sensing, imaging, and nonlinear optics, among others. In designing dielectric metasurfaces, there is great importance in precise, nanoscale control over light-matter interactions that are enhanced by tight confinement of electromagnetic fields within sub-optical wavelength volumes. Because dielectric systems and their modes are designed to exploit symmetry as well as symmetry breaking, visualization of the field symmetries of the modes and their dependence on polarization of the excitation light source is important. Here, we present a study of optical resonances in a dielectric metasurface consisting of a square lattice of TiO_2 nanorods, imaged via photoemission electron microscopy (PEEM) and illuminated in the ultraviolet-visible wavelength range. This approach involves true far-field photonic excitation by normal incidence illumination and allows for near-field imaging at a micron-scale field of view at sub-wavelength spatial resolution. The metasurface is designed to support two closely overlapping resonances of different symmetries such that their individual contributions to the overall electromagnetic field distribution can be investigated as a function of excitation wavelength and polarization. The resonances are chosen to occur at 450 nm, where two-photon photoemission (2PPE) avoids electronic transitions over the electric band gap (3.0-3.2 eV) of TiO_2. Around this wavelength, 2PPE is influenced purely by the photonic modes, which enables a direct, nonlinear map of the field intensity at and near photonic resonance. To verify the relation between photoemission intensity and the electromagnetic field strength, we perform finite-difference time-domain simulations of the metasurface. By comparing the simulations that reproduce the field patterns and the switching between the two photonic modes with differing symmetries to the PEEM images as a function of the excitation wavelength, we estimate the electron inelastic mean free path (IMFP) to be 35 nm. This estimated IMFP is significantly larger than that of deep ultraviolet or x-ray excited photoelectrons ranging from a few Angstroms to nanometers. Our work demonstrates that the PEEM visualizes the true field distribution of photonic volume modes within nanostructures as deep as the inelastic mean free path of the photoelectron and show that the PEEM is suitable for metrology of dielectric metasurfaces in the visible spectrum range, complementing other near-field microscopy characterizations.

The work at Sandia National Laboratories was supported by the US Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences and Engineering (grant BES 20-017574) and, in part, by Sandia's LDRD program. Surface Plasmon Polaritons Nearfields Photodetectors in 2D Materials and Heterostructures Kuo-Ping Chen; National Tsing Hua University, Taiwan

This study investigates plasmonic photodetection using graphene as a 2D material. It achieves non-scattering near-field detection of surface plasmon polaritons (SPPs) and reports a high photoresponsivity of 29.2 mA W−1, with polarization sensitivity. Various mechanisms for converting photoenergy into electrical signals in graphene are discussed, including the photovoltaic effect (PV), photoconductive effect (PC), photogating effect (PG), photothermoelectric effect (PTE), and bolometric effect (BOL). The proposed photodetector combines PV and PC effects, offering low power consumption and fast response.

10:45 AM EL07.17.02

High-Index and Low-Loss van der Waals Topological Insulators for Mid-Infrared Nanophotonics Sergey Menabde[1], Jacob Heiden[1], Vladimir A. Zenin[2], N. Asger Mortensen[2,2] and Min Seok Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]University of Southern Denmark, Denmark

Strong spin-orbit coupling in topological insulators (TIs) leads to an electronic band inversion and the topological Dirac surface states in the bandgap. These surface states are chiral and thus topologically protected from back-scattering by the time-reversal symmetry. Therefore, charge carriers in surface states are free to move parallel to the surface and conduct current, while the insulating bulk remains dielectric.

Such a conductive surface provides a condition for the manifestation of surface plasmons at optical frequencies in bismuth and antimony chalcogenides. For example, a particularly strong plasmonic response in visible and ultraviolet spectra has been reported in $Bi_{1.5}Sb_{0.5}Te_{1.8}Se_{1.2}$ (BSTS). Propagating surface plasmons in the visible spectrum have been directly observed with the scattering-type scanning near-field optical microscope (s-SNOM) in Bi_2Te_2Se (BTS). On the other hand, bulk Bi_2Se_3 (BS) is a polar dielectric and supports the THz plasmon-phonon-polaritons. THz near-field imaging by s-SNOM has been recently used to demonstrate the existence of the plasmon-phonon-polaritons in both BS and BTS.

According to the theoretical models developed for these three TI materials (BS, BTS, and BSTS), all of them are expected to have a high-index low-loss dielectric bulk and a conductive surface at mid-infrared (mid-IR) frequencies. Other topological insulators such as Bi_2Te_3 and Bi:Sb:Te family are known to have a very high refractive index, but their bulk is lossy in the mid-IR.

Motivated by this, we attempt to observe the interaction between the highly-confined hyperbolic phonon-polaritons (HPP) in hexagonal boron nitride (hBN) and the topological surface states in BS, BTS, and BSTS of optimized chemical composition $Bi_{1.5}Sb_{0.5}Te_{1.7}Se_{1.3}$. To this end, we place thin (30–115 nm-thick) exfoliated flakes of hBN on top of the exfoliated TI crystals and obtain near-field images of propagating HPP using s-SNOM. Surprisingly, the measured HPP dispersion does not reveal any unambiguous signatures of the conductive surface states in any of the three materials. To confirm this observation, we analyze the complex near-field signal over the samples with hBN and across bare TI flakes on a silicon (Si) substrate. Again, our rigorous near-field analysis does not exhibit any clear features of the conductive surface states in the TI crystals. At the same time, all experiments demonstrate the ultra-high refractive index and practically lossless nature of the three TI crystals in the tested mid-IR range (950 – 1600 cm^{-1}). Despite the possible existence of conductive surface states, our results suggest that in practice BS, BTS, and BSTS can be used as low-loss and ultra-high-index van der Waals dielectrics for numerous mid-IR applications.

This discovery is particularly important in the context of rapidly advancing field of mid-IR hyperbolic polaritons in van der Waals crystals which recently demonstrated a plethora of new phenomena such as ghost and sheer phonon-polaritons in low-symmetry crystals, nanolight manipulation in twisted van der Waals crystals, and electrical manipulation of hybrid plasmon-phonon-polaritons in van der Waals heterostructures. All these new applications may greatly benefit from low-loss and ultra-high-index van der Waals dielectrics which would provide polaritons with significantly increased momenta without introducing additional loss.

11:00 AM EL07.17.03

Metal/MoS2 Heterostructure for Photonic Applications Haotian Yu, Andres A. Forero Pico and Manisha Gupta; University of Alberta, Canada

2-dimensional (2D) materials, due to their unique electronic and optical properties, are becoming increasingly attractive for applications in nanotechnology, electronics, photonics and quantum applications. However, considering existing challenges in the fabrication of large-scale heterostructures, the potential of 2D material in photonic devices are still not completely explored and understood. Here, propose to grow metal/MoS2 heterostructures which can be used for as optical absorbers, metamaterials for biosensing applications and for other photonic applications. It has been reported that Ag grows in a Volmer-Weber mode and the deposition can cause damage to ML MoS_2 [1]. To overcome this challenge, we will grow the metal (silver, Ag) and 2D material, MoS_2, using pulsed laser deposition (PLD) to achieve monolayer control and conformal growth.

Ag is an excellent plasmonic material, and is able to evanescently confine electromagnetic waves and support local surface plasma resonance, enhancing the intensity of the electromagnetic waves near the interface. Monolayer (ML) MoS_2, acting as a 2D direct bandgap semiconductor, can generate electron-hole pairs and release photons during the light-matter interaction. Different from traditional metal-dielectric plasmonic devices, a Schottky barrier exist at the Ag/ML MoS_2 interface, and this quantum confinement effect can lead to selective wavelength absorption and emission due to modified density of states. These characteristics make the Ag/monolayer MoS2/Ag structure particularly attractive for advanced optoelectronic applications, leveraging the unique properties of MoS2 to enhance the functionality beyond what is possible with traditional plasmonic devices.

In this work, PLD was used for the growth of the heterostructures of Ag/ML MoS_2/Ag deposition. PLD demonstrated an extraordinary performance of growing large-area and high-quality monolayer MoS_2 as well as silver thin films. The current RMS roughness we achieved for ML MoS_2 and 75nm silver thin film are 0.2nm and 1.7nm respectively. Also, the growth procedure ensured that we were able to grow the heterostructure under high vacuum (~10^{-7} Torr) or oxygen isolated condition, preventing the formation of oxide at the interface between silver and MoS_2. Simulation results for these heterostructures using density functional theory (DFT) and experimental characterization results of these heterostructures will be presented.

11:15 AM EL07.17.04

Density Functional Theory and Modelling of Electronic and Magnetic Properties of 2D Hexagonal Boron Nitride Doped with IVA-Group Elements Kerem Anar[1], Berna Akgenc Hanedar[1,2] and Mehmet C. Onbasli[1]; [1]Koç University, Turkey; [2]Department of Physics, Kirklareli Universitesi, Turkey

Hexagonal boron nitride (h-BN) is a 2D material with unique properties including a wide bandgap, high thermal conductivity, chemical stability, and simple chemical stoichiometry. These characteristics make h-BN attractive for device applications in electronics, spintronics, and optoelectronics. h-BN films allow for defect states to act as coherent quantum emitters in 610-642 nm wavelength range with relatively long lifetimes and photostability. Due to the wide band gap, room temperature emission becomes feasible. However, different defect such as boron or nitrogen single, pair or triple defect types alter the crystal stability, crystal symmetry, electronic band structure, magnetic order, phonon density of states, emission characteristics, and Raman spectra. Because different defect types may form at the same time in chemical vapor deposition, exfoliation or even molecular beam epitaxy, a detailed understanding of the defect types and their corresponding characteristic signatures such as crystal stability and symmetry, electronic band structure, Fermi level tuning, density of states and Raman spectra is needed. To elucidate these signatures and to tailor h-BN for applications, we used density functional theory (DFT) to identify defect type (vacancy, dopant IVA element type), configuration, and concentration dependence of h-BN structural stability, electronic band structure and magnetic moments.

In 2D materials, substitutional doping during growth can be used to alter the electronic and magnetic properties in advanced technologies such as spintronics and optoelectronics. Here, we report the effects of doping IVA-group elements (C, Si, Ge, Sn, Pb) into 2D hexagonal boron nitride (h-BN) based on first-principles density functional theory (DFT) calculations. Doping was performed at boron sites for n-type doping and nitrogen sites for p-type doping at various concentrations from 3.125% to 9.375%. Pristine h-BN is a semiconductor with a large bandgap (~4.67 eV) and exhibits non-magnetic behavior. However, 3.125% doping with IVA-group elements can effectively reduce the bandgap (0.39 ~ 0.56 eV) and introducing new defect bands, while maintaining their semiconductor properties. Increasing the doping concentration to 6.25% causes the magnetization to vanish with both n-type doping (C and Si) and p-type doping (C and Ge) due to the strong ionic interactions of dopants. Interestingly, the magnetization becomes stronger upon increasing the doping level 9.375% with a total magnetic moment of up to 2.26 µB with Ge and 1.54 µB with Si impurities. This doping level also results in the material exhibiting half-metallicity. The presence of half- metallicity can be explained based on the unpaired electron in the 2p orbital of doping IVA-group atoms. Additionally, configurations for doping were examined to ascertain doping site importance.

This comprehensive investigation highlights the significant potential of defect engineering in 2D materials, offering a pathway to customize h-BN for specific technological applications. This comprehensive investigation highlights the significant potential of defect engineering in 2D materials, offering a pathway to customize h-BN for specific technological applications. By systematically doping h-BN with IVA-group elements, we have demonstrated the ability to modulate its electronic and magnetic properties, achieving desirable characteristics such as bandgap reduction, introduction of defect bands, and even half-metallicity at higher doping concentrations. These findings provide crucial insights into how substitutional doping can be strategically employed to enhance the performance of h-BN in advanced spintronics and optoelectronics applications. Future research should focus on further refining these doping techniques and exploring other elemental substitutions to fully exploit the unique properties of h-BN for next-generation device applications.

11:30 AM EL07.17.05

GeSn Thin Films Crystallized on Silica for Infrared Phototransistors Yicheng Wang[1], Priyanka Petluru[2], Shang Liu[1], Luke McClintock[3], Tenzin Norden[3], Aaron Muhowski[2], Julia Deitz[2], Tim Ruggles[2], Ping Lu[2], Prashant Padmanabhan[3], Jifeng Liu[1] and Tzu-Ming Lu[2]; [1]Dartmouth College, United States; [2]Sandia National Laboratories, United States; [3]Los Alamos National Laboratory, United States

Group IV GeSn alloy has recently attracted substantial attention in integrated photonics and quantum material applications due to its compatibility with Si complementary metal-oxide semiconductor (CMOS) processes [1,2]. Ge-rich GeSn alloy is known by its direct bandgap with Sn compositions above approximately 8%. In addition, GeSn alloy offers a tunable bandgap by adjusting the Sn composition, which extends the direct-gap absorption edge to short-wave infrared (SWIR) and even mid-infrared (MIR) ranges [3]. Lasing in a direct-bandgap GeSn alloy with a Sn composition of 13% has been demonstrated as an example of its optoelectronic applications [4]. However, the growth of high-crystallinity GeSn on Si is challenging due to mismatch lattice constants of GeSn and Si, as well as their low solid solubility under thermal equilibrium [5]. Thick Ge buffer layers (>500 nm thick) can be used in chemical vapor deposition (CVD) and molecular-beam epitaxy (MBE) to manage lattice mismatch. Nevertheless, these layers are not suitable for back-end-of-line (BEOL) CMOS device integration due to the requirement for high-quality Ge buffers to be annealed at temperatures exceeding 600°C [6]. Low-temperature crystallization of GeSn alloy has recently emerged as a possible approach for facile BEOL CMOS integration, as it requires lower annealing temperature (~500°C) and maintains reasonable material quality with large grain sizes [7]. Here we present the synthesis and characterization of crystallized GeSn films with 11% and 13% Sn composition and thicknesses of 30 nm and 100 nm on amorphous fused silica substrate for IR phototransistors. The GeSn films are deposited on the substrates through Physical Vapor Deposition and later crystallized by rapid thermal annealing process. Clear grain boundaries are observed on 30 nm-thick GeSn annealed at 500°C, with the apparent grain size being approximately 10-20 µm. On the other hand, 100 nm-thick GeSn annealed at 470°C shows radiation patterns, with grain sizes up to 300 µm. X-ray Diffraction (XRD) and electron back-scatter diffraction (EBSD) both demonstrate a very strong (111) preferred orientation, with subgrains also identified in the EBSD analyses. Further coupled with Raman Spectroscopy, the exact Sn compositions of the GeSn films are determined to be 10.6% and 12.7% [8]. Based on these high-crystallinity GeSn thin films, we demonstrate a 30 nm GeSn-on-silica phototransistor with Sn composition with responsivities of ~1.0 mA/W at 1600 nm, which is on the same order as GeSn photodetectors grown by MBE when normalizing the GeSn infrared absorption layer thickness [9]. Furthermore, the photocurrent/dark current ratio can be maximized via gating voltage to optimize the device performance, a feature in accessible in regular photodiodes or photoconductors. Extending similar approach towards BEOL CMOS integration, solid phase epitaxy of GeSn on thin low-temperature Ge buffer/Si seed layer [10] can be applied to potentially improve the quality of GeSn and thereby improve the performance of GeSn phototransistor.

This work has been supported by µ-ATOMS, an Energy Frontier Research Center funded by the U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), under the award DE-SC0023412. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Synthesis of BaTiO3 Thin Films for Photonics Temazulu S. Zulu[1], Larissa Little[1], Benazir Fazlioglu Yalcin[1], Ashley Cavanagh[1], Anne Ruperto[1], Lucy Nathwani[1], Keith Powell[1], Neil Sinclair[1], Charles Brooks[1], David R. Barton[2], Marko Loncar[1] and Julia Mundy[1]; [1]Harvard University, United States; [2]Northwestern University, United States

BaTiO3 thin films present exciting opportunities for use in electro-optic device fabrication. BaTiO3 has a Pockels coefficient that is about 30x higher than the currently used thin film LiNbO3 , a high refractive index (~2.4) and a wide bandgap (>3) making it ideal for use in integrated photonics. We can integrate BaTiO3 onto silicon substrates to make an electro-optic device. We use reactive-oxide molecular beam epitaxy (MBE) to synthesize high quality BaTiO3 thin films. We explore different thin film transfer methods to enable the pristine transfer of BaTiO3 onto silicon substrates for device fabrication. Our method could be a potentially straightforward, scalable, and efficient method for the nanofabrication of BaTiO3 thin films for integration into optical devices.

Probing Nanoscale Chirality Using Decoupled Optical Force Nanoscopy Yang Zhao; University of Illinois at Urbana-Champaign, United States

Scanning probe technologies offer unparalleled insights into nanoscale light-matter interactions but are often hindered by the complex interplay of concurrent light-induced effects. To address this challenge, we have recently developed a technique called decoupled optical force nanoscopy (Dofn). Dofn uniquely isolates light-induced forces—such as optical gradient, photoacoustic, and photothermal effects—by employing a specialized modulation and demodulation of the phases of the measured optical forces. In this talk, I will discuss how Dofn enables the precise probing of nanoscale chirality emerging from nanostructures, opening new avenues for understanding and manipulating chiral light-matter interactions at the nanoscale.

2:00 PM EL07.18.02
Non-Hermitian Skin Effect in a Su-Schrieffer-Heeger Chain of Nanocavities Through Nonreciprocal Loss
Chulwon Lee, Kai Zhang, Kai Sun and Hui Deng; University of Michigan, United States

Achieving nonreciprocal optical transport in one dimension is of major significance while the reciprocity principle fundamentally limits its realization. Most of the current nonreciprocal devices rely either on magnetic materials or external time-varying driving, yet they often suffer from compatibility issues and device complexity that hinder wide applications. Recently, advances in non-Hermitian theory have suggested new possibilities of routing transport in an open-driven lattice system, called the "skin effect". The most well-known approaches for realizing one-dimensional skin effects require either anisotropic or long-range interactions among lattice sites to produce pseudomagnetic fields. Yet implementing such interactions typically requires devices of complex designs and large footprints.
In this study, we present a theory model for realizing the one-dimensional skin effect via non-reciprocal loss, without requiring anisotropic or long-range hopping. We show that pseudo-magnetic fields emerge from a Su-Schrieffer-Heeger chain coupled with ancilla sites with nonreciprocal loss. We furthermore demonstrate how to implement the model with asymmetric photonic crystal nanobeam cavities. Numerical simulations using standard material parameters confirm clear nonreciprocity and skin localization of photonic modes, validating our theoretical model. Our study provides a new path toward magnetism-free non-reciprocal devices for unidirectional photon transport.

2:15 PM EL07.18.03
Non-Hermitian Skin Effect in Silicon Photonic Crystals Hriteshwar Talukder and Roberto Paiella; Boston University, United States

Recent theoretical work has established that non-Hermiticity (i.e., dissipation) can have a profound impact on the band structure of periodic wave systems and their related topological properties [1]. In fact, the energy eigenvalues and eigenfunctions of finite-size non-Hermitian systems can be markedly different from the predictions of Bloch theory based on periodic boundary conditions. Most remarkably, a macroscopic number of modes in these systems can become localized near a boundary – a phenomenon known as the non-Hermitian skin effect (NHSE). At the same time, the conventional bulk-boundary correspondence (one of the cornerstones of topological band theory) can also break down in the presence of non-Hermiticity.

In photonic micro- and nanostructures, sources of dissipation naturally exist, and can be accurately engineered, in the form of radiative scattering losses and material absorption or gain. As a result, these structures provide an ideally well-suited platform to investigate novel non-Hermitian topological phenomena, and possibly exploit them to enable useful functionalities. A particularly interesting platform in this context is photonic crystal (PhC) slabs, because of their high design flexibility and technological significance for multiple device applications in optoelectronics and integrated optics. So far, the emergence of the NHSE and related breakdown of Bloch band theory in PhCs has only been described in a few theoretical studies focused on purely two-dimensional structures with ad-hoc (and unrealistically large) values of the imaginary part of the refractive index [2, 3].

Here, we investigate PhC slabs consisting of rectangular arrays of triangular Si nanoparticles on a planar SiO_2 substrate, designed to support leaky modes (i.e., guided resonances that can couple to external radiation) at wavelengths within the Si absorption band. Using finite-element and finite-difference-time-domain simulations with realistic wavelength-dependent optical constants, we compute the dispersion and field distribution of these modes in several structures of different lattice constants. Evidence of the NHSE is provided by the observation of modes strongly confined at the edges of finite-size samples, combined with nonzero values of a topological invariant of the energy eigenvalues under periodic boundary conditions (their winding number in the complex energy plane).

The results of this study provide three key conclusions with important fundamental and practical implications. First, the NHSE can indeed be established in realistic PhC slabs, as long as the unit cells have sufficiently reduced in-plane symmetry. Second, the resulting skin modes display a distinctive chiral behavior, i.e., modes confined at opposite edges propagate along opposite directions, and therefore can be selectively excited with free-space radiation by controlling its direction of propagation. Third, the NHSE in Si PhC slabs persists even at photon energies below the Si band gap, where the imaginary part of the refractive index is negligibly small, so that dissipation is entirely due to radiation losses. Altogether, these conclusions suggest that novel non-Hermitian effects could be uncovered in practical semiconductor PhC structures, and used to engineer their spectral, angular, and spatial response for different applications such as modulators, lasers, and even passive devices.

All-Optical Light-Propagation Switching Jakob Lindenthal, Frithjof Pietsch, Markas Sudzius, Johannes Benduhn and Karl Leo; Technische Universität Dresden, Germany

Miniaturised photonic circuits have been employed in a broad field of fundamental, but also application-oriented research in the recent years. While the harnessing of CMOS fabrication techniques has enabled precise sub-wavelength feature control, the dynamic switching of nano-optical devices often involves additional thermo-optical or electro-optical elements. The high number of processing steps and materials lead to a costly device fabrication and an inherent proneness to the failure of single components. The present contribution demonstrates an all-optical switch utilising two counter-propagating beams to control the in-coupling efficiency of a nano-optical grating. The findings of the fundamental experiment are shown to support the development of a range of applications including all-optical logic gates and non-Hermitian photonic circuits. The demonstrated coupling control enables complexity reduction in integrated photonic circuits and provides a promising approach for a new, streamlined device architecture.

Optically Tunable Catalytic Cancer Therapy Using Enzyme-Like Chiral Plasmonic Nanoparticles Haeun Kang[1], Subin Yu[2], Ryeong Myeong Kim[3], Jeong Woo Han[3], Sehoon Kim[4], Ki Tae Nam[3], Luke P. Lee[2] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Harvard University, United States; [3]Seoul National University, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea (the Republic of)

Cascade enzymatic reactions in living organisms are one of the fundamental reaction mechanisms in coordinating various complex biochemical processes such as metabolism, signal transduction and gene regulation. While many studies have attempted to mimic cascade reactions using nanoparticles with enzyme-like activity, there still remains a challenge in developing strategies for the precise tuning of each reaction within complex reaction networks to enhance the catalytic activity. Here, we suggest a novel approach to optically control each stage of the cascade reaction, utilizing orthogonal input of circularly polarized light (CPL), right-handed CPL (RC) and left-handed CPL (LC), coupled with the introduction of chiral plasmonic enzyme-like nanoparticles, which are designed to respond distinctly to RC and LC.

To control the enzymatic activity of nanoparticles depending on the handedness, we took two prominent strategies based on the characteristic features in our chiral plasmonic enzyme-like nanoparticles; 1) generation of hot carriers dependent on CPL, which directly participate in enzymatic reactions and 2) enantioselective interaction with substrate D-glucose, the predominant chiral form of glucose in human body.

Chiral Au nanoparticles (D-Au) and Au-Pd nanoparticles (L-AuPd), which displayed cubic geometries and surfaces oriented in opposite directions, were successfully synthesized through seed-mediated method with introduction of L-/D-GSH ligand during the growth process. D-Au, which has glucose oxidase (GOD)-mimic properties and L-AuPd which mimic peroxidase (POD) reactions respond to RC and LC, respectively, with strong plasmonic effects. By sequentially activating GOD and POD reactions with RC followed by LC, we achieved 1.25- and 1.9-fold enhanced catalytic performance (overall 1.3 times enhancement) compared to non-controlled cascade reactions by creating an optimal acidic environment for the subsequent reaction. Moreover, the D-Au showed a 2-fold higher binding selectivity to the substrates, D-glucose, attributed to chirality matching. In both cellular-level studies and mouse models, the groups irradiated with RC+LC exhibited the highest radical generation and the most efficient cancer treatment outcomes compared to the other irradiation conditions. We believe that our system holds strong potential for practical medical applications, suggesting a promising platform for catalytic therapy.

Integrated Lithium Niobate Ultrafast Mode-Locked Laser Qiushi Guo; The City University of New York, United States

Mode-locked lasers (MLLs) generate ultrashort pulses with peak powers substantially exceeding their average powers. However, integrated MLLs that drive ultrafast nanophotonic circuits have remained elusive because of their typically low peak powers, lack of controllability, and challenges when integrating with nanophotonic platforms. In this work, we demonstrate an electrically pumped actively MLL in nanophotonic lithium niobate based on its hybrid integration with a III-V semiconductor optical amplifier. Our MLL generates ~4.8-ps optical pulses around 1065 nm at a repetition rate of ~10 GHz, with energies exceeding 2.6 pJ and peak powers beyond 0.5 W. The repetition rate and the carrier-envelope offset frequency of the output can be controlled in a wide range by using the driving frequency and the pump current, providing a route for fully stabilized on-chip frequency combs.

3:45 PM EL07.19.02
Ultra-High Speed Photonic Vertical NAND FLASH and Novel Integrated Vertical Cavity Surface Emitting Lasers (VCSELs) James Pan[1,2]; [1]American Enterprise and License Company, United States; [2]Northrop Grumman, United States

In recent years, Vertical NAND FLASH has replaced NOR FLASH in most of the hand held wireless digital markets, due to advantages of lower cost, higher packing density, and higher speed. However, the speed of NAND FLASH is still behind DRAM and SRAM used in computing tools, caused by the dielectric trapping, and tunneling processes, which result in longer WRITE and ERASE cycles. In this report, we will demonstrate an ultra-high-speed Photonic Vertical NAND FLASH with multiple VCSELs (Vertical Cavity Surface Emitting Laser), that may outperform DRAMs due to lower voltages and much faster nonvolatile memory operations. The new capability of integrated arrays of VCSELs with the high-speed Vertical Photonic NAND FLASH for lasing and nonvolatile data storage can be achieved.

A Photonic Vertical NAND FLASH memory consists of a vertical NAND FLASH transistor (which is a traditional vertical NMOSFET with multiple gates as Word Lines), VCSELs (Vertical Cavity Surface Emitting Lasers) in the top drain region (Bit Line), or in the bottom source region, and photon sensors in the channel and well regions. When gate voltages are applied to the Word Lines, and a drain voltage is applied to the Bit Line, the entire vertical NAND FLASH NMOSFET is turned on (READ operation). When a gate voltage is set to 0V, the vertical NAND FLASH NMOSFET is turned off, so as the lasers and photon sensors. Much faster READ, WRITE and ERASE operations may also be accomplished with the photonic processes.

(1) Device Cross Section and Process Integration of the Vertical Photonic NAND FLASH will be presented.
(2) Process issues, such as polysilicon well and channel regions, and how to deposition crystalline films for VCSELs, will be illustrated.
(3) Equivalent circuits will be presented for READ, WRITE, ERASE operations of Photonic Vertical NAND FLASH.
(4) Fowler Nordheim Tunneling, Frenkel Poole Tunneling, Traps-Enhanced FN Tunneling, and Photon-Enhanced Tunneling for Photonic NAND FLASH will be discussed. Photon-accelerated Hot Carrier Injection will also be analyzed.
(5) Integrated VCSEL arrays with vertical Photonic NAND FLASH - designs for various applications and markets.

Ultra-high-speed operations with much lower voltages and power consumption can be achieved with the Photonic NAND FLASH technology. Process integration is compatible with available NAND FLASH process flows. Potentially

Photonic NAND FLASH could outperform DRAMs.

4:00 PM EL07.19.03

Hybridized Semiconductor Nanowire Lasers for Integrated Circuits Francesco Vitale, Edwin Eobaldt and Carsten Ronning; Friedrich-Schiller-Universität Jena, Germany

Semiconductor nanowires are of major interest as a serving material platform, since they not only offer superior photonic properties, such as being an intrinsic nano-sized lasing system, but can also bridge the interface to electronic circuits. However, their integration into any on-chip integrated circuit requires direct contact of the semiconductor nanowires with any other material affecting their optical and lasing properties. We will focus in this presentation on such effects of lasing ZnO nanowires by hybridizing them with metals, 2D materials, and dye molecules. Coupling such nanowires with e.g. plasmonic structures results in higher losses and lasing thresholds, but significantly accelerates the dynamics and confines the light field even into much smaller structures. On the other hand, hybridizing them with atomically 2D materials or dye molecules can significantly change the gain envelope, likely due to charge and carrier transfer processes between the materials. This results in the possibility of suitable tailoring to the design requirements of on-chip applications.

4:15 PM EL07.19.04

Interferometric Measurements of Temperature-Dependent Optical Absorption in Low-Loss SiN Membranes for Laser Sails Tanuj Kumar[1], Demeng Feng[1], Shenwei Yin[1], Phyo Lin[2], Merlin Mah[2], Margaret Fortman[1], Chenghao Wan[1,3], Chengyu Fang[1], Kevin Schnittker[1], Joseph Andrews[1], Ronald Warzoha[4], Victor Brar[1], Joseph Talghader[2] and Mikhail Kats[1]; [1]University of Wisconsin-Madison, United States; [2]University of Minnesota, United States; [3]Stanford University, United States; [4]U.S. Naval Academy, United States

We have been evaluating candidate low-optical-loss materials for laser-light sails, which have been proposed as a mode of interstellar travel, and must reflect driving laser light while being highly robust to laser damage. For proposed laser sail missions, absorption coefficients of approximately 10^{-2} cm^{-1} or lower are required to maintain sail integrity at the highest laser intensities[1]. One candidate laser sail material is silicon nitride (SiN) suspended membranes[1,2], which can be formed in different stoichiometries, for example stoichiometric Si_3N_4 and silicon-rich SiN_x (x~1). The low levels of optical loss in such membranes cannot be measured using conventional measurements such as ellipsometry.

In this work, we use self-referencing photothermal common-path interferometry (PCI) to study absorption in thin, free-standing SiN membranes. PCI is a continuous-wave pump-probe technique for measuring optical absorption in low-loss materials[3], wherein we interferometrically measure the thermo-optic effect caused by a chopped high-power pump laser (1 W) using a less powerful probe laser (2 mW), with the probe's detector synchronized to the chopper via a lock-in amplifier. We show a new self-referencing technique for PCI by coating the sample with monolayer graphene that has an easily measurable absorbance of the order of 1%, slightly different from the well-known value of 2.3% due to Fabry-Perot effects in the membrane. Using this reference, we demonstrate a self-referencing PCI technique to find absorptivity values in Si_3N_4 and SiN_x (x~1). We found the room-temperature absorption coefficient of Si_3N_4 at 1064 nm to be $(2.09 \pm 0.76) \times 10^{-2}$ cm^{-1}, and that of SiN_x (x~1) to be 7.94 ± 0.50 cm^{-1}. These results not only point to the suitability of Si_3N_4 as a candidate material for laser sails, but also show self-referencing PCI as a viable method to measure loss in low-loss, free-standing membranes.

In addition, many dielectrics are known to suffer from increased optical absorption at higher temperatures due to bandgap narrowing, leading to thermal runaway in laser sail models when compounded with two-photon absorption[1]. We will present high-temperature absorptivity measurements of Si_3N_4 membranes – using small resistive heaters with feature sizes down to 70 µm – fabricated on top of the membranes using metal evaporation through a shadow mask to achieve localized heating on the membranes only, which avoids introduction of noise to PCI measurements caused by the heating of its optical components.

Manufacturing and Testing of Laser-Induced Blackbody Emitters Shomik Verma[1], Minok Park[2], Sean Lubner[3] and Asegun Henry[1]; [1]Massachusetts Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Boston University, United States

Optical properties of surfaces are important for a wide variety of energy applications. Emissivity is one property particularly relevant for applications involving radiative energy transport, and measures the amount of light a surface can emit compared to its maximum. Oftentimes, the emissivity spectrum, or emissivity as a function of wavelength, must be tuned for different applications. For example, thermophotovoltaic emitters should have high emissivity above the bandgap of the photovoltaic cell to ensure maximum power output from the cell, and low emissivity below the bandgap to prevent parasitic heating.

We have pioneered a laser processing technique to tune the optical properties of surfaces. In this technique, laser pulses are used to ablate away material, creating metasurfaces of microscale hills and valleys dotted with nanoparticles. From this processing technique, we can achieve a variety of possible emissivity spectra. However, it is difficult to know a priori what emissivity spectrum will result from a given set of laser processing parameters. This is because the laser ablation is a highly multiphysical process, so it is difficult to predict the surface profile, and it is further difficult to predict the optical properties of a given surface profile due to the expensive finite-difference-time-domain simulations required.

In this work, we directly map the laser processing parameters to the emissivity spectrum, bypassing the surface profile. There are three laser processing parameters: power, speed, and spacing. In order to create this mapping, we developed a high-throughput experimentation technique involving varying the laser processing parameters, creating 35,280 unique combinations. We then used each combination of processing parameters to engineer the surface of stainless steel, and measured the emissivity spectrum of each combination. Using this dataset, we develop a mapping between laser processing parameters and emissivity spectra, first with an forward machine learning model combined with global optimization to determine which laser parameters were ideal for a desired spectrum, and second with an inverse model to directly output the laser parameters for a desired spectrum.

Using the laser processing parameters identified, we manufacture a near-blackbody metasurface on tantalum (Ta) to increase its emissivity (~0.98 between 0.2 and 10 microns). We then use this surface as an emitter for thermophotovoltaic (TPV) power conversion. We used an experimental apparatus featuring an actively-cooled 1.2/1.0 eV tandem TPV cell with an Au back-reflector spaced 5mm away from the emitter. We show that the Ta metasurface more than doubles the TPV power density from 2.18 to 4.91 W/cm2 at 2100C while retaining the high efficiency of 28%.

We then demonstrate the thermal stability of the metasurface with both high temperature and long timescale annealing. For high temperature testing, we conduct step heating from 2100 to 1500C in increments of 100C for 10 minutes each, noting the above-bandgap emissivity drops from 0.98 to 0.95. For long-timescale annealing, we conduct heating at 1500C for 100 hours, noting the broadband emissivity decreases from 0.98 to 0.92. We supplement these measurements with an annealing model considering both evaporation through vapor pressure and surface diffusion.

Overall, we have developed a end-to-end methodology for designing metasurfaces for thermophotovoltaic applications. We first determine which laser processing parameters result in a desired emissivity spectrum of a metasurface. Then, we use the metasurface as an emitter for TPV, demonstrating the benefits of increased emissivity. Lastly, we demonstrate thermal stability with long-duration, high-temperature testing and modeling. This work demonstrates a promising way forward for high-performing metasurfaces for TPV applications.

Wavelength Tunable Infrared Perfect Absorption in Plasmonic Nanocrystal Monolayers Woo Je Chang, Zarko Sakotic, Alexander Ware, Allison Green, Benjamin Roman, Kihoon Kim, Thomas Truskett, Dan Wasserman and Delia Milliron; The University of Texas at Austin, United States

The ability to efficiently absorb light in ultrathin (subwavelength) layers is essential for modern electro-optic devices, including detectors, sensors, and nonlinear modulators. Tailoring these ultrathin films' spectral, spatial, and polarimetric properties is highly desirable for many, if not all, of the above applications. Doing so, however, often requires costly lithographic techniques or exotic materials, limiting scalability. Here we propose, demonstrate, and analyze a mid-infrared absorber architecture leveraging monolayer films of nanoplasmonic colloidal tin-doped indium oxide nanocrystals (ITO NCs). We fabricate a series of ITO NC monolayer films using the liquid–air interface method; by synthetically varying the Sn dopant concentration in the NCs, we achieve spectrally selective perfect absorption tunable between wavelengths of two and five micrometers. We achieve monolayer thickness-controlled coupling strength tuning by varying NC size, allowing access to different coupling regimes. Furthermore, we synthesize a bilayer film that enables broadband absorption covering the entire midwave IR region (λ = 3–5 μm). We demonstrate a scalable platform, with perfect absorption in monolayer films only hundredths of a wavelength in thickness, enabling strong light–matter interaction, with potential applications for molecular detection and ultrafast nonlinear optical applications.

Upconverting Nanoparticle and Polymer Composites for Bioimaging Forces in Cartilage Cindy Shi, Mia Cano, Jason Casar, Parivash Moradifar and Jennifer A. Dionne; Stanford University, United States

Physical forces play a major role within our bodies, from kiloNewton scale bite strength to picoNewton scale cell-cell interactions; however, current methods for measuring these forces, including traction force microscopy, atomic force microscopy, ultrasound imaging, and pressure-sensitive stents and catheters, are bulky and ex vivo, low resolution and accuracy, or painful and invasive. Upconverting nanoparticles (UCNPs) present a promising solution as force-sensitive optical probes. Ceramic UCNPs are known for their photostability and relative biocompatibility, and their near-infrared excitation allows deeper tissue penetration than visible or UV excited fluorophores. Furthermore, SrLuF:Yb, Er UCNPs have been shown to change integrated red to green emission ratio as a function of externally applied force. When packaged into polymers of various mechanical properties, UCNPs provide a minimally invasive platform to probe biological forces such as those in cartilage.
Here, we enhance UCNP force-dependent colorimetric emission by incorporating manganese in the UCNP-polymer composite system, either as a core dopant along with Yb and Er, or as a crosslinking ion in the polymer

matrix surrounding the UCNPs. We hypothesize that the Mn-Er interionic distance more drastically modulates the energy transfer between the Er red and green emission states. In the first method, SrLuF:Yb, Er, Mn @ SrYF UCNPs with Mn concentrations between 0 and 4.2 at. % are packaged into two different polymers, rubbery polydimethylsiloxane and stiff epoxy resin. In the second method, SrYbF @ SrYbF:0.20Er @ SrYF:0.10Mn UCNPs are packaged into alginate hydrogel crosslinked with Mn2+ or Ca2+, with the UCNPs designed for energy transfer to external ions.

We examine the optical effect of Mn concentration on UCNP emission with lifetime/decay measurements. We characterize the spectral force response of all UCNP-polymer thin films using a homebuilt simultaneous atomic force and confocal microscope setup. By integrating the red and green peak areas of the Er3+ emission spectrum, we calculate the change in red to green emission ratio (%ΔR:G) in the films with uniaxial compressive force applied as compared to the free-standing film. We identify that two UCNP-polymer combinations that give the greatest %ΔR:G slope, SrLuF:Yb, Er, 0.013Mn @ SrYF in epoxy resin (about 10x slope enhancement from 0% Mn UCNPs) and SrYbF @ SrYbF:0.20Er @ SrYF:0.10Mn in Mn-alginate (about 1.5x slope enhancement from UCNPs in Ca-alginate), and which best mimic cartilage mechanical properties of Young’s modulus, cyclability, and low friction. We then insert these UCNP-polymer composites between the bones of a chicken wing to demonstrate the facility of this platform for minimally-invasive optical force-sensitive imaging in situ. For future applications, with the diversity of UCNP architectures and polymer properties, we hope to extend UCNP force sensors for imaging a wider range of biological systems, including colonic gastrointestinal forces in relation to the gut-brain connection and cell to cell immune system interactions.

5:15 PM EL07.19.08

Boosting the Stability of the Efficient Tandem Blue Organic Light-Emitting Diodes Using Plasmon-Exciton-Polaritons Haonan Zhao, Claire Arneson and Stephen R. Forrest; University of Michigan-Ann Arbor, United States

Over the decades, short operational lifetimes of blue organic light-emitting diodes (OLEDs) stand out as one of the greatest challenges in organic electronics. Plasmon-exciton-polaritons (PEPs), a quasiparticle formed by the strong coupling between the plasmons in the metal and the excitons in an adjacent dielectric material, have been recently introduced to extend the lifetime of blue phosphorescent OLEDs[SF1] [1]. The PEP-enhanced Purcell effect has achieved 5-6X enhancement in device stability by reducing the phosphor triplet density, thereby slowing down destructive triplet annihilation processes. In previous studies, the stability of the emissive layers was enhanced via the strong coupling between the cathode and the adjacent electron transporting layer (ETL). Here, we introduce the polariton-enhanced Purcell effect from the anode and the hole transporting layer (HTL) to achieve the device lifetime enhancement from both the anode and cathode contacts in tandem blue PHOLEDs. We show that full-cavity tandem blue OLEDs with double-sided PEP-enhanced Purcell effects achieve a 10X increase in device lifetime compared to weak-cavity tandem devices. A tandem OLED structure shows a 3X increase compared to a single stack device due to a 50% reduction in current needed to achieve the same luminance as a single junction device. Furthermore, the full-cavity device narrows the emission spectrum useful in blue display pixels. Taken together, these polariton-enhanced Purcell effect full-cavity tandem device shows a 30X longer device lifetime in deep blue over an analogous, single-stack device.

Nanophotonic Cavity-Enhanced In Vitro Diagnostics—From Plasmonic to Quantum Plexcitonic Sensing Peng Zheng and Ishan Barman; Johns Hopkins University, United States

Nanophotonic cavities are uniquely suited for ultrasensitive biophotonic diagnostics owing to their strong capability to confine light into the deep subwavelength. Despite their tantalizing potential, the prevailing biophotonic diagnostic methods, as exemplified by surface-enhanced Raman spectroscopy (SERS), rely on reading the spectral peak intensity. Yet, the peak intensity-based nanophotonic transducer is subject to fluctuations, which can be ascribed to the SERS uncertainty principle, a tradeoff between “reproducibility” and “enhancement”. To address these challenges, herein, we first introduce our recent efforts in developing a frequency shift-based in-vitro diagnostic platform that harnesses nanomechanical perturbations in SERS for detecting serum biomarkers in the weak-coupling regime. Expanding from this classical sensing method, we further introduce a novel quantum plexcitonic sensing strategy based on Rabi frequency splitting in the strong-coupling regime. Collectively, this presentation showcases the vast potential of nanophotonic cavities to tackle various pressing issues in biomedical diagnostics.

EL07.20.02
Aptamer-Driven Metal-Enhanced Fluorescence for Highly Sensitive Liver Cancer Biomarker Detection Euni Cho[1], Nayoung Kim[1], Mingyu Bae[1], Jin-Ho Lee[1,1], Jin Kim[2] and Choeun Park[2]; [1]Pusan National University, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of)

Complete surgical removal remains the sole curative treatment for liver cancer, underscoring the critical impact of early detection on patient survival rates. Detecting liver cancer at an early stage is pivotal, as it enables timely intervention and improves outcomes. Monitoring the presence of cancer biomarkers in circulation serves as a potential method for early diagnosis. However, the concentration of these biomarkers is typically extremely low. Thus, highly sensitive biosensors capable of detecting these low concentrations are essential.
Here, we utilized metal-enhanced fluorescence (MEF) phenomena for precise analysis of liver cancer biomarkers. This method integrates fluorescence-labeled aptamer molecules with arrays of plasmonic gold (Au) nanostructure. The strategy of the suggested method relies on the change of conformation of the aptamer structure caused by its interaction with biomarkers. This conformational change dynamically adjusts the distance between the fluorophores and the gold nanostructure, modulating the ON/OFF signal of the fluorescence label. To develop this platform, a well-defined Laser interference lithography (LIL) technique and deposition of gold were employed to achieve the desired metallic nanostructure. A strong electromagnetic field was generated by localized surface plasmon resonance (LSPR) phenomena upon interaction with the incident light and gold nanostructures. This electromagnetic field could intensify nearby fluorophores' fluorescence when the distance between the fluorophore and the gold nanostructure is in the range. The systemic performance was optimized by testing various shapes and sizes of the gold nanostructure as well as the lengths of the aptamers. Furthermore, the 5-(and-6)-carboxy-fluorescein (FAM) was also carefully selected as the fluorophore, as it could exhibit strong interaction with the absorbance of a gold nanostructure, ensuring optimal plasmonic coupling and signal enhancement. Given the high sensitivity of our MEF-based aptasensor, we believe our biosensing technology has the potential to significantly advance biomedical research and clinical diagnostics by promoting early detection and personalized treatment strategies for cancer patients.

EL07.20.03

ZIF-8-Based Surface Plasmon Resonance Gas Sensor for Volatile Organic Compound Detection Anna E. Macià[1,2], Guillem Domenech-Gil[1,2], Ignasi Fort Grandas[1,2,1], Winnie E. Svendsen[3], Maria Dimaki[3], Mauricio Moreno Sereno[1,2] and Albert Romano-Rodriguez[1,2]; [1]Universitat de Barcelona, Spain; [2]Institute of Nanoscience and Nanotechnology (IN2UB), Spain; [3]Technical University of Denmark, Denmark

Surface plasmon resonance (SPR) sensors are capable of real-time detection of gas, chemical and biological analytes due to the probe behaviour of surface plasmons to boundary conditions. Because of gas molecules are much smaller than biomolecules, conventional SPR sensors are not sensitive enough to detect gas adsorption at the surface of the sensor. Consequently, the functionalization of the surface with a sensitive coating is a frequent strategy to enhance their sensitivity, which relies on the refractive index (RI) change of the sensitive film caused by the adsorption of analytes. Metal-organic frameworks (MOFs) are advanced materials with a crystalline structure which is appealing as sensitive coatings due to their intrinsic porosity and high surface-to-volume ratio. Zeolitic Imidazolate Frameworks-8 (ZIF-8) is a particularly interesting MOF for gas sensing applications due to its hydrophobic properties, which can heavily reduce cross-sensitivity with relative humidity (RH) – a major issue that decreases the sensitivity of many gas sensors.

Based on the previous description, we fabricated a ZIF-8-based SPR gas sensor to monitor the presence of volatile organic compounds (VOCs) by tracking the red-shift of the SPR wavelength due to the adsorption-dependent RI of the MOF. The substrates contain 4 diffraction gratings (DG) with periods of L = 400 nm and L = 500 nm which have been covered by a ZIF-8 layer, obtained through a layer-by-layer deposition method. We present the fabrication process of both SPR substrates and ZIF-8 film, the MOF characterization and its integration in the final device, and gas sensing results when exposing them to different concentrations of VOCs.

We present the calibration of the SPR substrates with liquids as external media to obtain the bulk sensitivity of the DG, which is around 387 nm/RIU and 527 nm/RIU for L = 400 nm and L = 500 nm, respectively. We describe the environmental conditions to fabricate reproducible ZIF-8 nanolayers of controlled thickness regardless of the substrate. We report, as well, the gas sensing study when exposing the sensors with various ZIF-8 thicknesses to different VOCs, showing that the dip in the SPR resonance red-shift is independent of the thickness if the film is thicker than the penetration depth of the evanescent wave into the nanolayer, and independent of the period of the DG used, which allows to fine tune the working SPR wavelength without strongly affecting sensitivity in a set-up miniaturization using LEDs and photodetectors. Gas sensing experiments show adequate sensitivity to the studied VOCs (red-shifts of around 35 nm) and, particularly noticeable, no sensitivity to RH thanks to the hydrophobicity of ZIF-8.

In this presentation we will discuss these aspects as well as the benefit of the planar geometry of the SPR substrates, which potentially allow multiplexed gas sensing on an array of DG with different surface functionalization coatings and film thicknesses.

EL07.20.04

Inverse Design of Nanohole Array Using Parameter-Based Genetic Algorithm for Optical Sensing Applications Seunghwan Moon, Chaeyeon Kim, Jihun Kang, Siwon Park and Jong-Souk Yeo; Yonsei University, Korea (the Republic of)

The electromagnetic metasurface is a sub-wavelength structure consisting of meta-atoms, which modulates light behaviors. There are two approaches when designing metasurface: forward and inverse design. The forward design approach, the conventional method, is based on the physical understanding of metasurface. On the other

hand, the inverse design approaches employ mathematical optimization algorithms or neural networks, which allow for achieving target optical properties without rigorous scientific understanding [1-2]. Most of the current studies that demonstrate the inverse design method start with the pixelating step of design space. Although the pixelating step can bring highly optimized structure based on a large degree of freedom, there are several limitations when pixelating nanophotonic metasurfaces. Since the fabrication technologies for nanoscale patterning are affected by physical limits, the size of a single pixel for inverse design space cannot be smaller than the technical resolutions. In addition, dealing with pixelated design space brings large amounts of calculation, thus requiring memory-efficient programming. Therefore, this research proposes a parameter-based genetic algorithm for the inverse design of materials as an alternative methodology for optimal design.
For practical implementation, a gold nanohole array (NHA) whose reflectance spectrum has a sharp dip at 700 nm was optimized for optical sensing characteristics. Four geometrical parameters of NHA such as hole diameter, pitch, lattice structure, and thickness, were optimized through a genetic algorithm (GA). Mimicking the replication process of chromosomes, GA, a type of evolutionary algorithm (EA), operates by iterating through initialization, selection, crossover, and mutation steps. For each iteration, the reflectance spectrum of suggested NHA geometries was evaluated by finite-difference time-domain (FDTD) simulations. The NHA with optimized geometry was fabricated on a sputtered gold film with chromium as an adhesion layer. The optimized design was patterned using e-beam lithography (EBL) with polymethylmethacrylate (PMMA) as a resist material, followed by a directed etch using argon ion plasma. Then, the NHA structure was characterized using non-contact atomic force microscopy (NC-AFM) and scanning electron microscopy (SEM). The analyte sensing characteristic was also evaluated using the spectrometer in the visible-NIR range. This study demonstrates that the optimum structure can be efficiently obtained through the inverse design, leveraging a parameter-based genetic algorithm.

Keywords: Inverse Design, Genetic Algorithm, Parameter Optimization, Nanophotonic Metasurface, Nanohole Array

Optimizing Material and Nanostructure Configurations for Efficient Light-Emission Through Inelastic Electron Tunneling Seunghwan Moon, Jihye Lee, Siwon Park, Young-Min Kim and Jong-Souk Yeo; Yonsei University, Korea (the Republic of)

In the Metal-Insulator-Metal (MIM) devices, electrons tunnel the gap along with the bias voltage. When the tunneling electron experiences energy loss, the type of tunneling is called inelastic electron tunneling (IET). The energy loss during IET can be coupled with other kinds of energy, such as photon emission, plasmon resonance, lattice scattering (phonon), etc [1]. This type of nanoscale light source can be used for ultrafast on-chip transduction from electron to photon and optical biosensors that allow point-of-care testing [2]. However, the light source has low light emission efficiency compared to conventional light-emitting diodes or laser diodes.

Therefore, we separated the light emission process into three steps and demonstrated MIM devices with various material and structure configurations for efficiency optimization in each step. 1)-Electrical Characteristic: IET occurs with the bias voltage inside the MIM gap. 2)-Energy Transformation from Electron to Light: Lost energy is transferred into plasmonic energy or photon emission. 3)-Light Outcoupling: Energy of plasmon or photon outcouples to far-field through scattering or transmission, respectively. To achieve high performance in 1)-Electrical Characteristics, both operatable bias voltage range and Fowler-Nordheim tunneling were investigated by demonstrating MIM devices with various materials through thin-film deposition and 2D material transfer techniques. MIM devices that utilize graphene as an electrode have endured a larger bias up to ± 8 V, which may allow light emission with a shorter wavelength and wide range light modulation. To optimize 2)-Energy Transformation from Electron to Light and 3)-Light Outcoupling, we designed and characterized the effects of diverse MIM structures with nanophotonic metasurfaces on plasmon coupling. A nanowire array (NWA) was selected as a basic structure, and it was expanded to the other metasurfaces, including a MIM device with an NWA-patterned top electrode and a fully NWA-patterned MIM device. Localized-Surface Plasmon Resonance (LSPR), Surface Lattice Resonance (SLR), and Fundamental and second-order modes of Gap-Surface Plasmon Resonance (Gap-SPR) were characterized through Finite-difference time-domain (FDTD) simulations and a spectrometer connected with a dark-field microscope, depending on the type of nanostructures. The effects of geometrical parameters on spectral optical characteristics and E/H-field confinements were also analyzed for coupling plasmon resonance in the desired wavelength range. In addition, an inverse design algorithm has been demonstrated, which can also be implemented to increase the outcoupling efficiency by controlling the geometry of metasurfaces [3]. This experimental investigation provides material and structural insights depending on the three light emission steps, enabling the efficiency enhancement of light emission through IET for on-chip light source applications.

Plasmonic SERS Substrates Based on Nanocellulose for Biomolecule Detection Kaori N. Sanchez-Carrillo[1], Raul Ortega-Cordova[2], Josue Mota-Morales[1] and Gonzalo Ramirez-Garcia[1]; [1]Universidad Nacional Autónoma de México, Mexico; [2]Universidad de Guadalajara, Mexico

In search of a higher life quality, the need to detect molecules in ultra-low concentrations has led to increasing efforts for identification and quantification. As such, Raman spectroscopy has gained attention, due to its selectivity and sensibility for identification of compounds, low sample preparation, high levels of detection and non-destructive analysis, have made it one of the pioneer techniques in identifying and analyzing biomolecules. These characteristics are increased through a technique called surface-enhanced Raman scattering (SERS), in which the increase in Raman signal can allow the detection of analytes at ultra-low concentrations, up to single-molecule, in complex samples. Hence, there is a surging need to design stable, uniform and reproducible SERS substrates, that exploit the scattered beams from the laser. In this context, cellulose-based plasmonic (AuNPs-based) substrates offer three-dimensional platforms, with high mechanical stability, which can enable an increased concentration of spots with an exceptional enhancement of the electromagnetic field (known as 'hotspots') through on-demand SERS using a collapsible mechanism of the cellulose substrate when the analyte is loaded. The presence of anisotropic gold structures, synthesized in a deep eutectic solvent (DES) through a one-pot synthesis, and immobilized by cellulose nanocrystals CNCs, follows current tendencies in green chemistry, which places them as an ideal alternative for the detection of a wide assortment of biomedical-interest analytes.

1-Dimensional Periodic Grating and Plasmonic Hybridized Metamaterial SERS Fabricated by Nanotransfer Printing Minjae Ku, Jisung Hwang, Hanhwi Jang, Chi Won Ahn, Jonghwa Shin and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

As expectations for human lifespan rise, the demand for rapid and accurate medical diagnostics has never been greater. Surface-Enhanced Raman Spectroscopy (SERS) excels in the biosensor field due to its high specificity, rapidity, and potential for single-molecule sensitivity, making it highly advantageous for industrialization. However, quantification in SERS is challenging due to the small hotspot size (1-2 nm) and substantial spot variation (>15%). In this study, we address these quantification challenges by integrating SERS with a one-dimensional periodic metasurface. We employed thermally assisted nanotransfer printing (T-nTP) to fabricate an 80 nm periodic grating pattern, providing a cost-effective and time-efficient alternative to ArF lithography. Grazing Incidence Small Angle X-ray Scattering (GISAXS) analysis confirmed that the pattern quality was comparable to that of ArF lithography, achieving significant efficiency gains in both time and cost. This approach reduced spot variation to approximately 1% and extended the hotspots, as demonstrated through Finite-Difference Time-Domain (FDTD) simulations. Additionally, we observed the electric field propagation in a one-dimensional direction due to Localized Surface Plasmon Resonance (LSPR) coupling, occurring exclusively in TM mode. This study confirms the potential of integrating grating-structured metasurfaces to achieve superior SERS performance and reveals unique optical phenomena. The resulting SERS chip, characterized by cost-effectiveness, time efficiency, and excellent performance, shows promise as a next-generation high-performance sensor.

Plasmonic-Magnetic Core-Shell Nanoparticles—Synthesis and SERS Characterization Seyed Danial Mousavi, Justine S. Gordon, Lindsey Walter, Guojun Shang, Zeqi Li and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States

The ability to harness plasmonic nanoparticles with magnetic functions would increase their use in a wide range of applications, especially in medical diagnostics of cancer where current detection methods such as X-ray and magnetic resonance imaging are costly, time-consuming, and invasive, making them less suitable for rapid screening and early detection. We have been developing nanoprobes for detecting cancer biomarkers such as proteins and DNAs. A key challenge is the ability to harness the multifunctional structures for the diagnostic and quick detection of these biomarkers. In this presentation, recent results from investigating tunable magnetic-plasmonic core-shell nanoparticles (NPs) for magnetic focusing and plasmonic signal amplification. This method effectively couples the magnetic and plasmonic properties of different-sized magnetic NPs (e.g., NiCo alloy, Fe_3O_4) with plasmonic NPs (e.g., Au, Ag, alloy) within a microfluidic platform. This strategy leverages the bifunctional capabilities allowing magnetic manipulation through magnetic focusing in the microfluidic system and plasmonic signal amplification for surface-enhanced Raman scattering (SERS) detection. The effectiveness of this approach in detecting different cancer biomarkers will be discussed.

EL07.20.09

Differential SERS Enhancement Factors in Chiral Plasmonic Nanostructures Emma M. Midkiff, Joshua Kim, Hannah Nardini and Ji-Young Kim; Rensselaer Polytechnic Institute, United States

The surface-enhanced Raman scattering-chiral anisotropy (SERS-ChA) effect is a pioneering technique in enantioselective sensing, utilizing the enhanced Raman properties of chiral plasmonic nanostructures. This effect allows for highly sensitive and selective detection of chiral molecules, making it valuable for pharmaceuticals, environmental monitoring, and food safety, where distinguishing enantiomers is essential. However, systemic design rules for chiral plasmonic nanostructures that amplify their Raman signals based on chirality remain underexplored. In this study, we newly define the differential SERS-ChA enhancement factor (SERS-ChA EFs) by calculating the difference between SERS enhancement factors (EFs) under left- and right-circularly polarized light. By simulating the effects of various geometrical parameters of chiral plasmonic nanostructure arrays on their optical dissymmetry and differential SERS-ChA EFs, we provide critical insights for designing efficient SERS-ChA-based sensors. We modeled 3D chiral helicoid arrays with different sizes, intermolecular gaps, and materials under left and right circular polarized light extinction ports. By solving Maxwell's equations for finite element analysis, we calculated theoretical spectra for their chiroptical activities such as circular dichroism and their g-factors over a wavelength range of 400-800 nm while analyzing SERS-ChA EFs across different lines and surfaces to identify array regions with the highest enhancement effects. Our methods revealed varying minimum interparticle distances required to observe collective behavior and anisotropies in effective hot spots, based on helicoid size and material. Our findings advance theoretical frameworks for chiral effects in SERS and enhance the practical application of chiral metasurfaces in SERS-ChA spectroscopy, paving the way for advanced enantioselective sensing technologies.

EL07.20.10

Nano Detection of Trace Atrazine in Drinking Water by Surface Enhanced Raman Spectroscopy with Silver Nanoparticles Isabelle Hsin Yuan Yu[1], Arthur McClelland[2] and Tingying (Helen) Zeng[3]; [1]Soong Ching Ling School, China; [2]Harvard University, United States; [3]InnoBridge Institute, United States

Atrazine is a chlorinated triazine herbicide, widely used on several agriculturally important crops such as corn, sorghum, sugar cane, wheat. Atrazine in drinking water has shown altering human reproductive system. There are previous reports to show data connecting atrazine to cancer formation, although a direct connection has so far been made only with the formation of ovarian tumours, uterine cancers, and leukaemia in animal test subjects. The presence of atrazine in drinking water has been monitored under the Safe Drinking Water Act; and EPA rules are required to monitor its concentrations using IR, GC, and HPLC. However, these methods can be time-consuming and require significant resources and facilities. The water quality control has become prioritized in many countries and communities. Methods for quick, cheap, and easy detection of pollutants in water have gained importance and have significant impacts to the public health. Thus, Surface-enhanced Raman Spectroscopy (SERS) has gained much attention in recent research, as it is resulted from plasmonic effect through the interaction of metal nanoparticles with substances; it is rapid, relatively easy to interpret, and can detect trace amounts of several pollutants,. In our experiments, we explored to the usage of silver nanoparticles to achieve SERS nano detection objective for trace atrazine analysis in drinking water. Our results demonstrated a minimum detected concentration of 5x10^-15 M of atrazine in our water samples, indicating this highly sensitive method is sufficient to allow the detection to be used in drinking water quality monitoring atrazine, even under the strictest international regulations.This nano method will make significant contribution to the public health near future.

Engineering Mesoscopic Quantum Phenomena with Si Optomechanical Crystals Irene Castro Fernández[1], Iago Sánchez[2] and Daniel Ramos[1]; [1]Consejo Superior de Investigaciones Científicas, Spain; [2]Centro Español de Metrología, Spain

Achieving the sensitivity needed to measure quantum fluctuations necessitates reaching the Standard Quantum Limit (SQL). Several experiments have successfully achieved SQL in different physical systems [1],[2],[3],[4]. To reach these precision levels in nanomechanical systems, it is crucial for the oscillator to be in its mechanical ground state. However, thermal interactions from the environment hide the quantum characteristics of a mesoscopic resonator, as coherent states are necessary to reveal quantum phenomena. Mitigating decoherence involves cooling the oscillator and decoupling it from thermal noise. Alternative methods to cryogenic cooling, such as back-action cooling, have achieved low thermal occupation in various systems [5],[6],[7]. Optomechanical systems provide an effective framework for achieving quantum-limited precision, cooling, and shielding from the environment. Various optomechanical systems have demonstrated these capabilities [8],[9]. Among different configurations, optomechanical crystals are particularly promising for their ability to confine and control both optical and mechanical modes at the nanoscale. By operating in the resolved sideband regime, it is possible to cool down the mechanical oscillator to its ground state, thus enabling the exploration of quantum phenomena in larger systems [10].

To enable the above-mentioned capabilities, we have designed an innovative optomechanical crystal aimed at advancing the field of quantum optomechanics. Our device comprises a photonic crystal with an infrared-wavelength photonic defect mode embedded in a phononic crystal, which shields the mechanical defect mode at 2,5 GHz. The optical mode is optimized to work in the resolved sideband regime (Q_{op},>>ω_{op} /Ω_m , being Q_{op} the optical quality factor and ω_{op} and Ω_m the optical and mechanical frequencies). The design optimization has been performed using 3D finite element method (FEM) simulations in COMSOL, further enhanced the Q_{opt} by machine learning techniques up to 10^6 . The system shows an optomechanical vacuum coupling rate of g_0,/2π=600kHz, obtaining a minimum number of phonons in the mechanical mode of 0,01 by simply confining tens of photons in the cavity at liquid helium temperatures, which would allow for optimized noise performance. Our careful design considerations and theoretical analyses show the potential of our optomechanical crystal to achieve these significant milestones even at higher temperatures.

This novel design seeks to unlock new possibilities in quantum applications. By integrating advanced simulation and machine learning techniques, our work provides a robust platform for exploring the quantum regime and achieving high levels of measurement sensitivity and coherence in a macroscopic system.

Tailored SERS Substrate—Ag-WS_2 Nanoflakes Grown by PLD for Highly Sensitive Chemical Sensing Applications Arvind Kaushik and Jitendra P. Singh; Indian Institute of Technology Delhi, India

Two-dimensional transition materials dichalcogenides (TMDCs) have a distinct advantage as a surface-enhanced Raman scattering (SERS) substrate because of their exceptional optical features, which facilitate efficient charge transfer with probe molecules and improve chemical enhancement. In this work, vertically oriented WS_2 flakes are synthesized on a Silicon (Si) substrate using the pulsed laser deposition (PLD) technique. WS_2 flakes are then used as SERS substrate for detecting low concentrations (up to 10^{-9} M) of Rhodamine B (RhB) and Methyl orange (MO) organic dyes with promising enhancement factors of nearly ~ 10^7 using 532 nm excitation laser. Using a thermal evaporation process, Ag nanoparticles (NPs) were decorated to further improve the plasmonic activity of vertical WS_2 flakes. WS_2-Ag nanocomposite substrate demonstrates superior detection capabilities when compared to pristine WS_2 flakes, achieving impressive sensitivity at ultralow concentrations of 10^{-16} M for RhB and MO dyes and an enhancement factor of the order of 10^8. The 633 nm laser was utilized to examine the SERS performance of WS_2-Ag substrate for Methylene blue (MB) dye. The MB dye was effectively detected down to an ultra-low concentration of 10^{-13} M. In addition to Ag NPs involvement, a charge transfer mechanism between WS_2 and RhB dye molecules is proposed to explain the nanocomposite SERS substrate's excellent detection capabilities and huge enhancement in SERS signal.

EL07.20.13

3D Hydrogel SERS Substrate for Enantioselective Sensing Kim-Anh Nguyen, Jiahui Xiao, Vivek Pandya, Abigail Spaniol, Austin Yuan and Ji-Young Kim; Rensselaer Polytechnic Institute, United States

Enantioselective sensing is crucial for distinguishing between chiral molecules, which can have vastly different biological activities, thus ensuring drug safety and efficacy. Additionally, it plays a significant role in environmental monitoring and food safety by detecting trace amounts of chiral pollutants and additives. The surface-enhanced Raman scattering-chiral anisotropy (SERS-ChA) effect, derived from opposite chiral plasmonic nanostructures, has emerged as a promising enantioselective sensing approach. However, developing highly selective and sensitive enantioselective sensors using the SERS-ChA effect is technically demanding, requiring a sophisticated manufacturing process and often posing challenges related to stability and reproducibility. Moreover, due to the inherent weakness of the Raman signal, achieving quantitative analysis of enantiomers with this technique remains difficult. In this work, we report the facile fabrication of a hydrogel SERS substrate for an enantioselective sensor with high reusability and reproducibility. Our polyethylene glycol diacrylate (PEGDA) hydrogel-based SERS-ChA substrate can be rapidly polymerized and customized, providing a flexible and tunable matrix with high water content for use as a biosensing platform. This platform effectively discriminates between different amino acid enantiomers. The 3D hydrogel SERS-ChA substrate can immobilize chiral gold nanoparticles (AuNPs), enhancing their density and interaction with target analytes. This improvement leads to increased stability, reproducibility, and sensitivity of SERS-based detection, facilitating both qualitative and quantitative analyses with superior detection limits. This 3D hydrogel SERS-ChA substrate-mediated biosensor platform shows promise for adaptation to larger biomolecules in various media, potentially enabling its use in complex diagnostic applications.

EL07.20.14

Synthesis and Degradation of Plasmonic Shell on ZIF-8 for Drug Delivery Kyungin Choi, Hyeon-Jeong Shin and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

Metal organic framework (MOF) are largely used in many applications including bio-applications like biosensing and therapy. The use of MOFs in bio-applications, especially drug delivery for therapy, probes needs to be stable enough to reach the target, and degrade easily to release the drug. Zeolitic imidazole framework-8 (ZIF-8) is one of the MOF series widely used with relatively large pore size. Here, we designed and synthesized the cubic ZIF-8 with plasmonic Au shell, ZIF-8@Au with controllable core and shell size. The synthetic yield of ZIF-8@Au was high for about 98%. In synthesis process, gold ion first substitutes the place of Zinc ion in outermost surface of ZIF-8. Gold shell is then formed over ZIF-8 core. The plasmonic shell protect the ZIF-8 core and drug inside and increase the stability of the probe. Additionally, coating ZIF-8 with an Au shell lowers the cytotoxicity of the nanoparticles compared to bare ZIF-8. In the decomposition process, gold ions replace the place of inner zinc that has become unstable due to solutions such as low pH. Particularly, with thin Au shell of about 4 nm, shell contraction inward, however, with thicker shell of about 10 nm outward contraction occurs. This result slow drug release, and formation of unique shape of particle. The concept, synthetic method, and degradation will aid in the design, synthesis, and application in collaboration of plasmonic metal and MOFs.

EL07.20.15

Design of Efficient Radiative Coolers with Nanoparticles via Deep Neural Networks Min Ju Kim, Mi Jin Hong and Gil Ju Lee; Pusan National University, Korea (the Republic of)

Highly demanded energy from conventional cooling systems overloads power grids and significantly contributes to greenhouse gas emissions. To efficiently address global warming, radiative cooling is an innovative technology that can reduce temperatures below the surrounding environment without the need for energy consumption. In a variety of applications, radiative coolers are utilized in various forms. For instance, they can be attached to vehicles or building exteriors to replace conventional cooling methods that result in environmental pollution or combined with solar cells to enhance their efficiency. Radiative coolers require strong emission within the atmospheric transparent window, which ranges from 8 μm to 13 μm. Depending on their application, radiative coolers can be engineered to be either solar-transparent, with high transmittance in the solar spectral region (0.3-2.5 μm), or solar-opaque with high reflectance in the solar spectrum. Due to the need for intricate spectral properties, the designs of diverse proposed radiative coolers are complex for both types, leading to high fabrication costs and complicated assembly processes.

Here, we propose an innovative inverse design methodology using a deep neural network, a type of deep learning algorithm, for creating thin-film radiative coolers. The designs for solar-transparent and solar-opaque radiative coolers consist of a polyethylene (PE) film with a thickness of 10 μm, embedded with nanoparticles based on Maxwell-Garnett effective medium theory. The nanoparticles are composed of SiO_2, TiO_2, Si_3N_4, Al_2O_3 and HfO_2, which are commonly used in radiative cooling applications. Using Maxwell-Garnett effective medium theory can suggest the appropriate material ratios to achieve the desired intricate optical constants, making it possible to find suitable materials for the design of radiative coolers. In our study, the calculation process of effective medium theory is integrated with a deep neural network to enhance design quality.

Deep neural networks are highly effective for designing photonic structures due to their ability to rapidly and accurately learn complex patterns. Our deep learning models, each tailored for specific purposes, identify the optimal optical constants, volume ratios of materials, and particle size distributions for the thin films. These three models are utilized in sequence to inversely design photonic structures, ensuring the desired optical properties for radiative cooling. The first model proposes optimal refractive indices for high emission within the atmospheric transparent window. Subsequently, the second model suggests the material volume ratios corresponding to proposed refractive indices. Finally, the third model, which considers optical properties within the solar spectral region, outputs the particle size distribution tailored for each type of radiative cooler. Consequently, our deep learning models can propose design variables when the desired optical properties are provided.

Finally, we assessed the optical and thermal performance of our inversely designed radiative coolers through optical simulations and net power calculations. The solar-transparent radiative coolers achieve high performance with 93.2% emissivity in the atmospheric transparent window and 93.3% transmittance in the solar region. In contrast, the solar-opaque radiative coolers show 94.9% emissivity in the 8 μm to 13 μm region and 90.4% reflectance in the solar region with a PE film thickness of 100 μm. Additionally, a solar cell integrated with a solar-transparent radiative cooler improves efficiency by reducing its temperature by 16.4 K during operation, with a heat transfer coefficient of 10 $Wm^{-2}K^{-1}$. Furthermore, the solar-opaque radiative coolers provide a cooling effect, capable of reducing the temperature by approximately 2.06 K under the same heat transfer coefficient. These two types of radiative coolers offer customized solutions for various applications.

EL07.20.16

Thermal Management with Graphene-Ag Nanocubes Heterostructures Ihsan Uluturk[1], Michael Leuenberger[2], Jin Ho Kim[1], Peter Stenhouse[1] and Richard M. Osgood[1]; [1]U.S. Army, United States; [2]University of Central Florida, United States

The main purpose of textiles throughout history is to regulate heat flow and provide warmth or decrease excessive heat for the wearer. In recent times, the textile industry has developed new materials that can ensure the wearer stays dry in hot environments and that repel moisture. The main downside of these new textiles, however, is that their electromagnetic response has not been fully optimized, allowing too much radiation to be absorbed and radiated back to the skin, causing the wearer to overheat. Our work is composed of two parts: simulation and experimentation. Simulations will first be conducted to better understand the thermal metamaterial consisting of a heterostructure with metallic nanoparticles, graphene, , and SU-8 spin coated onto silicon wafers.
Starting with theoretical modeling, we considered first a heterostructure made of Ag nanoparticles, graphene, $FeCl_3$ on silicon. When the $FeCl_3$ layer is thin, around 50 nm, the absorbance between 3 mm and 12 mm is around 2%, independent of the number of graphene layers. Such heterostructures could be useful for thermal management systems.
For $FeCl_3$ layer thickness of 1.2 mm or larger, it is possible to tune the absorbance resonance peaks of localized acoustic graphene plasmons (AGPs) in graphene by means of a gate voltage in the mid-IR regime, with absorbance reaching almost 100%. Such heterostructures are useful for cooling the textiles with respect to the 3 K temperature of outer space.
The positions of the localized AGPs resonance peaks can be tuned in the range between 3 mm and 12 mm by means of a gate voltage.
After realizing that $FeCl_3$ undergo strong oxidation, we replaced $FeCl_3$ by SU-8, resulting in high-quality SU-8 layers. Based on the simulation results, we have been fine tuning the recipe for spin coating the graphene ink on SU-8. We have also been fine-tuning the recipe to spin coat Ag nanoparticles onto graphene. The fabricated heterostructures made of Ag nanocubes/graphene/SU-8/Si wafer will be characterized in terms of refractive index, reflectivity, absorption, profilometry, FTIR, and ellipsometry.
Then, we replace the Si wafer by gold-coated Si wafers. The gold layer serves as a mirror for the Fabry-Perot cavity. The full heterostructure is placed on a hot plate and a thermocouple. The hot plate is heated up to 38 C to simulate the body temperature and standoff is created between heterostructures and the hot plate. Thermocouples will be used to measure the temperature difference between the heterostructures and gold mirrors to see if the heterostructures have a significant effect on the thermal management property.

EL07.20.17

Phenylboronic Acid-Based Photonic Hydrogel Nanocomposite Fiber Probe for Real-Time and Continuous Glucose Monitoring Israr Ahmed[1], Yarjan A. Samad[1,2] and Haider Butt[1]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Cambridge, United Kingdom

Diabetes mellitus (DM) is a significant global health issue characterized by elevated blood glucose levels, highlighting the urgent need for an affordable, rapid, and reliable continuous glucose monitoring (CGM) solution.

In this study, we developed phenylboronic acid (PBA)-based hydrogel sensors using a straightforward one-step polymerization technique. The glucose-sensitive hydrogel was directly polymerized onto the tip of a commercial optical fiber (OF). Gold nanoparticles (AuNPs) were synthesized via the Turkevich method, a simple chemical reduction process, and subsequently integrated into the polymerized fiber tip using a dipping technique. Fourier-transform infrared (FTIR) spectroscopy was conducted to characterize the sensing gel and confirm successful polymerization. The FTIR spectra validated the functionalization of the hydrogel with PBA and confirmed the complete polymerization of the sensing gel on the fiber tip. The synthesized AuNPs were characterized using transmission electron microscopy (TEM) and UV-vis spectroscopy. TEM analysis confirmed the spherical shape of the nanoparticles, with an average size of 10 nm, while UV-vis spectroscopy revealed a surface plasmon resonance (SPR) peak at 518 nm. The sensing mechanism relies on the binding interaction between PBA and the cis-diol groups in glucose, which increases osmotic pressure within the hydrogel matrix. This leads to swelling of the sensing matrix and a change in the optical signal output. The performance of the fabricated sensor was evaluated across a glucose concentration range of 0–20 mM using both transmission and reflection modes. The sensor exhibited a 25% overall increase in transmission percentage (1.25%/mM) and a 4 nm SPR blueshift (0.2 nm/mM) as glucose concentrations increased from 0 to 20 mM. In reflection mode, the sensor demonstrated a sensitivity of 0.5%/mM glucose concentration, indicating potential for remote sensing applications. Given that the SPR wavelength aligns with the green laser wavelength, a 532 nm green laser was used to validate these results by measuring the transmitted and reflected power. The sensor displayed a sensitivity of 3.75 μW/mM for transmitted power and 8.25 nW/mM for reflected power. The sensor also exhibited a rapid response time of 30 seconds and a saturation time of 3 minutes. Additionally, the sensor was tested over multiple cycles to demonstrate its reusability and repeatability. Finally, the sensor's readout methodology was simplified by integrating it with a smartphone.

EL07.20.18

Integration of 2D Materials in Suspended MEMS Devices Benedetta Bertoni[1,2], Lorenzo Alborghetti[1], Simone Zanotto[2], Leonardo Vicarelli[1], Filippo Fabbri[2], Alessandro Tredicucci[1], Stefano Roddaro[1,2] and Alessandro Pitanti[1]; [1]Università di Pisa, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Micro-electromechanical system (MEMS) resonators are small suspended structures, typically ranging in size from 10 to 1000 μm, that vibrate at specific resonant frequencies. Their peculiar frequency response has been used as the key mechanism for sensing applications of, among others, temperature [1], position [2] and mass. The possibility of achieving high measurements sensitivity is mainly due to a large Q factor, that can be tailored employing innovative mechanical solutions such as soft clamping and dissipation diluition.

An interesting route sees the combination of MEMS with weightless and stiff 2D materials (2DM) which can be used to enhance the device functionalities or exploit its existing capabilities to tune and investigate the material itself. Transferring the 2DM after the whole MEMS has been fully fabricated offers a large degree of flexibility and an optimal conservation of the 2DM quality, being essentially unexposed to any wet/dry etching process.

This combined platform offers several interesting advantages; for instance, the tunable thermal conductivity of MEMS can be exploited to investigate the 2DM properties under local heating. Furthermore, the MEMS mechanical motion can be used to impart a dynamic stress on the material, which would be of interest for photoluminescent transition metal dichalcogenides, such as MoS_2 and WS_2, where strain-dependent photoluminescent has been demonstrated at room temperature [3]. Finally, the 2DM can be employed as ultra-thin absorbers in broadband thermomechanical microbolometers (TB) [4].

In our work, we integrated ultra-thin (almost 2D) graphitic materials in silicon nitride (SiN) trampoline TBs in order to boost the overall absorbance, hence the detection responsivity, without impacting on the mechanical quality of the resonator. We chose graphene, specifically multi-layer graphene (MLG) due to its tunable conductivity, which is strongly linked to its absorption spectra.

The transfer technique is based on a multilayer PPMA-PVA vector, which allows us to precisely place the exfoliated MLG on a device region where it is enhancing its properties without impacting its operation.
Measuring the absorbance in the mid-IR range we found an average value of 30%, while SiN is basically transparent over a broad spectrum region.
Showing a substantial absorption enhancement over the bare TB trampoline, our approach offers interesting possibilities for material investigation and enhanced devices.

Dynamic Control of Broadband Directional Thermal Emission with InAs-Based Gradient ENZ Metasurfaces

Jae S. Hwang, Jin Xu and Aaswath P. Raman; University of California, Los Angeles, United States

Dynamic nanophotonic control of the spectral content, directionality or polarization of broadband far-field thermal radiation is a challenging, but a fundamentally enabling capability where these thermal emission devices can operate at switching speeds much higher than the conventional ‘static’ nanophotonic components where the modulation mechanism is bound to the thermal mass of the object. Thus far, several strategies have been investigated: III-V semiconductor based quantum wells for dynamic thermal emission control by coupling the in-plane resonance of a photonic crystal slab to the quantum well intersubband tansition. The thermal emission spectrum of this apporach had to be narrowband in nature, centered at a single wavelength with suppressed emission at all other wavelengths, which is attributed to the intersubband transition frequency set by the quantum well design. Gap plasmon polariton based micro strip cavities were also explored in the context of dynamic tuning of thermal emission via electrical gating. The thermal emission peak was also centered at a single wavelength corresponding to the excitation frequency of the gap plasmons. Here, we discuss dynamic electrical control of the spectral emissivity bandwidth of thermal radiation where the spectral emissivity modulation is broadband and angularly selective. We demonstrate this capability by using the concept of III-V semiconductor based gradient epsilon-near-zero (ENZ) materials, with a doping concentration of the gradient ENZ layer ranging from 1.010^{18} cm^{-3} to 1.910^{18} cm^{-3}, such that the resonance frequency of the constituent plasmonic thin films vary spatially along the depth dimension, creating a broadband directional thermal emission spectra: demonstrating thermal beaming between 17.5 to 19.5 m with the high emission angular range centered at 81. The epsilon-near-zero (ENZ) modes lying on the right of the light line are excited via subwavelength metal gratings designed using a genetic-algorithm based optimization method so that the gradient ENZ layer critically couples to free-space radiation at the ENZ wavelengths of the constituent plasmonic thin films over a range of angles. We use a rigorous coupled-wave analysis (RCWA) solver in conjunction with a semiconductor device solver to co-simulate the electric field dependent thermal emission spectra of the gradient ENZ structure. Here, we observe that it is possible to control the operational bandwidth of the thermal emitter by introducing an externally applied electric field and thus modulating the carrier concentration profile of the gradient ENZ layer. We observe a spectral emissivity modulation above 0.2 over a broad operational wavelength range (~2 microns) with maximum absolute emissivity modulation of 0.25 and relative modulation of 50% near the center wavelength (~18.0 m) of the zero-bias operational wavelength range. This highlights the remarkable control over spectral emissivity bandwidth that plasmonic gradient ENZ structures can provide by dynamically controlling the doping concentration profile of the gradient ENZ layer. We emphasize that in our approach the high emission angular range stays constant which has emissivity that is highly directional to the *same* set of angles, across a dynamically tunable spectral emissivity bandwidth. By constraining directional emission to particular angular ranges over arbitrarily controllable spectral ranges, improved performance may be possible for a range of applications in chemistry, health care, thermal imaging, IR sensing and spectroscopy. Ultimately, as these doped semicontuctor based platforms can be used to break time-reversal symmetry and reciprocity by externally applying a static magnetic field, we believe that this gradient ENZ materials framework can also open an avenue to explore devices for on-demand control of the spectral bandwidth of unequal absorptivity and emissivity for specific angular channels.

Magnetic Assembly of Plasmonic Chiral Superstructures with Dynamic Chiroptical Response Chaolumen Wu[1], Qingsong Fan[2], Zhiwei Li[2] and Yadong Yin[2]; [1]Stanford University, United States; [2]University of California, Riverside, United States

Plasmonic nanostructures exhibiting dynamically tunable chiroptical responses hold great promise for broad applications such as sensing, catalysis, and enantioselective analysis. Despite the successful fabrication of chiral structures through diverse templates, creating dynamic chiroptical materials with fast and reversible responses to external stimuli is still challenging. This work showcases reversible magnetic assembly and active tuning of plasmonic chiral superstructures by introducing a chiral magnetic field from a cubic permanent magnet. Manipulating the strength and direction of the magnetic field controls both the chiral arrangement and plasmonic coupling of the nanoparticle assembly, enabling fast and reversible tunability in not only the handedness of the superstructures but also the spectral characteristics of their chiroptical properties. The dynamic tunability further enables the fabrication of color-changing optical devices based on the optical rotatory dispersion effect, showcasing their potential for application in anti-counterfeiting and stress sensors.

EL07.20.21

Dual-Gradient Metasurfaces for Continuous Spectral and Coupling-Strength Encoding Andreas Aigner[1], Thomas Weber[1], Stefan A. Maier[2,3] and Andreas Tittl[1]; [1]LMU München, Germany; [2]Monash University, Australia; [3]Imperial College London, United Kingdom

Recent advancements in controlling light–matter interactions at the nanoscale have unlocked new possibilities to study complex and novel material systems. Two parameters are of critical importance for studying these interactions: the spectral overlap between an optical cavity mode and a material's absorptive features, and the quality factor (Q-factor) of the cavity. The ability to simultaneously control both parameters would offer unprecedented control to investigate complex systems, such as multicomponent molecular mixtures or materials with novel electronic properties.

We recently introduced a dual-gradient metasurface platform[1] that continuously encodes both spectral and Q-factor parameter spaces, all within a compact footprint. We used a dual-gradient metasurface design consisting of a two-dimensional array of smoothly varying subwavelength nanoresonators, each supporting a unique mode based on symmetry-protected bound states in the continuum. This results in 27,500 distinct photonic modes and a mode density approaching the theoretical limit for metasurfaces. When applied to surface-enhanced molecular spectroscopy, we demonstrated that our dual gradient achieves optimal sensitivity regardless of analyte concentration, which was previously unattainable.

Building on these insights, we have recently expanded our dual-gradient metasurface platform from the mid-infrared region to the visible spectrum (400–700 nm). Using a novel grating-based geometry, we addressed limitations of the original dual-ellipse design, achieving significantly higher Q-factors and strong signal modulation.

We are confident that dual gradients in the visible spectrum are an effective tool for studying nanoscale materials with optical transitions in this range, such as quantum dots and van der Waals materials.We are convinced that dual gradients provide a capable platform for investigating the full spectral and coupling-strength parameter space of complex material systems, with applications ranging from photocatalysis and chemical sensing to advanced quantum technologies, such as entangled photon generation.

Unlocking First- and Second-Order Nonreciprocal Photonic Responses via Strain, Magnetic Field and DC Biases Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

I will discuss the strategies to engineer dynamically-tunable photonic responses of semimetals and semiconductors via symmetry-breaking external stimuli. These include optical rectification, photoluminescence and second harmonic generation enabled by strain-gradient-induced inversion symmetry breaking in 2D narrow-gap chalcogenide and thio(seleno)phosphate semiconductors and Weyl/Dirac semimetals [1,2], magnetocaloric and magnetooptical effects in magnetic materials [3,4], electric-current-induced Fizeau drag in Dirac and Weyl semimetals [5], and explorations of nonreciprocal surface plasmon polariton tunability under a combination of reduced internal symmetries and external stimuli. This research has been supported by the MIT Lincoln Laboratory under award No. ACC-777 and the Army Research Office under award No. W911NF-19-1-0279.

Bio-Templating for 3D Second-Harmonic Photonic Crystals Viola V. Vogler-Neuling, Laurens Smulders and Ullrich Steiner; University of Fribourg, Switzerland

Three-dimensional nonlinear (second-harmonic) photonic crystals can simultaneously generate different nonlinear processes such as second-harmonic generation, optical parametric amplification, or other sum- and difference-frequency processes along different photonic crystalline directions. [1] However, creating these crystals presents a considerable challenge due to the chemical inertness of metal oxides.[2] Laser-poling and laser-erasing have been utilized in materials like lithium niobate and $Ba_{0.77}Ca_{0.23}TiO_3$.[3] We have demonstrated the first bottom-up fabricated 3D second-harmonic woodpile photonic crystal using a combination of sol-gel chemistry and soft-nanoimprint lithography.[4] Our objective is to study the emission of second-harmonic generated light near a complete photonic band gap and explore inhibited spontaneous emission.[5]

Soft-nanoimprint lithography is limited in its ability to stack sufficient layers to achieve a complete photonic band gap. Therefore, we applied a bio-templating approach. Previous research has utilized bio-templating of biological beetle of butterfly scales with sol-gel derived titanium dioxide, zinc oxide, and silicon dioxide.[6] Researchers have previously replicated scales from *Eupholus schoenherri*, *Pachyrynchus moniliferus*, *Eudiagogus pulcher,* and *Lamprocyphus augustus* with diamond-based symmetries among others.[6]

This study shows the first demonstration of bio-templating into a nonlinear optical material. We selected a barium titanate sol-gel with a refractive index of around 2.0 and a tetragonal phase.[4] We utilized green and red scales with rod-connected diamond symmetry from *Eupholus schoenherri* (band gap at 500 nm), and *Pachyrynchus niitasoi* (band gap at 690 nm).[7] The beetle scales were opened by plasma etching and then infiltrated with barium titanate sol-gel. The samples were subsequently heated to 400 °C to burn away the chitin of beetle scales. The resulting rod-connected diamond structure was heated to 700 °C for ten minutes to form tetragonal barium titanate.

We successfully replicated the photonic network into a nonlinear material and demonstrated, for the first time, a linear photonic band gap from a three-dimensional photonic crystal made out of a nonlinear optical material. By optimizing the filling factor through adjusting the ratio of barium titanate sol-gel to methanol, we found that a ratio of 1:0.5 (BTO:MeOH) achieved the largest reflectivity of 50 % for samples heated up to 400 °C. Due to shrinkage and the different refractive index, the band gap of the replicated network is blue shifted by 120 nm compared to the original biological scale.

Innovative Sustainable Photonic and Plasmonic Metamaterials Utilizing Bi- and Sb-Nanostructures Fernando Chacón-Sánchez[1], Carlota Ruiz de Galarreta[1,2], Martín Lopez-Garcia[1] and Rosalia Serna[1]; [1]Instituto de Óptica-CSIC, Spain; [2]Instituto de Ciencia de Materiales de Barcelona, Spain

The appeal of Bi and Sb-based materials lies in their suitability for a broad spectrum of sustainable energy and environmental applications, owing to their minimal toxicity and environmentally friendly characteristics [1]. Within the realm of nanophotonics, Bismuth and Antimony emerge as unconventional yet promising plasmonic materials with significant phase change capabilities [2-4]. The remarkable plasmonic behavior of Bi nanostructures across the ultraviolet and visible wavelength domains is attributed to interband transitions [3-4]. Moreover, Bi exhibits a relatively low melting point (~270°C), with its transition from solid to liquid phase coinciding with notable alterations in its optical properties. Leveraging this feature, we have demonstrated optical switching in Bi-nanocomposite films through both hot-plate annealing (phase-based light manipulation) and ns-laser irradiation (ultrafast response) [5-6]. Furthermore, our recent work highlights the successful application of bismuth nanostructures in producing vibrant structural colors via two distinct avenues: traditional Fabry-Perot cavities (FPC) and gap-surface plasmon metasurfaces [7]. We have evaluated their potential for coloring sustainable devices on both micro and macro scales, emphasizing their tunability for diverse applications. Towards real world applications, we implemented the FPC approach on industrial material surfaces like silicon and steel, integrating unconventional, ubiquitous materials and removing the need of a metallic back mirror, while achieving vivid and pure colors. Lastly, we will evaluate the differences between a Bi-based and a Sb-based approach.

Surface Enhanced Raman Scattering and Chemical Interface Damping in Plasmonic Slot Waveguides Ming Fu[1], Rupert F. Oulton[1] and Stefan A. Maier[1,2]; [1]Imperial College London, United Kingdom; [2]Monash University, Australia

To enhance the Raman scattering efficiency of photons by molecules, various techniques relying on either stimulated or surface enhanced Raman scattering (SERS) have been developed. But they are either limited by the poor control of scattered light, narrow bandwidth of resonance frequency, or restricted area of field enhancement. Here we present a unique waveguide approach to achieve broadband enhanced Raman scattering of molecules with precisely controlled propagation direction. We have demonstrated that 99% of the Raman photons can be coupled into the waveguide. As a corallary to this result we also observe strong chemical interface damping by adsorbed molecules.

We report directional broadband Raman scattering of light by monolayer of molecules which are chemically coated onto plasmonic slot waveguide[1]. The waveguides are decorated with optical antennas that allow light to couple in and out of the waveguide with approximately 30% efficiency. We have been able to spatially resolve the coupling in of the excitation laser and coupling out of Raman scattering. This enables us to precisely investigate how the scattered Raman photons from molecules couple into the waveguide, propagate and couple out via the antennas. We have experimentally determined the fraction of spontaneous Raman scattering coupled into a plasmonic waveguide (beta factor). The near-unity Raman beta factor is due to the largely enhanced spontaneous Raman scattering rate into the waveguide mode. The enhancement mechanism can be understood analogously to fluorescence emission enhanced by the Purcell effect, which is due to increased vacuum fluctuations and increased density of states. While Raman scattering in highly localised metallic hotspots offers high enhancement factors for a few molecules, here, a plasmonic waveguide offers predictable broadband enhancement for many molecules with a greatly improved interaction volume compared to other SERS approaches. The ability of waveguide-SERS to direct Raman scattering is relevant to Raman sensors based on integrated photonics with applications in gas and bio-sensing[2]. A side effect of the strong Raman enahncement in these plasmonic waveguide is the chemical interface damping due to the adsorbed molecules, which here are larger than plasmonic propagation losses. We quantify this effect for a range of molecular monolayers and discuss the physical origin of the additional scattering.

Polaritonic Nitrides for Near-UV-to-Far-Infrared Nanophotonics Bivas Saha; Jawaharlal Nehru Centre for Advanced Scientific Research, India

Polaritons, the hybrid quasiparticles of photons and electric dipoles (plasmons, polar phonon modes, excitons, etc.), have attracted significant interest in numerous nano-photonic applications. Due to their sub-diffraction mode confinement and field enhancement, plasmon- and phonon-polaritons are researched extensively to overcome the fundamental resistance-capacitance delay in electronics and the diffraction limit in photonic devices. However, applications of polaritons in practical devices are limited primarily due to the significant optical losses arising from the scattering of the free electrons and optical phonon modes. Therefore, materials exhibiting low-loss and high-quality plasmon and phonon-polaritons in the ultraviolet (UV)-visible and infrared (IR) spectral range are in great demand. Titanium nitride (TiN), an archetypal refractory transition metal nitride, has been studied extensively as an alternative plasmonic material to gold for visible spectral range applications. However, as the epsilon-near-zero wavelength of TiN cannot be varied readily, there is a pressing demand to develop new polaritonic materials that lead to strong light-matter interactions in near-UV to far-IR spectral range.

In this talk, we will present low-loss and high-quality plasmon and phonon-polariton resonances in epitaxial transition metal nitrides and group III-nitride semiconductors spanning from the near-UV to far-IR spectral ranges. Epitaxial hafnium nitride (HfN) heterostructures are developed as an alternative plasmonic material to silver for near-UV applications, such as solar mirrors. Similarly, with tuneable carrier concentration, polar semiconducting scandium nitride (ScN) thin films are designed to exhibit IR plasmon-polaritons with low optical loss and high propagation lengths. Polar phonon modes of ScN and gallium nitride (GaN) are further utilized to achieve surface phonon-polaritons and Reststrahlen band nanophotonics. Additionally, the optical properties of the nitride heterostructures are tuned by accessing their transdimensional regime, designing hyperbolic metamaterials, Ferrell-Berreman mode engineering, and activating surface-polaritons with nanostructure formation. Our recent findings also show an electron confinement-induced plasmonic breakdown in epitaxial ultrathin nitride metals that originate due to the strong Coulomb interaction among electrons. Our work elucidates that nitride thin films and heterostructures are excellent hosts for polaritonic resonances for a wide array of near-UV to far-IR spectral range applications.

N-Acetyl-β-D-Glucosaminidase Activity Assay for Monitoring Insulin-Dependent Diabetes Using Ag-Porous Si SERS Substrate Narsingh Raw Nirala and Giorgi Shtenberg; ARO Volcani Center, Israel

Determination of urinary or serum N-acetyl-β-D-glucosaminidase (NAG) activity as a tissue damage indicator is widely used in diagnosis of various pathologies, including diabetic nephropathy. Early and rapid biomarker detection is an important element of medical diagnosis, facilitating prompt therapeutic decisions and prognosis evaluation. Herein, we present a modified sensing approach for a rapid and reliable NAG activity determination in complex media using surface-enhanced Raman spectroscopy (SERS). Porous silicon (PSi) Fabry-Pérot interferometers were redesigned as sensitive SERS platforms utilizing the vast inherent surface area for silver (Ag) nanoparticles embedment. Interaction of the porous nanostructures with specific NAG-enzymatic products produces an indicative spectral fingerprint proportional in magnitude to its concentration. The sensitivity of Ag-PSi SERS substrates was evaluated in complex matrices presenting sufficient limits of detection compared with other advanced assays and techniques (0.07, 0.47 and 0.50 mU mL^{-1} for urine, milk and plasma, respectively). The augmented optical performance revealed recovery values of 96-109%, indicating successful and selective NAG recognition in biological fluids. Finally, the potential applicability of the suggested prototype for real-life scenarios was evaluated *in vivo,* in a model of insulin-dependent diabetes induced in sheep. Overall, the robust data confirm the application of SERS analysis for early diagnosis of pathology and for evaluation of clinical responses to pharmacological treatments.

10:45 AM EL07.22.04

Enhancement of Raman Spectra of (Bio)Analytes Using Copper Nanostructures in the (Deep) UV Spectral Range Shivani Yadav[1], Martynas Talaikis[2] and Vladimir Sivakov[1]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Center for Physical Sciences and Technology, Lithuania

Raman spectroscopy is an important approach in bioanalytics due to its high specificity and provides clear information about the chemical structure of the molecules under investigation - without the need for labels. In Surface Enhanced Raman Scattering (SERS), the molecules under investigation interact with rough metal surfaces, which enables ultra-sensitive detection down to individual molecules. For measurements in the visible and NIR spectrum (418-785 nm), gold, silver and copper nanostructures are highly efficient. Wavelengths from the deep UV to IR spectral range are used for excitation, allowing the identification and differentiation of individual components down to microorganisms and tissues. The UV range, in particular, is very promising for proteins because they specifically absorb light below 400 nm, thereby resonantly amplifying vibrational modes characteristic of the peptide backbone and some amino acid residues.

A large number of different fabrication strategies are available for the fabrication of a powerful SERS substrate. However, despite its enormous potential, SERS has not yet been applied in routine bioanalytical applications, often due to the challenges of preparing low-cost/efficient SERS surfaces with high reproducibility and signal amplification properties.

In the present work, for the first time on the basis of copper nanostructures deposited on silicon surface using galvanic displacement effect, we found significant enhancement of Raman signal of biomolecules (adenine, guanine, riboflavin) by copper nanostructures at excitation wavelengths of 244, 257, 325 nm. The obtained copper surfaces show significant chemical resistance to oxidation, which may be related to the binding of biomolecules to the surface. In addition, to study the interaction of biomolecules with the copper surface and possible energy transfer, the copper surface was coated with a layer of silica deposited by ALD. Differences in the intensity of the Raman signal on adenine were obtained depending on the thickness of the silicon dioxide layer, which can be related to the efficiency of the transition of electrons through the dielectric layer. A more detailed discussion of the discovery will be presented in the paper. The use of copper as a plasmonic material could play a crucial role in the field of SERS research, as this issue is very poorly understood and studied. According to existing publications, the SERS activity of copper nanostructures is associated only with the near-infrared spectral range (600-800 nm), where copper exhibits weaker SERS activity compared to gold or silver nanostructures. From this point of view, our discovery may provide a new stimulus for the development of materials for UV-SERS applications.

11:00 AM EL07.22.05

Shining a Light on Wastewater Pathogens—AI-Assisted Surface-Enhanced Raman Spectroscopy and Electrokinetics for Bacterial Identification in Wastewater Yirui Zhang, Liam K. Herndon, Punnag Padhy, Alexander Al-Zubeidi, Babatunde Ogunlade, Ariel Stiber, Alex M. Boehm and Jennifer A. Dionne; Stanford University, United States

Wastewater-based epidemiology can monitor population-level infections, provide early warnings about disease outbreaks, and help control the spread at the community level [1,2]. However, broad-spectrum bacterial identification in wastewater presents outstanding challenges; notably, current culturing or fluorescence-based methods [3] to identify bacteria are unsuitable for real-time, high-throughput screening of diverse bacterial species, and may not work well in the complex wastewater matrix. Here, we harness electrokinetics and artificial intelligence (AI)-assisted Raman spectroscopy as an innovative approach that promises the identification of a wide range of pathogenic bacteria in wastewater.

First, we synthesize gold nanorods that can electrostatically bind to bacteria surfaces, allowing for surface-enhanced Raman spectroscopy (SERS) [4] from cell surfaces. We collect SERS from bacteria spiked into filter-sterilized wastewater, including *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, and *Serratia marcescens* as model species, spanning concentrations from 10^9 cells/mL to 10^4 cells/mL. Spectral clustering analysis shows that bacterial signals become less distinguishable in wastewater as the concentrations decrease. To overcome this challenge, we incorporate electrokinetic effects into SERS by employing gold microelectrodes to apply electric fields, utilizing dielectrophoresis (DEP) [5] to rapidly displace and concentrate bacteria. The four types of bacteria responded to 100 kHz AC fields due to their dielectric responses, and were enriched at the microelectrode within minutes. The enrichment of bacteria is directly visualized through optical and electron microscopy, resulting in up to tenfold increases in Raman signal intensities under electrical fields at bacterial concentrations down to 10^4 cells/mL. Such enhancement may enable the detection sensitivity to reach environmentally relevant concentrations. Next, employing machine learning models [6], we identify biologically relevant Raman fingerprint peaks characterizing proteins, nucleic acids, and lipids from bacteria surfaces, allowing for rapid identification of bacteria species in wastewater. Finally, we demonstrate that mixtures of bacteria are distinguishable from SERS under DEP effects. We discuss development of unmixing algorithms to distinguish the bacterial signatures from wastewater and identify mixtures of different bacteria species. We also discuss integrating our method with microfluidic devices to monitor complex wastewater samples. Our method can enable generalized pathogen detection and molecular recognition in complex liquid samples, such as wastewater, blood, and seawater.

Towards Improved CAR T Therapy Monitoring with Label-free Raman-Based Immune Cell Quantification Ariel Stiber, Zinaida Good, Babatunde Ogunlade, Kai Chang, Patrick Quinn, Elena Sotillo, Crystal Mackall and Jennifer A. Dionne; Stanford University, United States

Chimeric antigen receptor (CAR) T cell therapy has emerged as a transformative immunotherapy for cancer, autoimmune diseases, and transplantation. In this treatment, a patient's immune cells are isolated and engineered to express a synthetic CAR on their surface to direct T cell reactivity towards target cells. Patient CAR T cell quantity throughout the therapeutic process is a contributing indicator of the efficacy of immune response as well as an immediate sign of toxicity through complications such as cytokine release syndrome and immune effector cell-associated neurotoxicity syndrome. However, current methods for quantification are costly in both time and money, precluding point-of-care clinical decision support. There is a critical need for real-time, low-cost CAR T cell quantification. Here, we develop a label-free, and cost-effective technique for CAR T cell counting in patient blood using surface enhanced Raman spectroscopy (SERS) and machine learning (ML). SERS provides a platform for non-destructive, fast, label-free cellular identification with single-cell resolution, eschewing the need for complicated sample preparation. Integrating ML algorithms with the ability to recognize patterns in complex datasets provides precise differentiation of cellular phenotypes from these minute spectral differences. Here, we achieve single-cell SERS spectral collection and classification of engineered T cells from natural T-cells.

We synthesize gold nanorods with a localized surface plasmon resonance peak around 660-700 nm for Raman excitation at 785 nm. These nanorods will be used for spectral collection of live immune cells in liquid, therefore we select a resonance peak close enough to 785 nm to be excited by our laser but blue-shifted enough to minimize the competitive extinction component of SERS signal intensity. We overcome the low and inconsistent electrostatic interactions between immune cells and as-synthesized gold nanorods through thiol-gold mediated nanorod surface modification. With these modifications, we demonstrate increased nanorod-cell binding, decreased nanorod aggregation, and significantly decreased single cell spectral acquisition times. Using these nanorods we collect and classify SERS spectra of live engineered (CAR) and non-engineered T cells to create a dataset of 1000 single-cell spectra of each cell time over 10 donors. This is used to train a robust ensemble ML model that accounts for variations cell-to-cell, patient-to-patient, and in nanorod-cell binding, with which we demonstrate successful classification of CAR T cells with high accuracy (≥ 90%). Our ML algorithm allows us to identify the specific vibrational modes that distinguish CAR from non-engineered cells by calculating feature importance scores for each wavenumber or groups of biologically relevant peaks, which we use to enhance our understanding of the differences between CAR and non-engineered cells. We apply this method both to cultured cells in 10% EDTA, as well as the more clinically relevant application of cells spiked into donor blood, and validate our results with flow cytometry and molecular assays. We also describe work to digitize patient blood samples for rapid processing and CAR T cell quantification, using acoustic bioprinting to encapsulate single cells in droplets. By conducting this procedure on patient blood throughout CAR treatment, we describe how we can generate efficient cell quantification data that can be correlated to therapeutic impact with significant time and financial advantage over previous methods. Our results demonstrate the promise of this platform for rapid, cost-effective, label-free, real-time CAR T cell monitoring during cancer therapy.

11:30 AM EL07.22.07

Low-Loss Phonon Polaritons for Enhancing Hydrogen Detection in the Mid-Infrared Guanyu Lu[1], S. Maryam V. Esfidani[2], Jongsu Lee[1], Yicheng Wang[1], Matthew Hershey[1], Koray Aydin[1], Thomas G. Folland[2] and Dayne F. Swearer[1,1]; [1]Northwestern University, United States; [2]The University of Iowa, United States

The field of nanophotonics focuses on confining and concentrating electromagnetic energy to length scales much shorter than the free-space photon wavelength. In the middle-IR (mid-IR) region, which coincides with the molecular fingerprint region (approximately 6-20 μm in wavelength), such sub-diffractional confinement benefits applications like enhanced molecular sensing. Phonon polaritons, quasi-particles comprising an IR photon and an oscillating ionic charge (optic phonon), enable sub-diffractional light-matter interactions in the IR spectrum. [1] These hybridized light-matter modes are advantageous for enhancing molecular sensing in the mid-IR due to their low loss, high photon-confinement, and heightened sensitivity to environmental changes. We have leveraged low-loss phonon polariton material, silicon carbide (SiC), to enhance hydrogen gas sensing in the mid-IR. Hydrogen, crucial for sustainability, is a promising energy carrier in transitioning away from fossil fuels, necessitating compact optical sensors for safe operations and simultaneous IR detection of other green energy-related molecules. However, as a homonuclear diatomic molecule, hydrogen has no dipole moment and is IR inactive. We propose and demonstrate a SiC metasurface platform [2] with palladium (Pd) metal as a hydrogen transducer material [3] for mid-IR sensitive hydrogen detection at room temperature using low-loss phonon polariton modes. These hybridized polar material/metal metasurfaces, fabricated through standard photolithographic processes, exhibit near-unit absorption for unpolarized IR light and high quality-factors (>70) before hydrogen loading. Upon hydrogen loading, Pd undergoes a phase transition from alpha-phase to beta-phase, altering the local dielectric environment of the SiC resonators and shifting the resonance of the narrowband phonon polariton modes. Using this platform, we demonstrate enhanced and reversible hydrogen detection from 0.5% to 5% concentration compared to Pd thin film, expanding current visible-light-based hydrogen sensors to the mid-IR and potentially integrating with other surface-enhanced infrared spectroscopy techniques.

11:45 AM EL07.22.08

Advanced Room-Temperature NIR Plasmonic Photodetection and Reconstructive Spectroscopy Eslam N. Abubakr[1], Oshita Masaaki[1], Saito Shiro[2], Suzuki Hironori[2] and Tetsuo Kan[1]; [1]The University of Electro-Communications, Japan; [2]IMRA Japan Co., Ltd., Japan

The development of plasmonic photodetectors, especially in the near-infrared (NIR) region, has gained significant attention due to their non-destructive nature. It is essential to provide absorption of longer wavelengths in the most accurate, reliable, and repeatable manner; however, fabricating NIR detectors can be challenging due to their inherently low energy. Prior studies have laid a solid foundation for NIR detection and spectroscopy. However, responsivity was limited to a few tens of μA/W, and spectroscopy of the longer wavelength range of NIR beyond 1400 nm is not yet clearly demonstrated. In this work, we achieved remarkable detection over a wide range of wavelengths up to 2300 nm with distinguished responsivity through a single filter-free tunable device. We emphasize extending the spectral range for reconstructive spectroscopy into longer NIR wavelengths, fostering enhanced understanding and application possibilities.

Gold is typically used in semiconductor manufacturing processes; however, it forms unstable contacts with Si, leading to potential device reliability issues. The introduction of an interlayer not only enhances device adhesion but also modifies charge carrier generation and transport processes. A low Schottky-barrier photodetector with a plasmonic assist that receives near-infrared (NIR) light at room temperature was demonstrated. A comparative study of Schottky plasmonic photodetectors employing titanium (Ti) as a Schottky interlayer metal, a diffusion barrier, an adhesion promoter, and to suppress the formation of intermetallic compounds or plasmonic resonance shifts with enhanced absorption led to a tenfold increase in device responsivity compared to previous studies. The study meticulously engineered a grating structure with a pitch of 1.4 μm. Grating design is determined by extensive experimental and modeling, ensuring a wavelength-specific plasmonic photodetection and a near one-to-one correspondence between incident angles and wavelengths within the NIR region.

It exhibited an exceptional photocurrent response at room temperature and zero biasing conditions, characterized by high linearity and sensitivity. In addition, it exhibited high sensitivity to low light intensities (less than 25 μW at 1900 nm). The device showed the capability to demonstrate clear SPR peaks for NIR even with parallel exposure to visible light. It maintained high stability with neither hysteresis nor deterioration in photocurrent measurements over a time span of 240 days so far. The sharp and selective SPR peaks facilitated expanding the spectral range for reconstructive spectroscopy to longer wavelengths. Since the degree of surface sensitivity can be controlled by collecting photoelectrons emitted at different emission angles to the surface plane by changing the incident photon energy, the reconstruction of multiple parallel incident wavelengths could be successfully demonstrated. This makes it a potent technique for investigating the electronic and chemical structures of various nanolayers and devices for green chemistry, where it could be efficiently utilized as a biosensor for biomolecular measurements with high sensitivity to refractive index changes. This research represents a significant leap in sensing, photodetection, and spectroscopy, with far-reaching implications across applications such as gas sensing.

Light acquisition for 1.2–2.3 μm-long NIR wavelengths became possible through a single device and is applicable in gas sensing, particularly within the vibrational absorption bands of alkane groups. This research builds upon a comprehensive array of experimental results, encompassing devices with diverse geometries and multiple interlayers, including Au, Ti, Mo, and Cr. These findings provide valuable design guidelines for optimizing device structures and insights into their application for various scenarios.

SESSION EL07.23: Nonlinear Plasmonics and Metasurfaces
Session Chairs: Yu-Jung Lu and Bivas Saha
Friday Afternoon, December 6, 2024
Hynes, Level 2, Room 208

1:30 PM EL07.23.01

Hybrid ScAlN-SiN Platform for Enhanced Nonlinear Photonics Jiangnan Liu[1], Shuai Liu[1], Abdur-Raheem Al-Hallak[1], Pierre-Luc Thériault[2], You Wu[1], Stephane Kena-Cohen[2], Mackillo Kira[1], Mo Soltani[3], Zheshen Zhang[1] and Zetian Mi[1]; [1]University of Michigan, United States; [2]Polytechnique Montréal, Canada; [3]Raytheon BBN Technologies, United States

Aluminum nitride (AlN) has wide applications in the field of photonic integrated circuits (PIC) due to the wide bandgap that enables a wide transparency window from ultraviolet (UV) to the infrared range. Additionally, it offers several exceptional properties such as piezoelectricity and second-order nonlinearity originate from the uncentrosymmetric wurtzite crystal structure, which enables its active functionalities in optomechanics, frequency conversions as well as electro-optic modulators. To further improve its properties, researchers have found that the addition of the rare earth element scandium (Sc) to AlN shows a five-time enhancement of piezoelectricity thus have great potential in the micro-electro-mechanical-system (MEMS) applications. Recently, ScAlN has also shown a great boost of second-order nonlinearity ($\chi^{(2)}$) compared to AlN, the d_{33} is more than 60 pm/V when the Sc concentration reaches 36%, which is exceeding $LiNbO_3$. However, more investigations on the growth dynamics of high quality ScAlN are required for such new materials and a major challenge for its direct implementation in high performance integrated photonics is the increasing loss associated with the Sc doping. In the meantime, silicon nitride (Si_3N_4) has been extensively studied to reduce the propagation loss in the photonic devices, yet it lacks second-order nonlinearity, greatly limits its applications in quantum photonics. In this work, we present a hybrid ScAlN-Si_3N_4 microring resonator structure that shows a high Q-factor of 1.4×10^5. We first deposit single-crystalline ScAlN on sapphire (Al_2O_3) substrate in a plasma assisted molecular beam epitaxy (PA-MBE) system, which provides high-quality materials with lower defect densities to suppress losses in the photonic components. Subsequently, Si_3N_4 is grown by low-pressure chemical vapor deposition (LPCVD) and fabricated to high Q-factor microring resonators by E-beam lithography and dry etching. The etch will stop at the ScAlN layer and optical guiding will be provided by the Si_3N_4. Such structure will benefit the device fabrication in terms of reducing optimization on the ScAlN etching condition and can potentially reduce the scattering loss from the ScAlN sidewall roughness. This device enhances the light-matter interactions in a platform combines both the high $\chi^{(2)}$ of ScAlN and the low-loss of Si_3N_4, which can be utilized as a fundamental component in quantum photonics.

1:45 PM EL07.23.02

Advanced Materials to Enhance Weaker Optical Processes—A Study on Designing New Hybrid Advanced Materials to Improve Nonlinear Optical Processes for Next-Generation Photonic Applications Rana Faryad Ali; Simon Fraser University, Canada

Nanophotonics research has focused recently on the ability of nonlinear optical processes to mediate and transform optical signals in a myriad of novel devices, including optical modulators, transducers, color filters, photodetectors, photon sources, and ultrafast optical switches. The inherent weakness of optical nonlinearities at smaller scales has, however, hindered the realization of efficient miniaturized devices, and strategies for enhancing both device efficiencies and synthesis throughput via nanoengineering remain limited. Here, we demonstrate a novel mechanism by which second harmonic generation, a prototypical nonlinear optical phenomenon, from individual lithium niobate particles can be significantly enhanced through nonradiative coupling to the localized surface plasmon resonances of embedded gold nanoparticles. A joint experimental and theoretical investigation of single mesoporous lithium niobate particles coated with a dispersed layer of ~10 nm diameter gold nanoparticles shows that a ~32-fold enhancement of second harmonic generation can be achieved without introducing finely tailored radiative nanoantennas to mediate photon transfer to or from the nonlinear material. This work highlights the limitations of current strategies for enhancing nonlinear optical phenomena and proposes a route through which a new class of subwavelength nonlinear optical platforms can be designed to maximize nonlinear efficiencies through near-field energy exchange.

2:00 PM EL07.23.03

Highly Nonlinear ENZ Driven Hybrid Tamm Plasmon-Polariton Nanostructures on the Si Platform Tornike Shubitidze and Luca Dal Negro; Boston University, United States

Materials with vanishingly small permittivity, known as epsilon-near-zero (ENZ) media, emerged as promising candidates to achieve nonlinear optical effects of unprecedented magnitude on a solid-state platform. Epsilon-near-zero (ENZ) materials, characterized by an almost vanishing permittivity, exhibit a plethora of fascinating optical properties, including a significant enhancement of second- and third-order nonlinear optical processes. Combined with their CMOS compatibility, these materials have been integrated into compact photonic devices and nanostructures that perform remarkable nonlinear operations such as order-unity refractive index modulations with sub-picosecond response time, enhanced harmonic generation, ultra-fast pulse shaping through frequency translation, and optical time reversal. Recently, record-high refractive index modulation $\Delta n \approx 2$ has been demonstrated in silicon dioxide/silicon nitride (SiO2/SiN) Tamm plasmon-polariton (TPP) structures with embedded ITO nanolayers fabricated by radio-frequency magnetron sputtering. These nonlinear TPP structures also exhibit significant third harmonic generation and non-reciprocal characteristics. Building upon these findings, we present here the design, fabrication, and nonlinear characterization of novel hybrid TPP structures coupled to TiN plasmonic nanoantennas deposited atop nonlinear ITO nanolayers. We demonstrate that these structures feature multiple high-Q resonant modes originating from the hybridization of TPPs and the localized modes of TiN nanoantennas, leading to sub-wavelength nanoscale confinement of the electric field inside the nonlinear ITO layer at the relevant ENZ wavelengths for enhanced nonlinear optical devices on the Si chip.

2:15 PM EL07.23.04

Enhanced Nonlinear Harmonic Generation from ZnO-Based Multifractal Photonic Membranes Tornike Shubitidze and Luca Dal Negro; Boston University, United States

Structurally complex photonic media with non-periodic refractive index variations on the wavelength scale display a very rich physics driven by wave interference effects in the multiple scattering regime and display profound analogies to the mesoscopic transport of electrons in disordered metallic alloys and semiconductors. In the last two decades, the study of disorder-induced phenomena for optical waves has stimulated the growing field of "disordered photonics", resulting in a wide range of applications to lasing, solar energy, speckle-based imaging and spectroscopy, and nonlinear optics. Recently, we designed and developed nano-perforated photonic membrane photonic structures with controlled multifractal geometry using silicon nitride (SiN) and we demonstrated experimentally distinctive optical resonances with enhanced light intensity distributed across extended device areas with characteristic multiscale intensity fluctuations.
In this talk, we build on our previous results by presenting the design, fabrication, linear and nonlinear optical

characterization of multifractal photonic membranes fabricated in optically nonlinear ZnO materials by magnetron sputtering deposition, electron beam lithography, and high-quality deep reactive ion etching. Using this approach in combination with the efficient localization landscape theory, we design and demonstrate multifractal photonic structures with enhanced harmonic generation efficiency driven by the excitation of multifractal modes. Finally, we perform third-harmonic imaging spectroscopy on the fabricated samples under different femtosecond pulsed excitation conditions and address the potential to achieve nonlinear instabilities of speckle patterns on a miniaturized optical chip.

2:30 PM EL07.23.05
Single Cycle Optical Nonlinearity of Transparent Conducting Oxides Ieng-Wai Un[1], Subhajit Sarkar[2] and Yonatan Sivan[3]; [1]South China Normal University, China; [2]SRM Institute of Science and Technology, India; [3]Ben-Gurion University of the Negev, Israel

Transparent conducting oxides (aka Low electron density Drude (LEDD) materials) became popular candidates for high-efficiency nonlinear optical applications due to their unique near-infrared “epsilon near zero” point. Their nonlinearity is extremely large, reaching even 100’s of percent of the refractive index/permittivity [1]. Only recently a comprehensive quantitative theoretical (Boltzmann-based) description of their electronic, thermal and optical response under the adiabatic approximation was obtained in [2,3]. These studies were capable of explaining experiments from the last decade or so, done with “standard” ultrashort optical pulses, i.e., for pulse durations of a few picosecond down to 50-100 femtosecond; however, they are not suitable to describe the dynamics due to intense *single-cycle* illumination. Such extremely short illumination is needed to probe the claims of instantaneous turn-on of the optical response [4] as well as the femtosecond scale turn-off dynamics required for the realization of temporal crystals. In particular, the formulation of [2,3] is not suitable to model the unexpectedly-short 50-100 femtosecond decay rate observed in [5].

To meet this challenge, we have significantly extended the formulation of [2,3] by replacing the Boltzmann description by the more advanced density matrix formulation. This way, we removed the assumption of adiabatic response and can treat (previously-ignored) coherent aspects of the photon-electron interactions [6]. We also account for spontaneous and stimulated emission of light, femtosecond scale ballistic and diffusive transport of charge and heat as well as the damage threshold of the material.

We study thin layers as well as particles (which were not studied so far, although they pose less difficulties in terms of coupling due to impedance). We will discuss various yet unpublished results, including the detailed dynamics of the populaiton iof the electron states and the coherences between them; high harmonic generation, spectral broadening and associated temporal pulse compression; the role played by the deviation from thermal equilibrium (the so-called “non-thermal” electrons) and the feasibility of stimulated emission; the permittivity dynamics, including sign change of the nonlinearity; we also study the importance of ballistic transport vs. diffusive transport effects. Finally, we characterize the damage threshold as a function of the layer thickness and pulse duration and correlate our findings to new experimental findings.

2:45 PM EL07.23.06

Understanding and Mitigating Low-Frequency Instability in Thin-Film Lithium Niobate Nanophotonic Devices

David R. Barton[1], Matthew Yeh[2], Evelyn Hu[2], Marko Loncar[2] and Gavin Smith[3]; [1]Northwestern University, United States; [2]Harvard University, United States; [3]University of New Hampshire, United States

Thin-film lithium niobate on insulator (TFLN) is a promising platform for integrated classical and quantum photonics due to its intrinsically large electro-optic effect and wafer-scale availability. The direct connection between driving electric fields and refractive index in this platform has enabled new schemes for creating pulsed lasers on chip, high-bandwidth and energy-efficient modulators, and devices for integrated nonlinear photonics. However, it is generally recognized that thin-film lithium niobate modulators have unstable electro-optic responses at low frequencies, and undesired photorefractive index changes due to defect absorption at high optical powers. Post-processing methods such as annealing have been developed to reduce these deleterious effects, but their microscopic origins remain unclear. It is also not known if these effects relate to fundamental materials issues, might be exacerbated for materials in thin-film form with possible strain inhomogeneities, and indeed might arise from thin-film preparation, which involves ion implantation, and chemical-mechanical polishing.

Here, we use a correlative approach combining materials characterization techniques and photonic device characterization to explore the structure-device-processing parameter space in integrated thin-film lithium niobate devices to attempt to identify a mechanistic insight for low-frequency instability in our devices. All our devices are fabricated on 600 nm thick x-cut Lithium Niobate on insulator wafers, and we explore fabrication processes that impact both the bulk and interfaces in our devices. First, we show through XPS that the etch conditions and standard acid cleans used in our thin-film processing dramatically impact the surface by removing lithium from the surface, locally reducing Nb^{5+} to Nb^{4+}, and creating a damaged amorphous Lithium Niobate layer. Specific chemical cleans remove the damaged layer, while annealing at moderate temperatures in an oxygen environment restores the surface Li:Nb ratio to its unprocessed status. Annealing our samples temporarily increases quality factors and reduces photorefraction, indicating that diffusion of mobile species such as Lithium or Hydrogen may indeed play a role in long-term stability of our devices. Finally, we find that the metal-Lithium Niobate interface is important for the low-frequency response of our devices. Etching through the oxide cladding in our structures dramatically improves the electro-optic response but leaves behind an amorphous lithium niobate interface for the electrical contacts. Any attempts to remove redeposition or clean the surface semiconductor-metal interface reduces the low-frequency response and degrades the response flatness. Together, these results point to the importance of surface and bulk conductivity and key interfaces within our electro-optic devices for stable low-frequency tuning, a requirement for deployable devices and systems in thin-film Lithium Niobate.

Spectrally Broadband and Highly Directive Thermal Emission with Dual Polarization Yae-Chan Lim, Komron Shayegan and Harry A. Atwater; California Institute of Technology, United States

We report a design concept to achieve broadband directive thermal emission with *dual polarization*. We theoretically demonstrate narrow angular selectivity within 5° over an 8 to 12 μm bandwidth for a range of emission angles. Additionally, we show that one can make emission angles distinct for different polarizations by tailoring the constituent optical modes. Throughout our theoretical analysis, we identify a new resonant mode, distinct from the Berreman mode, which has demonstrated broadband directive thermal emission for TM polarization. This new mode enables directive thermal emission for both polarizations. Based on the fundamental framework, we also report the design of a nanophotonic structure to validate the experimental feasibility of our findings.
Engineering the directivity of thermal emission has profound implications in thermal applications such as energy conversion, thermal imaging, and radiative cooling. Achieving directive emission over a broad bandwidth is a challenging task requiring an independent control of the spatial and temporal coherence. While recent nanophotonic strategies have enabled broadband directive thermal emission for transverse magnetic (TM) polarization, achieving directivity for both TM and transverse electric (TE) polarizations remains elusive. To enhance the efficiency and versatility of thermal applications, it is important to directionally emit both polarizations over a broad spectral range.

3:45 PM EL07.24.02

Three-Dimensional Bound State in Continuum Metasurface Enables Integratable *Q*-Switch Nanophotonic Biosensing Liaoyong Wen; Westlake University, China

Label-free optical biosensors are at the forefront of modern and future disease management, enabling rapid point-of-care (POC) diagnosis and continuous monitoring of biomarker or therapeutic drug levels. These optical biosensors typically comprise three main components: a light source, a sensing module, and a photoelectric transducer. Recently, nanophotonic metasurfaces have emerged as an alternative sensing module, facilitating the downsizing of optical biosensors through the use of normal incidence. Most metasurface biosensors operating in the visible or near-infrared (NIR) bands utilize affinity-based refractometric sensing (frequency-shift interrogation sensing mechanism). Consequently, researchers have extensively sought resonance properties with high Q factors and large frequency shifts in response to refractive index perturbations by designing various structures based on plasmonic and dielectric metasurfaces.

Despite these advancements, achieving high performance in miniaturized nanophotonic biosensors remains elusive due to inadequate signal bandwidth and frequency compatibility among the various components of the integrated system. Firstly, while the high Q factor of the metasurface enhances signal resolution in spectral interrogation, a narrow linewidth results in an ineffective response when illuminated by a relatively broadband light source, causing a bandwidth mismatch between the light source and the metasurface. Secondly, during the resonance frequency-shift interrogation, the dynamic resonance frequency of the metasurface easily moves out of the static illumination frequency, resulting in a frequency mismatch that the transducer struggles to detect. Thirdly, the high Q factor of the metasurface necessitates a transducer with a high spectral resolution to distinguish subtle resonance frequency shifts, increasing the complexity and cost of the transducer. These issues make it difficult to miniaturize the components and integrate small biosensors for practical use.

In this presentation, I will deliver a distinctive sensing module based on a three-dimensional bound state in continuum (3D BIC) metasurface, characterized by longitudinal displacement asymmetric structures. This design enables seamless integration with diverse light sources and photoelectric transducers through a Q-switched near-critical coupling (QSCC) mechanism. In this mechanism, the resonance peak demonstrates a notable in-situ intensity response to refractive index perturbations, diverging from the conventional resonance peak shifts. Wafer-scale 3D BIC metasurfaces were achieved through a cost-effective process involving a combination of aluminum 3Dprinting and stripping techniques. Under the QSCC mechanism, extremely high Q sensitivity 1.6×10^4 RIU^{-1} is achieved with 1500 %/RIU relative intensity sensitivity near critical coupling. Assisted with cross-validated deep neural net (DNN) models, the 3D BIC metasurface exhibits ~100% accuracy for lung cancer diagnosis, creating a new optical sensing data process method and showing great potential in clinical applications.

4:00 PM EL07.24.03
Metal-Semiconductor-Metal Heterostructures for Electrical, Optical and Plasmonic Applications Alois Lugstein, Zehao Song, Masiar Sistani, Fabian Schwingshandl and Maximilian Bartmann; Technische Universität Wien, Austria

We will address the controlled formation of monolithic metal-semiconductor-metal nanowire and nanosheet heterostructures. The main obstacles facing towards reliable synthesis of such hybrid systems are related to lateral strain relaxation, mitigating the limitations of material lattice compatibility and allow arbitrarily combined dissimilar materials unattainable in layered structures. The formation of axial heterostructures with atomically sharp interfaces and monocrystalline aluminum by using a thermally initiated exchange reaction will be presented. Together with the wafer-scale accessibility, the proposed fabrication scheme may give rise to the development of key components for a broad spectrum of emerging Si and Ge-based devices requiring monolithic metal-semiconductor−metal heterostructures with high-quality interfaces for electrical, optical and plasmonic applications.

Aluminum is excellent for plasmonics because of a broad response spectrum from ultraviolet to infrared, a self-limited native oxide layer protecting the metal surface and CMOS-compatibility. Current Si-based ICs technology already uses nanoscale Al interconnects, to route electronic signals between transistors on a chip. With regard to scaling and integration, notably with the maturity of electromagnetic simulations and current CMOS fabrication techniques, a variety of such plasmonic designs can be fabricated in a Si foundry right now. Germanium as the channel material is advantaged by its full *compatibility* with CMOS technology to create a monolithic solution.
The following particular features of the monolithic metal-semiconductor platform devices will be discussed:
Light absorption, surface plasmon polariton (SPP) generation and guiding as well as effective injection of hot electrons/holes arising from the non-radiative decay of SPPs, is realized in a monolithic Al-Ge-Al Schottky barrier field effect transistor.
The Al leads perform a dual function and simultaneously carry both optical and electrical signals, giving rise to exciting new capabilities.
Via electrostatic modulation of the effective barrier height of the Schottky junctions, the transfer of hot charge carriers can be tuned with respect to their energy. For excited carriers arising from the non-radiative decay of SPPs the momentum must be in the direction to the metal-semiconductor junction, so that the carrier’s kinetic energy component in that direction is sufficient to overcome the effective Schottky barrier. The difficulty of achieving both

energy and momentum matching is in general a main cause of the low quantum efficiency for extracting excited carriers in plasmonic devices. The actual monolithic device architecture is ideal in view of this as the SPPs are directly guided towards the Al-Ge interface.

As a direct consequence of the monolithic architecture and thus improved momentum matching the devices have proven to be extremely effective plasmon detectors with an external quantum efficiency of EQE = 2.5%. Although no optimization with respect to effective plasmon coupling or SPP waveguiding has been done yet, this is quite remarkable since for other electrical plasmon detectors EQEs of less than 1% have been reported.

Aside of barrier modulation a virtual p-n junction can be emulated in the semiconductor channel with top split-gates, with the distinct merit that carrier concentration and polarity are tunable by electrostatic gating. These investigations were carried out with a view to possible use for on-chip, CMOS-compatible plasmonic photovoltaics, with versatile implementations for autonomous nanosystems.

Finally we will demonstrated the key functionality of a CMOS compatible transistor that response to plasmon signals in a neuron/synapse like fashion performing typical synaptic behavior, such as the excitatory post synaptic current and paired pulse facilitation.

4:15 PM EL07.24.04

Enabling High-Dose X-Ray Imaging Modalities via Nanophotonic Thermal Management in X-Ray Tubes Simo Pajovic[1], Charles Roques-Carmes[2,1], Seou Choi[1], Steven Kooi[1], Rajiv Gupta[3], Michael Zalis[3], Ivan Celanovic[1] and Marin Soljačić[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States; [3]Massachusetts General Hospital, United States

X-ray imaging is one of the most important clinical tools for detection and diagnosis of disease. In the United States, over 80 million CT scans are performed each year, but they consume vast amounts of energy: for a single-source CT scanner, approximately 25,000 kWh per year with an additional 40% for cooling (in total, the equivalent of three U.S. homes). Furthermore, imaging modalities such as phase-contrast imaging can reveal detailed information about objects, but precisely due to insufficient cooling, many commercially available X-ray tubes are not bright enough to translate them to the clinic. Thus, the inability to meet demanding brightness and power requirements, primarily driven by cooling limitations, hinders the deployment of these transformative technologies. However, improved thermal management can address these challenges. In X-ray tubes, there is a thermal bottleneck that prevents high-power (i.e., high-brightness) operation, originating from radiative heat transfer between the anode, made of tungsten, and the evacuated housing. In systems that exchange heat via radiation, thermal management has been revolutionized by photonic crystals designed to achieve a desired emissivity [1]. For example, it has been theoretically and experimentally demonstrated that tungsten photonic crystals can be used as spectrally selective emitters for thermophotovoltaics [2]. We propose that using nanophotonics to tailor emissivity in X-ray tubes, where radiation is the dominant mode of heat transfer, could lead to improvements in thermal management, alleviating both the demanding power requirements of existing CT scanners and the thermal bottleneck preventing transformative imaging modalities reliant on high doses. To illustrate the concept of nanophotonic thermal management in X-ray tubes, we use rigorous coupled wave analysis (RCWA) to calculate the spectral directional emissivity of a tungsten photonic crystal via Kirchhoff's law of thermal radiation. Incorporating our nanophotonic design into a heat transfer model of an X-ray tube, we estimate the hottest (i.e., limiting) temperature in the X-ray tube as a function of the operating power. We predict that nanophotonic thermal management can lead to a >2× enhancement in the operating power of an X-ray tube at typical operating temperatures. Alternatively, we predict that at typical operating powers, our proposal can lead to a >15% reduction in the operating temperature, decreasing the cooling load. S. Design and Fabrication of Plasmonic Nano-Array Patterns for Near-Infrared Fluorescent Biosensors Anyang Wang, Yingjie Hang, Weirui Tan and Nianqiang Wu; University of Massachusetts Amherst, United States

Detecting biological samples in blood plasma poses challenges due to interference from the blood plasma matrix. Enhancing sensitivity through near-infrared (NIR) detection is imperative to mitigate this interference. In this work, we have designed plasmonic nano-array patterns to enhance near-infrared fluorescence. A cylinder nano-array pattern has been studied systematically to tune electromagnetic field and quality factor. In addition, a metal-insulator-metal configuration has been designed and fabricated to achieve a plasmonic gap mode, which is coupled to the NIR fluorophore. Next, fluorescence enhancement by this plasmon gap mode has been measured. Finite-difference time-domain simulation has been performed to understand the fluorescence enhance mechanism. The results provide guidelines to design plasmonic nanostructures for enhancing near-infrared fluorescence, improve sensitivity of biosensors.

Is CVD Diamond Ready to be (Eventually) an Electronic Material? Philippe Bergonzo[1,2]; [1]Seki Diamond Systems, United States; [2]University College London, United Kingdom

With the recent downturn in the gem business, can we consider that we have reached an inflection point where CVD diamond may soon benefit from the plethora of systems and highly skilled process engineers currently available on the planet, to explore its potential of electronic and quantum device applications? How can we facilitate progress in this area and contribute to diamond substrates and wafers to become more easily available? Since the early 90s, CVD Diamond was expected to become an essential material for electronics and sensing applications. More recently, quantum applications have made CVD diamond one of the top materials for quantum computing. However, the lack of available large area high-quality materials on a large-scale commercial basis continues to hinder progress in diamond research. Is this due to issues with substrates, production yields, equipment, or simply marketing opportunities? It is evident that all diamond breakthroughs have been affected in recent years by the potential impacts they could represent in the perspective of the flourishing business of lab-grown diamonds. For example, innovative approaches have demonstrated the feasibility of large heteroepitaxial substrates, but they have not yet become available to the community. The same goes for materials with low impurity levels and/or minimal crystalline defects.
Drawing from typical examples of diamond-based devices used for specific applications, a few examples will be used to illustrate a discussion on diamond material opportunities and challenges to address in the short term.

11:00 AM EL08.01.02
Diamond Exploratory and Applied Research Microwave Plasma CVD (DEAR-MPCVD) System Ratnakar D. Vispute[1], Kyle Schumann[1], Yedeal Deresse[1], Devin Newby[1], Pranay B. Kalakonda[2], Jagdish Narayan[2] and Wojciech Jadwisienczak[3]; [1]Blue Wave Semiconductors Inc., United States; [2]North Carolina State University, United States; [3]The Ohio State University, United States

CVD diamond is currently at the forefront of materials technology as it has many applications in quantum technologies, radiation hard electronics and photonics, detectors, sensors, and mechanical wear-resistant applications. Using chemical vapor deposition techniques, thin films of diamond can be grown on a variety of substrate materials and allow tailorable and exciting properties in diamond for a variety of advanced applications. Microwave (2.45 GHz) plasma CVD (MWCVD) reactors are among the most widely used techniques for diamond growth.

Blue Wave Semiconductors has recently introduced the Diamond Exploratory and Applied Research Microwave Plasma CVD (DEAR MPCVD) System. This system allows a large diameter easily exchangeable quartz tube for a dedicated doping application. In this presentation, we report recent advances in the DEAR MPCVD reactor in which microwave power is coupled into the quartz tube chamber to create a turbo (spinning) plasma discharge characteristics useful for surface diffusion of depositing species. The microwaves couple energy into gas phase electrons, which in turn transfer their energy to the gas through collisions and create turbo plasma flow above the substrate leading to the heating and dissociation of the gas molecules, formation of active species, and finally deposition of diamond onto a substrate.

We have designed and developed an optimized microwave cavity supporting larger diameter tube with differential pumping vacuum seals, multiple optical viewports (temperature plasma process and growth monitoring), and a sample stage which creates efficient microwave plasma above the substrate (substrate size up to 12mm x12 mm) with various CH_4/H_2 flow ratios, deposition pressure ranging from 20 Torr to 300 Torr, substrate temperature of 550°C-1100°C for deposition of homoepitaxial (HTHP and CVD single crystal diamond substrates), microcrystalline, nanocrystalline CVD diamond films (on silicon substrates) for a variety of applications. Microwave power from 650 W to 1.0 kW can be used in such systems giving growth rates from 0.2 microns/hr to excess of 10 μm/hr. We will present our systematic studies on the identification of various process parameters, process optimization, and growth of undoped and doped diamond required for radiation-hard devices. Our unique designs and system performance towards emerging applications will be highlighted. The optimization process yielded high-quality polycrystalline films on silicon as well as homoepitaxial films on single-crystal diamond. By using a critically optimized reactor design and process conditions for efficient etching and growth mechanisms, we have obtained high phase purity of CVD diamond without the incorporation of commonly found nitrogen and silicon impurities in CVD diamond films.

We have characterized the films for optical quality and defects using PL, CL, crystalline quality using x-ray diffraction, and surface morphology using SEM. Additionally, boron-doped diamond films have also been characterized by SIMS and electrical characteristics (resistivity, carrier concentration). Selective examples of applications of the DEAR MPCVD system will be emphasized, playing a great role in the exploration of a variety of dopants and novel device developments on a variety of substrate materials. These studies and advances in instrumentation allow us to support our customers for customized and low-cost CVD Diamond systems for innovation, exploration of new dopants and their concentrations, new research and development in diamond and related materials and integration of MPCVD with other deposition and processing techniques for demonstration of integrated diamond power electronics, optoelectronics, and quantum technologies.

11:15 AM EL08.01.03

Diamond Diodes and Transistors—Progress on High Power Density and High Frequency Specifications Anna M. Zaniewski[1,2], Jose Orozco[1], Jesse Brown[1], Uday Vulchi[1], Justine Vidallon[1], Manimozhi Sekar[1], Trevor Thornton[2,1], Robert J. Nemanich[2,1] and Manpuneet Benipal[1]; [1]Advent Diamond, United States; [2]Arizona State University, United States

Diamond offers many advantages as an ultra wide bandgap semiconductor; in addition to the large bandgap, diamond boasts extreme thermal conductivity, stability, and beneficial electrical properties. In this work, we describe recent progress on materials and fabrication challenges to realize all-diamond PIN diodes and FETs, fabricated with CVD (chemical vapor deposition) grown diamond. To produce these devices, we grow doped diamond epitaxial layers which are subsequently fabricated into devices with cleanroom techniques compatible with silicon tools. We will share characterizations of these devices and next steps for all-diamond power components and integrated circuits.

11:30 AM *EL08.01.04

Growth of Bulk Diamond by Microwave Plasma Enhanced Chemical Vapor Deposition Takehiro Shimaoka, Kaishu Nitta, Yamada Hideaki, Nobuteru Tsubouchi, Akiyoshi Chayahara and Yoshiaki Mokuno; National Institute of Advanced Industrial Science and Technology, Japan

Diamond has extreme physical properties such as high thermal conductivity, high carrier mobility, and high breakdown field. In addition, diamond electronics presents high temperature operation, radiation hardness and solar blindness. Because of these properties, they are expected to be utilized in power electronics, UV and radiation sensors and FETs for extreme environments. Large and high-quality diamond wafers are indispensable to realize diamond electronics devices. In this study, we report reduction of the dislocation density using bulk diamond growth by CVD which is developed to enlarge diameter of diamond substrates [1, 2].

In {100} growth, which is widely used in diamond CVD growth, most of the dislocations propagate to [001] direction [3, 4]. Using this feature, we attempted to reduce the dislocation density in diamond by forming orthogonal face to growth direction. [2, 3]. Samples were grown by microwave plasma enhanced CVD. {100} single crystal CVD diamond was used as substrate. First, several-mm thick single crystal diamond was grown on (001). Then (010) plane was sliced from bulk diamond by laser and was mechanically polished. After that, (010) diamond plate was used to evaluate etch pit density. Etch pit was formed using a hydrogen/oxygen plasma etching. Etch pit densities (EPDs) were evaluated using Laser microscope. EPDs of the (010) substrate and those of the epilayer on (010) substrate were the order of 10^3-10^4cm^{-2} , which was two order of magnitude lower than that of (100) CVD diamond substrate. In addition, the full width half-width of the XRC (004) curve was improved from 30 arcsec for (100) substrate to 10 arcsec for the (010) substrate. It is shown that three-dimensional bulk diamond growth by CVD is an effective for improving crystal quality while expanding the diameter of {100} single crystal diamond.

The Tin-Vacancy Qubit in Diamond—An Emerging Platform for Quantum Technologies Eric Rosenthal, Souvik Biswas, Giovanni Scuri, Hope Lee, Abigail Stein, Hannah Kleidermacher, Yakub Grzesik and Jelena Vuckovic; Stanford University, United States

The negatively charged tin-vacancy (SnV) center in diamond is a promising color center qubit for quantum applications. In comparison to other color centers including the more widely known nitrogen-vacancy center in diamond, the SnV has strong photon emission and reduced sensitivity to electrical noise. Furthermore, the SnV has a large spin-orbit coupling which allows for long spin lifetimes at temperatures of several Kelvin, obviating need for millikelvin operation in a dilution refrigerator. These properties make the SnV an excellent candidate for use as a spin/photon interface in quantum networks; future SnV based networks are expected to have much higher entanglement generation rates than the state-of-the-art networks today.

Despite these advantages, the SnV's large spin-orbit coupling also suppresses the magnetic dipole transition desired for quantum control. These transitions become allowed by strain of the diamond lattice, but there is an associated tradeoff between the performance of microwave spin control and spin readout as functions of strain and the vector orientation of an external magnetic field.

We understand this tradeoff to show [1] high-fidelity microwave spin control, where we demonstrate 99.5% pi-pulse fidelity using 50 ns microwave pulses. With this control, we demonstrate a spin coherence time of up to 0.65 ms measured at 1.7 Kelvin, using a dynamical decoupling sequence of 16 pi-pulses. Furthermore, we show [2] that rapid microwave spin control is compatible with single-shot spin readout. We demonstrate a readout fidelity of 87.4%, limited by low collection total collection efficiency. Finally, we introduce a technique based on weak quantum measurement to precisely measure this efficiency.

Overall, these results solve important outstanding problems in the understanding of the SnV qubit and demonstrate its use as a platform for quantum networks. Future work for the platform includes the combination of nanophotonic integration with spin-control and single-shot spin readout, and the application of such devices to multi-node networks.

2:00 PM EL08.02/QT04.02.02
Growth and Photoluminescence Studies of Tin Vacancy Centres in CVD Diamond Rani Mary Joy[1,2], Paulius Pobedinskas[1,2], Jan D'Haen[1,2], Rozita Rouzbahani[1,2], Miloš Nesládek[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium

Scalable quantum networks require nodes that are optically addressable long-lived quantum memories and efficiently integrated into a photonic circuit [1]. A promising candidate is the nitrogen vacancy (NV) centre in diamond due to its outstanding spin coherence at room temperature; however, enhancing its optical performance with nanostructures and stability remains challenging due to the sensitivity of the shallow NV centre to the diamond surface [2]. Potential alternatives are the Group-IV colour centres in diamond that exhibit inversion symmetry and are less affected by first-order electric fluctuations and minimal spectral diffusion [3]. Compared to the silicon and germanium colour centres, the tin vacancy centre in diamond has attracted attention due to its long spin coherence times at temperatures above 1 K, demonstrating its potential to function as quantum nodes [4].

In this study, we report the in-situ fabrication of SnV centres in free-standing (110)-textured microcrystalline diamond (MCD) using the microwave plasma-enhanced chemical vapor deposition technique and tin oxide (SnO_2) as the solid dopant source. Upon ignition of the methane-hydrogen diamond growth plasma, Sn deposits on the substrates. We demonstrate that the resulting CVD diamond growth inhibition can be partially alleviated by placing the substrate and dopant at different heights. Room temperature photoluminescence (PL) measurements

(λ_{exc} = 512 nm, 1 mW) confirm SnV formation in MCD as indicated by the zero phonon line (ZPL) at 620 nm. In addition to the ZPL, PL peak at 631 nm that correspond to the bound Sn in the diamond lattice are also observed [5]. Scanning electron microscopy analysis shows growth temperature-dependent surface morphology of the overgrown CVD diamond layer. We report that an optimal substrate temperature of 750 °C leads to a higher SnV density per unit surface area, and corroborate this observation with SnV formation in different growth sectors present in the diamond film.

Ultrafast Spontaneous Emission from Silicon Vacancy Centers in Plasmonic-Coupled Diamond Membranes

Hengming Li[1], Deniz Acil[1], Andrew Boyce[1], Nathan Wilson[1], Amirhassan Shams-Ansari[2], Srivatsa Chakravarthi[3], Christian Pederson[3], Qixin Shen[1], Nicholas Yama[3], Kai-Mei Fu[3], Marko Loncar[2] and Maiken H. Mikkelsen[1]; [1]Duke University, United States; [2]Harvard University, United States; [3]University of Washington, United States

Bright and fast single-photon sources are critical for realizing practical quantum information systems. Despite ongoing efforts, achieving these conditions via emitter-cavity engineering remains a challenge. Silicon vacancy (SiV) centers in diamond have emerged as promising candidates for quantum applications. However, further improvement in their lifetime and brightness is desired via integration with optical cavities. Here, we discuss our recent experiments on ultrafast spontaneous emission from SiV centers embedded in nanometer-thin diamond films [1] using the nanoparticles-on-film geometry [2] at two implantation depths. Cavity-coupled SiV centers display <8 ps instrument limited lifetime, corresponding to a 135-fold Purcell enhancement, and a 19-fold brightness enhancement. Nanoparticles are printed onto thin film diamond, creating arrays of ultrasmall mode volume cavities. [3] This research paves the way for generating ultrafast and bright single photons for future diamond-based photonic quantum devices.

Near-Infrared Diamond Color Centers and Hybrid Nanodiamond Materials for Quantum Sensing Philipp Reineck; RMIT University, Australia

Fluorescent color centers in diamond have emerged as a powerful platform for emerging quantum technologies from quantum communication and computing to sensing. Most diamond color centers explored for applications today emit in the visible or near-infrared wavelength range below 900 nm, which is incompatible with long-distance fiber communication and outside the second near-infrared biological transparency window (1000 nm – 1700 nm, NIR-II)[1]. At the same time, as quantum sensing technologies based on established visible color centers like the nitrogen-vacancy (NV) center mature, integrating diamond with other materials becomes critical for developing real-world applications. This presentation will discuss recent progress in two areas. 1. The discovery [2] and application[3] of fluorescent near-infrared color centers in diamond. 2. The characterization of nanodiamonds containing NV centers[4], their integration into functional materials like polymers[5] and glass[6], and their application in quantum sensing[7].

SESSION EL08.03: Functionalized Nanodiamond and Nanocrystalline Diamond
Session Chairs: Chia-Liang Cheng and Romana Schirhagl
Monday Afternoon, December 2, 2024
Sheraton, Second Floor, Back Bay A

3:30 PM *EL08.03.01
It's All in the Surface—Controlling the Properties of Diamond Nanomaterials Anke Krueger; Universität Stuttgart, Germany

Diamond materials have been used for a variety of applications ranging from tribology, via electrochemistry, biomedical engineering, drug delivery, quantum sensing, bioimaging as well as catalysis.
In most of these areas it was shown that a suitable surface termination and functionalization is needed for a tailored interaction with the target environment, stabilizing the charge state of color centers, preventing non-

specific interactions with biological compounds and tune the electronic properties of the diamond materials.
Here we will report on our recent advances in the tailored surface chemistry of diamond nanomaterials for a broad range of applications.[1-4] This includes the discussion of the influence of the type of diamond nanomaterials, i.e. detonation diamond and nanodiamond produced from materials resulting from HTHP and CVD synthesis. Reactivity differences will be discussed and methodology to address these in a practical manner.
Furthermore, the surface functionalization for targeted interaction of diamond materials with biological entities e.g. required for space-resolved quantum sensing and targeted drug delivery will be discussed together with strategies to prevent non-specific interactions with serum proteins.
Additionally, the tuning of the electronic properties of diamond materials for catalytic applications will be discussed in this presentation. Here, we will focus on the use of electronic states originating from non-diamond carbon and the functionalization if the diamond surface with suitable photosensitizers.
In summary, the importance of efficient and controlled surface functionalization of diamond nanomaterials will be highlighted.

This research has received funding from the Horizon Europe project SUNGATE (HORIZON-CL5-2022-D3-03, contract number: 101122061), the DFG (priority program SPP2370, projects KR3316/10-1 and KR3316/11-1) and the Carl-Zeiss Foundation (CZS Center QPhoton innovation project).

4:00 PM EL08.03.02
From Rough Diamonds to High Precision Low-Drift pH Sensors Gabriele Kalantaite[1], Charles Heise[2], Ahu Gumrah Dumanli[1] and Christopher Blanford[1]; [1]The University of Manchester, United Kingdom; [2]FUJIFILM Diosynth Biotechnologies, United Kingdom

In the pharmaceuticals industry, pH is a crucial factor for mediating chemical reactions, as it affects reaction yield and product quality. In the production of biological medicines, pH control is critical for ensuring the highest safety standards during manufacturing; thus, it requires accurate measurement of pH to reduce waste and ensure that end-products are of the correct composition and safe for consumption. Nanodiamonds can be functionalised to emit light due to fluorescence from the implanted nitrogen vacancies and other defects in their structures. As the intensity of the fluorescence has a strong dependence on the pH, nanodiamonds are ideal for pH monitoring. However, the detonation-based manufacturing methods produce non-uniform nanodiamonds, with varying size and agglomeration, thus they must be characterised prior to usage, using transmission electron microscopy (TEM), scanning electron microscopy (SEM) or atomic force microscopy for nanostructure, high-resolution TEM for size distribution and crystallinity, infrared spectroscopy for functional groups, and dynamic light scattering or centrifugal fractionation for size dispersion. Despite the useful photoluminescence properties of nanodiamonds, they have not been previously integrated into commercial devices, thus this study discusses the design and production of a nanodiamond-based pH sensor. The sensor is constructed using a functionalised glass slide with amine-hydroxyl bonds. Protocols have been designed to ensure consistent suspensions of nanodiamonds, and currently I have been developing nanodiamond immobilisation methods to allow photometric transduction. This work aims to ultimately develop a pH sensor with the accuracy of ±0.1 pH units, with negligible drift for one month of continuous use before replacement or recalibration.

4:15 PM ^EL08.03.03

Diamond-Based Structures for Photon-Enhanced Thermionic Emission Raffaella Salerno[1,2], Alessandro Bellucci[2], Eleonora Bolli[2], Matteo Mastellone[2], Andrea Orsini[2], Veronica Valentini[2], Riccardo Polini[1] and Daniele M. Trucchi[2]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Photon-enhanced thermionic emission (PETE) [1] represents a promising method for the efficient conversion of concentrated solar energy. In PETE devices, absorbed photons create photoexcited electrons in the conduction band. These electrons then thermalize and are thermionically emitted from the hot cathode surface. This process therefore enables the efficient conversion of both photons and heat generated from the absorption of concentrated sunlight.

Cathodic materials in PETE devices typically consist of heterostructures with layers designed for light absorption and electron emission. Hydrogen terminated diamond emitters are particularly interesting because of their negative electron affinity, which persists at temperatures up to 700°C. This makes silicon/diamond PETE cathodes [2] especially promising for highly concentrated, point-focus solar concentrating systems.

A study of the evolution and etching of detonation nanodiamond (DND) seeds has been performed to assess the optimal plasma assisted CVD parameters which optimize the diamond growth on the heavily doped silicon substrate. The temporal evolution of DND seed has been studied [3], highlighting their etching during the initial CVD diamond growth phase. This is fundamental to determine the minimum diamond film thickness that can be achieved given the initial DND seed density [4].

A detailed analysis of the PETE performance as a function of NCD film thickness, ranging from 40 nm to 1 μm, reveals the significant impact of grain boundaries within the diamond emitting layer. Raman spectroscopy and Kelvin-Probe Force Microscopy (KPFM) [5] indicate that grain boundaries serve as preferential paths for electron transport and emission, enhancing the overall emission properties. Specifically, an 80 nm-thick diamond emitter exhibits the highest emission current density, attributed to the optimized grain boundary distribution. The plasma enhanced CVD deposition parameters can therefore be varied in order to optimize the grain boundary density while minimizing the surface's electron affinity in order to maximize electron emission.

To further enhance photon absorption, the silicon substrate was nano-structured using femtosecond pulsed laser treatments, resulting in a tenfold increase in emission current density. These results indicate that the increase in photon absorption exceeds the recombination of charge carriers due to the introduction of additional defect centers.

Mechanisms of Sub-Bandgap Electron Emission in Vacuum and in Water from Diamond and Diamond-

Encapsulated Metal Nanoparticles Anand B. Ode, Nathaniel F. Rieders and Robert J. Hamers; University of Wisconsin-Madison, United States

While it is well known that electron emission from H-terminated diamond can be stimulated using above-bandgap light, sub-bandgap wavelengths can also induce electron emission into vacuum. Recently there has been intense interest in understanding electron emission into water because of the unique photochemistry that can be produced. When emitted into water, electrons can solvate allowing diamond to be used as a photocatalyst for normally high energy reactions such as the reduction of nitrogen to ammonia.[1] Because diamond's wide bandgap can be bridged only photons of 5.5 eV energy, there is interest in understanding the mechanisms associated with sub-bandgap excitation. These mechanisms, especially in water, remain poorly understood.
In this study, we seek to understand the mechanisms of sub-bandgap electron emission in vacuum and in water through measurements of total electron yield and the energy distribution of emitted electrons using valence-band photoemission spectroscopy stimulated by sub-bandgap light sources. Previous work showed that encapsulating metallic nanoparticles during growth of CVD films has been shown to enhance electron emission at both above and sub-bandgap wavelengths as compared to films without embedded nanoparticles.[2] However, the mechanism of the observed enhancements is not well understood.
In this talk, we will show energy distributions of electrons emitted from thin film diamond samples with embedded metallic nanoparticles into vacuum at photon energies at 21.2, 6.2, 4.75, and 3.05 eV. By controlling the diamond growth process, we are able to vary the thickness of the diamond shell surrounding the nanoparticles. We directly detect the solvated electrons produced in water using transient absorption spectroscopy. Our work shows strong evidence for the key role played by surface states in electron emission from diamond using sub-bandgap excitation. An additional emission pathway in vacuum is observed from diamond thin films with embedded nanoparticles. These experiments provide insight into possible emission pathways i.e. surface states, defects, or plasmonic enhancements from the metallic nanoparticles.

Investigation of the Nitrogen Bonding Configuration at Near-Surface and Subsurface of Low-Energy N_2^+ Implanted Polycrystalline Diamond Sayantan Maity; Technion-Israel Institute of Technology, Israel

The negatively charged nitrogen vacancy (NV^-) center in diamond is an excellent single photon emitter[1] and thus it has brought revolution in quantum sensing technologies,[2] biomarking,[3] and as a sensitive probe to magnetic field.[4] To achieve its best performance in quantum devices, we need to get an exact picture of the near-surface and subsurface region of nitrogen-populated diamond. This is essential since nitrogen-induced defects may be responsible for charge trapping which may destabilize the NV^- center.[5] On the other hand, the chemical composition of the diamond surface can cause the shifting of the Fermi level beyond the NV^- center.[6] Hence, one's aim should be the creation of nitrogen terminated diamond, without forming substantial defect. Over the years, we achieved to the conclusion that, focused ion beam implantation is a profitable technique to get enriched N-terminated diamond of high purity.[7-9] Location and density of N atoms can be precisely controlled on the diamond surface through ion implantation, leading to the formation of long coherence time.[10]
In this work, considerable low energy (100 eV) positive nitrogen ions (N_2^+) are irradiated on chemical-vapor-deposited (CVD-grown) polycrystalline diamond thin films at room temperature. We altered the ion dose within the

range of 1 × 10^{14} ions.cm^{-2} to 2 × 10^{15} ions.cm^{-2}. The bonding configuration of carbon and nitrogen and the chemical composition of the implanted layer are thoroughly scrutinized using X-Ray Photoelectron Spectroscopy (XPS). The thermal stability of the implanted layer and its different bonding configuration has also been examined. The results indicate that the controlled N_2^+ dose of low ion energy can populate the near surface region effectively, with creating minimal defect and variable intensities of the different C-N components.

Diamond Device Technology Using a FIB Dual Beam—Contacts and FET Fabrications Daniel Araujo, Gonzalo Alba and Mariko Suzuki; Universidad de Cádiz, Spain

For the development of new diamond electronic devices, technological operations in clean-rooms are a very heavy procedure to carry out proof of concepts. In particular, Schottky and ohmic contacts as well as gate fabrication of MOSFET, requires heavy technological steps where the size of the substrate also difficult such operations.

In this context, the FIB-dual beam (focused ions beam joined to a SEM e-beam) facility can make much simpler the consecution of the device. In the present contribution, FIB related technological steps carried out using modes as electron beam lithography (EBL), low T mask deposition or direct Ga+-Beam processes will be presented. The consecution of Schottky diodes, ohmic contacts and transistors will be shown as well as their TEM related characterization.

First ohmic and Schottky contact consecution will be presented with TEM-EELS characterization of the metal/diamond interfaces. Second, photo-switch diamond structures fabrication and its photo-electrical characterization will show the huge potential of the FIB-dual beam for the prototyping of diamond semiconducting devices.

9:15 AM EL08.04.02

Proven and Developing New Technologies for Developing 100mm+ Single Crystal Diamond Substrates with Supporting Data John Ciraldo; WD Advanced Materials, United States

Availability and production capabilities in diamond are rapidly expanding. To enable next-generation diamond-based solutions, particularly in the quantum and semiconductor realms, WD Advanced Materials (“WDAM”), in cooperation with key industry collaborators, has developed new processes for the synthesis of large-scale single-crystal diamond wafers for electronic applications.

Through the D2 SCALE program under the DARPA LADDIS initiative, WDAM has proven the efficacy of the homoepitaxial ELO approach to diamond expansion, with a **400%** increase in single-crystal substrate area. At the same time, industry-leading quality has been shown with ~$4.5\text{x}10^{4}$ dislocation density, a reduction of 3 orders of magnitude from the initial source substrate and narrow, uniform x-ray rocking curves. Moreover, the D2 SCALE program has developed a CMP process capable of achieving sub-nanometer surface roughness with no polishing-induced sub-surface damage and thermal conductivity values of **2100 – 2400** ± 200 W/(mK) values - in excess of current commercially available substrates and verified by an independent laboratory. Leading off these results, WDAM has just kicked off the D100 SCALE program under the DARPA UWBGS program, expanding on these capabilities through multiple novel growth technologies and supported by both CMP and Reactive Ion Beam Etch (RIBE) polishing processes, as well as novel wafering technologies to support wafer sizes in excess of 50-100mm. Through this talk, led by Chief Technology Officer John Ciraldo, WDAM will share third-party characterization data demonstrating exceptional material quality characteristics coupled with large substrate sizes, as well as providing details on the methods employed in D2 SCALE and the new technologies in development under D100 SCALE to achieve true device-grade substrates at 100mm+ scale. <!--![endif]----><!--![endif]----><!--![endif]---->

9:30 AM EL08.04.03

High Current Density Diamond Photoconductive Semiconductor Switches with a Buried, Metallic Conductive Channel Zhuoran Han, Jaekwon Lee, Stephen Messing, Thomas Reboli, Andrey Mironov and Can Bayram; University of Illinois at Urbana-Champaign, United States

Laterally configured diamond photoconductive semiconductor switches (PCSS) with a buried, metallic p+ current channel are reported. Above bandgap ($\lambda \leq 226$ nm) optical triggering enables responsivity of over 130 mA/W. The use of low-impurity semi-insulating diamond as an active absorption layer enables fast rise and fall times (~2 ns) and on/off ratios greater than 10^{11}. The PCSS excited with a laser energy of 20 nJ per pulse passes a high current density (44 A/cm) under a DC bias of 60 V, thanks to the buried metallic p+ current channel. The reported devices promise high current carrying capacity without the need for filamenting while leveraging the excellent optical, electronic, and thermal properties of diamond.
In this work, diamond PCSS structures with electrode spacings of 8 μm, 50 μm, and 100 μm were fabricated. The lateral PCSS devices were based on a 500 μm thick, 4×4 mm^{2} Type IIa high-pressure, high-temperature (HPHT) diamond substrate. A 500 nm thick layer of heavily boron-doped p+ diamond with an atomic doping concentration of 5×10^{20} cm^{-3} was grown on which a 1.5 μm thick layer of unintentionally doped layer was grown using microwave plasma enhanced chemical vapor deposition (MPCVD). The p+ diamond layer has a sheet resistance of 41.4 Ω/square and serves as the low-resistivity channel between electrodes. Rectangular ohmic metal contacts

composed of Ti (30 nm) / Pt (30 nm) / Au (100 nm) were deposited by e-beam evaporation, followed by thermal annealing at 450 °C in an ambient of argon gas. All three PCSS devices have the same contact width of 150 μm. Photoconductive measurements of the diamond PCSS devices were carried out using a tunable optical parametric oscillator (OPO) laser in the spectral range of 210-226 nm, with a laser pulse width of 5 ns. The laser spot size was fixed to a diameter of 2 mm using an aperture to keep the laser power density uniform, and the laser spectral width was below 0.1 nm. The optical power output was fixed to 40 μJ/pulse, which corresponds to a laser power density of 252 kW/cm^2 and total energy of 10 nJ, 127 nJ, and 191 nJ for the 8 μm, 50 μm 100 μm PCSS. The oscilloscope was triggered by a silicon photodiode that detected the scattered light of the laser.
In conclusion, buried channel diamond PCSS devices fabricated on Type IIa diamond showed large on/off ratios, fast rise-time, and high current densities when excited with an above bandgap laser source. The PCSS devices exhibit linear current-voltage characteristics up to a DC bias of +/−60 V, implying that even higher current densities are possible before carrier velocity saturation occurs. TCAD simulation and experimental data predict that over 90% of current conduction is through the buried, metallic conductive channel. The buried channel design enables higher photocurrents during the ON-state utilizing the high conductivity p$^+$ channel, while still maintaining large OFF-state resistances. This study's results advocate new designs for PCSS to realize higher ON-state current and efficiency.

Characterization of Electronic States of Al/c-BN and Al$_2$O$_3$/c-BN Interfaces Parker R. Steenblik, Gabriel B. Munro-Ludders, Ali Ebadi Yekta, Saurabh Vishwakarma, David Smith and Robert J. Nemanich; Arizona State University, United States

Epitaxial cubic boron nitride (c-BN) on diamond represents a new opportunity for diamond electronic devices. Cubic boron nitride with a 1.4% lattice mismatch with diamond has shown relatively shallow p- and n-type dopants by implantation, and there are results indicating in situ doping during growth. These results suggest c-BN/diamond heterostructures could be a basis for diode and transistor structures. This study explored the interface of Al and Al2O3 on epitaxial c-BN / diamond heterostructures. These interfaces could be relevant to MESFET and MISFET structures. Our study is focused on the interface properties and combines in situ photoemission and high resolution TEM. Epitaxial cubic boron nitride layers (50-100nm thick) were grown using BF$_3$ and N$_2$ as primary reactants via electron cyclotron resonance plasma enhanced chemical vapor deposition (ECR-PECVD) on boron doped poly-crystalline diamond substrates. Ultra-thin layers of aluminum deposited via UHV electron beam evaporation onto the epitaxial c-BN/diamond. In a separate study a thin layer of Al$_2$O$_3$ was deposited by ALD using Al$_3$Me$_3$ and an O$_2$ plasma onto the epitaxial c-BN/diamond as well. X-Ray and Ultraviolet Photoemission Spectroscopy (XPS and UPS) measured the as deposited c-BN and after the AL and Al$_2$O$_3$ deposition. Initially the c-BN surface showed a spectra characteristic of sp3 bonded c-BN. After the Al deposition a thin layer of sp2 bonded BN was indicated by the presence of the characteristic plasmon energy loss peaks by xps. XPS and UPS indicated a n-type Schottky barrier height of 4.3eV at the Al/c-BN interface as well as a band offset of 1.37eV at the Al2O3/c-BN interface. Understanding these interfaces paves the way for use of Al and Al$_2$O$_3$ in field effect transistors as metal contacts and oxide layers to c-BN.

Research supported by the U.S. Department of Energy (DOE) Office of Science, under Award No. DE-SC0021230 and the NSF through grant DMR-2003567.

Diamond Based Quantum Sensing for Detecting Stress Responses in Living Cells with Subcellular Resolution Arturo Elias-Llumbet, Nuan Lin, Claudia Reyes San Martin, Aldona Mzyk and Romana Schirhagl; Groningen University, Netherlands

Free radical generation plays a key role in many different biological processes including cell communication, immune responses or ageing. Since free radical generation also occurs when cells are under stress, it is elevated in many different diseases. Unfortunately, free radicals are short lived and reactive and thus the use of free radical generation as a biomarker is limited.
My group has pioneered using diamond-based quantum sensing to solve this problem. The method is based on NV centers, a defect in diamond, which converts magnetic signals into optical signals. As a result, one can detect signals that are equivalent to T1 in clinical MRI but by optical means with a microscope. Since these signals are easier to detect than small magnetic signals, this technique enables measurements down to the single electron level. In a cellular context that means that we have subcellular resolution at the nanoscale. Here I will show data from free radical measurements in living cells. I will further show our first clinical data we obtained with this technique. More specifically, I will show how we can use this technique to measure synovial fluid from arthritis patients and to assess the working mechanism of certain drugs[1]. In the second part of my talk, I will show the results on germ cells where we hope to contribute to a better understanding into male and female infertility.

Selective Temperature Sensing in Nanodiamonds Using Dressed States Nathaniel Beaver and Paul Stevenson; Northeastern University, United States

Techniques for temperature sensing at sub-micron length scales are an area of ongoing investigation, with applications ranging from characterizing heat dissipation in electronic devices to cellular metabolism. The nitrogen-vacancy (NV) center in diamond is a system with the potential to meet these needs, but is often limited by its overwhelming sensitivity to magnetic fields. Here, we demonstrate a method for suppressing the sensitivity to magnetic fields on-demand by a factor of seven without modifying the NV center, resulting in a technique that is selectively sensitive to temperature changes[1]. To achieve this, we combine optically detected magnetic resonance (ODMR) with an additional megahertz-range driving field to engineer dressed states for the NV center, enabling us to tailor its Hamiltonian to our specific sensing requirements. While this approach has been used elsewhere for enhancing temperature sensitivity in bulk diamonds[2], we show that it can be applied to nanodiamonds, which are easier to integrate with existing devices[3] but suffer from broader linewidths, shorter coherence times, and random orientations. We demonstrate a greatly reduced Zeeman shift of ~1 MHz over a 3G range for our dressed state approach, compared to ~7 MHz for the bare state, and characterize the nature of the dressed states. By combining numerical simulations with our experimental data, we explore the limitations and prospects of enhanced temperature sensing in nanodiamonds with further material improvements.

11:15 AM EL08.05/QT04.05.03

Remote Spin-Spin Interactions Mediated by Superconducting Circuits for Quantum Applications Carolina del Río Bueno[1], David Rodriguez[2], Marina Calero de Ory[2], Marcos Rubín Osanz[1], Daniel Granados[3], José Luis García Palacios[1], Dawid Pinkowicz[4], Nuria Crivillers[5], Maria Carmen Pallarés[1], Anabel Gracia Lostao[1], David Zueco[1], María José Martínez Pérez[1], Alicia Gomez[2] and Fernando Luis[1]; [1]Instituto de Nanociencia y Materiales de Aragón, Spain; [2]Centro de Astrobiología, Spain; [3]IMDEA Materials Institute, Spain; [4]Jagiellonian University, Poland; [5]Instituto de Ciencia de Materiales de Barcelona, Spain

Hybrid platforms combining molecular spins and superconducting circuits allow scaling up quantum computational resources by either exploiting the chemical design of molecules behaving as multiple qubits or qudits or via a proper engineering of the superconducting circuit [1-3]. Here, we address experimentally this second option. We focus on circuits based on lumped element LC resonators. Their relevant properties, resonance frequency ω_r and quality factor Q, can be widely tuned without affecting the transmission through the readout line. Here, we realize resonator pairs able to introduce communication channels between remote spin qubit ensembles . A superconducting chip consisting of seven LC resonator couples has been designed and fabricated. Resonators have ω_r ranging from 1.7 GHz to 3.0 GHz, which makes them individually addressable. Couplings between resonators in each pair have been engineered by the design of the two capacitors and their mutual distances. We explore their coupling to free radicals, model S=1/2 spin qubits, deposited onto either one or the two inductors of each pair. In the first case, we observe strong coupling of the spin ensemble to “its local” resonator and, besides, to photon modes in its remote companion. In resonator pairs hosting two different organic radicals we have observed evidences for the coherent coupling between the polaritonic light-matter states of both resonators. These experiments provide a method for performing spin resonance on a given specimen at two resonances simultaneously and pave the way for introducing coherent communication channels between two remote spin qubit ensembles, thus for scaling up this hybrid platform.

SESSION EL08.06: Electrochemical Applications
Session Chairs: Robert Bogdanowicz and Chia-Liang Cheng
Tuesday Afternoon, December 3, 2024
Sheraton, Second Floor, Back Bay A

1:45 PM *EL08.06.01
Electrochemical Applications of Conductive Boron-Doped Diamond Powders and Nanoparticles Takeshi Kondo; Tokyo University of Science, Japan

Conductive boron-doped diamond (BDD) electrode is known to exhibit several excellent electrochemical properties including wide potential window, low background current, as well as physical and chemical stabilities. Based on these properties, the BDD electrodes are expected to be used for a functional electrode material, which enables highly sensitive electrochemical analysis and highly efficient electrolytic processes. The BDD electrodes usually consist of a polycrystalline BDD thin film deposited on a conductive substrate, such as a conductive silicon wafer. Thus, the BDD electrodes are used as hard and planar electrodes, and this situation limits the range of application. In order to expand the application field of BDD electrode, we have developed BDD powder (BDDP) and boron-doped nanodiamond (BDND). BDDP was prepared by deposition of a BDD layer on the surface of commercially available diamond powder via microwave-plasma assisted chemical vapor deposition. BDND was also fabricated by the similar way using detonation nanodiamond as the substrate material.

A BDDP-packed electrolysis flow cell was developed for application to an efficient electrolytic water treatment system. A cylinder equipped with a filter was filled with BDDP (particle size 40-60 μm), and the packed bed was used as the anode. 0.1 M Na_2SO_4 containing 50 μM methylene blue (MB) as a model of organic pollutants was treated with the BDDP-packed electrolysis flow cell. As a result, the decomposition rate of MB was found to increase as the BDDP amount increased. This suggests that the entire BDDP-packed bed functions as an anode. In addition, no decrease in the decomposition rate was observed even when repeated electrolysis experiments were performed. Therefore, it is expected that the BDDP-packed electrolysis flow cell will be useful for an efficient and durable electrolytic water treatment system.

BDND can be used as a conductive material with excellent durability and large specific surface area. Since the BDND exhibits wide potential window in aqueous electrolytes, it is expected to be used for an electrode material for aqueous supercapacitor with a large cell voltage. The use of BDND as the electrode material and saturated $NaClO_4$ as the electrolyte demonstrated a large cell voltage up to 2.8 V, which should enable fabrication of an aqueous supercapacitor with high energy and power densities.

BDND can be also useful for a catalyst support of polymer electrolyte fuel cell (PEFC) cathode catalyst, which is durable to corrosion by application of high potential. Pt-supported BDND (Pt/BDND) was found to show good electrochemical activity, including oxygen reduction reaction activity. Durability tests using high potential cycling (+1.0–+1.5 V vs. NHE) showed that the electrochemically active surface area (ECA) retention rate during the test was greater for Pt/BDND than for conventional Pt/C.

2:15 PM EL08.06.02

Fabrication of Large Area Electrochemically Etched Single Crystal Diamond Membranes for Photonic and Quantum Sensing Applications Claudio Jaramillo[1], Kexin Wu[1], Yuchun Zhu[1], Valentin Goblot[1], Niels Quack[2] and Christophe Galland[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]The University of Sydney, Australia

Diamond has seen great advances and promising work in the development of the platform for applications in photonics and quantum technologies. Diamond can host color centers, impurities introduced in the crystal lattice, that create additional electronic states in the wide band gap of diamond, giving rise to transitions that absorb and emit light in the visible spectrum. This makes diamond ideal for applications in **quantum sensing, imaging and computing.**

Bulk diamond photonic platforms are widely used, where the crystal is etched and refractive index contrast is achieved by producing free standing waveguiding structures. This approach requires challenging microfabrication techniques such as Focused Ion Beam (FIB) milling or Faraday cage angle etching. However, it would be of interest to develop a Diamond-on-Insulator platform to enable the fabrication of diamond photonic chips on a larger scale.

Techniques such as epitaxial growth can provide a straight forward approach to achieve a thin film on a substrate, but the harsh crystal growth environment makes it difficult to obtain a high quality diamond. Hybrid integration involves the use of an independently grown diamond crystal, thinned down using milling and etching techniques and then bonded to the final carrier wafer ; however this requires a long and inhomogeneous etching and processing time, and most of the initial crystal is lost to processing.

We are proposing and developing a hybrid integration implementation, inspired by the SmartCut(c) technique developed for silicon. It involves the implantation of a high-quality crystal with high-energy ions to create a damaged layer that is etched away to release a thin membrane. Millimeter sized membranes can be obtained, using a safe and controllable electrochemical etching technique that is able to homogeneously release large area membranes. The membrane undergoes a strain relief process in order to regain high crystallinity post-implantation, and is further polished to achieve ca. 1 nm roughness. The membrane can then be bonded to a carrier wafer to create a working platform for photonic components, where the high parallelism inherent to this technique enables de fabrication of consistent photonic components. Additionally, the use of high NV-density membranes additionally enables their implementation for quantum sensing applications, such as in-situ nanothermometry where negatively charged NVs can be used as precise nanoscale temperature sensors through the measurement of their zero-field spin splitting.

Exploring Boron-Doped Diamond for Energy Conversion and Storage Applications Zuzana Vlckova Zivcova[1], Martin Jindra[1], Petr Čech[1], Andrew Taylor[2], Rene Pfeifer[2,3], Ladislav Kavan[1], Jiri Červenka[2] and Otakar Frank[1]; [1]J. Heyrovsky Institute of Physical Chemistry, Czechia; [2]The Czech Academy of Sciences, Czechia; [3]CiCBiomaGUNe - Centro de Investigación Cooperativa en Biomateriales, Spain

Boron-doped diamond (BDD) has emerged as a promising material for advanced energy applications, particularly in solar cell and battery fields. Applications explored include energy conversion in dye-sensitized solar cells (DSSCs) and perovskite solar cells (PSCs), as well as energy storage in aqueous batteries (ABs). In solar cell technology, BDD serves as an effective p-type semiconductor, enhancing charge carrier mobility and reducing recombination losses, thereby improving overall cell efficiency. Its remarkable optical transparency and high thermal conductivity further contribute to its suitability for high-performance photovoltaic systems. In battery technology, BDD's exceptional chemical stability and high electrical conductivity make it an ideal candidate for electrodes. The material's robustness and ability to operate under extreme conditions offer significant advantages in terms of battery longevity and performance. ABs, which are based on a saline aqueous electrolyte and a carbon-based electrode material, possess a narrow electrochemical stability window (1.23 V) in commonly used salt concentrations (ca. 1M) of aqueous electrolyte solutions. This window can be significantly enlarged by using highly concentrated “water–in–salt” (WIS) electrolytes [1] in combination with an appropriate electrode material. For this application, i.e. ABs with highly corrosive environments, the suitable electrode material appears to be BDD due to its excellent chemical stability and wide potential window compared to other carbon-based materials.

This work examines the basic electrochemical characterization of BDD electrodes and focuses on *in situ* Raman spectroelectrochemical (SEC) investigation in a standard glass cell [2], and in a micro-droplet setup [3]. This non-destructive, real-time method combining Raman spectroscopy and electrochemistry is employed to study the structural, chemical, and electronic changes of an electrode material as a result of different potentials applied. BDD films were grown by microwave plasma-enhanced chemical vapor deposition with different quality (sp^2 carbon content) and boron doping levels (B/C ratio in the gas phase). In BDD films containing a high amount of sp^2 carbon, modes belonging to these carbonaceous phases changed their intensities in the potential range of -1.0 V to 1.5 V vs. Ag/AgCl. Specifically, the intensity of the D, G, and D' Raman peaks increased in the cathodic direction, while bleaching of these peaks was observed in the anodic direction. Modes belonging to sp^3 carbon and the boron incorporated into the diamond lattice exhibited no changes with the applied potential, suggesting the high stability of this material in the bulk. The trend of a decreasing potential stability window of BDD with increasing content of sp^2 carbon at the same doping level was observed using cyclic voltammetry. In the case of WIS electrolytes, the dependence of the potential stability window size of highly doped BDD is surprisingly opposite, i.e., with increasing sp^2 carbon content, the potential window is wider. The influence of BDD stability with various sp^2 carbon content and boron doping levels in WIS electrolytes, determined by *in situ* Raman SEC, will be discussed.

Diamond Crystal Growth for Weak Magnetic Field Detection Tokuyuki Teraji; National Institute for Materials Science, Japan

The formation of negatively charged nitrogen-vacancy (NV^-) centers in diamond and the control of electron spin have attracted considerable attention for the realization of next-generation quantum devices. In sensing applications, relatively large amounts of NV^- centers are needed to increase sensitivity. This corresponds to an increase in the total number of sensors. Typically, 0.1-3 ppm [NV^-] is desired to detect weak magnetic fields. The electron spin dephasing time T_2^* is also an important factor for increasing sensitivity of DC magnetometry, and it has been reported that this value is inversely proportional to the nitrogen concentration [1].

Considering these facts, we optimized diamond growth conditions both by chemical vapor deposition (CVD) [2, 3] and by high-pressure high-temperature (HPHT) method [4]. ^{12}C isotope enrichment was applied to lengthen T_2^*. In the CVD method, nitrogen-doped homoepitaxial diamond thick films were grown and made freestanding, then cut diagonally to obtain diamond {111} single crystals; the dimensions of the CVD single crystal plates were typically $5\times1\times0.5$ mm^3. For HPHT crystals, bulk diamond crystals were grown, then {111} single crystals were obtained by cutting parallel to the {111} crystal facet planes; typical dimensions of HPHT {111} single crystal plates were $1.5\times1.5\times0.4$ mm^3. Concentration of NV^- centers and other defects were characterized by electron paramagnetic resonance, photoluminescence, secondary ion mass spectrometry, and Fourier transform infrared spectroscopy measurements [3, 5]. T_2^* have been characterized by Ramsey measurements using columnar excitation fluorescence microscope (CEFM) [6,7]. Diamonds with [NV^-] of approximately 1 ppm are most suitable for weak-field measurements. Our characterization results indicate that in this nitrogen concentration range, the strain distribution formed in the crystal is the predominant limiting factor for T_2^*.

Nitrogen-Vacancy Diamond Layers for Widefield Magnetic Sensing Teodoro Graziosi[1], Connor Hart[2], Andrew M. Edmonds[1] and Matthew Markham[1]; [1]Element Six UK Ltd, United Kingdom; [2]Quantum Catalyzer, United States

Nitrogen Vacancy (NV) defects in single crystal diamond have been used to demonstrate a wide range of sensing applications, of which widefield magnetic imaging is of particular interest. The technology leverages a thin NV-containing layer and Optically Detected Magnetic Resonance (ODMR) to measure the magnetic characteristics of a device or sample under test, using a camera to detect changes in luminescence and produce a magnetic-field map.

NV layers and the measurement system around it, a Quantum Diamond Microscope (QDM), have been employed in a range of disciplines, including bioimaging[1,2], geoscience[3,4], and electronics[5,6]. The thickness, NV concentration and the strain in the sensing layer will affect performance and can be tuned depending on the type of sample being tested.

Typically, the thickness will range from sub-μm to few 10s of μm, thus it is practical to grow the high [NV] layer on a diamond substrate with low (or no) luminescence in the NV emission window to improve the magnetic image contrast. To have greater control of [NV] and [NV^-]/[NV], it is preferable to treat a N-containing layer after growth, rather than relying on the as-grown NV only. The low luminescing substrate thus needs to have a low concentration of nitrogen to avoid generating NV from the treatment after the sensing layer overgrowth. Electronic grade single crystal diamond (ELSC) can be a good platform to use as a substrate (typically [N_s^0] < 5 ppb), and no NV luminescence is observed post treatment.

The ODMR shift will be influenced by the strain in the NV layer. For widefield sensing, it is critical to ensure that the strain field is uniform, and to avoid large, localized strain shifts, as these may be mistaken for magnetic signals of interest. Stress gradients can also degrade per-pixel sensitivity and sensitivity homogeneity across an image.

Here we present the challenges of growing the NV layer on a high-purity single crystal diamond substrate and explore strategies which can be utilized to grow large areas (>> 1 mm x 1 mm) of low and uniform strain in the NV layer. We identify the source of the problematic high strain as the subsurface damage present in the high purity substrate ahead of the NV layer overgrowth. Raman spectroscopy is employed to identify the high-damage region and it will be demonstrated that it can be a helpful tool for feedback on the substrate-processing methodology. The requirements on thickness, strain, and doping of the sensing layer for example applications in widefield imaging will be discussed, and we present a use case of a QDM for diagnostics of integrated circuits and electronic devices. Low-strain NV-layer sensors and optimized excitation and readout, enables uniform, state-of-the-art magnetic sensitivity better than 100 nT $Hz^{-1/2}$ $\mu m^{3/2}$ and spatial resolution <1 μm across millimeter-scale fields of view.

Towards High-Quality Nitrogen Doped Single Crystal Diamond Sarah Roberts[1], Alexander Loomis[1], Aaron J. Hardy[2], Jonas Becker[1] and Shannon Nicley[1]; [1]Michigan State University, United States; [2]Fraunhofer USA, United

States

The nitrogen vacancy defect (NV^-) in diamond is a strong candidate for quantum sensing applications. Many researchers have demonstrated success in utilizing the NV^- defect for sensing temperature [1] and magnetic field [2], however, the challenge of repeatably manufacturing NV^- defects has not been adequately addressed. Here, a parametric study of a chemical vapor deposition (CVD) reactor was performed to understand the effects of substrate temperature, reactor pressure, and substrate surface preparation on the incorporation of nitrogen in single crystal diamond (SCD). Eight (100) SCD substrates (MTI) were used for deposition. The pressure was varied from 250 mbar to 370 mbar and substrate offcut from 0.5 degrees to 2 degrees with respect to the (100) surface while holding the feed gas composition constant at 1238 ppm N:C with 4% CH_4 in H_2.
The study was further expanded to determine the effect of lower methane concentrations on growth quality and defect incorporation. Previous CVD work on SCD demonstrated the operation of a high-power density and high pressure microwave plasma assisted chemical vapor deposition (MPACVD) reactor and studied operation conditions such as pressure, substrate temperature, and methane (CH_4) composition [3]. Because this reactor was designed to increase growth rate, higher gas phase methane concentrations were explored, from 3 percent to 9 percent. However, the effect of methane concentrations below 3 percent on SCD growth quality were not explored.
To investigate methane concentrations of 3 percent and below in the gas phase, three (100) CVD diamond substrates (MTI) were used for three depositions with varying methane percentages from 1-3% of the total gas phase composition. All depositions were performed at 320 mbar, 2000-2100 W, and a total gas flow rate of 400 SCCM. Each sample was characterized using differential interference contrast microscopy (DICM), birefringence imaging, Fourier Transform Infrared (FTIR) spectroscopy, ultra-violet and visible spectroscopy (UV-Vis), and Raman spectroscopy to determine the quality of the growth. Vertical growth rate was determined by thickness measurements taken before and after deposition using a linear encoder.
We found that the substrate surface roughness was correlated with the growth quality and nitrogen incorporation. Two (100) HPHT substrates (NDT) were used to optimize hydrogen etching conditions to prepare the surface for deposition such that the effects of substrate surface conditions on defect incorporation can be isolated from process variable effects. The results of these experiments will be utilized to re-evaluate the effects of reactor pressure and offcut as well as establish a repeatable technique for growth of high quality, nitrogen doped single crystal diamond.

Isotopically Engineered Diamond for Quantum Technology Christian Osterkamp[1], Christoph Findler[1,2] and Johannes Lang[1]; [1]Diatope GmbH, Germany; [2]Ulm University, Germany

Reliable supply of CVD diamond layers and tailored to need color centers for quantum technology applications is key in order to bridge the gap between laboratory research, where unique diamond samples are used to show the potential of certain technologies and commercial products where uniformly produced diamonds are used. In order to master the challenges in the individual disciplines of diamond based quantum computing and quantum sensing, customized diamond material must be produced.
In particular, the generation of qubit chains, in which NV centers are coupled to ^{13}C nuclear spins, is a technological challenge, as individual atomic distances have to be controlled.

However, the realization of such diamond qubit chips is essential for the advancement of diamond quantum computing.
The diamond material must also be pushed to the limit in the field of sensor technology. Atomically small sensor elements that are shielded from the immediate environment and surrounded by few to no defects must be produced in a repeatable and consistent quality.
We at Diatope engineer these systems through the unique combination of CVD diamond growth, ion implantation and annealing and quantum characterization from a single source at a single location.

Enhanced Field Electron Emission and Plasma Illumination Performance of Flexible Laser-Induced Graphene-Boron-Doped Diamond Nanowall Hybrid Nanostructures Mohsen Khodadadiyazdi[1], Mateusz Ficek[1], Shradha Suman[2,3], Salila Kumar Sethy[2,3], Kamatchi Jothiramalingam Sankaran[2,3], Bartlomiej Dec[1], Mattia Pierpaoli[1], Sujit Deshmukh[4], Miroslaw Sawczak[5], William A. Goddard III[6] and Robert Bogdanowicz[1]; [1]Gdansk University of Technology, Poland; [2]CSIR-Institute of Minerals and Materials Technology, India; [3]Academy of Scientific and Innovative Research (AcSIR), India; [4]Brno University of Technology, Czechia; [5]Polish Academy of Sciences, Poland; [6]California Institute of Technology, United States

This study demonstrates a scalable fabrication method for flexible laser-induced graphene (LIG)-boron doped diamond nanowall (BDNW) hybrid nanostructures. Direct laser writing on polyimide film is enhanced in the presence of BDNW powder fabricated by chemical vapor deposition (CVD), where the appreciable absorbance of BDNWs at the CO_2 laser wavelength increases the local film temperature. Furthermore, thanks to superior thermal conductivity and heat capacity of BDNWs, more uniform heat distribution and longer lasting thermal shock is possible during lasing process of polyimide film decorated with BDNW. In addition to graphene formation, the thermal shock due to laser irradiation produces graphitized and amorphous carbon at the diamond grain boundaries, increasing the thermal and charge transfer capacity at the LIG-diamond interfaces. Developing flexible and robust field electron emission (FEE) cathode materials with long-lasting stability is crucial for electronic devices that rely on plasma illumination (PI). A promising strategy to achieve this goal is utilizing hybrid nanomaterials based on conductive diamond nanostructures. In this work, a two-step technique was employed to fabricate hybrid nanostructures of boron-doped diamond nanowalls by LIG on flexible polyimide foils. The obtained results revealed that the presence of BDNW increased the defect density in the LIG while significantly enhancing the electrical conductivity simultaneously. It was found that the PI properties of BDNW/LIG hybrid nanostructures, when utilized as a cathode in a PI device, were superior compared to those of neat LIG. The breakdown voltages of BDNW/LIG hybrids were lower than LIG, i.e., 320 versus 350 V. Moreover, the current density (J_{PI}) was higher for BDNW/LIG hybrids, reaching 9.48 mA/cm^2 at an applied voltage of 600 V. The rate of J_{PI} enhancement with applied voltage was much higher for BDNW/LIG hybrids. Additionally, it was observed that upon BDNW incorporation, the lifetime stability of LIG cathodes was enhanced almost twice.

EL08.08.02

Chemical Vapor Deposition of Silicon Vacancy Ensembles in Low Strain Diamond with a NIRIM Type Reactor
Alexander Loomis, Logan Crooks, Andrew R. Kirkpatrick, Jonas Becker and Shannon Nicley; Michigan State University, United States

In recent decades, improved technology and information theory have brought us closer to a second quantum revolution that utilizes quantum mechanics to its full potential [1]. Diamond is a great platform for optically active defects for quantum information processing, able to host hundreds of different color centers within its wide bandgap. It is transparent from infrared to ultraviolet wavelengths and growth with ^{12}C-enriched methane allows for nuclear spin-free material, suppressing spin-spin interactions to improve coherence times. The silicon vacancy (SiV) color center in diamond has particularly favorable properties for broadband quantum memories based on off-resonant Raman transitions. The SiV features inversion symmetry and large ground state splitting (50GHz) making it immune to first-order Stark shifts and large memory bandwidths [2]. The storage time of a quantum memory in a dense SiV ensemble is determined by its inhomogeneous broadening [3] which is heavily influenced by the strain in the material, and therefore growth of high-quality material with high optical density is needed. Growth of this material will be made possible through a NIRIM-type chemical vapor deposition (CVD) reactor. The reactor is based on a space constrained design [4] and modified for higher vacuum to ensure an extremely low leak rate to achieve very high sample purity. The reduced volume the thin cylindrical quartz tube used in this chamber compared to bell-jar style reactors, and the laminar flow design over the sample surface allows for precise control over gas concentrations and improved purity leading to improved sample quality required for quantum memory applications. In this poster, I will introduce the properties of the SiV and the potential of in-situ silicon doping during CVD.

EL08.08.03
Optimization of Substitutional Phosphorus in n-Type Diamond Milos Sretenovic[1,1], Sarah Roberts[1], Alexander Loomis[1,1], Luke Suter[2], Aaron M. Hardy[2], Matthias Muehle[2], Timothy Hogan[1], Jonas Becker[1,2] and Shannon Nicley[1,1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA, United States

n-type diamond holds great potential for a wide array of technological applications, including high-power electronics, quantum computing, and biomedical applications. Phosphorus is currently the most promising n-type dopant, yet major challenges still exist such as its low incorporation rate and a tendency to form phosphorus-vacancy complexes that compensate substitutional phosphorus atoms and reduce overall conductivity [1]. Achieving controllable levels of P is an area of significant interest [2-4] and so controlled parameter studies of the growth of P-doped diamond are needed.

To observe the substitutional behavior of phosphorus-doped diamond, we will grow two series of single-crystal P-doped diamond samples, one isothermal series in a pressure range of 150 to 250 torr, and another isobaric series over temperature from 800 to 1050°C. The growth will be done by Microwave-Plasma Assisted Chemical Vapor Deposition (MPACVD) using phosphine feed gas on (111) oriented single-crystal diamond substrates. The phosphorus concentration of each sample will be determined by Hall effect measurements and samples will be fully characterized by AFM for surface analysis, XRD determination of miscut orientation, and UV-Vis and FTIR spectroscopies. We will present our findings and report the optimized growth conditions for substitutional phosphorus and n-type conductivity.

EL08.08.04

NV Diamonds for Industrial Quantum Sensing Applications Christian Osterkamp[1], Simon Schmitt[1], Johannes Lang[1] and Christoph Findler[1,2]; [1]Diatope GmbH, Germany; [2]Ulm University, Germany

The nitrogen-vacancy (NV) center in diamond is a promising candidate for advanced quantum sensing technologies due to its outstanding properties. Achieving high-performance NV centers requires not only precise control over the NV concentration but also the use of isotopically purified diamond material. This study focuses on the fabrication of isotopically purified NV diamonds using a combination of Chemical Vapor Deposition (CVD) and Ion-Implantation methods, leveraging the NV center's intrinsic sensing capabilities for material control and optimization.
Reliability and reproducibility of the created NV centers and the underlying diamond material are of high importance in order to use such materials in real-world products.
The use of isotopically purified ^{12}C diamond material resulted in NV centers with significantly improved spin coherence times, enhancing their sensitivity for quantum sensing applications. The integration of these high-quality NV diamonds into prototype quantum sensing devices, such as real-time spectrum analyzers is the goal of this project.
Especially the creation of a pure ^{12}C layers with low background fluorescence and high crystallinity with a thickness of a few hundred nanometers are of high importance. Furthermore, the development of NV-rich diamond layers, which are produced by nitrogen doping during CVD growth with subsequent electron irradiation and annealing, is another field of research with potential applications in the area of diamond quantum sensing technology.

EL08.08.05

Broadband Light Extraction from Shallow NV Centers Using Low-Q Silicon Antennas Minjeong Kim[1], Maryam Zahedian[1], Wenxin Wu[1], Chengyu Fang[1], Zhaoning Yu[1], Raymond A. Wambold[1], David A. Czaplewski[2], Jennifer T. Choy[1] and Mikhail Kats[1]; [1]University of Wisconsin-Madison, United States; [2]Argonne National Laboratory, United States

Negatively charged nitrogen-vacancy (NV) centers are fluorescent lattice defects whose energy levels are highly sensitive to external conditions, making them good candidates for sensing applications. The NV zero-phonon transition line is at a wavelength of 637 nm, with most room-temperature fluorescence occurring in the vibrational sideband from 630 to 800 nm [1]. However, diamond's high refractive index (~2.4) results in total internal reflection for NV fluorescence at angles exceeding the critical angle of approximately 25°, and even at normal incidence the Fresnel reflectance at the interface is high. Therefore, efficiently extracting fluorescence from NV centers in diamond is a challenge [2]. Previous methods for enhancing photon collection from bulk diamond involve etching the diamond substrate [2-3]. However, this method can cause surface damage and potentially compromise NV properties by increasing surface roughness or altering chemical termination [4].
We have developed a silicon-based antenna that is placed directly on a flat diamond surface and enhances the output of NV centers across their entire room-temperature emission spectrum. This design is effective for shallow NV centers, and for this work we targeted an emitter depth of 10 nm. The antenna, consisting of a crystalline

silicon (Si) pillar with a diameter of 500 nm and a height of 220 nm, outcouples a substantial portion of light from the NV centers. The Si pillar is compatible with the standard silicon device layer used in silicon photonics [5]. We used crystalline Si because, due to its indirect bandgap, it exhibits sufficiently low loss at wavelengths longer than 500 nm, whereas polycrystalline and amorphous silicon have higher absorption coefficients at these wavelengths [6].

We fabricated the antenna by transferring a single-crystal silicon membrane from a silicon-on-insulator (SOI) wafer onto the diamond surface via an epitaxial lift-off technique. The structure was defined using electron-beam lithography and silicon etching, leaving the diamond surface unetched. Our process is as follows: (1) Undercut the SOI piece using hydrogen fluoride (HF) and buffered oxide etchant (BOE) solution; (2) Transfer the Si membrane onto the diamond substrate; (3) Deposit a SiO2 hard mask using plasma-enhanced chemical vapor deposition (PECVD); (4) Spin ZEP520A resist onto the substrate; (5) E-beam exposure and development; (6) Etch the SiO2 layer using CHF3 and O2 to create the features in the hard mask; (7) Etch the Si layer using HBr/O2 to form Si pillars; (8) Remove the resist residue with O2 plasma.

The optical performance of the fabricated antenna was evaluated using a home-built confocal microscope, with excitation from a 515 nm green laser. Utilizing an objective lens with a numerical aperture of 0.95 to both excite and collect light, we achieved a 3.6-fold increase in the saturated single-photon count rate and observed a decrease in lifetime to about 7 ns, compared to 18 ns for similar shallow NV centers in bare diamond. For at least one NV and silicon pillar, we observed a second-order correlation g^(2)(0) =0.31, confirming that this fluorescence originated from a single NV center. Our method can be adapted to enhance the emission into free space of various color centers in diamond and in other wide-gap materials.

We acknowledge support from the NSF (1839174-CHE). Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

EL08.08.06

Formation of Nitrogen-Vacancy (NV) Centers in Diamond by Ultrafast Laser Irradiation and Quantification of Nitrogen Concentration Farha Islam I. Mime, Timothy A. Grotjohn and Marcos Dantus; Michigan State University, United States

Nitrogen (N) is a common impurity in both natural and synthetic diamonds and is extensively studied as the presence of nitrogen influences the diamond’s electronic and optical properties. Determining nitrogen concentration is essential for the development and optimization of diamond-based devices, and it also offers important insights into the nitrogen doping profile variations across the diamond sample. A traditional technique for determining nitrogen concentration inside a diamond is Secondary Ion Mass Spectrometry (SIMS) analysis, which requires ultra-high vacuum conditions and provides more knowledge on depth distribution but has limited spatial resolution due to the primary beam diameter. Cathodoluminescence, by comparison, has a poor depth resolution of a few tens of nanometer (nm). This work explores the potential of nitrogen-vacancy (NV) centers for quantifying nitrogen concentration within diamond samples.

Diamonds with NV centers consisting of a substitutional nitrogen atom and an adjacent vacancy are being considered as registers for a qubit state, as quantum sensors, and as a possible component in hybrid quantum

information processing for their excellent room temperature electron spin properties as well as their capability as single photon emitters. Since the formation and number of NV centers correlate directly with the amount of nitrogen within the diamond lattice, presenting a unique opportunity to use the number of created NV centers to map nitrogen concentration with exceptional spatial resolution.
An effective method to create vacancies and eventually NV centers at deterministic positions with high spatial precision is provided by laser writing that utilizes a highly focused laser spot to displace carbon atoms from the lattice in a diamond. The number of vacancies generated by this method can be effectively controlled by adjusting the laser parameters. Here, we demonstrate the creation of NV centers in nitrogen-doped diamonds at predetermined positions through femtosecond laser irradiation. Since the laser-generated heat is used for annealing, the NV centers are formed within the laser beam focal spot. To resolve NV centers in diamonds with sub-50 nm spatial resolution, Stimulated Emission Depletion (STED) microscopy, a super-resolution microscopy technique that breaks the diffraction limit of the light is being built. The intensity of NV centers is directly linked with the number of NV centers created and, consequently, the concentration of nitrogen present in the diamond material, which offers a promising approach to map the distribution of nitrogen within the laser written area. This method provides a non-destructive, simplified process for quantifying nitrogen concentration at the nanoscale range within diamond samples. We are using this technique to study selective area growth of diamond and initial results will be reported.

EL08.08.07

Selection of Fluorescent Nanodiamonds Based on Optical Properties by Resonant Optical Force Yoshiki Saito[1], Yuto Makino[2,1], Takao Horai[1], Yosuke Minowa[3], Hajime Ishihara[1] and Masaaki Ashida[1]; [1]Osaka University, Japan; [2]Daicel Corporation, Japan; [3]Kyoto University, Japan

Fluorescent nanodiamonds (F-ND) have significant potential in bio-sensing and quantum information processing because of their high photostability and low toxicity. Their small particle size and chemical stability make them suitable for applications such as fluorescent markers and single-photon emitters.
Our group has successfully synthesized NDs containing a few SiV or GeV centers using a detonation process (SiV-DND/GeV-DND)[1,2]. This method enables rapid large-scale synthesis. However, this process also produces DNDs without a color center (Undoped-DND), necessitating efficient post-process optical property-based selection[3,4]. However, because the optical properties of F-ND are attributed to color center, existing sorting methods such as chromatography, centrifugation, and mass spectrometry are not applicable to F-ND.
Recent advances in optical force-based selection have shown promise. When a material refracts, absorbs, or scatters light, optical force is exerted. Recently, selective manipulation using resonant optical response has been demonstrated. Since a large force acts only on substances that resonantly absorb light, selective transport is possible. While effective for 1D nanomaterials such as carbon nanotubes[5], its application to 0D nanomaterials has been limited by weak optical forces and large Brownian motion. Previous studies have required complicated setups to reduce the effects of non-resonant optical force and Brownian motion, which act besides resonant optical force, and only a few particles could be sorted under room temperature conditions [6].
This study aims to develop a practical, large-scale optical sorting system for SiV-DND based on resonant optical force. The small volume of SiV-DND significantly reduces non-resonant optical force compared to resonant optical force. By loosely focusing a high-intensity laser beam, it is possible to overcome three-dimensional Brownian motion without restricting the dimensions of movement, allowing for effective sorting.
A water dispersion of SiV-DND/GeV-DND was prepared and sealed in a glass capillary. For selective manipulation, the capillary was irradiated with a CW laser (1.68 eV: SiV resonant light, 1.58 eV: SiV/GeV non-resonant light) along its axis. In addition, the capillary was irradiated with a CW laser (2.34 eV) from a direction perpendicular to the axis of the capillary, and the time evolution of the fluorescence intensity of SiV-DND and GeV-DND was monitored. The fluorescence intensity of SiV-DNDs increased under resonant light irradiation and decreased under non-resonant

light irradiation. GeV-DND showed minimal changes, indicating that the SiV-DND separation by resonant optical force was successful.
Furthermore, we quantified the optical forces exerted on the SiV-DND/GeV-DND and calculated the transport distances induced by these forces. Theoretical calculations confirm that each DND has a very small non-resonant optical force due to the very small particle size. On the other hand, for SiV-DNDs, the resonant optical force due to the large dipole moment was confirmed to be dominant. Finally, the high durability of SiV-/GeV-DND enables long-term selection with high-power laser beams. [3,4].
This new and scalable sorting system for 0D nanomaterials has achieved large-scale practical separations at room temperature. It enables the purification of fluorescent DND with homogeneous fluorescence properties, paving the way for large-scale manufacturing and application in biotechnology and quantum technologies. The versatility of this method suggests the potential for broad application in the production of other fluorescent nanoparticles.

Super-Spectral-Resolution Raman Spectroscopy for Advanced Diamond Characterization and Identification

Yishai Amiel[1], Romi Nedvedski[2], Yaakov R. Tischler[2] and Hadass Tischler[1]; [1]Jerusalem College of Technology, Israel; [2]Bar-Ilan University, Israel

As the field of diamond devices grows, and the methods of growing diamond proliferate, more advanced spectroscopic methods are needed to characterize, identify, and distinguish between diamond samples. Raman spectroscopy is an extremely powerful laser-based method for characterizing materials based on their unique inelastic scattering spectrum and it is an excellent tool for characterizing diamond, diamond impurities, and nano-diamond powders, etc., however, the power of the technique is limited by the resolution of the spectrometer. Here we introduce Super-Spectral-Resolution Raman Spectroscopy (SSR-RS), a method which greatly improves the spectral resolution of the Raman spectrometer and demonstrate that with SSR-RS we can distinguish between natural and lab-grown diamonds. In SSR-RS, a Fabry–Perot (F-P) Etalon filter (Finesse > 30, FSR = 2 cm^{-1}), mounted on an angle-tunable motor, is added to the classical micro-Raman setup, and Raman spectra are automatically acquired for many different angles of the F-P filter. In previous published super-resolution Raman experiments, the mirror distances "d" within the F-P were varied [1, 2]. Here, the F-P etalon itself is fabricated as monolithic structure, plane and parallel by design through a set of innovations developed by Light-Machinary. With a low-resolution grating of 150 g/mm, which by itself exhibited a best-case resolution of 40 cm^{-1}, we applied the SSR-RS technique to diamond to obtain a linewidth fit parameter of less than 1 cm^{-1} . To baseline SSR-RS, we used the super-spectral-resolution method to extract the linewidth of the laser excitation itself and obtained a laser linewidth of better than 0.007 cm^{-1}. In essence, the modelling aspect of SSR-RS is a kind of “point-spread-function” fitting of the spectrum. Further investigations were carried out on the spectra of a natural diamond compared to a lab-grown diamond, where in both cases, a spectral resolution improvement of at least 40X of the original spectrum has been obtained. Using SSR-RS, we were able to observe differences between natural vs. lab-grown diamond due to different Raman shifts and Raman shift linewidths. The SSR-RS technique promises to be an important spectroscopic technique for characterizing advanced diamond devices and differentiating between seemingly indistinguishable diamond samples.

Step Flow Growth Analysis of Doped and Undoped Diamond Epilayers

S M Asaduzzaman[1], Alec M. Fischer[2], Fernando A. Ponce[2] and Timothy A. Grotjohn[1]; [1]Michigan State University, United States; [2]Arizona State University, United States

Diamond, with its superior properties, is widely used or anticipated to be used in various applications including thermal management substrates, protective coatings, nuclear radiation detectors, biosensors, and electronic devices. Recently, diamond has gained interest for high power devices due to its high breakdown voltage and exceptional thermal and carrier transport properties. The growth of high-quality, thick diamond films is critical for such applications but often encounters issues such as hillock formation on on-axis (100) surfaces with no miscut. Suppression of hillock formation is possible with miscut surfaces, although this can result in varied surface morphology and non-uniform impurity incorporation.

In this study, we report on the variations in the optical properties of ~30-micron thick and thicker CVD grown diamond films grown by step-flow at different miscut angles from (100) substrates. The substrates used were commercially available high-temperature high-pressure (HTHP) Ib type single crystal diamond. Prior to epitaxial growth, the miscut substrates were prepared through laser cutting, mechanical polishing, and Hydrogen-plasma etching. Among the samples, one was polished by Chemical Mechanical Polishing (CMP) before the ~30-micron diamond growth with a lightly boron-doped concentration. The other samples were mechanically polished followed by a 3-micron etching via Reactive Ion Etching (RIE) before the ~30-micron diamond deposition. Each sample underwent a short (10-minute) hydrogen-plasma etching to clean the surface at the start of the diamond deposition. The homoepitaxial diamond films were grown using a 2.45 GHz microwave plasma-assisted CVD technique, resulting in ~30-micron thick or thicker single crystal diamond films. The diamond deposition was performed with a mixture of hydrogen, methane, diborane, and carbon dioxide as feed gases, achieving a growth rate of 2-3 μm/hr.

Cross-sections of the grown samples were prepared by laser cutting and polishing. Cross-section cathodoluminescence (CL) imaging reveals variation in band-A emission across the epitaxial growth regions, particularly near the top. For example, the epi-layer grown on a CMP surface was quite smooth. The CL analysis showed a strong overall luminescence near the top region of the diamond film, indicative of high-quality crystalline structure with minimal defects. Additionally, typical defect-related emissions are observed from the high-pressure high-temperature (HPHT) diamond substrate, reflecting the presence of NVN defects characteristic of such substrates. Crucially, no band-A emission is detected near the interface or in the bulk of the diamond film. This absence of band-A emission indicates that there are very few point defects, which signifies that both the interface and the bulk of the diamond film are of high quality. Other samples not subject to the CMP polish and different preparation conditions will also be reported on with respect to their defect properties as analyzed with CL. These observations collectively suggest that the CMP surface preparation and the subsequent CVD process have been effective in producing a high-quality diamond film growth with minimal defects, both at the interface and in the bulk of the thick epi-layer.

Processing Diamond Materials for Improved Performance in Quantum Sensing and Power Electronics

Adam Biacchi[1], Michele Kelley[1], J. Trey Diulus[1], Sean Blakley[2], Robert McMichael[1] and Andrei A. Kolmakov[1]; [1]National Institute of Standards and Technology, United States; [2]U.S. Army, United States

Single-crystal diamond grown by chemical vapor deposition (CVD) is a strong candidate material for several emerging applications. The nitrogen-vacancy (NV) center found in diamond has proven to be the most promising platform for room temperature quantum sensing on the nanoscale. This optical technique can measure magnetic field, electric field, strain, and temperature. It takes advantage of a short-lived excited state with a high quantum efficiency of emission. While the physics of NV diamond sensing is established, the reliability and performance of NV diamond has been limited by batch-to-batch inconsistencies and impurities from their preparation.

The combination of desirable electronic, mechanical, and thermal properties found in diamond also make it optimally suited as a semiconductor material for power electronics and devices operating in extreme environments. It is mechanically robust, chemically inert, non-toxic, with a high thermal conductivity and large carrier mobilities. However, this unique combination of characteristics also engender substantial fabrication difficulties not found in metals and traditional semiconductors. Additionally, the high temperatures and potentials power electronic diamond devices operate at can preclude use of traditional silicon fabrication methods and device components. For this reason, novel materials science processing methods must be developed to fully realize the potential of diamond for these applications.

Here, we detail our CVD-grown diamond processing efforts to enhance its performance in quantum sensing and power electronics. We constructed a distillation apparatus that allows for treatment of diamond by refluxing perchloric acid without the need for a dedicated perchloric acid fume hood. A thorough spectroscopic investigation including photoluminescence, Raman, X-ray photoemission, energy-dispersive X-ray, and optically detected magnetic resonance spectroscopies to determine the effects of this procedure and subsequent thermal processing steps. As-received general-grade NV diamonds are found to have a layer of graphitic carbon and other impurities present which are largely removed through this processing. This results in an improvement in quantum sensing performance, including substantially longer T_2 and T_2^* times, and allows for the accurate measurement of the ionization energy of the long-lived ^1E singlet state. We also report the development of a processing method for the deposition of alumina on conductive diamond for use as a gate dielectric. We deposited 40-50 nm of Al_2O_3 on H-terminated or B-doped CVD-grown single-crystal diamond using both thermal and a plasma-assisted atomic layer deposition processes, after which it was subjected it to a variety of processing conditions up to 600 °C. Subsequently, metal electrodes were deposited and the electrical breakdown potential of the gate dielectric was determined. Coupled with thorough structural characterization, we revealed the conditions under which diamond devices can be processed and operated without damaging the fidelity of a deposited alumina gate dielectric. Collectively, these advances in diamond processing represent a step towards bringing this material closer to wide commercial applicability in sensing and power electronics.

Characterization of High Quality Epitaxially Grown Diamond Thin Films

Pranay B. Kalakonda[1], Ratnakar D. Vispute[2], Naveen Narasimhachar Joshi[1], Jagdish Narayan[1] and Roger Narayan[1]; [1]North Carolina State University, United States; [2]Blue Wave Semiconductors Inc., United States

Single crystal diamond is an ideal material for high power, high frequency, and high temperature applications due to its superior electrical and thermal properties when compared to other wide bandgap semiconductors. Apart from electrical and thermal properties, diamond exhibits intriguing optical and spin characteristics due to its ability to host a multitude of impurities and vacancy centers such as nitrogen-vacancy (NV), silicon-vacancy (SiV) centers, etc. thus making it suitable for various quantum applications. High quality single crystalline diamond thin films with excellent control over the doping or impurity concentration is much desired. Here, heteroepitaxial and homoepitaxially grown diamond thin films are characterized and a parallel has been drawn by contrasting the quality and characteristics of these films. Heteroepitaxial diamond was grown via hot-filament CVD (HFCVD) technique, on (0001) and (11-20) oriented sapphire substrates with Ni buffer (Magnetron Sputtering) and Q-carbon (PECVD) seed layer. Both Ni and diamond were grown using domain matching epitaxy (DME) paradigm. A very thin Q-carbon seed layer (10-20nm) deals with the nucleation barrier. Homoepitaxial diamond thin films were grown in a microwave plasma enhanced CVD (MWPECVD) reactor on HPHT synthesized diamond substrates, and provided by Blue Wave Semiconductors Inc. Line width of diamond peaks obtained by Raman and PL measurements, HR-XRD rocking curves establish the quality of the films. The presence of impurities can be found by other characteristic peaks in Raman and PL measurements. High-resolution SEM images show the surface features. The surface roughness and depth profiling were obtained from AFM analysis. Heterostructure growth and orientation relationships were determined from cross-sectional HRTEM, EBSD analysis and XRD phi scans.

Beyond Substrates—Engineering Substrates to Further Diamond Technologies John Ciraldo; WD Advanced Materials, United States

Through DARPA led programs WD Advanced Materials (WDAM) has been developing methods to produce and finish large-scale, device-grade diamond substrates to support technologies in the semiconductor and quantum fields. However, it is necessary to look forward at how these substrates can be further enhanced to support device fabrication in these industries. Key, and common, examples are substrate doping to enhance electrical properties, and the creation of NV^- centers in diamond to support quantum efforts. Through this talk, led by Chief Technology Officer John Ciraldo, WDAM will discuss production of heterostructures for the creation of vertical devices. The primary focus, however, will be on more advanced methods technologies that can be implemented at wafer scale to support device fabrication. Examples include selective deposition techniques that allow for the fabrication of horizontal devices and integration of quantum and electronic regions in diamond. Alternative methods of production pattered quantum regions in otherwise extrinsic diamond will also be discussed.
We will additionally provide an overview of p-type and n-type doping at manufacturing scale, as well as production of isotopically enriched quantum material at the same scale. Data on conductivity, carrier concentrations, NV^- densities, T2* values, etc. will be provided for commercially available substrates at >25mm scale, as well as a discussion of timeline to bring these materials to market at 50mm+ scales.

EL08.08.13

Device-Grade Diamond Roadmap for 100mm and Beyond—Synthesis, Characterization and Promising Developments John Ciraldo; WD Advanced Materials, United States

Availability and production capabilities in diamond are rapidly expanding. To enable next-generation diamond-based solutions, particularly in the quantum and semiconductor realms, WD Advanced Materials (“WDAM”), in cooperation with key industry collaborators, has developed new processes for the synthesis of large-scale single-crystal diamond wafers for electronic applications.
Through this talk, led by Chief Technology Officer John Ciraldo, WDAM will share an overview of recent product

development breakthroughs supporting these emerging technologies, including R&D results, output from the D2 SCALE under DARPA's LADDIS initiative, future research from D100 SCALE under the DARPA UWBGS initiative, and the latest on a new U.S.-based consortium, created to supply synchrotron-grade diamond to the national market through the DOE ARDAP program.
Program overview will cover modified growth systems in both 2.45GHz and 915MHz tools, as well as novel wafering and polishing technologies being developed under the DARPA-led programs.
WDAM will share third-party characterization data demonstrating exceptional material quality characteristics coupled with large substrate sizes, including anonymized comparisons to other commercially available products. In furtherance of the team's form factor expansion efforts, WDAM will also present 30mm+ wafers with x-ray mapping, highlighting narrow rocking curves of about 30arcseconds, ultra-high doping concentrations, and evidence of strong electronic transport properties. The discussion will conclude with a summary of production capabilities and roadmap for bringing device-grade and quantum-grade material to market at these larger scales and with improved extrinsic material properties.

EL08.08.14
Preparation of CVD Diamond Material and Its Application in High Parameter Mechanical Seal Zhengxiong Ou, Yue Xia, Hui Song and He Li; Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

Mechanical seal is the key device to prevent the leakage of medium in a rotating equipment. It is widely used in petrochemical, aerospace and other industries. Its sealing performance is mainly determined by the friction pair of mechanical seal. Under the harsh conditions of high pressure, high speed, and high temperature, traditional ceramics materials are difficult to meet the needs of extreme environments. It is urgent to develop new materials with low friction and high wear resistance to meet the requirements of high reliability and long life of mechanical seal equipment.
CVD diamond material has excellent performance of hardness, friction, wear resistance and corrosion resistance. Therefore, it is an ideal material for mechanical seal friction pairs in extreme environment. In this paper, micron crystalline diamond (MCD) films and nano-crystalline diamond (NCD) films were prepared on SiC friction pairs by hot filament chemical vapor deposition (HFCVD). The roughness of the friction pair surface can be modified by grinding and polishing. Different selections of friction pairs are used to evaluate the performance of mechanical seals. Diamond can greatly improve the friction coefficient and wear rate of silicon carbide friction pairs, its dry friction coefficient can be as low as 0.1, the wear rate can be as low as $4.00\times10^{-7}mm^{3}.N^{-1}.m^{-1}$, and PV value can be greater than 63.5MPa. m/s. In oil drilling, the friction pairs made of diamond material can work normally for more than 1000 hours.

EL08.08.15
Fabrication of Hexagonal-Shaped Diamond Plates at Room Temperature by Solution Chemistry Daniel Choi; Khalifa University of Science and Technology, United Arab Emirates

Diamonds have captivated researchers and industries alike for their exceptional properties and diverse applications. Hexagonal diamond naturally synthesized when meteorites strike surface of earth at very high velocities, due to high temperature and pressure of impact some parts of graphite present in meteorites turns in to hexagonal diamond. These hexagonal diamonds are unique and bearing exceptional physical and electronic properties. Fabrication of hexagonal diamond using anodized aluminum oxide (AAO) nonporous template was performed by the two steps electrodeposition process. Initially, the cobalt nanowires were deposited in the nanocavities of AAO template by applying constant current across the electrodes. Current applied and deposition times were varied to identify suitable cobalt nanowire deposition for the second stage of the hexagonal diamond deposition. In the second stage hexagonal diamonds were deposited over cobalt nanowires by applying constant voltage. The yield of diamonds was increased by keeping the crystallography of cobalt nanowires similar to the crystal structure of hexagonal diamond, by altering the pH of cobalt sulphate aqueous solution. Reproducibility of diamonds was achieved by the optimization of the deposition process. Material characterization with high-resolution transmission electron microscopy (HRTEM) and energy dispersive spectroscopy (EDS) were performed on the samples deposited. HRTEM bright field and diffraction studies were performed on Individual Hexagonal diamond particles and acquired diffraction patterns are indexed with lonsdaleite diffraction data obtained from crystallographic database. The ZA [001] of diffraction data matched with the experimental data and d-spacing of high-order reflections of experimental diffraction pattern matched with standard data with minimum deviation. Investigation of mechanical and electrical properties by Atomic Force Microscopy (AFM) was also conducted. The elastic modulus and thin-film resistivity of hexagonal diamond are found to be 800-900GPa and 10-100 GW·m, respectively.

EL08.08.16

Study of the Interfacial Properties of Heterostructures Based on Aluminum and Hydrogenated Diamond

Felippe Folegatti and Eliezer F. Oliveira; University of São Paulo State–UNESP, Brazil

Recently, scientific research has demonstrated that the use of hydrogenated diamond as a P-type material can be a relevant innovation for the production of new generation field-effect transistors (FET) [1-3]. To create FETs based on hydrogenated diamond, it is necessary to evaluate its behavior in contact with the materials that are used to form the NPN junction. In the case of the source and drain terminals of the FET, N-type metallic materials are generally used to form a Schottky barrier at the interface with the P-type material. Due to its ease of production and integration, one of the most used metals is o Aluminum [4]. Although there are already studies on the evaluation of the properties of composites based on pure diamond and aluminum [5], it is still not known whether (and how) the use of hydrogenated diamond would alter such properties, which is essential to determine the feasibility of use in FET construction. Through theoretical studies of Molecular Dynamics using reactive force fields, in this work we study how the degree of hydrogenation on the diamond surface affects the diamond/metal interface, especially when subject to temperature variations. Using degrees of hydrogenation on the diamond surface of 0%, 15%, 25%, 50%, 75% and 100%, we notice that at room temperature, 75% hydrogenation is already capable of preventing chemical interaction between the diamond and the aluminum. However, from 500K onwards, even with 75% hydrogenation of the surface, a small fraction of aluminum atoms begin to interact with the diamond. As electronic devices can be subject to high temperatures and to ensure that interfacial properties do not change during operation, our results suggest that a high degree of hydrogenation of the diamond surface (>75%) is required to ensure that there is no chemical interaction. between the diamond.

A First-Principles Study to Understand the Role of Defects at Diamond/c-BN Interface Shikha Saini, Kevin Tibbetts, Mark Polking and Bilge Yildiz; Massachusetts Institute of Technology, United States

Diamond and cubic boron nitride (c-BN) are ultrawide band gap materials with potential applications in high-power and radio frequency (RF) electronics due to their high thermal conductivities, high breakdown fields, and high mobilities. We have developed a protocol for preparing high-quality heteroepitaxial c-BN films on diamond substrates for next-generation power and RF field-effect transistors (FETs). However, developing practical electronic devices based on these heterojunctions remains challenging due to a limited understanding of the electronic structure and intrinsic interfacial defects at the diamond/c-BN interface and their impacts on dopant activation and free carrier density. In this work, we present results from a first-principles study of various diamond/c-BN interface types, including B- and N-terminated (100) and (111) interfaces, as well as the non-polar (110) interface. Our findings show that interface states cross the Fermi level for both C–B and C–N interfacial bonds, suggesting strong p-type (type-II band alignment) and n-type (type-I band alignment) doping, respectively. Notably, no interface states were observed at the (110) interfaces. We further analyze the formation energies of potential substitutional, vacancy, and interstitial defects at these low-index interfaces, which can be beneficial or detrimental to the carrier density. For instance, we show that B_C and C_N defects at the (110) interface induce p-type doping, forming a two-dimensional hole gas (2DHG) in the diamond substrate. The intrinsic electron-deficient nature of these defects and the type-II band alignment are key factors in forming a 2DHG at the interface. However, we have observed that these B_C and C_N defects can be compensated by external dopants such as O and F, which are commonly introduced unintentionally in c-BN epitaxial growth processes. This leads to more stable configurations under B-rich conditions, viz. B_CO_C, B_CO_N, C_NF_N, and C_NO_N. Moreover, we find that substitutional defects and their combination are detrimental to n-type carrier density at the C-N (100) interface. Therefore, it is essential to determine the ideal interface types, dopants, and growth conditions conducive to the formation of high-density 2D electron and hole gases. Our comprehensive analysis provides insights into the structure and properties of diamond/c-BN heterointerfaces and offers a detailed roadmap for engineering next-generation power and RF FETs.

EL08.08.18

Fabrication of 2DHG Multi-Finger Diamond Vertical MOSFETs and *I-V* and RF Characteristics Yuki Takano[1], Akira Takahashi[1], Kosuke Ota[1,2], Yukihiro Chou[1], Fuga Asai[1], Tatsuya Fujishima[2], Atsushi Hiraiwa[3] and Hiroshi Kawarada[1,2,3]; [1]Waseda University, Japan; [2]Power Diamond Systems, Inc., Japan; [3]The Kagami Memorial Research Institute for Material Science and Technology, Japan

We fabricated 2DHG multi-finger diamond vertical MOSFETs and measured DC and RF characteristics for the first time. Diamond has a wide bandgap (5.5 eV), high thermal conductivity (22 W/cmK), and high breakdown field(10 MV/cm). Therefore, diamond is a promising semiconductor material for use in High-Power RF amplifier[1-2]. The vertical multi-finger structure is suitable for both higher breakdown voltage and integration, and it is necessary to increase RF output power density.

The fabrication process is as follows. The device was fabricated on a (001)-oriented p + diamond substrate. 0.5 μm undoped layer and 1.0 μm nitrogen-doped layers were deposited on the substrate by microwave plasma vapor deposition(MPCVD) to block the vertical leakage current. Next, the depth of 3.0 μm gate trench was formed by inductively coupled plasma reactive ion etching(ICP-RIE). After gate trench etching, 200 nm regrown undoped diamond layer([N]:< 1×10 16 cm -3 ,[B]:<3×10 14 cm -3) was deposited by MPCVD. Source trench was etched to reach p+ substrate by ICP-RIE.

After that, source and drain electrode (Ti/Pt/Au: 50/50/200 nm) was deposited and annealed at 600 to form TiC for ohmic contact. After Hydrogen-termination and Oxygen-termination for defining the channel region, 100 nm of Al 2 O 3 was deposited as the gate insulator by atomic layer deposition at 450 using H 2 O as an oxidant. Finally, 300nm of Al was deposited on the entire gate trench as the gate electrode.

In this device, the whole p + diamond substrate operates as source. 2DHG is induced on both the surface and sidewall of H-terminated regrown layer. The hole current passes through the regrown layer from p + diamond substrate, and then flows up along the H-terminated regrown layer on gate trench sidewall toward the drain electrode on the substrate surface. The total gate width(W GT) is
defined by gate width of each finger(W GU) and the number of fingers (N f) as W GT = W GU ×N f ×2, since there exist two current paths from source to drain at each finger.
In DC measurement, maximum drain current density(I D,max) of 297 mA/mm at V DS = -40 V and V GS = -30V was obtained from the device with W GT = 50×5×2=500 μm, trench width (W T) = 8 μm, and gate length(L G) = 3.7 μm. Another device with W GT = 100×5×2=1,000 μm, W T = 8 μm, and L G = 3.7
μm showed the results of I D,max = 289 mA/mm (=289 mA as actual current) at V DS = -40 V and V GS = -30V. Also, I D,max = 250 mA/mm (=500 mA as actual current) were measured from the device with W GT = 100×10×2= 2,000 μm, W T = 8 μm and L G = 3.7 μm. Therefore, the actual output current increased almost proportionally to the expansion of the gate width by increasing N f .
In RF measurement without deembedding, f max of 0.88 GHz was obtained at V DS = -40 V and V GS =-30V from the device with W GT = 50×5×2= 500 μm, W T = 2 μm and L G = 3.7 μm. After gate redeposition for more suitable gate length, f max of 1.3 GHz was obtained at V DS = -40 V and V GS = -30V from the device with W GT = 25×5×2= 250 μm W T = 4 μm and L G ≒ 2 μm. The relatively low
fmax is caused by parasitic capacitance C DS between the bottom source and the upper drain. It can be decreased by avoiding the overlapping of the two layers.
In this work, we fabricated 2DHG multi-finger diamond vertical MOSFETs for the first time.
I D,max of 297 mA/mm and f max of 1.3 GHz without emdedding were obtained from the devices. The device structure demonstrated in this work shows the possibility of efficient integration and gate width expansion as RF device, which is the advantage of diamond’s high thermal conductivity compared with GaN.

Diamond p-Type Lateral Schottky Barrier Diodes with High Breakdown Voltage (4612 V at 0.01 mA/mm)

Zhuoran Han and Can Bayram; University of Illinois at Urbana-Champaign, United States

Diamond p-type lateral Schottky barrier diodes (SBDs) with a 2-μm-thick drift layer are fabricated with and without Al_2O_3 field plates. Schottky contacts composed of Mo (50 nm) / Pt (50 nm) / Au (100 nm) showed a barrier height of 1.02 ± 0.01 eV and ohmic contacts of Ti (30 nm) / Pt (30 nm) / Au (100 nm) achieved a specific ohmic contact resistance of 1.25 $\pm 0.98\times10^{-4}$ Ω-cm^2. Their forward and reverse bias characteristics are studied in detail. Both SBDs, with and without Al_2O_3 field plates, exhibit rectifying ratios larger than 10^7 at room temperature, and a peak current density of 5.39 mA/mm under 40 V forward bias at 200 °C. The leakage current density at room temperature is stable at approximately 0.01 mA/mm for both diodes. The SBD without the Al_2O_3 field plate exhibited a breakdown voltage of 1159 V, while the SBD with the Al_2O_3 field plate is stable under a reverse voltage of 4612 V, which is higher than many diamond SBDs previously reported.
The fabrication of the SBDs starts with a 2 μm p- drift layer ([B] < 8 × 10^{15} cm^{-3}]) that was grown on a 3 × 3 mm^2 Type Ib (100) high-pressure high temperature (HPHT) diamond substrate. Then, 200 nm p+ diamond ([B] ~ 3 × 10^{20} cm^{-3}]) was selectively grown to form the ohmic contact region. Ohmic metal contacts were formed by e-beam evaporation of Ti (30 nm) / Pt (30 nm) / Au (100 nm), followed by thermal annealing at 450 °C in an ambient of Ar gas for 50 minutes. The specific contact resistance of ohmic contacts was determined by TLM measurements and measured to be 1.25±0.98 × 10^{-4} Ω-cm^2. Next, a 300 nm Al_2O_3 field plate was deposited by e-beam evaporation,

followed by a lift-off process. Al_2O_3 was chosen as the field oxide because of its high dielectric constant relative to diamond (k = 8.63±0.07 for the as-deposited Al_2O_3) which reduces the electric field strength and a large band offset for the oxygen-terminated diamond. The exposed diamond surface was ozone-treated at room temperature for 1.5 hours to obtain a stable oxygen termination prior to the Schottky contact deposition. Schottky metal stack of Mo (50 nm) / Pt (50 nm) / Au (100 nm) was deposited by e-beam evaporation. The inner and outer radii of the Al_2O_3 field plate are 40 μm and 80 μm, respectively. The radius of the Schottky contact is 60 μm, and the separation between the ohmic and Schottky contact is 80 μm.
Both diodes exhibit a rectifying ratio of 10^7 in the range of +/−5 V. The linear current densities at a 40 V forward bias are 0.049 mA/mm and 0.044 mA/mm for the SBD with and without the field plate, respectively. The SBDs were reprocessed several times before high-temperature and breakdown measurements and showed good reproducibility in forward *J-V* characteristics. The max difference in forward current densities at the 40 V forward bias between four fabrication batches is 15% and 6% for the SBD with and without the FP, respectively. During reverse bias measurement, the diamond wafer was submerged in 3M™Fluorinert™electronic liquids to prevent air breakdown. The lateral SBD without the field plate broke down at 1159 V when the leakage current drastically increased to the compliance limit of 50 μA. After the first breakdown, reverse current density increased at low reverse bias, which confirmed the generation of leakage paths. No physical damage to the Schottky contact was identified post-measurement. However, repeated breakdown measurements showed a decrease in the breakdown voltage. The SBD with the field plate exhibited stable leakage current up to 4612 V, which is the limit of the Fluorinert™electronic liquids. The leakage current density at 4612 V reverse bias is less than 0.01 mA/mm, which is similar to that of the SBD without the field plate prior to breakdown. The relatively high stable leakage current can be attributed to a high surface roughness of the epitaxially grown drift layer (RMS roughness = 7.5 nm), caused by rough polishing and random growth defects.

High Quality Mesoscopic Circuits on Diamond Anvils Kaiwen Zheng, Zackary Rehfuss, Shannon Gould, Kater Murch and Sheng Ran; Washington University in St. Louis, United States

Diamond anvil cells are crucial tool for characterizing material properties in high pressure environments. Due to the limited size of the diamond culet and the slanted geometry of the facets, it has been challenging to fabricate robust contact leads onto these surfaces. We present a novel fabrication procedure to produce high-quality metallic structures onto the diamond culet without the need for customized equipment. Feature sizes down to 500 nm can be achieved by utilizing bi-layer resist and electron beam lithography. Metallic lift-off structures with strong adhesion to the diamond surface are realized by optimizing the surface treatment. We showcase the potential for our process by presenting a few experiments utilizing structures fabricated using our technique.

Intrinsic Carrier Mobility in CVD-Grown Single-Crystal Diamond Kazuki Konishi[1], Ryo Ikebe[1], Daiki Totsuka[1], Rintaro Toda[1], Ikuko Akimoto[2], Hideto Matsuoka[3,4], Jan Isberg[5] and Nobuko Naka[1]; [1]Kyoto University, Japan; [2]Walayama University, Japan; [3]Hokkaido University, Japan; [4]Osaka Metroplitan University, Japan; [5]Uppsala

University, Sweden

In designing electronic devices, diffusion length, lifetime, and mobility of charge carriers are crucial parameters. High-purity intrinsic diamond has recently been recognized as a material showing the highest electron and hole mobilities among bulk semiconductors [1,2]. The mobility drastically increases when the diamond crystal is cooled at cryogenic temperatures. This property helps improve the charge collection efficiency and mitigate degradation in radiation detectors [3]. We have so far reported a comparative study of electron mobility in single-crystal diamond of the highest purity based on the time-of-flight, charge collection, and cyclotron resonance (CR) measurements [4]. This study confirmed the overall consistency among the three different measurement methods, yet highlighted some quantitative discrepancies whose reason is unclear. In this presentation, we will review the intrinsic carrier mobility in single crystals of high-purity diamond grown by the chemical-vapor-deposition method, measured by a new variety of CR methods.

In diamond, momentum relaxation owing to scattering by acoustic phonons is considered to determine the low-temperature carrier mobility. Therefore, the mobility is expected to increase with decreasing temperature. As opposed to this expectation, we observed saturation of the carrier mobility below ~7 K with the time-resolved cyclotron resonance (TRCR) method conducted under photoexcitation using pulsed laser light. We attributed this effect to carrier-carrier scattering and developed a continuous-wave cyclotron resonance (CWCR) method, in which photoexcitation of low-density carriers into the sample volume was achieved [1]. We further reduced carrier heating due to microwave absorption [5] by changing the microwave cavity resonator and improved the previous record of electron mobility. Nevertheless, we found a trend that the CWCR mobility saturates at a value slightly below the theoretical one at 10^8 cm^2/V/s. We will discuss the reason for the observed asymmetric CR lineshape and the possible effects of strain fields on charge carriers around dislocations, that are unintentionally incorporated into the diamond crystal.

Functionalised Diamond Based SERS Industrial Sensing System for Harsh Environment and High Pressure Systems

Ralph Moors, Kieran Twaddle and Richard B. Jackman; University College London, United Kingdom

A ruggedised and integration ready surface enhanced Raman spectroscopy system has been developed for metrology in harsh environments and in industrial systems. The sealing technology has been proven to hold pressure at elevated temperature and pressure of 175 Bar and 200 °C. The diamond window features a gold nanoparticle functionalised surface to create plasmonic enhancement at the diamond/target environment interface. A fibre coupled Raman laser back-illuminates the diamond window, so that environment isolation is maintained by the diamond boundary. The system is designed for integration with pressurised water reactors (PWR) and has applications in a variety of industrial systems and fields, leveraging the outstanding optical properties and chemical and physical resilience of diamond. FEA simulation was used to inform the nanoparticle material and size. SERS substrates were fabricated by dewetting evaporated gold by thermal processing. The nanoparticles are overgrown with a thin layer of polycrystalline diamond to protect them from the target environment.

9:30 AM EL08.09.03

Reduction of the Electric Field Strength by the Thick Undoped Layer in the (001) C-H Vertical Diamond MOSFETs Ryosuke Yamamoto[1], Nobutaka Oi[1,2], Kosuke Ota[1,2], Kento Narita[1], Atsushi Hiraiwa[1], Tatsuya Fujishima[2] and Hiroshi Kawarada[1,2,3]; [1]Waseda University, Japan; [2]Power Diamond Systems, Inc., Japan; [3]The Kagami Memorial Research Institute for Materials Science and Technology, Japan

High-performance p-type power metal-oxide-semiconductor field-effect transistors (MOSFETs) comparable to n-type ones are essential in implementing high switching speed and high-power complementary circuits. With wide bandgap (E_g = 5.47 eV), diamond is suitable for p-type MOSFETs. As an electronic device material, diamond has outstanding potential. In particular, the breakdown electric field of diamond (E_c = 10 MV/cm) surpasses that of other wide-bandgap semiconductor materials, being three times as high as that of GaN (E_c = 3.3 MV/cm) and that of 4H-SiC (E_c = 2.8 MV/cm). For the power MOSFETs, a vertical structure is suitable for a thick drift layer which improves breakdown voltage (V_B). In vertical diamond MOSFETs, a layer stack structure with a trench is basic [1]. On a p^+ substrate as a vertical current path, an undoped layer for reduction of electric field strength and an N-doped layer for current blocking are deposited. After the trench is formed from the upside surface to the p^+ substrate, a regrown undoped layer is deposited to induce 2-dimensional hole gas (2DHG) and secure the sub-surface channel by hydrogen-terminated (C-H). Previous studies have reported a high breakdown voltage of 580 V with a p^- drift layer in vertical p-type diamond trench MOSFETs [2]. As another way to improve the V_B, the reduction of the electric field strength by thickening the undoped layer is proposed. In this study, we investigated the effects of an undoped layer on reducing electric field strength in a (001) p^+ diamond substrate without p^- drift layers using a device simulation and measuring fabricated devices.

To estimate the electric field of the device off-state, we conducted a device simulation using SILVACO Atlas at V_{GS} = +40V and V_{DS} = -600 V [3]. The device is a vertical structure with a trench whose fundamental structure resembles the device fabricated in ref [1] (Fig.1 (e)). On the (001) p^+ diamond substrate, we used a 1 μm thick undoped layer ([N]: ~ 6.0×10^{16} cm^{-3}, [B]: ~ 6.6×10^{15} cm^{-3}) and a 1 μm thick N-doped layer ([N]: ~ 4.0×10^{18} cm^{-3}). Including the trench sidewall and bottom of the trench surface, a 200 nm thick regrown undoped layer ([N]: ~ 1×10^{16} cm^{-3}, [B]: ~ 1×10^{15} cm^{-3}) was used as a conductive layer. As the device dimensions, the source-gate length (L_{SG}), the gate length (L_G), and the gate-trench length (L_{GT}) are 3 μm. The trench depth (D_T) is 3 μm and the gate-drain length (L_{GD}) is 6 μm. In the simulation model, the donor level of nitrogen was 1.7 eV, and the acceptor level of boron was 0.37 eV. The negative charge was set in the Al_2O_3 layer to reproduce the induction of 2DHG in the C-H channel region [4]. In the simulation results, the electric field concentration occurred at the boundary between the p^+ substrate and the undoped layer, and the corner contacting the undoped layer, N-doped layer and the regrown undoped layer. The maximum electric field (E_{max}) was 8.8 MV/cm at the corner with the 1 μm thick undoped layer. To reduce the electric field strength, we also conducted a simulation with a model increasing the undoped layer to 4 μm thick. The electric field strength at the corner was reduced to 3.4 MV/cm at the boundary by increasing the undoped layer thickness. With the 4 μm thick undoped layer, the E_{max} was 4.6 MV/cm at the boundary on the p^+ substrate. To verify the reduction of the electric field strength with an undoped layer in the simulation, we are now fabricating the devices with the 1 and 4 μm thick undoped layer. We will report the simulation results and the device breakdown voltages of the fabricated ones.

Combined Local DLTS/CV Measurement of Al_2O_3/OH-Diamond (111) Interface by Time-Resolved Scanning Nonlinear Dielectric Microscopy Kohei Yamasue[1], Tsubasa Matsumoto[2], Norio Tokuda[2] and Yasuo Cho[1]; [1]Tohoku University, Japan; [2]Kanazawa University, Japan

Diamond is a wide bandgap semiconductor material promising for power device applications. Al_2O_3/OH-diamond (111), where an Al_2O_3 layer is deposited on an OH-terminated diamond (111) surface by ALD, realizes a high-quality MOS interface permitting an inversion-type MOSFET with normally-off operation [1]. However, the obtained channel mobility is insufficient and improving the interface quality remains a challenge. To investigate the interface at the microscopic level, here we performed nanoscale imaging of the interface charge states using time-resolved scanning nonlinear dielectric microscopy (time-resolved SNDM). Time-resolved SNDM is a scanning probe microscopy technique that detects electrostatic capacitance with high sensitivity [2]. Because this technique can measure microscopic MOS capacitance change for an arbitrary voltage pulse sequence, we can perform microscopic DLTS (deep level transient spectroscopy) and CV (capacitance-voltage) profiling at the same position with nanometer precision. This unique capability allows us to obtain simultaneous images reflecting interface defect density (D_{it}) and surface potential fluctuations.

The sample consists of an Al_2O_3 layer (50 nm) deposited by ALD, a B-doped p^+ CVD diamond (111) layer (200 nm), an underlying high-temperature high-pressure synthesized p-doped (111) substrate (300 μm) for ohmic contact formation, and a gold electrode layer. The diamond (111) surface was atomically flattened by using etching by Ni carbon solid solution reaction and subsequent hydrogen plasma etching treatment prior to OH-termination and ALD. At each measurement point, we applied a rectangular voltage pulse (height: 7 V, width: 5 μs) for local DLTS and a subsequent triangular pulse (1.5 cycles, amplitude: 50 V_{pp}, length of 1 cycle: 100 μs) for local CV profiling, both superimposed on a common dc bias of 2 V_{dc}. For noise reduction, capacitance response was averaged over 160 repetitions of this pulse sequence. The D_{it} image was obtained by analyzing the response from local DLTS. In addition, by analyzing the local CV profiles, feature voltages V_d and V_a were extracted for obtaining spatial fluctuations of the local CV profiles near the depletion and accumulation states, respectively. The measurement was performed in air at room temperature.

By using our technique, we simultaneously obtained D_{it}, V_d, and V_a images of the Al_2O_3/OH-diamond(111). We found that the fluctuations of V_d and V_a were approximately 0.4 V and 0.6 V, respectively. This means that the surface potential fluctuations are higher in the accumulation state compared to the depletion state. In addition, through the correlation analysis of the images, we found that the D_{it} image has significantly higher correlation coefficients with the V_a images than the V_d image. In fact, the spatial features of the fluctuations in the D_{it} and V_a images show a high degree of correspondence. This implies that observed fluctuation increase from the depletion to the accumulation is mainly caused by the capture of dominant carriers (holes) by interface defects. Device simulations have shown that the observed non-uniform interface charge states can lead to a decrease in channel mobility through Coulomb scattering. Our results demonstrate that time-resolved SNDM imaging is useful for microscopic understanding of interface charge states and evaluating their impact on the carrier transport properties at the interface.

Diamond Quantum Sensors for Nano- and Microscale NMR Spectroscopy in Materials Research Dominik Bucher; Technische Universität München, Germany

The nitrogen-vacancy (NV) point defect in diamond has emerged as a new class of quantum sensors for the detection of magnetic signals at the nanoscale. This technique also allows the measurement of magnetic resonance signals with unprecedented sensitivity. In my talk, I will briefly introduce the fundamentals of diamond-based quantum sensing. In the next part, I will report on the recent progress of our research group: First, I will introduce NV-NMR spectroscopy for probing surfaces and interfaces. This new technique allows us to detect and quantify (sub)monolayers of self-assembled molecules on an alumina oxide surface and their formation in real time under chemically relevant conditions. Secondly, I will present a novel experimental scheme that combines pulsed gradient spin echo (PGSE) with NV-NMR to quantify molecular diffusion and mobility within microstructures. Finally, I will briefly present our recent results on the use of NV centers to perform wide-field optical NMR microscopy on a camera. This technique allows magnetic resonance imaging (MRI) in real space on microscopic length scales. In the last part of my talk I will discuss how NV-NMR can potentially extend current microscopy and surface spectroscopy capabilities to probe the structure and dynamics of thin films, nanomaterials and their interfaces.

11:00 AM EL08.10/QT04.10.02
A Quantum Spin Probe of Single Charge Dynamics in Diamond Jonathan Marcks[1,2], Mykyta Onizhuk[2], Yuxin Wang[2], Yizhi Zhu[2], Yu Jin[2], Benjamin S. Soloway[2], Masaya Fukami[2], Nazar Delegan[1,2], F. J. Heremans[1,2], Aash Clerk[2], Giulia Galli[2] and David Awschalom[2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Electronic defects in semiconductors form the basis for many emerging quantum technologies. Understanding defect spin and charge dynamics in solid state platforms such as diamond is crucial to developing these building blocks, as well as applying these systems for sensing applications. However, many defect centers are difficult to access at the single-particle level due to the lack of sensitive readout techniques. We exploit the intrinsic correlation between the charge and spin states of defect centers to measure defect charge populations and dynamics through the steady-state spin population, read-out at the single-defect level with a nearby optically active nitrogen vacancy center. We directly measure ionization and charge relaxation of single dark defects in diamond, effects we do not have access to with traditional coherence-based quantum sensing. These spin resonance methods will find use in studying single-particle dynamics in other solid state defect systems as well as electron systems external to the diamond. [1]

11:15 AM EL08.10/QT04.10.03
High-Throughput Discovery of Complex Quantum Defects in Semiconductors Yihuang Xiong[1], Jiongzhi Zheng[1], Shay McBride[1], Xueyue Zhang[2,2], Sinead M. Griffin[3] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Quantum technologies would benefit from the development of high-performance quantum defects acting as spin-photon interfaces. While some color centers in diamond and silicon have been emerging in quantum applications, they are far from perfect, and there is still a need to search for and develop novel quantum defects. In this talk, we will show how, by searching a high-throughput computational database of more than 22,000 charged complex defects in silicon, we identify a new class of defects formed by a group III element combined with carbon substituting on a silicon site. These defects are structurally, electronically, and chemically analogous to the well-known T center in silicon. We will discuss the experimental evidence for these defects and propose a potential synthesis route that utilizes hydrogenation/dehydrogenation steps, similar to those used for the T center. Lastly, we will also discuss how the same methodology can be used to find novel quantum defects in diamond. Our work motivates further studies on the synthesis and control of this new family of quantum defects and demonstrates the use of high-throughput computational screening to discover new complex quantum defects.

Electron-Nuclear Spin Register Beyond the Coherence Limit of a Central Spin Alex Ungar[1], Alexandre Cooper-Roy[2], Calvin Sun[1] and Paola Cappellaro[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Waterloo, Canada

Electronic spin defects in the environment of an optically active spin can be used to increase the size and thus the performance of solid-state quantum registers, with applications in quantum metrology and quantum communication. Previous works have exploited the optically-active nitrogen-vacancy (NV) center spin in diamond to identify and control other electronic spins directly coupled to the central NV. As this direct coupling is limited by the central spin coherence time and the coupling rate decreases with distance, this approach significantly restricts the maximum attainable size of the register. To address this problem, we present a scalable approach to increase the size of electronic spin registers. Our approach exploits a weakly coupled probe spin together with double-resonance control sequences to mediate the transfer of spin polarization between the central NV spin and an environmental spin that is not directly coupled to it. We further expand the size of the quantum spin register by identifiying and controlling associated nuclear spins, that can act as quantum memories. Our work paves the way for engineering larger quantum spin registers with the potential to advance nanoscale sensing, enable correlated noise spectroscopy for error correction, and facilitate the realization of spin-chain quantum wires for quantum communication.

Influences of Extended Structural Defects on Electronic and Magnetic Properties of NV Centers in Diamond Crystals Christian Elsaesser[1,2], Reyhaneh Ghassemizadeh[1], Wolfgang Körner[1] and Daniel F. Urban[1,2]; [1]Fraunhofer Institute for Mechanics of Materials, Germany; [2]University of Freiburg, Germany

Due to its outstanding coherence properties, a negatively charged nitrogen-vacancy (NV) center in a diamond crystal is a promising atomic defect complex for solid-state quantum-sensing and quantum-computing devices. However, its functional performance can be limited by the presence of other atomic or extended defects in diamond crystals. We have studied the influences of extended structural defects, namely planar stacking faults and twin boundaries [1], free surfaces [2], and linear dislocation cores [3], on the stability and physical properties of the NV center by means of a density-functional-theory analysis. The focus of this presentation will be on NV centers at dislocation cores in diamond.

We model the cores of two prominent dislocations in diamond, namely the 30° and 90° partial glide dislocations, and calculate the defect formation energy, structural geometry, electronic defect levels and zero-field splitting (ZFS) parameters. Our simulations reveal that dislocation cores potentially attract NV centers with an energy release of up to 3 eV. The properties of NV centers at most lattice sites in the near vicinity of the dislocation cores have strong deviations with respect to their bulk values. However, the lowest-energy configuration of a NV center at the core of a 30° dislocation has very bulk-like properties. Its electronic level spectrum is only slightly modified and ZFS values deviate by less than 5% from their bulk values. These results open a perspective to align multiple NV centers along this dislocation type with a linear-chain arrangement whose collective behavior may become advantageous for quantum-technology applications.

1:45 PM ^EL08.11.02

Characterization of Defect-Dopant Interactions in CVD-Grown Diamond Eveline Postelnicu[1], Haoxue Yan[1], Tri Nguyen[1], Santiago Corujeira Gallo[2], Alastair Stacey[3,4] and Kunal Mukherjee[1]; [1]Stanford University, United States; [2]Quantum Brilliance, Australia; [3]RMIT University, Australia; [4]Princeton Plasma Physics Laboratory, United States

Dopant incorporation in diamond is crucial for applications in power electronics, radiation detection, and quantum sensing. However, the interplay between inherent defects in diamond epitaxy and dopant segregation, as well as the influence of dopants on defect density is not yet well understood. We have performed correlative microscopies and spectroscopies to gain further insight into dislocation properties and generation mechanisms in boron-doped homoepitaxial CVD-grown diamond. Using site-coincident electron channeling contrast imaging (ECCI) and cross-sectional transmission electron microscopy (XTEM), we demonstrate ECCI as a rapid, non-destructive measure of threading dislocation density that can achieve similar accuracies as XTEM.[1] Dislocations emanated from the highly defective interface, indicating polishing damage as the source of dislocation generation. Two-beam condition imaging reveals that most dislocations have a mixed character (consistent with polishing damage[2]), while some exhibit purely edge or screw quality. By coupling cathodoluminescence (CL) characterization (which had been previously used to characterize dislocation density in diamond[3]) with ECCI, our site-coincident analysis found only 20-40% of dislocations exhibit A-band luminescence. Despite prior reports finding no correlation between Burgers vector and dislocation luminescence[4], our ECCI contrast line analysis indicates a potential correlation between Burgers vector and A-band luminescence. To investigate the role of boron in dislocation luminescence, we performed spatially resolved secondary ion mass spectrometry (nanoSIMS) to track the ^{11}B isotope throughout the diamond layer across regions with varying dislocation density (10^8 cm^{-2} and 10^7 cm^{-2}). Using a 100pA Cs^+ ion beam with estimated spot size of 250nm and detectivity limit of 10^{17} cm^{-3}, we found no difference in boron uniformity among the two distinct dislocation density regions. Prior reports found boron segregation in 2nm-diameter regions surrounding dislocations with density 2-2.5x the background doping density of 10^{21} cm^{-3}.[5] For our 10^{19} cm^{-3} boron-doped film, we can rule out boron segregation exceeding 10^{22} cm^{-3} solely at the dislocation core (diameter <1nm) and any segregation of 10^{20} cm^{-3} or greater for 10nm diameter regions around the dislocations. We will discuss further correlated XTEM-CL to elucidate the role of Burgers vector in dislocation luminescence and the effects of boron doping on dislocation density and luminescence in films with boron density ranging from 10^{19}-10^{21} cm^{-3}. Understanding dislocation luminescence mechanisms will aid in the continued development of rapid and accurate dislocation characterization. Further insight into dislocation generation and the interaction between dislocations and intentional dopants like boron will facilitate strategies to reduce dislocation density, advancing the scalability of diamond devices and substrates.

Order in Disorder—Magnetoresistance Anisotropy of Superconducting Boron Doped Diamond Jyotirmay Dwivedi[1], Saurav Islam[1], Jake Morris[1], Kalana Halanayake[1], Gabriel Vázquez-Lizardi[1], Anthony Richardella[1], David Snyder[1], Luke Lyle[1], Danielle Reifsnyder Hickey[1,1], Nazar Delegan[2], David Awschalom[3] and Nitin Samarth[1,1]; [1]The Pennsylvania State University, United States; [2]Argonne National Laboratory, United States; [3]The University of Chicago, United States

Two decades after its discovery, superconductivity in heavily boron-doped diamond (HBDD) presents unresolved fundamental questions regarding its origins and properties [**1**]. Superconducting HBDD is also of potential interest for heterogeneous quantum technologies that exploit the transduction of quantum information between Josephson junction-based qubits and spin-based quantum defect qubits. We report electrical magnetotransport measurements of homoepitaxial HBDD films in the transition regime from the normal to the superconducting state. Although these single-crystal films bear the hallmarks of inhomogeneous granular superconductivity, the dependence of electrical resistivity on temperature (T), magnetic field vector (**H**), and current density (**J**) reveals a surprising anisotropy, accompanied by the emergence of a spontaneous transverse voltage below T_c, onset at H=0, known as the 'Hall anomaly' , previously observed in other quasi-2D [**2**] and high T_c superconductors [**3**]. This transport anisotropy further shows three phases with distinct symmetries depending on the relative position in T-H phase space, which is closely followed by the temperature dependence of Hall anomaly. Similar exotic transport behavior has been reported in polycrystalline HBDD that can be modeled by a disordered array of Josephson junctions [**4**]. However, based on transmission electron microscopy and atomic force microscopy, our single crystal films lack any obvious structural disorder. This indicates that the hidden anisotropic order observed in disordered superconducting diamond might be related to the symmetry of the order parameter itself. Understanding the source of the magnetoresistance anisotropy and Hall anomaly in homoepitaxial HBDD can give us insights into the origins of its superconductivity and may help achieve higher T_c beyond the BCS limit as theoretically predicted [**5**].

Diamond Superconducting FETs and High Current Vertical FETs Using Heavily Boron Doping Masaharu Takeuchi[1], Chiyuki Wakabayashi[1], Minoru Tachiki[2], Shuuichi Ooi[2], Ryo Matsumoto[2], Yoshihiko Takano[2] and Hiroshi Kawarada[1,3]; [1]Waseda University, Japan; [2]MANA National Institute for Materials Science, Japan; [3]The Kagami Memorial Research Institute for Materials Science and Technology, Waseda University, Japan

Recently, gate-controlled supercurrent (GCS) transistors have attracted attention as major components in superconducting circuits. In the transistors, the supercurrent is modulated by directly applying an electric field to metallic superconducting nanobridges or nanowires of metals such as Nb, Ti, V etc. [1] However, these thin metal superconductors device are based on side gate structure not suitable for device integration and degrade their performance by oxidation which is crucial for realistic application. Here, we report on a top-gated superconducting thin film transistor using a superconducting boron (B) -doped diamond for the first time. The B concentration was around 10^{21}cm^{-3} and the superconducting transition temperature was 5 K. The large superconducting critical current (I_c) exceeding 100 μA was successfully controlled by a top-gated structure at 1.4 K with a channel width of 25 μm. It is relatively high compared with other metal GCS transistors [2]. The I_c is completely suppressed and a phase transition from the superconducting to the normal state is observed at V_{GS} around −20 V. But the suppression does not occur at positive V_{GS} above +20V. This asymmetric nature is different from the symmetric gate control of metal GCS transistor. The I_c control by the gate has been observed up to 3 K. The top-gated structure enabled the suppression of I_c without using nanostructures such as nanobridges, which require precision miniaturization techniques. As I_c suppression is possible with field-emitted current of 1 nA at the same channel (25 μm in width), the mechanism may be heating the superconductor by the field-emitted electrons from the gate to the superconductor. However, many other mechanisms are also discussed in metal GCS transistors [2].

New Applications of Diamond for Thermal Solutions John Ciraldo; WD Advanced Materials, United States

It is well known that diamond exhibits extreme thermal properties that, harnessed effectively, can be used to significantly enhance electronics performance. Full diamond devices are expected to operate with superior performance with lower junction temperatures. But beyond diamond devices themselves, it is well established that diamond can be incorporated with other materials to achieve superior performance in existing technologies. A god example of this is GaN on diamond devices, that demonstrate significantly better performance than GaN on silicon, sapphire, or silicon-carbide. Another approach that has proven to be similarly beneficial is the application of diamond to top surfaces of devices, and GaN devices in particular. The latter, however, while effective, is limited somewhat in impact by challenges in deposition and device risks from high-temperature depositions. Advancing technologies in automotive, data, computation, and power, combined with investments and support through the CHIPS act, have driven new efforts in integrating diamond into existing and nascent technologies. Through this talk, led by Chief Technology Officer John Ciraldo, WDAM will share an overview of new technologies and approaches being developed through WDAM with various collaborators in the semiconductor industry to address these problems. Novel approaches to diamond coating, including interlayers to improve thermal transport and conformality of PCD on device structures, use of diamond coating in silicon cooling systems, and substrates that use isotopic enrichment to achieve higher levels of thermal conductivity than is otherwise possible with diamond will be discussed, combined with data on film properties, lifetime wear, and thermal conductivity will be provided to justify these novel approaches. Use of diamond for both thermal transport and electrical shielding in devices, as well as approaches for integrating diamond in novel heterogenous structures will also be discussed as part of future developments.

3:45 PM EL08.12.02
Integration of CVD Diamond Heat Spreaders with High-Power Amplifier MMICs for Enhanced Thermal and RF Performance Teodoro Graziosi, Ian Friel, Michael Pearson and Vishnu Sreepal; Element Six UK Ltd, United Kingdom

CVD diamond can enable significant performance enhancements in a range of industrial applications due to its superlative material properties. However, certain diamond properties such as its chemical inertness, low thermal expansion coefficient, high stiffness and high yield stress, while desirable in some applications, can present challenges of integration in others. In this paper we present the successful die-attach integration of metallised CVD diamond heat spreaders with high power RF amplifier monolithic microwave integrated circuits (MMICs), resulting in a substantial improvement in RF performance.

Heat spreaders with room temperature thermal conductivity between 1000 and 2200 $Wm^{-1}K^{-1}$ were metallised with Ti/Pt/Au for facilitating adherence to the diamond and bonding to the semiconductor die. A nano-silver sinter paste was dispensed on each metalized diamond heat spreader using a time and pressure-controlled dispenser and gold metalized MMIC dies wet mounted to the diamond using a die-bonder. Sintering was then carried out by a pressureless sintering process under nitrogen atmosphere, using a temperature profile for drying and then sintering the silver nanoparticles. This process was repeated to attach the die-diamond stack to a CuMo cooling block.

The RF device tested was a 400 W GaN-on-SiC S-band (~3 GHz) amplifier MMIC, and the performance impact of the diamond heat spreaders was evaluated by comparing to identical amplifiers mounted directly to a CuMo block. In all cases it was found that the diamond heat spreaders led to a significant decrease in MMIC temperature and a decrease in thermal resistance of the MMIC package by up to 30%. Thermal simulations show that the amplifiers with diamond heat spreaders can be operated at their maximum junction temperature of 250°C at 10× to 100× longer pulse widths than the device without a diamond heat spreader.

These results successfully demonstrate an attachment method applicable to the integration of CVD diamond to a range of electronic and optoelectronic materials and devices.

4:00 PM EL08.12.03

Multi-Functional CVD Diamond Window for Infrared Imaging Raphaël Guillemet[1], Doriane Jussey[1], Mane-Si Laure Lee[1], Elyess Traouli[1], Brigitte Loiseaux[1], Patrick Garabédian[1], Sirine Ben Khemis[2], Emmanuel Scorsone[2], Edoardo M. Rossi[3] and Marco Sebastiani[3]; [1]Thales Research & Technology, France; [2]Commissariat à l'énergie atomique et aux énergies alternatives, France; [3]Università Roma Tre, Italy

Diamond is well known for its outstanding thermal, electrical and mechanical properties. However, it is also of great interest for optical applications. Indeed, it is for instance well suited for broadband applications of multi-band operation due to its good optical transmission over a very wide spectral range from visible to LongWave InfraRed (LWIR) 400nm-15µm. Besides, diamond structuration enables the realization of optical components such as lenses, gratings and so forth. Going further at a smaller scale in structuring diamond can also enable the realization of "artificial" materials, such as metasurfaces or metamaterials. By controlling the shape of the structures, one can control the wavefront of the light in order to achieve gratings [1], or antireflective coatings [2]. In this paper, we report on technology developments to elaborate full diamond and diamond-based active meta-surfaces, leading to robust optical windows combining broadband antireflective properties and superhydrophobic/anti-rain/anti-mist behaviors obtained by nanostructuration. A final growth of boron-doped diamond electrodes on the top of the structures enables to add anti-fouling property through electrochemical principles, driven by application of a low electrical current.

The technological process used for the fabrication of 2'' diameter LWIR windows is based on nano-imprint lithography, which is a scalable well-known lithography technique compatible with curved surfaces. Then a plasma etching step leads to periodic conical diamond structures of ~2.5µm-period and ~8µm-height. The multi-functionality of the nanostructured window is demonstrated through several characterization means:

1. The achieved double sided-transmission is measured by FTIR (Fast-Fourier Transform Infrared Spectroscopy) at ~85% in the [8µm-14µm] range, as compared to ~68% transmission in the case of flat polished diamond, showing a transmission increase up to 12% on one side at 0° of incidence,
2. The mechanical hardness of the diamond nanostructures, fabricated on silicon for MWIR (MidWave InfraRed) multifunctional optics realization, is assessed by nano-indentation and nano-scratching experiments, showing quasi-indestructibility,
3. The thermal dissipation in the diamond is observed in the MWIR range using a temperature mapping microscope, and we show an accelerated de-icing of the diamond-based window when compared to a germanium window, typically used in cryostat systems,
4. The superhydrophobic feature is validated through drop contact angle measurement. The nanostructured

diamond window is also integrated in front of a LWIR imager to characterize its benefits on imaging applications, especially during rainy conditions,

5. Finally, a growth of boron doped diamond, with a doping level compatible with optical specifications and thus inducing a very low absorption in IR regions, leads to antifouling properties. We show the efficient electro-chemical cleaning and the resilience of a diamond window, previously contaminated with a mix of oil/gasoline.

Those properties open the way to achieving the ultimate optical window that can operate in the harshest environments.

4:15 PM EL08.12.04

Diamond Growth on Ge Substrates for IR Windows Applications Sirine Ben Khemis[1], Emmanuel Scorsone[1], Raphaël Guillemet[2], Arnaud Etcheberry[3], Mathieu Fregnaux[3] and Muriel Bouttemy[3]; [1]Université Paris-Saclay, CEA-List, France; [2]Thales Research & Technology, France; [3]Institut Lavoisier de Versailles, France

Germanium (Ge) is a crucial material for LWIR (Long-Wave InfraRed) applications. Its unique combination of optical, electronic, and thermal properties makes it an ideal material for a wide range of LWIR applications, from telecommunications and imaging to advance photonic and optoelectronic devices [1]-[2]. To further enhance the optical properties, nano-structuration processes were developed to form a graded-index medium between air and the Ge substrate [3]. However, optimal optical properties alone are insufficient for most applications; mechanical resilience is also critical. Unprotected Ge substrates suffer from low mechanical resistance, brittleness, and challenges in chemical/mechanical cleaning for long-term measurements. Initial attempts to protect Ge substrates with diamond-like carbon layers were unsuccessful, as the required thickness for effective protection compromised the transmittance properties of Ge IR windows.

This study addresses these challenges by exploring diamond film deposition using microwave plasma-assisted chemical vapor deposition (MPCVD). Diamond offers a unique combination of high mechanical strength, mechanical-chemical durability, and transparency across ultraviolet, visible, and infrared ranges. However, several limitations hinder straightforward diamond deposition on Ge substrate: (i) Ge's low melting point, leading to thermal damage and cracking or delamination of the film, (ii) high thermal expansion mismatch between the two materials causing spontaneously diamond layer delamination, and (iii) poor adhesion of the diamond film due to Ge being a non-carbide forming material.

To overcome these limitations, intermediate silicon nitride thin film (SiNx) is used in this present work. Our investigation will focus on studying the efficiency of SiNx to protect Ge substrate and enhance the adhesion of the diamond film. We focus also on determining the optimal SiNx thickness requisite for achieving the diamond adhesion while preserving optical transparency. Extensive surface and interface characterization, including scanning electron microscope (SEM) and x-ray photoelectron spectroscopy (XPS), were employed for this purpose. Moreover, optimizing the diamond film quality and thickness is essential. This includes controlling deposition parameters to ensure uniform coverage and mitigating thermal stress to avoid cracking or delamination. These steps are crucial for maintaining the integrity of the Ge substrate and enhancing the performance of the optical devices. Finally, nanostructured Ge surfaces were developed in this work using nano-imprint lithography, resulting in periodic conical diamond structures. This study delves into the efficiency of the diamond deposition on a nanostructured Ge substrate for a better optical performance.

4:30 PM EL08.12.05

Integrated Microwave Coupling Device for Scanning Nitrogen-Vacancy Magnetometry Jodok Happacher, Juanita Bocquel, Brendan Shields and Patrick Maletinsky; Universität Basel, Switzerland

Scanning Nitrogen-Vacancy (NV) magnetometry has emerged in recent years as a leading technique for high-sensitivity nanoscale magnetic imaging. Efficient and robust delivery of microwave (MW) quantum control signals to NV centers in diamond scanning probes remains a significant challenge, in particular in cryogenic environments. Reducing the heat load and enabling a larger accessible sample space while achieving an optimized spin manipulation is crucial to widen the scope of applications.

Here, we present the design and the implementation of a new type of scanning NV magnetic imaging probe. The microwave coupling loop is directly integrated onto the scanning probe holding structure thereby eliminating the need for external MW delivery solutions. In this geometry, the NV sensor is in close proximity and at a constant distance to the coupling loop due to the rigid attachment. The microwave power required for spin manipulation is thereby decreased and made independent from the scanning probe position over the sample, two key aspects for imaging with good magnetic sensitivity. The device is created through a subtractive manufacturing process followed by the evaporation of a conductive material on its top side to form the MW stripline and loop. This original approach is simple, highly reproducible, and more importantly enables large-scale production as it does not rely on lithography. The characterization and the proof-of-principle scanning NV magnetometry experiment demonstrate that this new devices can outperform state-of-the-art MW delivery solutions, making it a compelling alternative. This holds for low-temperature experiments but is also anticipated to generally reduce the technical barriers for the broader adoption of NV magnetometry across a larger research community.

We acknowledge financial support through the NCCR QSIT (Grant No. 185902), the Swiss Nanoscience Institute, and through the Swiss NSF (Grant No. 188521).

4:45 PM EL08.12.06

Miniaturising the NV$^-$ Diamond Maser, Towards Faster and Quantum-Noise Limited Amplification of Qubit Readout at Room Temperature Wern Ng, Yongqiang Wen, Neil M. Alford and Daan M. Arroo; Imperial College London, United Kingdom

Masers, the microwave analogue of the laser, can amplify the weakest microwave signals which would allow them to revolutionize medical diagnostics and mobile communications. Previous studies explored them as low noise amplifiers in sensing and cryogen-free noise reduction through absorbing thermal photons. However, to this day continuous-wave masers are still trapped in specialist laboratories due to requiring large electromagnets, cryogenic cooling, and vacuum chambers.

We present the first room-temperature continuous-wave maser that can be transported easily out of the laboratory and onto the benchtop. The device uses an NV$^-$ diamond gain medium that has been manufactured with

isotopic purity to achieve significantly longer coherence times that allow it to sustain masing under more compact and less uniform magnet systems. We then provide further avenues towards miniaturisation through developing methods to reduce the magnetic field requirements of the gain material with angular orientation. Finally, new developments towards lower frequency masing with diamond, to match common frequencies used by 5G telecommunications and transmon qubit readout, will be discussed.

This lays the foundations for reducing the footprint of the magnet systems in the future, as well as spurs the search for new materials that could mase at different microwave frequencies, thus widening the applicable bandwidth of ultra-sensitive sensing which masers can provide. This opens opportunities for other research groups and industries to use its exquisite low-noise capabilities in mobile communication and the growing quantum computing field, which relies on faint microwave signals for qubit readout.

SESSION EL08.13: Laser Modification of Diamond
Session Chairs: Shannon Nicley and Jason Smith
Thursday Morning, December 5, 2024
Sheraton, Second Floor, Back Bay A

9:00 AM *EL08.13.01

Nanotexturing of Diamond Surfaces via Ultra-Short Laser Pulses Inducing Enhanced Optical and Electronic Properties Alessandro Bellucci[1], Matteo Mastellone[1], Riccardo Polini[2], Stefano Orlando[1], Antonio Santagata[1] and Daniele M. Trucchi[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Roma Tor Vergata, Italy

One of the main advantages of using ultra-short laser pulses is the capability to minimize unwanted thermal effects during surface material processing, instead occurring when longer laser beam pulses are employed. Indeed, ultra-short laser pulses, delivering extremely high radiation powers, trigger non-linear effects like multiphotonic absorption which lead towards a strong laser-matter interaction, even for dielectrics and wide bandgap semiconductors, such as diamond.
In the last decades, the use of ultra-short laser pulses paved the way for accurate diamond micro- and nano-structuring, thanks to the effective formation of Laser-Induced Periodic Surface Structures (LIPSS). The creation of subwavelength LIPSS through lasers allows a straightforward engineering of the diamond's electronic bandgap that is crucial for developing diamond-based optoelectronic devices.
A specific case of surface texturing with a defined subwavelength periodicity of the diamond surface is represented by the development of “black diamond” films, i.e., diamond films with drastically enhanced optical and electronic properties, developed by the authors’ group.
The texturing at the nanoscale and the significant improvement in the photoelectronic sensitivity for photons with sub-bandgap energy open the applicability for visible wavelength band optics, where the exceptional resilience of diamond is an added value. In this framework, the most direct application of surface-treated thin diamond film at the nanoscales is as antireflection coatings and selective absorbers for thermal solar applications.
Regarding specific applications, our group has proposed LIPSS on diamond for the development of high-temperature solar cells, as well as advanced opto-electronic platforms and photo-electro-chemical devices. With this aim, a strategy of defect-engineering is pursued for the fabrication of black diamond-based devices, with the possibility of locally controlling the optical, electronic, and chemical properties of diamond opening new perspective to functional enhancements of wide band gap materials.

9:30 AM EL08.13.02

Laser-Induced Graphitization Interior to Bulk Diamond Forming Monolithic Electronic Structures Travis C. Wade[1,2], Glenn Hess[1], David Kerns[1], Jimmy Davidson[1], John Fraley[3], Brian Canfield[4], Trevor Moeller[4], Steve May[5] and Mark Viste[5]; [1]International Femtoscience Inc., United States; [2]Evolve Diamonds LLC, United States; [3]Missionshire Advanced Technologies, United States; [4]University of Tennessee Space Institute, United States; [5]Medtronic, United States

Diamond is a transparent ultra-wide bandgap insulator which has many unique properties (e.g., high dielectric strength, exceptional thermal conductivity, chemical inertness, etc.). As a metastable allotrope of carbon, diamond's sp3-hybridized lattice can be transformed into sp2-hybridized graphite through the selective application of localized heating. Since diamond is transparent in a wide wavelength range (from ultraviolet to radio waves), laser radiation can be focused not only on the crystal surface but also at any point in its bulk. The techniques of laser microstructuring of diamond crystals make it possible to form graphitized microstructures of different shapes in their bulk. The influence of the processing parameters on the internal structure and conductivity of laser-modified material in diamond bulk is analyzed.

Two laser wavelengths, two optical configurations, and variable energy densities were precisely applied to single crystal substrates of CVD and HPT origins and varied purity levels. The nature of the graphitization as dependent on Gaussian beam and Bessel beam application was examined visually and electrically. The localization of laser graphitization associated with the Gaussian beam and the continuum nature of conversion of the Bessel beam is reported. Dimensionally equivalent 'wires' and 'plates' of graphitic regions were created in the interior of the diamond achieving relevant electronic structures. For example, parallel plates of conductive graphitized regions sub-micron thick and > 1,000 microns square, with varying spacing and area, were created. Parallel plates with spacings as small as 1 micron were formed. These parallel plates were laser formed vertically and horizontally to the largest diamond surface resulting in capacitors which were evaluated electrically and the capacitive values are reported.

The aforementioned properties of diamond, particularly in single crystal, are of keen interest given the anticipated high breakdown voltage of diamond. The methods and materials described extrapolate to capacitors of unparalleled energy density.

9:45 AM EL08.13.03

Modeling Fs-Laser-Induced NV Centers Generation in Diamond Lucas Nolasco, Lucas Andrade, Sebastiao Pratavieira, Sergio Muniz and Cleber Mendonca; University of São Paulo, Brazil

The nitrogen-vacancy (NV) color center in diamond is under investigation for quantum applications due to its advantageous properties, including photostability, long coherence time, single-photon emission at room temperature, and optically detectable and controllable spin states. Various techniques have been studied for the controlled formation of NV centers, with femtosecond laser micromachining standing out for its micro/nanometric precision in creating microstructures within the surface or volume of materials. Such high precision is due to nonlinear optical absorption, which is confined to the laser focal volume, and minimized thermal effects, as the femtosecond laser pulse duration is shorter than the molecular vibrational period. This method produces vacancies in the lattice, which when near substitutional nitrogen atoms, generate NV centers. Thus, micromachining can accurately produce color centers in specific locations. In this study, fs-laser-induced generation of nitrogen-vacancy centers in CVD diamond was performed at distinct fluences, pulse durations (185 fs – 1 ps), and wavelengths (1030, 515 and 343 nm) to identify the optimal conditions for its creation, with implications for developing novel quantum technologies. The fs-laser processed samples were analyzed by confocal microscopy, with the sample excited at 543 nm to identify the NV^- zero-phonon line emission at 637 nm. From the confocal microscopy images, it was possible to determine the NV center defect area as a percentage of the total area from each fabricated microstructure. Thus, it was possible to analyze the effect of experimental conditions on the concentration of new defects. We observed the generation of NV centers is proportional to the peak laser fluence and inversely proportional to the pulse duration and wavelength. A three-state model based on the diamonds nonlinear excitation was used to interpret the observed results, from which it was possible to determine the effective multi-photon absorption cross-section and the saturation fluence for colors center generation for each excitation wavelength. Therefore, our results shed light on the understanding and controlling of NV centers generation in diamond under fs-laser irradiation.

Nanodiamond-Based Quantum Sensing of Mechano-Regulated Metabolic Plasticity in Cardiac Fibroblasts
Aldona Mzyk[1], Ezgi Yilmaz[1], Abigäel Dezerces[1], Arthur Dervillez[1], Agostina Crotta Asis[2], Giovanni D'Angelo[2] and Kirstine Berg-Sørensen[1]; [1]Technical University of Denmark, Denmark; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Quantum sensors based on single electronic spins, or small spin ensembles in diamonds, can deliver nanoscale spatial resolution in detecting magnetic fields. We have only just started scratching the surface of the application potential of quantum technology in biomedical research and development. Our group has been developing novel nanodiamond-based quantum sensing protocols to investigate mechano-regulation of metabolism at sub-cellular level. In this study, we have focused on the mechano-regulation in the heart scar formation. The myocardial scar formation known as cardiac fibrosis is a key contributor to heart failure. Anti-fibrotic therapies are still under development due to limited understanding of molecular processes behind scar formation. The cardiac fibrosis starts with changes in the mechanical properties of a heart extracellular matrix (ECM), which leads to transdifferentiation of cardiac fibroblasts (quiescent stage) into myofibroblasts (activated stage). We have very little knowledge about how mechanical stimuli govern metabolic plasticity of these cells. Free radicals (FRs), a class of reactive molecules with an unpaired electron, have emerged to be crucial for intracellular signalling. However, as FRs are short lived and difficult to detect with the state-of-the art-methods, therefore their role in cardiac metabolic plasticity remained unknown. In our research, we aimed to reveal the role of FRs in plasticity of cells in response to mechanical stimuli using a quantum sensing technique called T1 relaxometry combined with optical trapping (fluorescent nanodiamonds were used as sensors) and complemented by lipidomics. We have studied how mechanical stimuli influence FR generation, looked at the correlation between FRs level and viscoelastic properties of mitochondria network as well as the lipids profile across the population of cardiac fibroblasts. As a result our research shed light on the mechanobiology of the heart scarring process.

11:00 AM EL08.14.02
Fluorescence Traceable Carboxyl Silicon Carbide Nanoparticle-Mediated Gene Delivery System

Development and Application Chia-Yu Chang[1,1], Yu-Chuan Liang[2], Szabolcs Czene[3], David Beke[3,4], Adam Gali[3,5,6] and Chia-Ching Chang[1,1,2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Academia Sinica, Taiwan; [3]HUN-REN Wigner Research Centre for Physics, Hungary; [4]University of Notre Dame, United States; [5]Budapest University of Technology and Economics, Hungary; [6]MTA-WFK "Lendület" Momentum Semiconductor Nanostructures Research Group, Hungary

Silicon carbide (SiC) nanoparticle is similar to nano-diamonds with a sp^3 core structure. Similarly, SiC nanoparticles are biocompatible materials that may be used for biomedical applications. In this study, two-nanometer scale carboxyl modified SiC (c-SiC) nanoparticles were conjugated with His-tag containing red fluorescence protein, His-mCherry-SiC, and formed a nano-complex. Furthermore, the plasmid DNA molecules those contained the fusion gene of green fluorescence protein and partial sequence of hemagglutinin (HA) were conjugated with the His-mCherry-SiC nano-complex and formed DNA-His-mCherry-SiC nanoparticle. The HA peptide fragment may be used as antigen to induce the anti-avian flu antibody. Due to the ultra-small size of this nanoparticle, it can be uptake by cell easily. Therefore, SiC nanoparticles were transfected into primary chicken embryonic fibroblasts DF-1 cells. The GFP-partial HA fusion protein can be found inside the DF-1 cell. At the same time, this fusion protein can be secreted into cell culture medium, as well. Therefore, this system may be used for avian flu vaccine applications. In summary, we have developed a gene delivery system can be used for gene editing and delivery with high efficiency.

11:15 AM EL08.14.03

Study on Nanodiamond for Drug Delivery in 3D Cellular Models C.Y. Huang, Y.J. Su, Y.C. Lin, J. R. Lin, C.C. Chang, C. H. Tsou and Chia-Liang Cheng; National Dong Hwa University, Taiwan

Nanodiamond (ND) and ND-based hybrid complexes are promising for drug delivery due to their biocompatibility, variable sizes, structure, surface chemistry, and physical properties. Recent works have demonstrated exciting advantages of ND for theranostic applications, including bio imaging and drug delivery. ND's surface chemistry allows advanced methods of functionalization with the molecules of interest extending the applications, for example, ND enhanced drug delivery and efficiency has been observed, including effects on chemoresistant tumors and direct delivery across blood-brain barrier.

In this presentation, ND-HSA-DOX (Nanodiamond-Human Serum Albumin-Doxorubicin) complexes are synthesized to form a stable ND dispersion and tested in both 2D and 3D cellular models. When drug molecules are conjugated onto ND, the composed ND-X complexes are demonstrated in a 3D cellular model (multicellular tumor spheroid, MCTS), consisted of large collection of cells in a three-dimensional format extend about 0.7 mm in diameter; resemble the configuration of a tumor, ideal for evaluating the cytotoxicity and cytotoxicity mechanism of ND-drug complex and their efficacy. The drug molecules can be released in a pH dependent manner and enhanced drug efficacy can be achieved. Although this work presents only few examples, they demonstrate wide perspectives of development of ND with new synergy properties and of their use. In this study, the mechanism of ND-drug complex penetrating into the 3D tumor spheroid will be discussed.

Photocatalytic Membranes for Solar Fuel Generation Prashant Kamat; University of Notre Dame, United States

Semiconductor nanoparticles embedded in polymer matrix offer a convenient approach to navigate the electron and hole flow in a photocatalytic membrane. In addition, it also facilitates separation of reduction and oxidation products. We have embedded sevral semiconductor nanoparticles (CdS, $AgInS_2$ and In_2S_3) in a Nafion membrane to induce photocatalytic reactions using visible light. In additon we have also deposited cocatalysts such as Pt, Pd on these membranes to facilitate production of H_2. By inserting the photocatalytic membrane in an H-cell, we can separate the oxidation and reduction products and track the electron flow using steady state photolysis and transient absorption spectroscopy. Using viologen as a probe we have obtained insight into the interfacial electron transfer processes. Directing such vectorial charge transfer in a photocatalytic membrane will be useful in suppressing undesired side reactions (e.g. reoxidation of a reduced product) and facilitating product separation. This approach offers a convenient way for photocatalytic generation of solar fuels.

11:00 AM EN01.01.02
Surface Restructuring and Ion Exchange in Molten Salts for Enhanced $SrTiO_3$ Water Splitting Photocatalysts
Mingyi Zhang[1,2], Paul A. Salvador[2] and Gregory S. Rohrer[2]; [1]Pacific Northwest National Laboratory, United States; [2]Carnegie Mellon University, United States

Semiconductor-based photocatalysis offers a promising method for generating solar fuels by directly converting water into hydrogen and oxygen under light exposure. However, its commercial application is limited by poor efficiency, primarily due to the recombination of photogenerated charge carriers and surface back reactions. Al-doped $SrTiO_3$ synthesized in a $SrCl_2$ melt, stands out as one of the most efficient photocatalysts for water splitting, exhibiting a quantum yield close to unity. Despite extensive discussions on the effect of Al^{3+} doping, the role of the molten $SrCl_2$ has yet to be fully understood. By analyzing the surface structure and chemistry of $SrTiO_3$ catalysts with AFM and XPS, we found that the treatment with $SrCl_2$ melt leads to a more negatively charged surface, attributed to an increased concentration of surface hydroxyl groups. The resulting potential drop varies with crystallographic orientation. Consequently, the potential difference between the (1 0 0) and (1 1 0) surfaces increases from 0.07 V to 0.21 V, generating a significantly stronger electric field within the particle and enhancing charge separation. Furthermore, we present a novel strategy for designing $SrTiO_3$ photocatalysts based on ion exchange reactions between perovskite oxides and molten salts. In this process, the A-site cations in oxides can be exchanged with alkali earth cations in molten salts. Notably, $SrTiO_3$ derived from $BaTiO_3$ via the reaction, $BaTiO_{3(s)} + SrCl_{2(l)} = SrTiO_{3(s)} + BaCl_{2(l)}$, demonstrates exceptional photocatalytic performance (AQY = 11.4% under 380 nm) and produces hydrogen from pure water at a rate twice that of conventional $SrTiO_3$ without ion exchange. The enhanced photocatalytic efficiency is attributed to its nonequilibrium structure, featuring a Sr-excess phase near the surface, which compensates for donor defects that typically act as charge traps and recombination centers. Our results highlight the potential of using molten salts to design and synthesize highly efficient photocatalyst materials.

11:15 AM EN01.01.03

Nano-Architecture Based Improvement in Photocatalytic Activity of Near-Infrared Range Absorbing Nanocomposites Syed Abdul Basit Shah[1], Luca Cozzarini[1], Rostyslav Lesyuk[2], Christian Klinke[2], Maria V. Diamanti[3] and Vanni Lughi[1]; [1]Università degli Studi di Trieste, Italy; [2]Universität Rostock, Germany; [3]Politecnico di Milano, Italy

This study sheds light on our efforts of harvesting and utilizing the near infrared range (NIR) solar energy for photocatalytic activity. In addition, the effect of nanoarchitecture on the photocatalytic activity of prepared nanocomposites was also studied. The photocatalytic activity of TiO_2 nanopowders, nanotubes and nanosponges were compared under different configurations, such as loading of II-VI semiconductor quantum dots (core-coreshell structures), perovskite nanocubes and nanoplatelets, as well as for varying illumination conditions. The as prepared nanocomposites were characterized by steady-state and time resolved photoluminescence and fluorescence life-time imaging to study the charge carrier dynamics. Furthermore, TEM and SEM were employed to observe the morphology and XRD to study the phase structure. The photocatalytic activity of prepared nanocomposites was tested under various illumination conditions (solar simulator 300 – 800 nm) for hydrogen evolution and (650 nm, direct-diffused sunlight) for degradation of aqueous Rhodamine B dye (RdB) to evaluate the performance and confirm the charge transfer. This work could be considered as essential to understand and control the charge carrier dynamics and photocatalytic activity through the nanoarchitectutre design. It could serve as a reference for architectural development at the nanoscale for future applications involving a wide range of nanomaterials.

11:30 AM EN01.01.04

When Free Radicals Meet the Solid, Ion and Gas in Photochemical Methane Oxidation to Methanol Gang Wan and Arun Majumdar; Stanford University, United States

C-H bond oxidation in methane under mild conditions constitutes long-standing challenges that are of fundamental and technological importance, from biological to industrial and environmental. Methanol is a key vector to fuel a future. Currently, the methane-to-methanol conversion relies on energy intensive processes involving a syngas intermediate. In recent decades, intensive efforts have been focused on developing direct methane-to-methanol conversion as an alternative and more sustainable pathway. Free radicals are one of key mediators underpinning many active sites in thermal catalysis and the enhancement effects induced by light and electric fields, including methane to methanol oxidation. However, it remains unclear how free radicals as active species mediate the C-H bond activation and dictate the products distribution.

In this talk, we combine rational design of TiO_2-noble metal composite photocatalysts, experimental design of methane oxidation experiments with the in-situ free radical detection. Our results unravel interactions between these free radicals and the solid co-catalysts, ions, and gas molecules in water, as well as their impact on

methane removal and its selective oxidation. Our studies highlight the neglected while important interplay between photogenerated radicals and co-catalysts, ion impurities, and gas molecules in promoting methane removal and controlling products distribution. Furthermore, we report an inherent trade-off in both photochemical oxidation of methane to methanol. A new design principle featuring isolating different reaction steps is developed to circumvent this trade-off. Furthermore, our findings and strategies are generally applicable to thermochemical methane oxidation using H_2O_2.
Our molecular-level insights into free-radical-mediated photochemical and thermochemical methane oxidation are expected to promote methane removal and its selective functionalization and offer informative design principles for chemical bond activations driven by light, heat, and electric fields.

11:45 AM EN01.01.05
Highly Selective Photocatalytic Methane Coupling by Au-Modified Bi_2WO_6 Muchun Fei[1], Benjamin Williams[1], Lizhuo Wang[2], Haoyi Li[1], Yucheng Yuan[1], James Wilkes[1], Tianying Liu[1], Yu Mu[1], Jier Huang[1], James Nyakuchena[3], Jun Huang[2], Wei Li[1] and Dunwei Wang[1]; [1]Boston College, United States; [2]The University of Sydney, Australia; [3]Marquette University, United States

Photocatalytic oxidative coupling of methane (OCM) to ethane promises a route to value-added C_2 products from an abundant and low-cost feedstock. However, selective activation of C-H bond of CH_4 without overoxidation to CO_2 has been a major challenge. An important reason for overactivation of CH_4 is the fact that the BDEs of the subsequent C-H bonds are lower than that of the initial C-H bond. Thus, when thermal energy is applied to overcome the activation barrier, it is often exceedingly difficult to activate only the first C-H bond. Photocatalysis can be performed at significantly lower temperatures and addresses this concern. However, the cooperative interactions between the metal co-catalyst and the oxide photocatalyst, which are necessary for elucidating the variations in reactivity observed on different oxide photocatalysts, remain relatively unexplored. Another inspiration for our work revolves around the correlation between the nature of the oxide support (and/or catalyst) and overoxidation in selective oxidative reactions. It has been acknowledged that the surface lattice oxygen replenished from oxygen dissociation acts as a relatively mild oxidant, preventing overoxidation in preferential oxidation of carbon monoxide (PROX). Inspired by previous studies, we established a correlation between improved C_2H_6 selectivity and production with the nature of the photocatalyst, which should feature more facile release of surface lattice oxygen and, consequently, the easier formation of oxygen vacancies (O_v) on the oxide surface. Specifically, we present the use of Au-modified Bi_2WO_6 as a prototypical photocatalyst, demonstrating high performance OCM through photocatalysis. A C_2H_6 production rate of 1.69×10^3 $\mu molg^{-1}h^{-1}$ with approximately 85% selectivity was achieved which ranks among the top-performing photocatalytic OCM systems. Efforts were also made in establishing the correlation between improved OCM performance and photocatalyst system by examining the nature of the oxide photocatalyst. Our findings indicated that the oxygen within the oxide surface, likely contributed and/or later regenerated from the adsorbed oxygen at the vacancy sites, afforded a desired reactivity to selectively activate the C-H bond without significant overoxidation. Surprisingly, it was revealed that the Au co-catalyst plays dual roles of activating the oxide photocatalyst for enhanced CH_4 activation and promoting C-C coupling to yield C_2H_6 as the main product.

Metal-Free Light Harvesters for Sustainable Solar Fuel Production Demetra S. Achilleos; University College Dublin, Ireland

The accelerated consumption of fossil fuels and the concomitant rise in greenhouse gas emissions emphasize the need for transitioning towards renewable “green” resources. Solar-driven photocatalysis is a promising approach for mitigating simultaneously both the energy and environmental concerns.[1] However, the development of economically and environmentally sustainable processes creates the pressing need for new materials of low cost and toxicity, photocatalysts and co-catalysts, which enable and maintain substantial solar energy conversion efficiencies.

Carbon dots (CDs) and carbon nitride (CNx) can efficiently serve as metal-free photocatalysts for this purpose since they fulfil these requirements.[2-6] In particular, they are hydrophilic materials of low toxicity which are chemically and photochemically robust, can be synthesized at low cost, and show optimum photocatalytic properties upon pre-/nano-designed synthesis. In this work, we describe the synthesis of CN_x and CDs from low-cost organics and/or Earth abundant waste (circular economy), the structure of which bestow the derived photoabsorbers with distinctive photocatalytic performances. These light harvesters upon solar light irradiation, when combined with noble-metal free co-catalysts in aqueous photocatalytic systems, not only facilitate “green” fuel synthesis but also waste utilization to synthesize value-added chemicals. The use of waste materials also eliminates the need for additional sacrificial reagents traditionally used in great excess, which add to the overall cost of the process and result in toxic by-products.[7] We anticipate that this approach could be a breakthrough in the development of “green”, scalable, economically and environmentally sustainable photocatalytic systems for solar fuel production.

2:00 PM EN01.02.02

Photoreforming of Plastic Waste to Hydrogen Using Single-Atom Anchored Pt Decorated Graphitic Carbon Nitride Yin-Hsuan Chang[1], Ting-Han Lin[1,2], Jia-Mao Chang[1], Ciao-Yun Huang[1], Ying-Han Liao[1] and Ming-Chung Wu[1,2]; [1]Chang Gung University, Taiwan; [2]Chang Gung Univesity, Taiwan

Advancements in catalytic technologies—such as electrocatalysis, thermocatalysis, and photocatalysis—offer promising alternatives to traditional waste disposal methods like landfilling, incineration, and mechanical recycling. Among these, photocatalysis stands out for its applications in sustainable waste management and renewable energy generation. A significant breakthrough in this area is photo-reforming, which transforms plastic waste into hydrogen fuel using sunlight. This method is especially appealing as hydrogen, with its high energy density, is a green energy carrier for transport, heating, and chemical synthesis, contributing to net-zero emissions and a more sustainable energy system.

Graphitic carbon nitride (g-C_3N_4) is notable as a semiconductor with a relatively narrow bandgap of 2.7–2.8 eV, aligning the energy levels of its valence and conduction bands to meet the thermodynamic requirements for water splitting and photoreforming reactions. The structure of g-C_3N_4 is based on a conjugated polymeric system composed of tri-s-triazine units, featuring a two-dimensional layout that promotes electron mobility and enhances the separation of charge carriers within composite materials.

In this study, bulk g-C_3N_4 was initially synthesized using a high-temperature thermal polymerization method. Urea was heated to 550 °C for 3 hours at a 2.0°C/min heating rate. After cooling, the product was acid-washed with HCl and then rinsed with deionized (DI) water until neutral. To obtain g-C_3N_4 nanosheets (C_3N_4-NS), exfoliation of bulk g-C_3N_4 was performed using an ultrasonic processor with isopropanol as a solvent. For the decoration of Pt single atoms, the precursor solution was prepared by dissolving $PtCl_2$ and NaCl in DI water, then dried in a water bath.

Various polymers were tested for photoreforming using the C_3N_4-Pt photocatalyst to establish photocatalytic performance. Photoreforming of PET, PVC, PMMA, PP, and PS was first evaluated in a sealed photocatalysis system equipped with a xenon lamp. Due to these polymers' chemical inertness and insolubility, they were pretreated in a NaOH solution (stirring for 48 hours at 40 °C) before photoreforming, which contributed to the depolymerization of plastics into their corresponding constituent monomers. Subsequently, the supernatant containing water-soluble monomers was collected and used as feedstocks to initiate the photoreforming reaction. After 12 hours, PET photoreforming showed the highest hydrogen production of 533.18 μmol g^{-1} h^{-1}. This high efficiency can be attributed to the fact that the ester bonds in the PET polymer chain are easily broken under alkaline conditions, forming terephthalic acid (TPA) and ethylene glycol (EG). Exploring the photocatalytic performance across a range of polymers, including PET, PVC, PMMA, PP, and PS, for photoreforming using the C_3N_4-Pt photocatalyst highlights the potential of this technology for sustainable plastic waste management.

The significant hydrogen production observed in PET photoreforming underscores the effectiveness of this approach. The application of photocatalysis to plastic waste recycling presents a promising avenue for converting a wide range of polymers into valuable chemicals and fuels. Future advancements in this field will likely focus on optimizing catalyst design, reaction conditions, and pretreatment processes to enhance efficiency, selectivity, and applicability to various types of plastic waste, paving the way for more sustainable and circular approaches to plastic use and disposal.

2:15 PM EN01.02.03

Pd Single Atoms on g-C_3N_4 Photocatalysts—Minimum Loading for a Maximum Activity Jeyalakshmi Velu[1,2], Nawres Lazaar[2], Shanshan Qin[2] and Patrik Schmuki[2,3]; [1]University of Chemistry and Technology, Prague, Czechia; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [3]Regional Centre of Advanced Technologies and Materials, Czechia

The pursuit of sustainable hydrogen production via photocatalysis has accelerated, with precious single atom catalysts (SACs) are increasingly studied as co-cocatalysts to elevate the efficiency of photocatalyst while reducing precious metal consumption. In this study, we introduce a novel method for anchoring palladium single atoms (Pd SAs) on exfoliated graphitic carbon nitride (g-C_3N_4) using a highly dilute palladium precursor through a 'Reactive Deposition Approach'. This approach demonstrates that a remarkably low Pd loading of 0.05 wt% (equivalent to a metal density of 10^6 μm^{-2}) is sufficient to achieve excellent photocatalytic activity, characterized by minimum charge transfer resistance and maximum hydrogen production efficiency. Highly dispersed Pd SAs has been identified by various characterization techniques, ie., HRTEM, EDS mapping and X-ray photoelectron spectroscopy.

The Pd SAs/ system exhibits a hydrogen production rate of 0.22 mmol/h/mg of Pd under 65 mW/cm^2, 365 nm LED illumination, with stable performance over time. This rate is nearly 50 times higher than that of decorated with Pd nanoparticles (1.5 wt%), highlighting the superior efficiency of single-atom catalysts at a fraction of the metal loading. The substantial increase in catalytic activity is attributed to optimized electron transfer pathways and the higher number of active sites provided by atomically dispersed Pd on the g-C_3N_4 substrate.

A key feature of this work is the successful anchoring of Pd SAs using the reactive deposition approach, which prevents agglomeration and ensures a high degree of atomic dispersion. This strategy is critical in reducing charge transfer resistance and enabling more efficient electron transfer between g-C_3N_4 and Pd SAs. The dispersed Pd atoms serve as highly effective catalytic sites, promoting proton reduction and facilitating rapid hydrogen evolution reactions (HER). Furthermore, the strong interaction between Pd atoms and the g-C_3N_4 structure stabilizes the single atoms, preventing nanoparticle formation and ensuring every Pd atom contributes fully to the catalytic process.

These findings offer a sustainable and cost-effective pathway for designing SAC-based photocatalysts the maximize both performance and co-catalyst's atom efficiency, advancing the development of hydrogen production technologies. Future work will explore the application of this strategy to other co-catalytic systems and photocatalytic processes, with the goal of furthering progress in sustainable energy.

2:30 PM EN01.02.04

Boron (B)-Doped Carbon Nitride (gC_3N_4) Materials for Photocatalytic Applications Ioanna Itskou[1], Andreas Kafizas[1,1], Sharminaz C. Sageer[2,2], Daniel M. Dawson[2,2], Irena Nevjestic[1,1], Catriona M. McGilvery[1], Gwilherm Kerherve[1], Sandrine Heutz[1,1], Sharon E. Ashbrook[2,2] and Camille Petit[1]; [1]Imperial College London, United Kingdom; [2]University of St Andrews, United Kingdom

Graphitic carbon nitride (gC_3N_4) has been deployed in various applications, including photocatalysis. Among photocatalytic reactions studied, H_2O splitting for the production of H_2 is the most common one, and carbon nitride can serve as pure catalyst, cocatalyst, catalyst support, or part of a heterojunction. Photocatalytic CO_2 reduction is another reaction of interest, combining utilisation of CO_2 emissions and production of sustainable fuels and chemicals. Research on the use of carbon nitride for this purpose is less extensive, and almost always includes the use of dopant materials or heterojunctions. For instance, the role of boron (B) as dopant for gC_3N_4 has started to be explored but mostly for application in zinc batteries, photodegradation of organics, and photocatalytic H_2O splitting/H_2 production. Only a couple of studies have investigated the role of B-doping on CO_2 photoreduction and B-gC_3N_4 seems superior to the pristine material, for all reactions studied. Yet, the relationship between the structure/chemistry of B-doped gC_3N_4 on its chemical, sorptive and optoelectronic properties, as well as CO_2 photoreducing activity remains largely unknown. If understood, a greater control of and more efficient B-doped gC_3N_4 could be reached.

In our study, we aim to bridge this knowledge gap in (photo)chemistry of B-gC_3N_4. We produced two sets of B-doped gC_3N_4 samples through calcination of melamine mixture with varying amount of either amorphous boron, or boric acid. Once synthesised, we characterized our samples using: XPS, solid-state NMR, XRD, (S)TEM, EELS, N_2 sorption (77 K), CO_2 sorption (288, 298, 308 K), DRS UV-Vis, steady-state PL, TAS and EPR. We confirmed the successful B-functionalisation of gC_3N_4 using both B precursors (from 0.5 to 11 at% B), and suggest the choice of precursor affects the final chemical structure. We could control better the amount of doping using boric acid, owing to its greater reactivity with melamine. Introducing B causes oxygen (O) to be also included in the structure forming B-O bonds. Although we spot homogeneity of B-doping in bulk, heterogeneities in both morphology and elemental dispersion occur in the nm to μm scale. High B content results in increased BET area and enhanced CO_2 adsorption. B-doping lowers the band edges, without changing the bandgap of the material. All samples show similar tri-s-triazine structure and light absorbance, however different relaxation patterns and creation of mid-gap states. The samples share similar charge carrier lifetimes and kinetics, even though B-doping up to 5 at%

increases the amount of excitons. We noticed differences in the amount of unpaired electrons, which could be linked to the chemical structure changes caused by B integration from different precursors. Most of the samples show change in EPR signal intensity before and after irradiation, an indication of excited electrons. We have also tested our materials for CO_2 photoreduction and photocatalytic NO_x removal; in both applications, our materials exhibit different photoactivity and product selectivity than what is reported in literature. Our study provides for the first time a comparison between (i) B precursors and (ii) B-doping amounts for B-doping of C_3N_4, and thorough investigation of their effect on the material's chemical, sorptive and optoelectronic properties, with differences to literature.

2:45 PM EN01.02.05

Coalescing Solar-to-Chemical and Carbon Circular Economy—Mediated by Metal-Free Porphyrin and Triazine-Based Porous Organic Polymer Under Natural Sunlight Neha Saini, Deepak Kumar Chauhan and Kamalakannan Kailasam; Institute of Nano Science and Technology, India

Harnessing renewable solar energy to valorize CO_2 has emerged as a promising and enduring solution to address energy and environmental challenges. However, achieving high efficiency and selectivity in the photocatalytic reduction of CO_2, without relying on metals, photosensitizers, or sacrificial agents, remains a formidable hurdle. In the continuing pursuit of sustainable synthesis, in this study, we present the development of a novel metal-free heterogeneous photocatalyst, composed of porphyrin and a triazine-based porous organic polymeric network (TPT-porp) for the photocatalytic reduction of CO_2 coupled with oxidative benzylamine homocoupling under natural sunlight for the first time. Astonishingly, we achieved an exceptional CO production rate, reaching 1786 $\mu mol\ g^{-1}\ h^{-1}$, with an outstanding selectivity of >90% and selective oxidation of benzylamine, yielding N-benzylbenzaldimine with a conversion of 65% and selectivity exceeding 98% in 6 h of irradiation under natural sunlight. This unique approach represents the effective utilization of e^- and h^+ to promote the overall (dual) photoredox process, making the process atomically viable and sustainable. A remarkably high AQY of 9.34% (at $\lambda = 430$ nm) and a solar-to-fuel conversion of 0.24% was attained for CO production. A series of controlled experiments, EPR studies, $^{13}CO_2$ labelling experiments, and DFT studies were employed to unravel the underlying mechanism of this dual photoredox process. In summary, our pioneering study opens up unprecedented avenues for the investigation of metal-free heterogeneous photocatalysts capable for dual photoredox processes, and these findings offer tremendous potential for advancing the field of sustainable photocatalysis.

Toward Practical Photoelectrochemical Fuel Production Ji-Wook Jang; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Photoelectrochemical water splitting technology, mimicking natural photosynthesis, stands out as one of the most promising technologies for solar hydrogen production. For this technology to become commercially viable, it must meet three critical criteria: efficiency, stability, and scalability. Notably, the solar-to-hydrogen conversion (STH) efficiency must reach at least 10%. Two primary strategies are key to achieving these goals. The first strategy involves enhancing the efficiency of stable inorganic materials such as TiO_2, Fe_2O_3, and $BiVO_4$. The second strategy focuses on stabilizing high-efficiency materials. In this presentation, I will explore both approaches, with particular emphasis on the latter. I will introduce methods for stabilizing efficient organic or inorganic-organic hybrid-based semiconductors possessing superior charge-transfer characteristics, lower band gap, and tunable energy levels. Moreover, I will discuss several strategies for scaling up photoelectrodes while minimizing losses in STH efficiency. Finally, I will extend these approaches to the production of other solar fuels, such as hydrogen peroxide (H_2O_2) and ammonia (NH_3).

Large-Scale Stable Hybrid Perovskite-Based Photoelectrochemical Water Splitting Devices Wooyong Jeong, Gyumin Jang, Juwon Yun, Chang-seop Jeong, Young Sun Park, Hyungsoo Lee, Jaehyun Son, Chan Uk Lee, Junwoo Lee, Soobin Lee, Subin Moon and Jooho Moon; Yonsei University, Korea (the Republic of)

Photoelectrochemical (PEC) water splitting is a promising technology for directly converting solar energy into easily storable green hydrogen (H_2). Yet, the use of PEC devices is not widespread because of their low performance, poor stability, and the absence of large-scale deployment. Recently, the lead halide perovskite (LHP)-based integrated photoelectrodes has helped overcome these drawbacks and facilitated unbiased PEC water splitting systems, achieving high solar-to-hydrogen (STH) efficiency exceeding 13%. However, despite the significant role of large-scale deployment and stable long-term operation for practical commercialization, research in the field of LHP-based photoelectrodes has been limited to STH improvements. Herein, we present novel strategy involving the bathing of LHP film in an antisolvent containing cyclohexylammonium iodide (CHAI) for the fabrication of high-quality large-size LHP films for use in practical unbiased PEC water splitting. The effects of CHAI-antisolvent bathing and its impact on the performance of large-area LHP film-based coplanar devices are demonstrated. Consequently, parallelly illuminated coplanar LHP-based photoelectrodes with dimension of 8 cm × 8 cm could be stably operated without any applied bias, exhibiting a record-high STH efficiency of 9.89% and T_{80} (the time at which the photocurrent density drops to 80% of its initial value) of 24 h with a considerable hydrogen production rate. Furthermore, degradation mechanism of LHPs during PEC operations will be briefly presented. Through operando electrochemical impedance spectroscopy analysis and in-situ photoluminescence analysis, we found that charge accumulation at the interface of PEC device/electrolyte promotes ion migration in the perovskite layer. Moreover, the highly increased capacitance and trap density at hole transport layer measured from drive-level capacitance profiling elucidated not only the location of the accumulated charge but also the mechanism of accelerated ion migration. Our findings provide a pathway for LHP-based PEC water splitting devices to achieve mass production of solar hydrogen and high operational stability.

4:15 PM EN01.03.03

Enhanced Photocatalytic Activity of Cs_4PbBr_6/WS_2 Hybrid Nanocomposite Philip N. Immanuel, Achiad Goldreich, Jonathan Prilusky, Hila Shalom and Lena Yadgarov; Ariel University, Israel

Photocatalytic processes are among the prime means for mitigating the pollution caused by toxic effluents. In this context, photocatalysis presents a promising path and is undergoing rapid evolution. Halide perovskite-nanocrystals (HP-NCs) are excellent candidates due to their negative conduction band minimum and low work function, essential for photocatalysis. Yet, HP-NCs face limitations within this domain because they are prone to chemical degradation when exposed to external factors like high temperature, polar solvents, oxygen, and light. A practical approach toward stabilizing HP-NCs involves hybridizing them with a chemically inert material that can provide steric stabilization and act as a co-catalyst. Transition-metal dichalcogenides emerge as outstanding candidates to sterically stabilize the HPs as they are stable, chemically inert, and can serve as co-catalysts, enabling suppressed charge recombination. Here, we investigate the photocatalytic performance of Cs_4PbBr_6/WS_2-nanocomposites towards organic dye degradation in polar solvents under visible light illumination. We found that the presence of WS_2 nanostructures significantly stabilizes the HP-NCs and promotes dye degradation rate compared to pristine Cs_4PbBr_6-NCs. Using transient absorption measurements, we found that the WS_2-nanostructures act as an electron transport channel, effectively reducing charge recombination in the NCs. Our findings pave the way for implementing Cs_4PbBr_6/WS_2-nanocomposites as stable and superior photocatalysts.

Overall Solar-Driven Water Splitting with Organic Semiconductor Bulk Heterojunction Based Devices Nicolas J. Diercks, Jin Su Park, Benjamin Goldman, Jun-Ho Yum and Kevin Sivula; École Polytechnique Fédérale de Lausanne, Switzerland

Developing inexpensive, robust, and efficient light harvesting material systems is imperative to make direct solar-to-fuel energy conversion by photoelectrochemical (PEC) or heterogeneous photocatalytic (PC) approaches economically viable. In recent years, organic semiconductors have emerged as promising materials for application in this field due to their molecular tunability and scalable processability. The bulk heterojunction (BHJ) concept, which has proven successful in the field of organic photovoltaics, offers a promising route to inexpensive and high-performance production of solar hydrogen by the PEC or PC approach.

In this presentation, the design and performance of organic semiconductor-based BHJ photoelectrodes for both solar-driven water reduction[1] and oxidation[2] will be discussed. The integration of a BHJ photoanode and photocathode into one bias-free tandem PEC device for overall water splitting (OWS)[3] and the use of a BHJ deposited on a novel, transparent porous gas-diffusion electrode for H_2 production in the gas-phase[4] are also presented. In addition, an approach utilizing BHJs in a PC sheet assembly for OWS is introduced. We demonstrate OWS at ca. 1% solar-to-H_2 efficiency, and discuss insights gained regarding the stability of BHJs for PEC or PC application. Finally, the challenges toward the further development of BHJ-based systems for industrially viable OWS are examined.

High-Throughput Screening from Binary Combinatorial Library of Zero-Dimensional Lead-Free Halide Perovskites for Photocatalysis Astita Dubey[1,2], Doru C. Lupascu[2], Sergei V. Kalinin[1] and Mahshid Ahmadi[1]; [1]The University of Tennessee, Knoxville, United States; [2]Universität Duisburg-Essen, Germany

The urgent demand for lead-free, stable, and efficient catalysts for energy conversion applications necessitates efficient and fast discovery of materials.1 In this study, we present a one-dimensional (1D) binary combinatorial library of zero-dimensional lead-free halide perovskites, specifically MA3Bi2I9 and Cs3Bi2I9, using an automated pipetting robotic method. Leveraging Bayesian optimization for high-throughput screening, we extensively investigated the properties of these perovskites. Both end members maintain a hexagonal crystal structure with P63/mmc symmetry. However, the combinatorial library exhibits significant variations in lattice parameters and crystal distortions, despite retaining the hexagonal structure.
High-throughput screening was conducted to assess the ambient and water stability of the binary library by analysing their band gaps via absorbance spectra. The photocatalytic performance against rhodamine B dye revealed that the composition with 49% Cs substitution possesses the highest rate constant, achieving complete degradation of the dye within 15 minutes. This optimal composition shows the most significant change in surface potential under white light illumination and contains iodine vacancies, as identified by X-ray photoelectron spectroscopy. Additionally, cathodoluminescence and photoluminescence spectra indicate the presence of shallow defect states, which contribute to the mitigation of charge carrier recombination. Our hunt for identifying an efficient catalyst within a 1D binary combinatorial library has arrived at a significant finding, demonstrated by the successful degradation of toxic dye.
Our findings highlight the potential of these lead-free halide perovskites as efficient catalysts for energy conversion applications. The demonstrated stability, photocatalytic efficiency, and defect management in the 49% Cs-substituted composition present a promising pathway for future research and development in water splitting, and CO2 conversion.

High-Efficiency Solar-to-CO Conversion via Molecular Mn(I) Complex Catalysts in a CO_2 Flow Electrolyzer Coupled with Silicon Photovoltaics Keita Sekizawa, Shunsuke Sato, Naonari Sakamoto, Tomiko M. Suzuki and Takeshi Morikawa; Toyota Central R&D Laboratories, Inc., Japan

Solar-driven CO_2 conversion combining photovoltaics (PV) and electrochemical systems (EC) aims for negative CO_2 emissions by directly storing solar energy as fuel and chemicals. Present-day PV+EC systems face challenges due to high overvoltages in the EC, even when using precious metal catalysts, necessitating expensive high-voltage PV. Molecular metal complex catalysts can permit lower overvoltages and the use of Earth-abundant metals. In this work, we report the use of non-planar molecular Mn(I) complex catalysts1) with electron-withdrawing groups in a zero-gap MEA reactor, enabling CO_2 electrolysis at much lower potentials than conventional metallic silver or planar molecular catalysts. The Mn complex with pyrrole groups in the ligand showed excellent activity when incorporated into polypyrrole chains. Adding phenol further enhanced the catalytic activity. The MEA reactor with this Mn complex polymer and an Fe-based anode catalyst in an alkaline anolyte promoted the CO_2 reduction reaction at an extremely low potential of 1.35 V with 94% CO selectivity. A PV+EC system with this configuration, directly coupled to an inexpensive three-series Si PV unit, showed stable operation for 50 hours with a solar-to-CO conversion efficiency of over 20%.2) This advancement in solar CO_2 electrolysis technology based on molecular catalysts represents a promising step toward practical and sustainable carbon-neutral energy solutions, leveraging abundant materials and efficient solar energy utilization.

Growth and Photoelectrochemical Characterization of Epitaxial ZnTe Photocathodes for Carbon Dioxide Reduction Lily Shiau, Sol A Lee and Harry A. Atwater; California Institute of Technology, United States

We report on growth and photoelectrochemical (PEC) characterization of single crystal, epitaxial zinc telluride (ZnTe) thin film photocathodes, highlighting their potential as efficient materials for photoelectrochemical CO_2 reduction. We investigated the photoelectrochemical stability and catalytic selectivity of ZnTe photocathodes in a CO_2-saturated electrolyte (0.1 M $KHCO_3$) using a three-electrode compression cell. Utilizing degenerately doped (100) ZnTe, we have demonstrated high selectivity (60%) for CO_2 reduction to CO without cocatalysts.

To gain a deeper understanding of the fundamental charge transport and reactivity mechanisms of ZnTe, we utilized molecular beam epitaxy (MBE) to grow single crystalline, degenerately-doped ZnTe thin films on gallium arsenide (GaAs) substrate oriented along (100), (110), and (111)A. ZnTe thin films with thickness of 300 nm, grown in the temperature range of 340–360°C, were doped with nitrogen via *in situ* RF plasma nitrogen activation. Characterization techniques including RHEED, XRD, AFM, and Hall effect measurements confirmed their epitaxial nature and p-type conductivity with doping concentrations ranging from 10^{18} to 10^{20} cm^{-3}. Notably, we have also observed a correlation between the CO_2R selectivity and the ZnTe film crystal orientation. This work can be leveraged to develop catalyst-free tandem ZnTe-based carbon dioxide reduction photocathodes.

9:15 AM EN01.04.03

Plasmon Photocatalysis for Sunlight-Powered Reduction of CO_2 to CO—The Impact of Photothermal Heating of the Catalyst Bed on Reactor and Process Design Pascal Buskens[1,2], Francesc Sastre[1], Jonathan van den Ham[1], Man Xu[1,3], Nicole Meulendijks[1], Jelle Rohlfs[1], Anthony Sanderse[1], Roberto Habets[1] and Pau Martínez Molina[1]; [1]TNO, Netherlands; [2]Hasselt University, Belgium; [3]Delft University of Technology, Netherlands

To transition from the current fossil-based chemical industry to a climate neutral one, both the use of renewable energy and sustainable feedstock are essential. Here, we present the use of CO_2 as sustainable feedstock and sunlight as renewable energy source for the photocatalytic conversion of CO_2 to CO. Combined with green

hydrogen, this provides access to renewable syngas, which is pivotal for the decarbonisation of industry.[1]
Various technologies are explored for CO_2 conversion to CO, including approaches driven by electrical or thermal energy. We selected photochemical conversion using sunlight, since it provides following advantages: (i) high energy efficiency with minimized conversion and transportation losses, (ii) high process selectivity with minimized need for energy and cost intensive downstream processing, (iii) ease of scaling up and down (numbering up) making a good fit with small, medium and large sized CO_2 sources, (iv) steep learning curves and fast cost reductions expected based on technology modularity, (v) decentralized and potentially off-grid production, and (vi) low carbon footprint for direct use of sunlight.[2]
The catalyst we developed for sunlight-powered production of CO is plasmonic Au/TiO_2. This was prepared by deposition-precipitation of Au on anatase, and we achieved a Au loading of 3.12% w/w (ICP-AES).[3,4] The average size of the Au nanoparticles was 1.6 nm (lognormal distribution), and their (111) lattice planes were perfectly alligned with the (101) TiO_2 planes. The catalyst displayed a strong plasmonic absorption in the visible, with a maximum in the wavelength range between 500 nm and 600 nm. We demonstrated that under illumination with sunlight (irradiance up to 14.4 kW/m^2), CO was produced at high selectivity of 98% without external heating of the reactor. In comparative dark experiments at similar catalyst bed temperature (~200°C), only CH_4 was produced. Under optimized conditions, we achieved a CO production rate of 429 mmol/g$_{Au}$ per hour, and reached an apparent quantum efficiency of 4.7%.[3] When studying the CO production rate as function of solar irradiance, we obtained an exponential relationship indicating the presence of a photothermal contributor.[3,4] To quantitatively distinguish between photothermal heating and non-thermal contributors, we performed experiments using a tailored fiber Bragg grating-based fiber optic sensor (FBG-FOS) for *in operando* temperature monitoring. We previously demonstrated this concept for off-line measurements only.[5] The FBG-FOS enabled us to obtain temperature data during catalysis at various depths inside the catalyst bed: at the surface (0 mm), and at 0.15 mm, 0.30 mm and 0.50 mm depth. We observed substantial temperature gradients inside the catalyst bed during catalysis, with the highest temperature achieved at the surface of the catalyst bed. These temperature gradients are caused by the fact that more than 90% of the light was absorbed in the top 100 μm of the catalyst bed, as determined by UV-vis-NIR spectrophotometry. The temperature gradient remained intact due to the low thermal conductivity of the catalyst powder bed.
To complete photochemical reaction systems for sunlight-powered chemical production, additional components such as reactors, solar concentrators and sensors for on-line process monitoring are required.[6] We designed a complete system for sunlight-powered reduction of CO_2 to CO, and validated it using natural sunlight as energy source. We will particularly highlight the impact of photothermal heating on reactor and process design.

Photocathode Materials for Carbon Dioxide Reduction in Aqueous Media

Joel W. Ager[1,2], Rajiv R. Prabhakar[1] and Sudhanshu Shukla[3,4]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]imec, Belgium; [4]Hasselt University, Belgium

The prospect of performing solar to chemical energy conversion using the using non-equilibrium electrons and holes produced by illumination of semiconducting materials has been of interest since the pioneering work of Fujishima and Honda on water splitting by TiO_2 [1]. There are many reports of materials, notably metal oxides,

which function as photoanodes for water oxidation [2]. However, far fewer materials have intrinsic activity (that is, without use of electron transport/protection layers and/or co-catalysts) as photocathodes for hydrogen evolution and, especially for CO_2 reduction (CO_2R) [3]. Moreover, many studies of semiconductor photocathodes are performed in non-aqueous solvents because the materials corrode rapidly if water is used [4].
Reports of photocatalytic CO2R using metal sulfides are suggest a starting point for materials discovery [5]. More specifically, the $Cu(In,Ga)(S,Se)_2$ (CIGS) alloy family is interesting due to the extensive study of its properties as photovoltaic materials and its wide bandgap tuning range. Indeed, co-catalyst free $Cu(In,Ga)S_2$ (CIGS) thin-film photocathodes (Eg ~ 1.8 eV) reduce CO_2 to CO and $HCOO^-$ in aqueous media at faradaic efficiencies of 28-32% and 14%, respectively. Extensive structural characterization (Raman, ambient pressure XPS, XAS) shows that Cu $(In,Ga)S_2$ (CIGS) photocathodes are stable for at least a few hours. Interestingly, as would be predicted by considerations of equilibrium (Pourbaix) stability, Se-alloyed photocathodes are not stable and corrode rapidly. Additionally, $Cu(In,Ga)S_2$ films with lower bandgaps also appear to be unstable.
These finding merit a revisiting of high-throughput computational searches for CO_2R photocathode materials, as $Cu(In,Ga)S_2$ was not previously identified as a candidate [6]. More generally, our findings suggest that the previously unexplored Cu-deficient surface composition and specific surface defects, especially deep anti-site defects, might be playing a key role in governing the unique photoelectrochemical behavior of CIGS. More generally, the stable performance of CIGS photocathodes for CO_2R in aqueous media provides an opportunity to study complex, light-driven, catalytic processes at a semiconductor-electrolyte interface.

This research is based on work performed by the Liquid Sunlight Alliance, which is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Fuels from Sunlight Hub under Award Number DE-SC0021266. SESSION EN01.05: Earth Abundancy
Session Chairs: Virgil Andrei and Ludmilla Steier
Tuesday Morning, December 3, 2024
Hynes, Level 3, Room 300

10:30 AM *EN01.05.01
Photoelectrochemical Production of Solar Chemicals with Earth-Abundant Materials Sixto Gimenez; Universitat Jaume I, Spain

The development of sustainable strategies to produce added-value chemicals and fuels using renewable resources is particularly attractive to promote a transition towards a more sustainable energetic landscape, overcoming the dependence of fossil fuels at a global scale. One of the most promising alternatives involves the use of renewable electricity (wind, solar, hydropower, etc...) to power electrochemical conversion processes, which convert abundant molecules (e.g., water, carbon dioxide, and nitrogen) into higher-value products (e.g., hydrogen, hydrocarbons, oxygenates, and ammonia). In this context, the use of materials based on earth-abundant elements (Fe, Ni, Cu, etc...) is key to ensure the scalability and large-scale implementation. We will discuss the use of some earth-abundant (photo)electrocatalysts based on these elements for different reactions of wide technological interest, also focusing on the mechanistic understanding of the physical-chemical processes taking place during operation.

11:00 AM EN01.05.02

Spatially Segregated Catalyst and Light-Absorption in Silicon Microwires for Enhanced Photoelectrochemical Hydrogen Evolution Reaction Soohyeok Park, Yebin Ahn, Hyein Cho, Sangbeom Hong and Han-Don Um; Kangwon National University, Korea (the Republic of)

As a photocathode material in photoelectrochemical (PEC) cells, crystalline Silicon (c-Si) has been widely used due to its relatively narrow bandgap of 1.12eV, non-toxicity, and high stability compared to conventional oxide-based materials. Despite these advantages of c-Si, the photocathode only with c-Si shows relatively-low Faraday efficiency because it requires a high overpotential to reduce CO_2 in specific products. To overcome the high overpotential of c-Si based photocathode, applying PEC catalysts (e.g., Ag, Au) is essential to reduce the high overpotential and significantly increase the Faradaic efficiency. Although the effective CO_2 reduction reactions through c-Si photocathodes can be induced by coating the PEC metal catalyst onto the c-Si photocathodes, it has to discuss the geometry of c-Si photocathodes to enhance their optical and electrical properties. Generally, when a planar c-Si substrate is used as the photocathode in the PEC cell, the planar c-Si photocathode generates low current density due to high reflectance from the metal catalyst and planar c-Si surface. To overcome the limit in low current density originating from the planar structure, c-Si microwires have been investigated for the Si photocathodes because of their superior light absorption and effective carrier separation. However, the conventional c-Si microwire-based photocathode is fabricated by coating the particle-shaped catalysts onto the entire surface of c-Si microwires, leading to increased electrical loss due to surface and interface recombination at the metal-Si contact. Additionally, the catalyst-coated area causes optical shading loss that incident light is reflected by the catalyst, resulting in a reduction in photocurrent due to the decreased light absorption. These electrical and optical losses must be minimized to improve PEC cell performance.

One important parameter related to the electrical and optical losses caused by the catalyst is the proportion of the catalyst coated on the surface of the Si photocathode. When the proportion of catalysts coated on the Si surface increases, the electrical loss by recombination and shading loss by reflection also increases, resulting in the degradation of cell efficiency. Conversely, both types of losses would decrease by reducing the proportion of catalyst, improving the saturated current density. However, the diffusion length of photocarriers should be increased up to half the distance between the catalysts, leading to a higher probability of recombination before photocarriers move to the catalyst. Considering the diffusion length of photocarriers within the Si substrate and the losses caused by the catalyst, it is necessary to control the proportion and placement of the catalyst on the Si photocathode to maximize the efficiency of the PEC cell.

Typically, c-Si-based optoelectronic devices can suppress surface recombination and improve the photocarrier lifetime by depositing a passivation layer on the c-Si surface. The improved lifetime means increasing the diffusion length of photocarriers from tens to hundreds of micrometers, enabling the PEC catalyst to be placed in localized areas on the c-Si photocathode instead of coating the catalyst onto the entire surface of the c-Si photocathode. In this abstract, we aimed to fabricate a Si photocathode with surface-passivated microwire arrays that segregate between the absorption region capable of absorbing light and the catalyst region coated with the catalyst. In the

absorption region, we fabricated the tapered microwire arrays to minimize light reflection in terms of morphology, and confirmed that light absorption was maximized compared to other structures through optical simulation. The catalyst region was constituted by each single catalyst wire array and we controlled the shape of the tip at the catalyst wire for inclined catalyst coating and figured out that this shape effectively reduced the light reflection at the top of the catalyst wire.

11:15 AM EN01.05.03

Optimal Electrical and Optical Heterostructure of Copper Oxide for Photoelectrochemical Water Splitting Mi Jin Hong, Min Seong Kim, Su Bo Lee and Gil Ju Lee; Pusan National University, Korea (the Republic of)

Climate change is a serious global challenge arising from exponentially increased carbon emissions. With the extensive increase in atmospheric greenhouse gas concentration and its chain effect on the environment, the development of eco-friendly and sustainable sunlight harvesting technologies has been highly demanded. The continuing efforts for sustainable energy have triggered the renaissance of a plenty of solar-to-fuel strategies such as CO_2 reduction, oxygen reduction, and water splitting. In particular, photoelectrochemical water splitting stands out due to its critical role in converting abundant water into hydrogen energy. Hydrogen functions as an indispensable resource in many fields such as public transport, business, and green energy.

In current developments, the most paramount feature in a photocatalyst is the selection of materials from among the various available semiconductors. Owing to sufficient band alignment near the reduction potential, several p-type semiconductors are appropriate to convert water to hydrogen energy. Especially, cuprous oxide (Cu_2O) and cupric oxide (CuO) are spotlighted as promising materials for photocathode due to high abundance on Earth, ease of processing, and cost-friendly fabrication process. Moreover, Cu_2O has spacious inclusion of reduction potential and CuO can highly absorb overall visible light. Accordingly, the strategic design of an innovative heterostructure of copper oxides is vital for evolving the water splitting field.

Here, we propose a novel heterostructure that consists of Cu_2O nanowires on a CuO/Cu_2O mixed-phase film. This design operates as the highly efficient photocathode because CuO components in the mixed-phase film contribute to high absorption from light incidence while the nanostructure of Cu_2O results in an enlarged reactive area and outstanding electrical properties. To design the optimal heterostructure, we introduce a Cr intermediate layer and conditional adaptation of the anodization time, which induces various dimensions of slanted nanowires. The Cr-based layer lying between Cu_2O nanowires and the mixed-phase film has functional roles such as adhesion, protection for the beneath film, and the aid of optical improvement. Cr converts into chromium oxide during the annealing process, which does not obstruct light propagation to underlying film. Chromium oxides can assist efficient water splitting by blocking the backward reaction and maintaining stable operation. Additionally, the anodization time determines elemental change and structural parameters such as the diameter, length, and fill factor of the nanowire array. The straightforward fabrication process of electrodeposition, sputtering, and thermal treatments support the successful formation of Cu_2O nanowires on the mixed-phase film. Finally, the atomic layer deposition of TiO_2 improves the durability of the photocathode.

Last, we computationally and experimentally demonstrate the remarkable photoelectrochemical performances of an ideal configuration of copper oxides. We numerically calculated optical efficiencies of the photocathode. Light penetration is observed from Cu_2O nanowires at short wavelengths to the mixed-phase film at longer wavelengths. Also, linear sweep voltammetry and electrochemical impedance spectroscopy indicate the electrical characteristics, which consequently affect the incident photon-to-electron conversion efficiency. Compared with single films and the over-anodized sample (*i.e.,* CuO nanowires), Cu_2O nanowires on the mixed-phase film verify the utmost photoelectrochemical capabilities due to the high absorptance (~90%) in the visible region and lowered the impedance component. With the superior ability to generate hydrogen, this advanced design could be applied to CO_2 reduction, leveraging the extensive reduction capacities of nanostructured Cu_2O.

11:30 AM *EN01.05.04
Photoelectrochemical and Photocatalytic Water Splitting with Low-Cost Semiconductors David Tilley; Universität Zürich, Switzerland

Cuprous oxide (Cu_2O) is a highly promising material for practical large-scale water splitting due to its low cost, earth abundance, suitable bandgap (2.1 eV), excellent charge transport properties, and ease of synthesis. The main challenge is the stability in aqueous media, which necessitates coating with protective overlayers. In this presentation, I will discuss the fabrication and treatments of cuprous oxide photocathodes for performance enhancement as well as other emerging materials under investigation in our laboratory, such as antimony sulfide (Sb_2S_3). To conclude, I will outline how studies on thin films can contribute to the advancement of photocatalytic particles and particle sheets, representing disruptive potential in the domain of green hydrogen production.

Discovering Synthetic Pathways to Surpass Present Limitations of Metal Oxide Photoabsorbers Ronen Gottesman; The Hebrew University of Jerusalem, Israel

An approach to exploring and developing synthetic pathways far from thermodynamic equilibrium (i.e., plasma deposition processes) combined with flash photonic heating of multinary metal oxide thin film photoelectrodes will be presented – to break present limitations and bottlenecks in achieving stable and efficient solar fuel production. The research and development of metal oxide semiconductors for solar energy conversion confront scientists with two significant challenges: i) the need to exceed normal temperature limits for glass-based $F:SnO_2$ substrates (FTO, ~550°C) to achieve the desired density, crystallinity, and low defect concentrations, and ii) minimizing the formation of structural defects, trap states, grain boundaries, and phase impurities in multinary materials which may contain ions that vary widely in size, oxidation state, and vapor pressure under heating treatment conditions. The unique possibilities of our synthesis method can be utilized to form a holistic approach that will overcome these challenges and also provide a wide-ranging array of synthesis "tuning knobs" under highly controlled synthesis conditions.
The practicality of our approach will be demonstrated, using the emerging multinary metal oxide semiconductors for photoelectrochemical water-splitting α-$SnWO_4$ and $CuBi_2O_4$, that even subtle changes in conventional solid-state synthesis significantly impact their phase-purity, optoelectronic properties, physical working mechanisms, and performances. In contrast, synthesizing these photoelectrodes using our approach increased their crystallinity, conductivity, and photoelectrochemical device performance.
In summary, our synthesis methods can successfully address a primary need to focus on novel syntheses and design approaches of disruptive and innovative materials and NextGen devices that meet the chemical and physical requirements for reducing global warming through sustainable development. Furthermore, insights and lessons learned would be strongly transferable to other emerging materials for photocatalysis and

photoelectrocatalysis.

2:00 PM EN01.06.02

Growth and Characterization of Epitaxial $FeWO_4$ Photoanode Thin Films with Controlled Oxygen Stoichiometry

John Hylak and Harry A. Atwater; California Institute of Technology, United States

Iron tungstate ($FeWO_4$) is a promising new photoanode material for solar fuels devices, with a favorable band gap and chemical stability. However, synthesis of high quality thin films of n-type photoactive $FeWO_4$ has not been achieved, and is not well understood, due to challenges in achieving phase purity, and the unclear role of oxidation in determining optical absorption and electrical conductivity properties.

We report here the first growth of single phase epitaxial $FeWO_4$ thin films, using oxygen plasma assisted molecular beam epitaxy, and investigate the film structural, optical, and electronic transport properties. The films are grown on c-plane sapphire (0 0 0 1) at 650 °C substrate temperature by evaporating elemental Fe and molecular WO_3 from effusion cells with atomic O flux provided by an rf atom source. The $FeWO_4$ films are oriented in (1 0 0) growth direction and exhibit 3 rotational twin variants where $FeWO_4$ [0 1 0] and [0 0 1] are aligned to sapphire [1 2 0] equivalent and [1 0 0] equivalent in-plane directions, respectively.

Optical absorption measurements revealed a 1.7-1.9 eV fundamental band gap with an additional transition near 3 eV consistent with a high $FeWO_4$ joint density of states in phase pure, O stoichiometric $FeWO_4$ films. Electrical conductivity was measured using the Van der Pauw technique with indium ohmic contacts. We observe that resistivity decreases over 2 orders of magnitude from >10000 Ω cm to 100 Ω cm as films are increasingly oxidized. Hall measurements indicate that overoxidized films are n-type with 1 $cm^2 V^{-1} s^{-1}$ mobility and 10^{16}-10^{17} cm^{-3} carriers. Films with higher resistivity had indeterminate carrier type due to changing sign of the Hall voltage. The resistivity trend with oxidation is likely due to increased Fe^{3+} in the lattice of over-oxidized films facilitating electron polaron hopping. The extremely high resistivity of under-oxidized films suggests oxygen vacancies are not a principal factor for n-type conductivity in $FeWO_4$.

Epitaxial growth of $FeWO_4$ is driven by lattice match for a supercell consisting of 3 $FeWO_4$ unit cells stacked along the [0 1 0] direction. Additionally, matching hexagonal oxygen sublattices is factor guiding the epitaxial growth. Growth of $FeWO_4$ with high phase purity occurs within an atomic O flux window generated by a plasma sustained with 80-100 W of rf power. This range is specific to our cation flux conditions, which are stoichiometric in Fe and W and are effused at a rate sufficient to grow $FeWO_4$ at 100 nm/hr. A deficient atomic O flux (60 W rf power) causes epitaxial breakdown based on XRD observation of polycrystalline $FeWO_4$ with reduced oxide impurities. Excess O flux (120 W rf power) induces growth of hematite (Fe_2O_3) as a competing major phase.

Our initial study of oxygen stoichiometry in $FeWO_4$ thin films suggests that a limited amount of over-oxidation is beneficial to photoanode synthesis. This is because oxidation decreases the total resistivity, causes n-type conductivity, and retains the sub-2eV optical transition. In the future, we will report on photoelectrochemical measurements of $FeWO_4$ and also on (1) the relation between overoxidation and the strong sub-2 eV optical transition (2) optimizing cation/anion flux balance in oxide MBE processes to achieve faster growth rates for thicker films, and (3) MBE growth on conductive substrates.

2:15 PM EN01.06.03

Enhanced TiO2 Photocatalysts with Open Porous Framework Structure for Improved Continuous Photocatalysis and Solar Fuel Production

Erik Greve, Tim Tjards, Marie Elis, Jonas Lumma, Salih Veziroglu, Rainer Adelung, Franz Faupel and Fabian Schütt; Kiel University, Germany

Titanium dioxide (TiO_2) has emerged as a leading photocatalyst for solar energy conversion and environmental applications due to its high stability, non-toxicity, and suitability for carbon dioxide (CO_2) reduction [1]. This study presents synthesis and characterization of a novel TiO_2 photocatalyst with enhanced mass transport properties to improve photocatalytic performance in continuous reactors. TiO_2-Aerogels, with their high surface area and porosity, show potential for enhancing photocatalytic applications, especially in flow-through photoreactors. However, the small pore size (< 1 µm) of TiO_2-Aerogels limits their effectiveness due to purely diffusive mass transport [2]. To overcome this limitation, a highly open porous and interconnected TiO_2 photocatalyst was synthesized through liquid phase deposition (LPD) adopted from Mbulanga et al. [3] on a sacrificial tetrapodal zinc oxide (t-ZnO) backbone. The resulting framework aeromaterial (FAM) features pores with diameters between 1 µm and 100 µm, a density of 0.03 g/cm^3 (99.3% porosity), and a gravimetric surface area of approximately 40,000 cm^2/g. Unlike common TiO_2-aerogels, this synthesis route produces an interconnected open-porous structure capable of withstanding gas flow velocities up to 0.16 m/s.

Characterization of the synthesized TiO_2 photocatalysts was conducted using X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). The findings reveal a highly porous structure predominantly in the anatase phase post heat treatment at 500°C for 4 hours. Photocatalytic performance was evaluated by the degradation of methylene blue under UV light irradiation (365 nm), with the highly porous TiO_2 demonstrating superior weight-specific activity compared to Degussa P25-TiO_2. Additionally, a flow-through reactor was designed for the continuous decomposition of methylene blue, showcasing the practical capabilities of FAM-TiO_2 in real-world applications. These results highlight the potential of the synthesized TiO_2 photocatalyst for enhanced photocatalytic performance in environmental and energy applications, particularly in solar fuel production such as hydrogen and e-fuels.

Development of Ag/TiO_2 Nanocomposite Electrode for Photoelectrochemical Water Splitting Yaowapa Treekamol; Khon Kaen University, Thailand

In this research, refined Ag/TiO_2 nanocomposite electrodes are developed for photoelectrochemical (PEC) water splitting. The nanocomposites were successfully prepared by sol gel and wet ball milling methods. Their crystal structure and phase purity were investigated by using XRD and Raman techniques. The results confirm mixed anatase and rutile phases of TiO_2. FTIR spectra confirms the presence of hydroxyl groups which enhances photocatalytic activity of composites due to a greater reduction of the recombination rate of electron and hole pairs. A red shift in UV-vis spectra is detected resulting in an alteration of Ag/TiO_2 nanocomposites bandgap energy. Moreover, the photoelectrochemical properties were studied by electrochemical analyzer under illumination conditions. The nanocomposite electrode shows a significantly higher photocurrent density compared to TiO_2 electrode at the potential 2 V (vs. Ag/AgCl). It can be explained AgNPs acted as a photosensitizer improving the photocatalytic activity. Further, the IPCE confirms that the higher IPCE efficiency of nanocomposites compared to TiO_2 is because of the light absorption by SPR effect of silver nanoparticle. Therefore, it can be explained that the Ag/TiO_2 nanocomposite is a potential material for photoelectrode for PEC cell in hydrogen production applications

3:15 PM ^EN01.07.01

Outdoor Performance of Up-Scaled Bismuth Vanadate Photoanodes During Photoelectrochemical H_2 Production Anna Hankin[1], George Creasey[1,1], Arend Moelich[2], John Rodriguez Acosta[1], Thomas Shalvey[3], Dora Alicia Garcia-Osorio[3], Jon Major[3], Alexander Cowan[3], Craig McGregor[2] and Andreas Kafizas[1]; [1]Imperial College London, United Kingdom; [2]Stellenbosch University, South Africa; [3]University of Liverpool, United Kingdom

We have designed, built and characterized a prototype photoelectrochemical demonstration system capable of splitting water into hydrogen and oxygen using only photon energies. The reactor was operated during Mar-May 2024 at Stellenbosch University (33.93° S, 18.86° E), while mounted on a 2-axis tracking platform. Light was directed laterally both into the (photo)cathode and photoanode compartments, which were separated by an ion-permeable membrane. Double-sided irradiation was achieved by two methods that were compared with each other: (i) using mirrors (Ag-coated mirror for the (photo)cathode side and Al-coated mirror for the photoanode side) and (ii) linear Fresnel lenses coupled with stepped Al waveguides. The latter irradiation method delivered light, concentrated by a factor of up to 4, though theoretical simulations show that through design improvement the concentration factor could ultimately reach ≈ 15.

The reactor was operated in two modes:
Photoelectrochemical (PEC), utilising an FTO|WO_3|$BiVO_4$|$NiFeO_x$ photoanode and a FTO|Au|Sb_2Se_3|CdS|TiO_2|Pt photocathode[2];
PV-assisted photoelectrochemical (PV-PEC), utilizing the same FTO|WO_3|$BiVO_4$|$NiFeO_x$ photoanode, Ni cathode and an externally mounted c-Si PV.

In mode I, a pH gradient was employed to assist water splitting, with a pH ≈ 0.8 aqueous catholyte comprising 0.1 M H_2SO_4 and anolyte comprising 1 M H_3BO_3 + 1 M NaOH at pH ≈ 9.3. In mode II, both electrolytes were 1 M H_3BO_3 + 1 M NaOH. A cation-permeable membrane, Nafion^{TM} 115, was utilized in all experiments. The reactor was operated in batch recycle mode. The areas of the (photo)electrodes and the PV were all 30 cm^2.

We observed that our bismuth vanadate (BVO) photoanodes usually degraded within hours, for which we propose two reasons. Firstly, when coupled with c-Si PV, the potential of the photoanodes was observed to increase into the dark current regions under low irradiance. While the c-Si PV is able to generate a significant photocurrent even on cloudy days, the bismuth vanadate photoanode is unable to match this through its own electron-hole generation. When anode potentials exceeded ≈1.1 V (RHE), the photoanode is thought to have degraded through oxidation of the bismuth; the degradation was irreversible. Secondly, the photoanodes degraded equally quickly under concentrated irradiance; we are currently investigating whether this was caused by overheating, high flux of bubbles or both. It is currently unclear whether the issue is with the adhesion of the WO_3 layer to FTO or due to the bismuth film itself.

I shall discuss the experimental results from reactor testing, the performance under various modes of irradiation, and the effects of electrode materials, geometries and relative configurations within the reactor on its design, overall performance and further scale-up, as well as the future role of photoelectrochemical systems in energy storage.

3:45 PM EN01.07.02

Revealing the Role of Catalytic Oxygen Species of Transition Metal Oxide Coated $BiVO_4$ in Photoelectrochemical Water Splitting Zhaoyi Xi[1,2], Chenyu Zhou[1], Kim Kisslinger[1], Ashley Head[1], Fang Lu[1], Xiao Tong[1] and Mingzhao Liu[1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook University, The State University of New York, United States

Light harvesting based on photocatalytic generation of chemical fuels, or artificial photosynthesis, has long been sought as a renewable solar energy technology. Solar water splitting within a photoelectrochemical is a typical realization of artificial photosynthesis. Bismuth vanadate ($BiVO_4$, BVO) is an outstanding photoanode material for photoelectrochemical water splitting, and transition metal oxide coating as cocatalyst is a common strategy to improve the performance of photoanode. Here, we review our recent progress on bismuth vanadate multilayer samples coated by different transition metal oxides as cocatalyst, such as cobalt oxide, iron oxide and nickel oxide, which were synthesized by using pulsed laser deposition (PLD) method. BVO samples with different cocatalyst coatings were then used in both photoelectrochemical chlorine generation, and water splitting reactions. Through different approaches on both samples' fabrication and during photoelectrochemical reaction, we successfully controlled and regulated the surface oxygen species which were found to have a huge influence on solar energy conversion performance. Detailed mechanistic research and in situ surface characterizations were performed to understand the inherent correlation between different oxygen species and performance, which will have a heuristic effect towards future photoanode material design for both solar water splitting, chlorine generation, and transition metal choosing as cocatalyst.

The Impact of Plasmonic Nanoparticles on Chemical Vapour Deposited Nano-Structured Heterojunction Water Splitting Photoanodes Brian S. Tam, Jenny Nelson and Andreas Kafizas; Imperial College London, United Kingdom

Bismuth vanadate ($BiVO_4$)-coated tungsten trioxide (WO_3) is a visible light absorbing heterojunction system popular in the literature as an earth-abundant photoanode for water splitting. While the photoanode performance of $BiVO_4$ is limited by its short electron diffusion length and relatively large recombination rate, these factors are mitigated by forming a heterojunction with WO_3, which has complementary conduction and valence band energy levels for water oxidation. Additionally, nanostructuring is shown to improve charge carrier separation across the heterojunction interface, reducing recombination and improving the efficiency of the water oxidation reaction.[1] Employing plasmonic nanoparticles along with photocatalysts is an exciting approach that may enhance photocatalysis by improving light absorption and scattering, and enabling hot-electron injection, and plasmon-induced resonance energy transfer.[2]

Photocatalysts are often fabricated by spincoating, electrodeposition or photo-deposition, which offer useful control, but homogenous samples may be difficult to be achieved for larger-area depositions.[3] We utilize a scalable atmospheric-pressure chemical vapour deposition (CVD) method for producing nanostructured photoanodes consisting of $BiVO_4$ coated onto WO_3 nanoneedles; optimal thickness and morphology is easily controlled by varying deposition parameters such as substrate temperature. WO_3 nanoneedles have previously been shown with transient absorption spectroscopy to have fast water oxidation kinetics.[4]

With a bandgap of 2.4 eV, $BiVO_4$ only has a maximum solar-to-hydrogen conversion efficiency of up to 9.2%, which may not be competitive with photovoltaic-coupled electrolysis for commercialisation.[5] In this work, approaches in plasmonics-enhanced photocatalysis are employed to attempt to boost the conversion efficiency of nanostructured WO_3/ $BiVO_4$ heterojunction photoanodes beyond the 9.2% limit. The bare heterojunction photoanodes show up to 60% incident photon to current conversion efficiency when illuminated with light between 300-500 nm in wavelength under 1.23 V vs RHE of applied potential. Flat $BiVO_4$ photoanodes both with and without the heterojunction with WO_3, in contrast, show a much lower performance. One advantage of the CVD method is the possibility for sequential deposition over large substrate areas, and is a technique commonly used by industry for semiconductor fabrication. We demonstrate the deposition of Bi, Pd, and Au nanoparticles by CVD showing surface plasmon resonance enhancement that yields a potentially transformative route for fabricating efficient, large-area thin film photoelectrodes.

Supply Risk Considerations for Photoelectrochemical Water Splitting Materials Martin Hillenbrand, Christoph Helbig and Roland Marschall; University of Bayreuth, Germany

The goal of a sustainable energy future has amplified the importance of Green Hydrogen – an energy carrier that promises a cleaner environment without the emission of greenhouse gases. However, the production capacity of Green Hydrogen through electrolyzers remains constrained due to limited supply of renewable power, necessitating advanced research, and technological innovations. One such potential alternative is photoelectrochemical (PEC) water splitting, which converts and stores energy from solar radiation directly via splitting of water into hydrogen and oxygen.

In order to upscale the PEC technology in the future, frequently the need for high abundance of used materials in PEC water splitting is mentioned, however a quantitative analysis has not been performed so far.

This study delves into the supply risks associated with various materials currently under research for PEC water splitting. Utilizing Raw Material Criticality Assessment methods, we evaluate the present and future supply risks of selected PEC materials to determine their viability for large-scale Green Hydrogen. Recognizing the nascent stage of extensive PEC installations, our analysis differentiates the supply risk between present and future scenarios. Our findings indicate that, in the present, the lowest supply risk is given for α-Fe_2O_3, CuO, and Cu_2O, followed by Ta_3N_5. However, projections suggest that a-$SnWO_4$ will have an even lower supply risk score in the future, hinting at a potential shift in the research landscape which is currently dominated by other materials including $BiVO_4$ and a-Fe_2O_3. These materials show higher supply risk scores in our future assessment. Additionally, we quantify the potential surge in demand that would accompany the large-scale deployment of the most promising PEC materials.

Designing the Ultimate Metal Oxide Photoelectrode Aron Walsh; Imperial College London, United Kingdom

A chemically stable, visible-light absorbing and electrically conductive metal oxide would be desirable for solar energy harvesting technologies including low-cost photovoltaics and photoelectrochemical fuel production. I will present an overview of routes to tailor the electronic characteristics of metal oxides to achieve this goal. My understanding draws from early efforts in cobalt spinel photoelectrodes, symmetry breaking in copper delafossites, through to the study of lone pair-containing compounds such as $BiVO_4$ and Sn_2TiO_4 [1]. We have developed computational screening techniques to explore and design photoactive materials, including descriptors for understanding charge carrier (polaron) formation and dynamics in metal oxides [2]. A combination of modelling and experiment has been used to further our understanding of prototype systems such as Fe_2O_3 and WO_3,[3] while exploring novel chemistries such as ternary Bi_2WO_6 and quinary $Bi_6NbWO_{14}X$ (X = Cl,I) [4]. I will illustrate how compositional and structural degrees of freedom can be exploited to discover multi-component multi-functional metal oxides with superior performance.

Tungsten Sulfide Decorated One-Dimensional Sb_2S_3 Photoanode Combined with Iodide Oxidation Reaction for Bias-Free Solar Fuel Generation

Young Sun Park, Hyungsoo Lee, Juwon Yun, Gyumin Jang, Chang-seop Jeong and Jooho Moon; Yonsei University, Korea (the Republic of)

The unassisted solar fuel photosynthesis using photoelectrochemical (PEC) configuration composed of photocathode and photoanode has emerged as a promising technology to solve both of energy crisis and environmental contamination. However, the lack of competitive photoanodes, which is ascribed to inferior light harvesting and suboptimal charge separation/injection characteristics of photoabsorbers constituting photoanodes, has been paramount barrier for efficient unbiased solar fuel production system. The one-dimensional (1D) nanostructured photoabsorber can be rational methodology to improve light absorption *via* complex morphological property that allow light scattering as well as superior electron-hole separation ability by employing the favorable crystallographic direction. Along with these beneficial optoelectronic capabilities, the mesoporous 1D nanostructure promotes charge carrier injection to electrolyte *via* large surface area, and the

passivation strategy that alleviate surface trap states further elevates the extraction of photo-induced holes from photoelectrode to electrolyte by repressing charge carrier recombination.

Herein, we demonstrate solution-processed 1D Sb_2S_3 nanorod arrays deposited on substrate modified by Au seed layer. This Au seed layer modulate the interaction between molecules in precursor solution and substrate, resulting in self-orientated crystalline structure. Moreover, the $(NH_4)_2WS_4$ treatment was performed on the surface of Sb_2S_3 nanorod-based absorber, resulting in formation of WS_x layer which passivates surface states distributed on surface of photoabsorber. The resulting photoanode (denoted as WS-1D Sb_2S_3) was used to enable an iodide oxidation reaction (IOR), a prominent alternative to sluggish oxygen evolution reaction, revealing a photocurrent density of nearly 10 mA cm^{-2} at 0.6 V versus the reversible hydrogen electrode. Afterwards, by coupling WS-1D Sb_2S_3 photoanode with perovskite-based photocathode in a parallel illumination configuration, the unbiased solar-to-hydrogen conversion device was afforded, exhibiting a solar to hydrogen conversion efficiency of 2.95% without external bias along with the stability of 2 h. Our study demonstrates the feasibility of unbiased solar fuel generation device using IOR on Sb_2S_3-based photoanode with facile morphology control and a surface passivation process.

Dimensionality-Driven Polymorphism in Ruddlesden-Popper Phases of Ba-Zr-S Perovskites

Prakriti Kayastha[1], Erik Fransson[2], Paul Erhart[2] and Lucy Whalley[1]; [1]Northumbria University, United Kingdom; [2]Chalmers University of Technology, Sweden

Chalcogenide perovskites, in particular $BaZrS_3$, has gained a lot of popularity in the last few years due to its great potential as an alternative lead-free photovoltaic absorber material. This is due to promising optoelectronic properties such as defect tolerance, strong dielectric screening, and light absorption [1]. In our previous work, we demonstrated that phase pure synthesis of this material is challenging due to the coexistence of competing $Ba_{n+1}Zr_nS_{3n+1}$ Ruddlesden-Popper (RP) phases [2]. The properties of these competing RP phases remain understudied, especially given that they are expected to affect the photovoltaic performance. For the n=2 phase, a high-temperature *I4/mmm* and a low-temperature $P4_2/mnm$ phase has been reported [3]. We have also shown that the high-temperature *I4/mmm* phases of n=1,2,3 RP phase have imaginary phonon modes at the X-point in reciprocal space, which indicates the existence of a stable lower symmetry structure [4].

In this work, we present our machine learning potential model trained on n=1 to n=6 RP phases and the n= perovskite phase with the neuroevolution potential method [5]. These models have been trained on properties derived from the HSE06 hybrid exchange-correlation functional, which is shown to provide more reliable phase transition temperatures for the perovskite phase compared to the traditionally used generalized gradient-based functionals [6].

Using molecular dynamics we study phase transitions in RP phases across a variety of n-values. Whilst cooling the high-temperature RP phases, octahedral tilting along the X-mode leads to a second-order phase transition. We consider 48 unique tilted structures to systematically investigate all possible ground-state structures. We observe long-range ordering of octahedral tiling in the perovskite layer and show the dependence of the phase transition temperature with increasing n-value. We find that small-n RP phases adopt a different long-range ordering pattern compared to that of large-n RP phases. We demonstrate a limit where the large-n RP phase transitions coincide with the transition of the n= ∞ perovskite.

Molecular Co-Catalysts of Molybdenum Sulfide Clusters on Antimony Selenide Photocathodes for Hydrogen Generation Pardis Adams and David Tilley; Universität Zürich, Switzerland

Molybdenum sulfide is a highly effective non-precious metal catalyst for hydrogen evolution, mainly active at edge sites with unsaturated molybdenum or terminal disulphide and possesses a catalytically inert basal plane. To enhance activity at low loading density, two molybdenum sulfide clusters, $[Mo_3S_4(H_2O)_9]Cl_4$ ($[Mo_3S_4]^{4+}$) and $(NH_4)_2[Mo_3S_{13}]$ x $2H_2O$ ($[Mo_3S_{13}]^{2-}$), were investigated. These molybdenum sulfide molecular catalysts were deposited on Sb_2Se_3 photocathodes using a simple soaking method, forming a thin catalyst layer. When paired with Sb_2Se_3 both $[Mo_3S_4]^{4+}$ and $[Mo_3S_{13}]^{2-}$ displayed excellent catalytic activity and can achieve up to 20 mA cm^{-2} under one sun illumination. $[Mo_3S_{13}]^{2-}$ proved to excel catalytically and demonstrated improved photovoltage and an average faradaic efficiency of 100% for hydrogen evolution. This superiority is due to the effective loading and higher catalytic activity of $[Mo_3S_{13}]^{2-}$ on the Sb_2Se_3 surface.

9:00 AM EN01.08.04
From Sunlight to Clean Fuel—Functionalized GaS for Efficient Solar-Driven Water Splitting Levna Chacko and Sofer Zdeněk; University of Chemistry and Technology, Prague, Czechia

The quest for a sustainable energy future relies heavily on technologies that harness clean, abundant resources. Alkaline water electrolysis (AWE) reigns as the most established and widely used system for large-scale hydrogen production, boasting megawatt-level capabilities. However, despite its maturity, AWE currently operates at around 70% efficiency, falling short of the desired 90%. While its counterparts, proton exchange membrane (PEMWE) and anion exchange membrane (AEMWE) systems, offer impressive efficiency, their high initial costs and shorter lifespans hinder their widespread commercial adoption. Despite the economic advantage of AWE over its counterparts, integrating AWE with intermittent energy sources like solar and wind power necessitates significant advancements in design to ensure efficient operation under dynamic conditions.

Herein, we have developed a pioneering integrated system, combining a solar panel that converts sunlight into electricity – with an alkaline water electrolyzer. This device features gallium sulfide (GaS) as the anode material, and a modified TM-doped GaS – as the cathode. Density functional theory (DFT) calculations suggest that the interaction between metal chalcogenides and transition metals (TM) can effectively modify the electrical structure of these materials to enhance their catalytic performance. Usually, the efficiency of these integrated systems has been hampered by suboptimal water electrolysis performance, mainly due to inadequate oxygen evolution reaction (OER) electrodes. However, the electrochemical measurements demonstrated that this novel design effectively addresses the major efficiency bottleneck in AWE: the limitations of the oxygen evolution reaction (OER) electrodes. GaS based nanocatalyst delivered low overpotential for both hydrogen evolution reaction (HER) and OER. The integrated system also demonstrated an overall voltage of 2.50 V to reach a current density of 2 A/cm^2 employing the alkaline water electrolyzer.

The successful integration of this AWE device with a commercially available silicon solar cell marked a significant breakthrough. It demonstrated the feasibility of producing "green hydrogen" – hydrogen fuel generated entirely from renewable electricity, with zero carbon emissions. This method of green hydrogen production holds great promise for cost-effective, clean energy generation. This research paves the way for further advancements in AWE technology. By overcoming the challenge of OER electrode efficiency, it opens the door for widespread adoption of AWE systems powered by renewable energy sources, heralding a future fueled by clean, sustainable hydrogen.

9:15 AM EN01.08.05

Dual-Defective SnS_2—A Promising 2D Photocatalyst for Water Splitting Toward Hydrogen Fuel Batjargal Sainbileg, Michitoshi Hayashi and Li-Chyong Chen; National Taiwan University, Taiwan

Solar-to-hydrogen fuel conversion through photocatalytic water splitting is a promising green pathway for achieving carbon-neutral and net-zero targets worldwide. In this regard, designing efficient photocatalytic materials that can efficiently split water into hydrogen is essential. Using First-principles calculations based on the density functional theory (DFT), we demonstrate that the dual-defective SnS_2 (Ni-SnS_2-V_S), incorporating both nickel doping and sulfur vacancy, becomes a promising 2D photocatalyst semiconductor compared with pure SnS_2. In particular, the Ni-SnS_2-V_S monolayer not only displays suitable band alignment that perfectly overcomes the redox potentials for overall water splitting, but also exhibits enhanced photocatalytic activity, spatial separation of charge carriers (electrons and holes), and a broadened optical absorption spectrum. Therefore, the dual-defective SnS_2 can serve as an efficient photocatalyst for overall water splitting to produce hydrogen fuel. Remarkably, the dual-defect method can be an effective strategy to enhance the electronic and catalytic behaviors of 2D materials, offering atomic-scale guidance for the development of solar-fuel generation.

9:30 AM *EN01.08.06

Thin Film Chalcogenides from Solar Cells to Solar Fuels Jon Major; University of Liverpool, United Kingdom

Thin film absorber layers based on chalcogenides such as CdTe, CIGS, and more recently $Sb_2(Se,S)_3$, are established staples of solar cell research. These materials have good power conversion efficiencies from a range of vapour transport deposition processes and in the case of CdTe have even made the leap from the laboratory to mass scale module production. The same factors that make these materials attractive for photovoltaics, low-cost materials, rapid deposition techniques and high optical absorption, make them equally suited for solar driven photoelectrochemical (PEC) water splitting for the production of hydrogen. This talk will focus on how chalcogenide thin films deposited via an industrially scalable close space sublimation (CSS) process, can be utilised effectively as PV absorbers and then transferred to use as photocathode materials in PEC devices. We will discuss the challenges of modifying the device architecture between PEC and PV technologies, as well as routes to grain structure control in polycrystalline CdTe and Sb_2Se_3 and how it ultimately determines device performance.

Defects Activity in Metal Halide Perovskites Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Metal halide perovskites (chemical formula ABX_3, A = formamidinium (FA+), methylammonium (MA+), or Cs+ , B =

Pb2+, Sn2+, X = I−, Br−, or Cl−) have demonstrated their potential as a material platform for a new generation of optoelectronic technology. One superior feature of metal halide perovskites is their continuously tunable bandgap from near infrared to ultraviolet by designing the chemical composition of the semiconductor crystalline unit. This enables them to provide light absorbers customizable for various applications.
In this presentation I will assess the most recent advances in elucidating the (photo)chemistry of defects related to the chemical composition of the perovskite crystalline unit, with a special emphasis on the surface properties. I will show how they define the charge carrier dynamics and interface energetics in the semiconductor. Based on such understanding I will discuss the main electrical and spectroscopic features related to the activity of defects and how to interpret them to exploit these semiconductors in catalytic processes.

11:00 AM EN01.09.02

Enhancing the Open Circuit Voltage in Organic Solar Cells via Restricted Photon Emission to Reduce Boltzmann Losses Francisco B. Bernal Texca[1] and Jordi Martorell[1,2]; [1]ICFO-The Institute of Photonic Sciences, Spain; [2]Universitat Politècnica de Catalunya, Spain

Shockley and Queisser established a theoretical efficiency limit for planar single-junction photovoltaic devices using detailed balance principles and determined a maximum power conversion efficiency (PCE) of 33.16%. However, they also proposed that higher efficiencies could be achieved if the cell is surrounded by a blackbody at the sun temperature. Losses, termed Boltzmann losses, arise when the illumination of a planar-geometry cell is restricted to a narrow solid angle, causing a mismatch between the photon absorption and emission cones. These losses were due to entropy generation from unequal absorption and emission solid angles. The nanostructuration of the solar cell is an alternative to reduce the photon emission cone, thereby decreasing Boltzmann losses and increasing the open-circuit voltage (V_{oc}). It has been theoretically shown that for single-junction nanostructured solar cells under AM 1.5G illumination, a maximum efficiency of 42% can be reached for a solar cell with a bandgap energy of 1.43 eV. In this study, we present a proof-of-concept optical strategy to reduce the mismatch between absorption and emission cones in organic solar cells. By reducing the radiative recombination, we achieved an increase in V_{oc} of approximately 30mV solely through optical means. This study proposes a new pathway for planar geometry single-junction solar cells, potentially surpassing the PCE values set by the Shockley-Queisser limit.

Crystalline silicon (*c*-Si) photovoltaics, which currently comprise over 90% of the solar cell market, are also among the promising candidates for solar-to-chemical conversion such as water splitting and CO_2 reduction [1-3]. However, they are nearing the thermodynamic single junction limit, presenting significant challenges for further efficiency enhancements in *c*-Si photovoltaics. One promising method to exceed this limit involves sensitizing *c*-Si with organic molecules capable of singlet exciton fission (SF), a process that generates two triplet excitons (electron-hole pairs) from a single photon. Efficient transfer of these triplet excitons to *c*-Si could potentially enhance photocurrent and power conversion efficiency (PCE). Previous studies have shown coupling between *c*-Si and the archetypal SF material (tetracene), facilitated by passivating interfacial layers of hafnium oxynitride, as evidenced by magnetic-field-dependent photocurrent measurements [4]. However, the photovoltaic performance did not improve due to insufficient passivation and poor carrier extraction at the surface between tetracene and *c*-

Si. We have developed a novel interfacial heterostructure that effectively passivates surface defects and facilitates intermediate charge separated states necessary for the transfer of triplet excitons from tetracene to *c*-Si. Utilizing *c*-Si solar cells with shallow p-n junctions and a microstructured geometry, we demonstrate, for the first time, enhancements in short-circuit current and PCE attributed to SF in tetracene.

Toward a Full Slot-Die-Coated Green Solvent Ink Perovskite Solar Cell Alejandra Florez Velasquez[1], Feray Ünlü[1], Natalia Maticiuc[1], Daniel Ramirez Zora[2], Rafael Betancur[2], Franklin Jaramillo Isaza[2] and Eva Unger[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Universidad de Antioquia, Colombia

Perovskite Solar Cells (PSC) have potential as thin film photovoltaic technology due to their high efficiency and low cost compared with similar technologies. However, the efficiency in large-area modules of perovskite photovoltaics (PPV) is still significantly lower than the power conversion efficiency (PCE) in silicon solar cells, representing an opportunity to achieve large-scale devices with better performance[1]. In this sense, Slot-Die Coating (SDC) is one of the best options for reaching efficient large-area devices since it allows the processing of several layers and enables the manufacture of rigid and flexible devices. As a continuous manufacturing method, SDC still has significant obstacles to overcome, especially regarding device reproducibility and stability, especially when the devices are manufactured under ambient conditions[2].

It is expected to find information concerning the adverse effects of water on the stability of PSC devices, especially in the perovskite layer [3–5]. However, it has been demonstrated that water in perovskite precursor did not negatively impact the perovskite thin-film preparation process and enabled perovskite's humidity tolerance under ambient conditions fabrication[6]. Water can also help prolong the film-drying process, forming perovskite thin films with large grain sizes by depositing them with pre-metered methods such as SDC and DBC.

On the other hand, existing reports[7] place planar structures as among the most widely used structures for scaling PSCs because the simple structure of planar PSC devices does not need to prepare mesoporous layers, which can save cost and time. Also, it has a high conversion efficiency[8], and the p-i-n structure can be manufactured at low temperatures[9]. Nevertheless, it is also well known that the increment in the area leads to defects that decrease the PCE, which turns the interlayers into an excellent tool to achieve better devices.

This work is focused on scaling the perovskite layer on a planar structure, using the SDC nickel oxide (NiO_x) layer as hole transfer material and a self-assembled monolayer (SAM) to improve the interaction with the perovskite layer. In addition, we use an SDC water-based $MAPbI_3$ formulation, which is processable under ambient conditions, reaching efficiencies around 10% approaching the scaling of PSC to room temperature manufacturing conditions and using green solvent inks for the active layer.

Local Mapping of Photovoltage of Planar and Bulk Heterojunction Polymer Solar Cells by Photo-Illuminated Kelvin Probe Force Microscopy

Chitlada Mani-Lata, Ryota Hasegawa, Masakazu Nakamura and Hiroaki Benten; Nara Institute of Science and Technology, Japan

Over the past few decades, polymer solar cells have gained attention as alternative sustainable energy resources because of their benefits over inorganic devices, such as their light weight, flexibility, wide range of material choices, etc. Despite the positive legacy, the power conversion efficiency (PCE), which is roughly 18~20%, is limited because of the ambiguity of the operational mechanisms. To surpass this limit, the relationship of the morphology-photovoltaic functions crucially needs to be unravelled. One of the effective approaches is Kelvin probe force microscopy (KPFM), where the surface potential of the active layer of organic solar cells is evaluated as the contact potential difference (CPD) between the sample surface and the AFM probe. Nevertheless, the interpretation of the obtained data and the relationship between the data and the open-circuit voltage (V_{OC}) of the device has not been well established. In this study, with the illumination below the sample, the photovoltage is evaluated by the CPD shift under the illumination from the dark condition (△CPD) for donor-acceptor planar heterojunction devices (PHJ) first and moves to the bulk heterojunction devices (BHJ). Finally, the spatial distribution of △CPD and its correspondence to the device V_{OC} were discussed.

Firstly, the surface topography and the corresponding △CPD image of PHJ devices reveal the homogeneous distribution of photovoltage, with FWHM smaller than 10 mV. Next, △CPD was characterized in different donor devices, and the values of△CPD are approximately the same as the device V_{OC}s. We conclude that, in PHJ, only holes are accumulating on the donor surface since electrons travel to the bottom electrode (cathode) through the acceptor layer, causing the shift in the surface potential to be as equal as the V_{OC}. As to the BHJ devices, △CPD observed on the active layer shows lower values than V_{OC}, even though △CPD on the top electrode (anode) matches the device V_{OC}. The proximity between donor and acceptor results in averaging the surface potential caused by hole and electron accumulation in the same space, leading to smaller values of △CPD.

In conclusion, the successful evaluation of V_{OC} by △CPD mapping, as demonstrated in PHJ devices, provides a promising approach to insightfully study the morphology-V_{OC} relationship in polymer solar cells.

SESSION EN01.10: Operation under Harsh Environments
Session Chairs: Virgil Andrei and Ludmilla Steier
Wednesday Afternoon, December 4, 2024
Hynes, Level 3, Room 300

3:30 PM *EN01.10.01
(Photo-)Electrochemistry for Space Applications Katharina Brinkert[1,2]; [1]Universität Bremen, Germany; [2]University of Warwick, United Kingdom

Water electrolysis is not only a highly relevant process for the production of green hydrogen on Earth: it is also key for producing oxygen and hydrogen in the *Environmental Control and Life Support System* (ECLSS) onboard the *International Space Station* (ISS). One of the major challenges associated with water electrolysis in reduced gravitational environments is however the near-absence of buoyancy forces in orbit. Consequently, phase separation - such as the detachment of gas bubble from an electrode surface - is severely hindered. This causes increased reaction overpotentials, leading to a high energy inefficiency of the *Oxygen Generator Assembly* (OGA) on the ISS: forced water recirculation loops are perquisite to detach and collect gas bubbles. At present, the OGA requires therefore about 1.5 kW - a third of the energy consumed by the entire ECLSS [1]. This high energy demand as well as the high total mass makes the OGA unfeasible for application in future space architectures.
Here, a two-folded approach is presented for producing hydrogen and oxygen at lower energy input in space environments: firstly, the technological feasibility to utilise photoelectrochemical devices in lunar and Martian habitats is assessed in numerical simulations [2]. These devices integrate the processes of light absorption, charge separation and catalysis and present therefore weight and volume advantages in comparison to the traditionally used photovoltaic-driven electrolyser in the OGA [3,4]. Secondly, alternative phase separation methods for (photo-)electrolyser systems in space are presented utilising magnetically-induced buoyancy and custom-tailored electrocatalyst nanostructures [5,6]. Both concepts have been tested in microgravity environment generated for 9.2 s at the Bremen Drop Tower, where (photo-) current-voltage (*J-V*) profiles and gas bubble trajectory analysis confirm efficient gas bubble detachment and movement in the near-absence of buoyancy as well as the production of oxygen and hydrogen close to terrestrial efficiencies.

Co-Catalyst Epitaxy on Semiconductor Support for Stable and Efficient Photoelectrochemical Water Splitting Under Concentrated Solar Light Wan Jae Dong; Korea University, Korea (the Republic of)

Hydrogen (H_2) emerges as a clean energy solution produced through solar water splitting, providing a sustainable alternative to carbon-emitting fossil fuels. Over the years, many semiconductor photoelectrodes have effectively harnessed solar energy to produce green H_2 via photoelectrochemical (PEC) water splitting. These photoelectrodes, when exposed to sunlight, save voltage compared to electrocatalysts that operate in the dark. However, unlike electrochemical reactions, the maximum photocurrent density (J_{ph}) is limited by the amount of photogenerated charge carriers in the semiconductors, which restricts H_2 production rate. To overcome this, concentrated solar light can be used to increase the number of photogenerated charge carriers. This approach has been validated through the integration of photovoltaic-electrocatalyst (PV-EC) devices, which also help reduce the costs associated with semiconductor light absorbers, co-catalysts, and electricity. Despite the advancements in PV-EC systems for H_2 production, there hasn't been a detailed study on the performance and long-term stability of a photoelectrode that can simultaneously absorb light, excite electrons, separate charge carriers, and catalyze the hydrogen evolution reaction (HER) under concentrated solar light. Thus, fundamental studies are necessary to better understand the PEC HER processes and to develop more efficient and durable photoelectrodes capable of fully utilizing concentrated solar energy.

Photoelectrodes are typically made by applying Pt co-catalysts onto semiconductor materials. While Pt co-catalysts are highly effective for the hydrogen evolution reaction (HER), their low adhesion has caused instability and limited the long-term functionality of photoelectrodes. Researchers have explored various solutions to enhance stability, such as using reduced graphene oxide binders, metal oxide overlayers, or hydrogel protection to encapsulate Pt NPs, preventing their detachment. These passivation layers prevent the agglomeration and detachment of Pt co-catalysts and suppressed the photocorrosion of photoelectrodes, highlighting the importance of considering both mechanical and chemical factors when designing photoelectrodes. However, these approaches can block active sites and hinder the mass transfer of reactants and products. There is still a significant need for innovative strategies to anchor Pt co-catalysts onto photoelectrodes for efficient and stable PEC water splitting, especially as the challenge may become more pronounced when using concentrated solar light to accelerate the H_2 production rate.

In this study, we demonstrate a stable and efficient method for producing high-yield H_2 using Pt nanoparticles (NPs) decorated on GaN nanowires (NWs) grown on an n^+-p Si photoelectrode. Under concentrated solar light at 640 mW/cm^2, the pristine Pt/GaN/Si system exhibited a high photocurrent density at 0 V vs. reversible hydrogen electrode (V_{RHE}) (J_0) of over 100 mA/cm^2. However, this performance degraded within 0.5 hours before stabilizing. The rate of performance degradation was significantly faster under concentrated solar light compared to conventional 100 mW/cm^2 illumination. Surface chemical and microstructure analysis revealed that concentrated solar light caused rapid surface modifications and the removal of some Pt NPs. However, Pt co-catalysts with an epitaxial relationship with GaN NWs remained strongly anchored on the surface, even after vigorous H_2 gas evolution. This finding led us to redeposit Pt NPs on the reacted surface of the photoelectrode, where more anchoring sites were available, resulting in enhanced HER activity and stability. This work identifies the stable bonding form of Pt NPs on single crystalline GaN NWs and elucidates strategies to develop efficient and durable photoelectrodes that operate under concentrated solar light.

Improving the Photoelectrochemical Stability and Performance of $BiVO_4$ Photoanode in a Harsh Environment Using Two-Dimensional Protective Layers

Neway B. Tadesse; Chinese Academy of Sciences, China

Hydrogen production from water splitting using photoelectrochemical (PEC) technology has become an important alternative to sustainable and green energy sources. However, getting photoelectrodes with long-term stability, particularly in harsh environments, requires unwavering effort. Herein, we have introduced a conformal surface engineering of the photoelectrode using In_2Se_3, a novel two-dimensional (2D) protective layer to secure the performance and stability of $BiVO_4$ at elevated pH electrolytes. The method involves In_2Se_3 self-assembling between immiscible solvents, then transferring onto the $BiVO_4$ electrode, resulting in a uniform coating. $BiVO_4$ after In_2Se_3 coating shows superior stability at higher pH (12 and 13) than pure BiVO4, at a potential 0.6 V vs RHE under 100 mW cm^{-2} of simulated air mass 1.5 illumination. The elemental and morphology analysis after stability tests proves the role of In_2Se_3 for effectively suppressing vanadium ion dissolution. Moreover, the incident photon-to-current conversion efficiency and absorption spectra suggest that In_2Se_3 improves the photocurrent of $BiVO_4$ by photon absorption and charge separation. These results suggested that In_2Se_3 and other novel 2D materials are promising as a protection layer for photoelectrodes that work for long-term stability during PEC operations.

Effects of Near Freezing Conditions on the Operating Behaviour of Directly Coupled Photovoltaic Anion Exchange Membrane Electrolysers Sonya Calnan[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Loughboough University, United Kingdom

The global demand for hydrogen generated using renewable energy sources is ever increasing in the race to reduce carbon-based emissions. Direct coupling of photovoltaic modules to electrolysers is a potentially low-cost approach to achieve long term energy storage of excess low-carbon emission electricity using hydrogen. However, efficient transfer of energy from photovoltaic (PV) modules to electrolysers demands appropriate sizing of both components to achieve power matching over a wide range of irradiance and weather conditions. Electrolysers with anion exchange membranes (AEM) allow the use of non-precious metals, and at the same time, require less voltage than a diaphragm separator, to draw a given electric current. Other approaches include replacing the oxygen evolution reaction at the anode with less energy intensive reactions. In the absence of power electronics for voltage management, the electrolyser experiences severe voltage fluctuations due to the variable output of the photovoltaic modules. Modulation of the voltage fluctuations can be partially achieved by circulating the electrolyte behind the photovoltaic module to increase the PV voltage while reducing the electrolyser voltage demand. We study the effect of irradiance and ambient temperature, under outdoor operation in Berlin Germany, on the rate of hydrogen production in a directly coupled PV electrolyser configuration in which active heating is not used. Close to freezing under clear sky conditions, the temperature of both the electrolyser and PV modules remains above that of the ambient. In such cases, we achieved hydrogen production rates of 80 – 100 mL/min at solar to hydrogen efficiencies ranging from 7- 10 % for a 2600 sq.cm silicon PV module and an electrolyser short stack cell consisting of three 112.5 sq.cm electrodes. However, below -5°C ambient temperature, hydrogen production stopped because the 1.0 M KOH electrolyte froze blocking the tubes and ducts and dehydrating the membrane. Nevertheless, after thawing the electrolyser, tests showed that the performance could be revived almost to the original levels. Tests are planned to investigate, in more detail, the nature of the degradation of AEM electrolysers when operated in freezing conditions to inform the development of more robust membrane and electro-catalyst materials. The results of studies on PV coupled electrolysers may also be transferred to other passively heated devices using liquid feeds such as photoelectrochemical and photocatalytic cells.

SESSION EN01.11: Poster Session I

Diffused Light-Harvesting via Multiple Semitransparent CdTe Solar Cells for Continuous Energy Production

Anudeep Katepalli[1], Anton Harfmann[1], Mathias Bonmarin[2], John Krupczak[3] and Donglu Shi[1]; [1]University of Cincinnati, United States; [2]Zurich University of Applied Sciences, Switzerland; [3]Hope College, United States

This research reveals the potential for continuous electricity generation by harnessing diffused LED light within buildings, particularly in modern cities with a high density of high-rises where lights are on at night and often wasted. This promotes the development of energy-neutral infrastructures, suggesting a promising pathway for sustainable indoor energy solutions and leveraging advanced PV technology to achieve higher efficiency and reliability. This study highlights the innovative application of semitransparent CdTe photovoltaic (PV) cells in harvesting diffused LED light to generate electricity. The research focuses on the power conversion efficiencies (PCEs) of these cells, which are found to be comparable to those achieved under natural sunlight. Remarkably, the highest PCE for CdTe PV cells with an average visible transmittance (AVT) of 40% surpasses that under natural sunlight, even at a significantly lower light power density 30 mW/cm^2. Experimental results underscore the importance of spectral response, particularly near the bandgap energy of CdTe (1.5 eV), for optimizing PCE. LEDs with wavelengths in the near-infrared range, close to the CdTe bandgap, are identified as optimal for energy conversion. A novel aspect of this research is the use of multi-panel configurations to enhance light harvesting efficiency. By stacking semitransparent CdTe panels, we observe a substantial increase in energy output. In an ascending order configuration of AVT, the multi-panel system achieves an impressive PCE of 17.7%, representing a 93.6% increase compared to a single panel. Furthermore, a descending order configuration yields a total PCE increase of 251.8%, demonstrating the significant advantages of multi-layer stacking. This research reveals the potential for continuous electricity generation by harnessing diffused LED light within buildings, thus promoting the development of energy-neutral infrastructures. The findings suggest a promising pathway for sustainable indoor energy solutions, leveraging advanced PV technology to achieve higher efficiency and reliability.

Transparent Sn-Decorated W-Doped TiO2 Multiphase Nanotube Arrays as Efficient Photocatalysts for Solar Fuel Production

Nageh K. Allam; The American University in Cairo, Egypt

Photoelectrochemical water splitting is a crucial step in realizing a green hydrogen economy. Herein, we demonstrate, for the first time, the rational design and optimized fabrication of earth-abundant W-doped TiO_2 thin nanotubular structures decorated with Sn in mixed polymorphs (anatase/brookite/rutile) on F-doped tin oxide substrates via a direct-current sputtering technique and subsequent electrochemical anodization followed by thermal treatment. Sn decoration and W doping along with optimized annealing conditions were elucidated as determinant factors controlling the structural and optical features of the fabricated nanotubes. The resulting highly crystalline polymorphic nanotubes showed an enhanced photocurrent at 0.4 V_{SCE} (1.75 mA/cm^2) with a noticeable narrowing in the optical band gap and 25 times compared to pristine TiO_2 nanotubes. The photoluminescence spectra revealed enriched oxygen (O) vacancies upon doping with W and decoration with Sn. The Mott–Schottky plot unveils the variations in the density of charge carriers upon annealing at different temperatures and their role in annihilating these O vacancies. Importantly, the electrochemical impedance spectroscopy elucidation helps to reveal the charge-transfer mechanism in the mixed polymorph junctions of the fabricated nanotubes under dark and illumination conditions, revealing reduced charge-transfer resistance under light-on conditions, which is consistent with the produced photocurrent, lifetime of the electrons, and density of the impurity levels. Moreover, the density functional theory investigation unraveled the development of a homojunction between the brookite and rutile phases that improved the photocatalytic activity toward the oxygen evolution reaction, in agreement with the experimental findings. The findings of this work represent a crucial milestone toward the development of visible-light, earth-abundant, light-absorbing photoanodes for solar-assisted water splitting.

EN01.11.03

A Study on Vanadium Dioxide Protective Layer and Defect Inactivation for Stability and Efficiency of Bismuth Vanadate Photoelectrode via Spontaneous Valence-Charge Control Kun Woong Lee, Dong Su Kim and Hyung Koun Cho; Sungkyunkwan University, Korea (the Republic of)

Photoelectrochemical (PEC) cells for water splitting have garnered significant interest as a promising solar-to-energy conversion technology. Bismuth vanadate ($BiVO_4$), a key photoanode material, offers numerous advantages but suffers from surface defects and photo-corrosion instability. To address these challenges, we introduce an innovative passivation strategy. Recognizing the role of V^{5+} ion dissolution in photo-corrosion, we propose a surface photoelectrochemical reduction-oxidation technology that transforms detrimental photo-corrosion into beneficial photo-oxidation by strategically introducing V^{5+} and H_2O_2 into the photoelectrochemical deposition electrolyte. This approach induces a surface phase transition of metal, resulting in the formation of an ultrathin and atomically controllable vanadium dioxide (VO_2) photoelectrochemical protective layer that enhances conductivity.
Characterization of the $BiVO_4/VO_2$ photoanodes reveals enhanced charge transport (86%) and efficient transfer of photogenerated carriers (95%) through the VO_2 protection layer. This advancement enables near-ideal performance, high stability, and exceptional durability. $BiVO_4/VO_2/CoFeO_x$ photoanodes exhibit a high photocurrent density of 6.2 mA/cm^2, an onset potential of 0.25 V_{RHE}, and an applied bias photon-to-current efficiency of 2.4% at 0.62 V_{RHE}, maintaining vigorous active oxygen evolution over 100 hours.

EN01.11.04

Transition Metal-Doped MoS_2 Ultrathin Film for CO_2 Photoreduction Tsai-Yu Lin[1,2,1], Mohammad Qorbani[1], Heng-Liang Wu[1], Kuei-Hsien Chen[2] and Li-Chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

Photocatalytic CO_2 reduction is a promising approach which can not only attenuate this greenhouse gas but also generate solar fuels, simultaneously. However, there is still significant challenges, i.e., low efficiency and selectivity, hindering the studied photocatalyst to be applied for industrial-scale applications. It seems introducing the catalytic active sites and shedding light on the reaction pathways would address the above-mentioned issues. In this regard, we propose introducing transition metal dopants into the crystal structure of inert MoS_2 to modify its basal plane for CO_2 activation. Beyond active site modulation, dopants can further change the electronic structure resulting in a tunable semiconducting type, tunable opto-electrical response, stabilizing the favored intermediates, and forming dopant–vacancy pairing. Wafer-scale MoS_2 ultrathin films, ~3 nm confirmed by atomic force microscopy, are synthesized by one step and facile solution-based thermal decomposition method. This method, by adding the dopant precursor, can assist to directly introduce dopant into the MoS_2 crystal structure without further post treatments. Raman scattering spectroscopy is widely used to investigate the lattice vibrational modes of the pristine and doped MoS_2. The TEM image provides direct evidence of Ni substitution at the Mo site. Moreover, the photocatalytic performance of doped MoS_2 demonstrates significant enhancement compared to pristine MoS_2. According to the results, by fine tuning the growth parameters, this work demonstrated that the solution based thermal decompaction is a promising way to fabricate doped large-scale transition metal chalcogenides ultrathin films. This method shows potential applications in catalysis and other related fields.

EN01.11.06

Small-Polaron Mediated Recombination in Titanium Dioxide from First Principles James A. Quirk[1] and Keith McKenna[2]; [1]Newcastle University, United Kingdom; [2]University of York, United Kingdom

Nonradiative recombination leads to losses in efficiency in optoelectronic devices such as photovoltaic cells and light-emitting diodes. Charges trapped at point defects or self-trapped as a small polaron may act as recombination centers. Using various phases of titanium dioxide as an example, we provide first-principles predictions that small hole polarons in the bulk of the crystal would exhibit significant rates of recombination with electrons in the conduction band.[1] However, small hole polarons trapped at a model grain boundary are predicted to have much higher nonradiative recombination rates, which can be attributed to softer phonon modes in the vicinity of the boundary as well as greater electron-phonon coupling. These findings have ramifications in materials other than titanium dioxide, and we propose strategies to reduce the degree of recombination that would occur at grain boundaries.

EN01.11.07

Tuning the Surface Properties of Polymer Hole Transport Materials (HTM) to Improve Interfacial Properties in Perovskite Solar Cells Andrew Mottur[1,2], Ashford Hollis[1] and Alan Sellinger[1]; [1]Colorado School of Mines, United States; [2]Bates College, United States

Perovskite solar cells (PSC) have achieved remarkable improvements over the past decade. They have comparable efficiency to silicon based devices, are easier and less expensive to manufacture, and have more versatility. Despite these positives, the widespread implementation of PSC is limited due to relatively rapid degradation of the cell during operation. One prevailing degradation route arises due to poor interfacial contact between the hole transport layer (HTL) and the perovskite active layer. This study aims to enhance the performance and longevity of these cells by tuning the wettability and thermal properties of a proven hole transport polymer CzFl, developed by the Sellinger group. This work will specifically deal with the design and synthesis of the novel CzFl-CN polymer, which incorporates a cyano group into the polymer side-chain. The polymer will be synthesized in three molecular percentages (15%, 20%, 25%), which will then be characterized to confirm structure (NMR), measure the molecular weight and the uniformity of the polymers (GPC), calculate the thermal properties (DSC, TGA), quantify the optoelectronic properties (UV-Vis), and assess the wettability of the polymers (goniometer).

EN01.11.08

Photoelectrochemical Redox Deposition of Rh_2P Nanoparticles on Cu_2O Photocathodes for Unassisted Solar Hydrogen Production Coupled with Glycerol Oxidation in Acidic Environments Ji Hoon Choi[1,2], Hak Hyeon Lee[1], Sungho Jeon[2], Eric A. Stach[2] and Hyung Koun Cho[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Pennsylvania, United States

Despite the theoretically validated approach of using photoelectrochemical (PEC) cells for solar-driven green hydrogen production, reported studies still fall short in achieving hydrogen production efficiencies suitable for practical applications. Among various studies on solar hydrogen production, the hydrogen evolution reaction (HER) under acidic conditions has been identified as a simple method to increase reaction rates and reduce overpotential losses. However, prolonged acidic exposure during PEC operation deactivates noble metal electrocatalysts (such as Pt and Rh), reducing device stability. To address catalyst degradation in acidic environments and enable stable/efficient PEC cell operation, we propose a process design based on the photo-illuminated redox deposition (PRoD) approach using an advanced Cu_2O-based photocathode. This approach allows for the growth of crystalline Rh_2P nanoparticles (NPs) with an average size of 20 nm on TiO_2/Al-ZnO/Cu_2O without annealing. Additionally, atomic-level precise reaction control was performed using several cyclic voltammetry coincident with light irradiation to create a system with optimal catalytic activity. The optimized photocathode, composed of $Rh_2P/TiO_2/AZO/Cu_2O/Sb–Cu_2O/ITO$, achieved an excellent photocurrent density of 8.2 mA cm^{-2} at 0 V_{RHE} and demonstrated durable water-splitting performance in a strong acidic solution. Notably, the Rh_2P-loaded photocathode exhibited a 5.3-fold enhancement in mass activity compared to a catalyst utilizing Rh alone. Furthermore, *in situ* transmission electron microscopy (TEM) was performed to observe the real-time growth process of Rh_2P NPs in a liquid cell. Finally, the fabricated Rh_2P/Cu_2O-based photocathode was integrated with a $BiVO_4$ photoanode for unassisted solar hydrogen production in acidic environments. Here, the oxygen evolution reaction (OER) at the photoanode was replaced with the glycerol oxidation reaction (GOR). Driving GOR with glycerol, a low-value substance, significantly improved the photocurrent density and lowered the onset potential compared to OER, ultimately maximizing HER at the photocathode.

EN01.11.09

Organic and Metal Chalcogenide-Based Light Absorbers for Assembling with Microbes—A Solar to Chemical Approach Through Living Microbial Photo Hybrids Muhammed Rishan[1,2], Prabeesh Punathil[1], Ewan McQueen[3], Reiner S. Sprick[3], Elizabeth Gibson[2] and Shafeer Kalathil[1]; [1]Northumbria University, United Kingdom; [2]Newcastle University, United Kingdom; [3]University of Strathclyde, United Kingdom

Rapidly increasing carbon footprint in the atmosphere is a global pressing challenge that has direct implications for climate change. Solar-to-chemical conversion is a promising way of renewable energy generation with the advantage of storing intermittent solar energy in the form of storable chemical bonds. To demonstrate this, we propose a semi-artificial way of photosynthesis by incorporating anaerobic bacteria over a synthetic light-absorbing material to form a biohybrid system. This biohybrid can convert CO_2 and sunlight into value-added chemicals and fuels through photo-assisted microbial catalysis. We are trying to achieve this through the process called microbial photosynthesis. This happens through bacteria hacking the photochemical activity of the light-absorbing semiconductor, that's by capturing the reducing equivalents (electrons or hydrogen) after photoexcitation to undergo the microbe's metabolism converting CO_2 into chemicals and fuels. Therefore, the photocatalytic performance of the light-absorbing semiconductor is crucial in the process that the overall performance of the biohybrid is majorly relied on it. We have been working on two classes of materials for Integrating with bacteria in microbial photosynthesis, those are nanocomposite metal chalcogenide and organic semiconductor. Both these materials are proven to be biocompatible with added benefits such as solution processibility, low toxicity, tuneable surface Interaction and cheap fabrication from earth-abundant elements. Cu_2ZnSnS_4 is a semiconducting quaternary metal chalcogenide we have been working on for Integrating with bacteria, this material has a narrower band gap of 1.5eV and a large optical coefficient. On Integrating with an anaerobic microbe *Sporomusa ovata*, the biohybrid has performed microbe-assisted photocatalytic CO_2 reduction into acetate and ethanol in appreciable yield with long-term stability. In parallel, nitrogen-containing linear poly (phenylic) organic semiconductor is another light-absorbing material we have been hybridizing with microbes. On Integrating with methanogenic/acetogenic bacteria, these materials have performed CO_2 to chemical conversion with appreciable yield. Considering the optical/spectroscopic relevance of this material, we are Investigating the enigmatic electron transfer mechanism happening between the light absorber and microbe through photoluminescence (PL) spectroscopy and transient absorption spectroscopy (TAS).

EN01.11.11

Utilizing Neural Network Potential for Facilitating Experimental Discovery of New Metal Oxide Photocathodes Toward Water Splitting Shuya Masuda[1,2], Yosuke Harashima[1], Shogo Takasuka[1], Tomoaki Takayama[1] and Mikiya Fujii[1]; [1]Nara Institute of Science and Technology, Japan; [2]Sumitomo Electric Industries, Ltd., Japan

Metal-oxide-based photocathodes are attractive components in photoelectrochemical cells for hydrogen production. This is due to both the ease of the synthesis and their stability under water-splitting conditions. However, most metal oxides are classified as photoanodes (namely, n-type semiconductors), resulting in a few metal-oxide-based photocathodes (p-type semiconductors). Therefore, in order to facilitate the experimental discovery of new metal oxide photocathodes, it is important to establish a methodology to easily classify candidates of the metal oxides as p- or n-types. In this study, we exhibit a new method to classify the p- and n-types. The key to developing our method lies in the combination of defect chemistry insight from materials science and the neural network potential of a machine learning technique. This combination has brought a sufficient classifier for semiconductor properties. Furthermore, the aforementioned method was employed to extract the candidates from the Materials Project database, leading to the experimental discovery of a new metal oxide photocathode.

Photocatalyst for Overall Solar Water Splitting—Semiconducting Scandium/Yttrium-Chalcohalides Yan-Fang Zhang[1], Peixuan Li[1], Lei Gao[2] and Shixuan Du[1]; [1]Chinese Academy of Sciences, China; [2]Kunming University of Science and Technology, China

Solar-driven photocatalytic water splitting stands as a pivotal technology for the production of hydrogen, representing a significant step towards sustainable and renewable energy solutions. This presentation highlights the potential of two-dimensional materials as photocatalysts with tunable electronic properties for superior photocatalytic performance. Utilizing first-principle calculations, we have discovered a series of scandium/yttrium chalcohalide monolayers (ScSeCl, ScSeBr, ScSeI, ScTeI, YTeCl, YTeBr, and YTeI) in the α phase, showcasing promising characteristics for overall solar water splitting. These materials exhibit optimal band gaps and band edge positions, aligning well with the visible light region of the solar spectrum. Our findings indicate a notable increase in visible light response with the number of layers, particularly in α-ScTeI, where the absorption intensity increases from 15% in the monolayer to 45% in the seven-layer configuration. Moreover, monolayer and bulk α-ScTeI demonstrate advantageous properties such as low exciton binding energy, elevated carrier mobility, and prolonged hot carrier cooling time, positioning them as exceptional candidates for photocatalytic applications. This research underscores the potential of van der Waals scandium/yttrium chalcohalides as high-efficiency photocatalysts for solar water splitting. The results presented here motivate further experimental research to develop scalable and cost-effective strategies for green hydrogen production, contributing to the global shift towards clean energy.

EN01.11.14

Synergistic Photothermal and Photocatalytic Reduction of Carbon Dioxide to Methane via the Integration of Topological Bismuth Selenide and Zinc Indium Sulfide Photocatalysts Jia-Mao Chang[1], Ting-Han Lin[1,2], Yin-Hsuan Chang[1] and Ming-Chung Wu[1,2]; [1]Chang Gung University, Taiwan; [2]Center for Sustainability and Energy Technologies, Taiwan

Photothermal catalysis is a technique that employs a hybrid photocatalyst to absorb photons and convert them into thermal energy. Light is the energy source in this process, generating electron-hole pairs from the hybrid catalyst. The intense non-radiative relaxation produces heat, increasing the reaction temperature and lowering the activation energy, thereby enhancing the catalytic reaction. This energy conversion pathway improves catalytic efficiency without requiring an additional heat source. Consequently, natural solar-driven synergistic photothermal catalysis for CO_2 reduction is promising for sustainable and efficient CO_2 conversion. In this study, a series of $Bi_2Se_3/ZnIn_2S_4$ photocatalysts were prepared using the solvothermal method. $ZnIn_2S_4$, with an appropriate energy level, acts as the primary catalyst to drive the redox reaction in CO_2 photoreduction. Bi_2Se_3, possessing a narrow bandgap (0.3-1.2 eV), exhibits excellent light absorption from ultraviolet to near-infrared. Incorporating Bi_2Se_3 induces the "thermal island" effect in the composite, resulting in a notable increase in bulk temperature under light irradiation. After 15 minutes of halogen lamp irradiation, the temperature of the $Bi_2Se_3/ZnIn_2S_4$ photocatalyst rises from 27.9°C to 49.1°C, significantly higher than that of bare $ZnIn_2S_4$ (36.8°C). This temperature increase facilitates the acceleration of the photocatalytic reaction. As expected, 0.10 wt% $Bi_2Se_3/ZnIn_2S_4$ exhibits the highest activity under simulated sunlight. The production rates of CO_2 to CO and CH_4, are 0.19 and 3.64 μmol/g/h, respectively. The total electron consumption rate of 29.51 μmol/g/h is 134.1 times that of $ZnIn_2S_4$. The high CH_4 selectivity of up to 95.1% is achieved. Temperature-dependent photoluminescence spectra reveal that $Bi_2Se_3/ZnIn_2S_4$ photocatalyst has a relatively low exciton binding energy (E_b = 373.7 meV) compared to $ZnIn_2S_4$ (E_b = 546.6 meV). The thermal effect effectively dissociates excitons into free carriers, enhancing charge transfer and improving photocatalytic activity. Furthermore, we employ photo-assisted Kelvin Probe Force Microscopy (Photo-assisted KPFM) under various wavelength LED light sources, including UV at 365 nm, blue at 470 nm, green at 530 nm, and red at 656 nm to measure the light-induced contact potential difference (CPD) and evaluate the photoresponse. Compared to $ZnIn_2S_4$, the $Bi_2Se_3/ZnIn_2S_4$ photocatalyst exhibits a significant potential change due to its broad absorption properties. This further indicates that introducing Bi_2Se_3, with its intrinsic topological surface state, enhances the level of non-radiative relaxation, thereby facilitating the photothermal effect. In summary, this work highlights that the $Bi_2Se_3/ZnIn_2S_4$ composite material exhibits excellent photothermal effects and high selectivity for photocatalytic CO_2 reduction to CH_4, providing new insights into photothermal conversion.

Advancements in 2D Nanostrctured Materials for Environmental Remediation—Role of Surface Charge, Charge Transfer Resistance and Recombination Time Manika Khanuja; Jamia Millia Islamia, India

Transition metal dichalcogenides (TMDs) represent a class of two-dimensional materials with the general formula MX_2, where M is a transition metal (e.g., W, Mo, Ti) and X is a chalcogen (S, Se, Te). These materials have gained significant attention in recent years due to their unique electronic, optical, and chemical properties, which arise from their layered structure and quantum confinement effects. TMDs exhibit a wide range of characteristics, from semiconducting to metallic, making them versatile candidates for various applications in electronics, optoelectronics, catalysis, and environmental science.

This study presents a comprehensive optimization of MX_2 for sustainable environmental solutions, with a focus on enhancing its performance in pollutant degradation and charge transfer processes.We employed impedance spectroscopy to investigate charge transfer mechanisms in optimized MX_2 structures, providing crucial insights into their electrochemical behavior. Zeta potential measurements were conducted to assess and improve the stability of MX_2 nanostructures in various environmental conditions, ensuring their long-term effectiveness.

A key innovation in this research was the synthesis of novel composites combining MX_2 with polymers, oxidesand various nanocomposites comprising 0D/1D/2D nanostructures. These composites demonstrated remarkable synergistic effects, resulting in a significant reduction of pollutant degradation time by 80-90% compared to pristine materials. This breakthrough has important implications for water treatment and environmental remediation technologies.

To quantify the photocatalytic efficiency of our optimized MX_2-based materials, we performed Incident Photon-to-Current Efficiency (IPCE) measurements. These results provide valuable data on the quantum efficiency of the system, offering insights into its potential for solar-driven environmental applications. Our findings highlight the exceptional potential of optimized MX_2 and its composites in advancing sustainable environmental solutions. The dramatic improvement in degradation efficiency, coupled with enhanced stability and charge transfer properties, positions this material as a promising candidate for addressing pressing environmental challenges.

This research paves the way for the development of highly efficient, stable, and sustainable MX_2-based technologies for environmental remediation and beyond.

EN01.11.17

Synergistic Enhancement of Hydrogen Production Through Photo-Piezocatalytic $BaTiO_3/ZnIn_2S_4$ Heterostructures Ting-Han Lin, Jia-Mao Chang, Yu-Chi Peng, Yen-Chang Chen, Yin-Hsuan Chang, Kun-Mu Lee and Ming-Chung Wu; Chang Gung University, Taiwan

Solar-to-Fuel technologies are crucial for the energy transition, enhancing green energy availability and mitigating climate change by offsetting emissions. Hydrogen energy, notable for its zero emissions, relies on solar irradiation to drive essential photocatalytic reactions for fuel production. Improving charge transfer and electron-hole pair separation is key to boosting catalytic efficiency. Additionally, integrating the piezoelectric effect, triggered by mechanical strain, enhances charge carrier separation, thus enhancing the efficiency of Solar-to-Fuel systems. In this study, we synthesized visible-driven $ZnIn_2S_4$ nanosheets as photocatalysts and integrated them with nanosized $BaTiO_3$ piezocatalysts for hydrogen production via water splitting and biomass reforming. To develop a highly active primary photocatalyst, we optimized the synthesis conditions of $ZnIn_2S_4$ to control its preferred crystal phase, phase ratio, and planar spacing effectively. The optimal conditions, identified at a stabilizing agent concentration of 75% and a temperature of 120°C, allowed the photocatalyst to exhibit superior performance.We then engineered a heterostructure to create $BaTiO_3$/ZnIn2S4 photo-piezocatalysts, observing a well-dispersed distribution of nanocubes onto nanosheets. Significant modifications in the morphological and crystal structures, as well as optical properties, were observed as the heterostructure was developed. In photo-piezocatalysis, the optimal $BaTiO_3/ZnIn_2S_4$ achieved a hydrogen production rate of 154.04 $\mu mol●g^{-1}●h^{-1}$, which is 3.55 times higher than that of pristine $BaTiO_3$ or $ZnIn_2S_4$ alone. This increase is attributed to the synergistic effects of photocatalysis and piezocatalysis. To elucidate the synergistic pathways of energy-induced charge carriers, we employed in-situ X-ray photoelectron spectroscopy (XPS) under Xenon illumination. Notable upshifts in the binding energies of elemental orbitals in $BaTiO_3$ indicated a decrease in electron density upon irradiation, suggesting that photogenerated holes from $ZnIn_2S_4$ migrate to the interface and attract localized electrons within $BaTiO_3$, thereby enhancing its self-polarization effect. This mechanism highlights the dynamic interaction at the heterojunction, crucial for enhancing photocatalytic activity. Further investigating the dynamics of charge carriers, we used a photo-assisted Kelvin probe analyzer to measure the contact potential difference (CPD) under UV illumination and in the dark. We observed a gradual decrease in the CPD shift of $BaTiO_3/ZnIn_2S_4$ compared to pristine $ZnIn_2S_4$, which we attribute to the coverage of polarized $BaTiO_3$ nanocubes on the composite surface, affecting the electrostatic environment. Additionally, ultrasonic treatment combined with illumination effectively inhibited the recombination of photogenerated electron-hole pairs in $ZnIn_2S_4$. Simultaneously, a high concentration of anions attracted onto the $BaTiO_3$ enhanced the reduction activities due to the screening charge effect of piezocatalysis. These observations confirm the charge carrier interaction and underscore the synergistic effect within this heterostructure. Consequently, the $BaTiO_3/ZnIn_2S_4$ heterostructure demonstrates efficient hydrogen production through photo-piezocatalysis, applicable not only in water splitting but also in the reforming of biomass into hydrogen. This photo-piezocatalyst holds promising potential for future applications in green energy production, offering a sustainable and versatile solution for renewable energy technologies.

EN01.11.20

Post-Synthesis Metal Cation Doping of TiO_2 at Room Temperature by Electrochemically Augmented Interstitial Atom Injection from Surfaces Raylin Chen, Jaeyoung Hong, Ian Suni, Grace McKnight, Xiao Su and Edmund Seebauer; University of Illinois, United States

Metal doping of semiconducting metal oxides has been long investigated for photocatalysis applications including water splitting for solar hydrogen production. However, incorporation of metal cation dopants during synthesis is often not readily controllable with respect to concentration, spatial distribution, or formation of secondary chemical states or phases. Existing post-synthesis doping methods also have problems – ion implantation causes irreversible lattice damage, and inward diffusion suffers from poor controllability and requires high-temperature annealing that degrades nanostructures. Here we demonstrate an electrochemically augmented method for metal dopant introduction (specifically, Mn) into single-crystal rutile TiO_2 from aqueous solution by injection of dopant interstitial atoms from surfaces. The concept generalizes an idea already demonstrated for injecting adsorbed O into oxides as interstitials,[1] whereby lowered chemical coordination at clean surfaces facilitates the conversion of adsorbates into interstitials with energy barriers near or even below 1 eV. The atomic configurations for interstitial injection resemble those for site hopping in the bulk, with barriers only slightly higher. The modest hopping barriers of metal interstitials in oxides suggest a similar concept may work for metal doping, especially with electrochemical facilitation of any change in oxidation state during injection. We describe diffusion measurements near room temperature using a conventional 3-electrode electrochemical cell with $MnCl_2$ dissolved in water labeled with ^{18}O. Post-diffusion depth profiling of the TiO_2 with secondary ion mass spectrometry (SIMS) demonstrates Mn penetration up to depths of 200 nm after 1 h in an exponentially shaped profile, with near-surface concentrations >1 atom%. Depth-profiling x-ray photoelectron spectroscopy reveals Mn mainly in oxidation states of +4 and +2 when an N_2 atmosphere is used during diffusion. SIMS shows that ^{18}O simultaneously injects into the solid. Evidence is presented for clustering of some Mn and O interstitials to form small complexes.

Metal-Free Photocatalysts for the Conversion of Plastic Wastes into Valuable Chemicals and Fuels at Ambient Conditions

Xin Ying Kong and Teck Peng Loh; Nanyang Technological University, Singapore

Plastic has significantly enhanced the convenience of modern life. As one of the most robust synthetic materials, plastics offer a range of advantageous properties, including lightness, durability, affordability, and wide applicability, leading to their ever-increasing demand and production over the past decades. However, only 9% of global plastic waste had been recycled in 2019, 19% had been incinerated, while the remaining 72% of plastics remained in the environment. This results in severe environmental pollution, and the current unsustainable trajectory signifies the urgent need for innovation plastic recycling technologies that not only mitigate environmental issues but also valorize plastic waste as a resource.

To date, most plastic products are made of non-biodegradable polymers, including polystyrene (PS), polypropylene (PP), polyvinyl chloride (PVC), polyethylene (PE), and polyethylene terephthalate (PET). These materials can persist for 100 to 1000 years in natural environments, contributing to severe environmental pollution and ecological issues. Although some plastics, such as polycarbonate (PC), polyurethane (PU), and polylactic acid (PLA) are labelled as biodegradable, the decomposition of such plastics require specific conditions like microorganisms, enzymes, or light exposure for their decomposition into water (H_2O) and carbon dioxide (CO_2), a greenhouse gas. Given the escalating environmental concerns and the need to repurpose the carbon content in plastic waste, the development of efficient technologies for upcycling plastic waste – transformation of plastic waste into valuable compounds, is a pressing necessity. However, this is a great challenge, as plastics are typically composed of long-chain organic molecules with highly stable and kinetically inert C–C bonds, requiring selective cleavage to chemically transform plastic waste into its monomer or value-added small molecules.

In this study, we developed a green approach to convert the unwanted plastic wastes into energy-rich fuels and high-value chemicals through the development of metal-free organo-photocatalysts with the co-existence of tri-coordinatied nitrogen vacancies and oxygen-linked heptazine units. This photocatalyst was designed to act as chemical scissors, selectively cleaving the highly stable and kinetically inert C–C bonds in biomass and plastics, thereby transforming them into commercially valuable small molecules. Based on our preliminary studies, we have successfully transformed a wide range of plastics, from resin codes 1–7, including conventional plastics, co-polymers, real-life plastic wastes, mixed plastics, and contaminated waste plastics into value-added platform chemicals and liquid organic hydrogen carrier, serving as a form of fuel. This was incredibly achieved without requiring any pre-treatment of the plastics, unlike other methods documented in the literature that typically require sorting, cleaning, or pre-treatment of plastic wastes in strong alkaline or acidic condition. Remarkably, our innovative photocatalytic chemical reactions can take place at room temperature and atmospheric pressure, contrasting with the most established plastic conversion method of pyrolysis, which requires elevated reaction temperatures (160–1000^{o}C). To the best of our knowledge, no existing research has yet demonstrated the capability to photocatalytically upcycle such a diverse array of plastics under ambient conditions. Our project aligns with global objectives for sustainable waste management, aiming to mitigate environmental pollution and promote a circular economy by harnessing the latent value in plastic wastes for waste-to-treasure conversion.

EN01.11.22

Development of Monolithic Dual-Perovskites for Two-Step Thermochemical Water Splitting Seyfettin B. Sanli, Gulhan Cakmak and Berke Piskin; Mugla Sitki Kocman University, Turkey

Thermochemical methods based on solar energy come to the fore in hydrogen production. It is possible to produce hydrogen without the need for purification via the two-step thermochemical water splitting (TWS) method. TWS uses metal oxides as redox materials allowing for the production of pure hydrogen at lower temperatures as compared to thermolysis. Therefore, the thermodynamics and kinetics of redox reactions are the important factors that determine hydrogen production efficiency and are influenced by the structural properties of active materials used in these reactions. For this purpose, perovskite-oxides draw attention to be able to use in TWS reactions due to providing higher structural stability with allowing compositional diversity. In the TWS method, for effective hydrogen production, there is a need for structurally stable metal oxides performing high redox capacity, high reaction kinetics, and high stability during the thermal cycles [1].

It was aimed to improve hydrogen production capacity with the existence of hetero-interfaces as well as preserve stability during the redox cycles. It is known that the production capacity of perovskite oxides in the literature is decreased significantly (40%-80%) in the initial cycles. It is aimed to improve structural stability and stabilize the hydrogen production rate (>80%) of perovskite oxides with the hetero-interface approach.

In this study, the perovskite families were firstly doped with A-site and B-site elements and then the compositions were optimized due to their hydrogen production capacities. For this purpose, a total of 9 perovskite oxides including $La_{1-x}Sr_xMn_yAl_{1-y}O_3$-LSMA (Sr=0.4-0.6, Al=0.4-0.6) and $La_{1-x}Ca_xMn_yAl_{1-y}O_3$-LCMA (Ca=0.4-0.8, Al=0.4-0.8), LCMF (Ca=0.4-0.8, Fe=0.4-0.8) and LCMC (Ca=0.4-0.8, Co=0.4-0.8) compositions were synthesized by Pechini method. These compositions then were evaluated in thermochemical redox reactions (T_{red}=~1400 °C, T_{ox}=~800 °C) and three compositions with the highest hydrogen production were chosen for further studies. Determined hydrogen production for the three highest from each family were used to form monolithic structure to create hetero-interface.
Among the dual-peroistvskite, LSMA6464-LCMF6482 was the composition with the highest hydrgen production with a first cycle production value of 155.54 μmol/g. This composition maintained its performance by 57.14% in the 3rd cycle. This composition was followed by LSMA6446-LCMF6446 and LSMA6455-LCMF6464 with 131.47

μmol/g and 127.09 μmol/g, respectively.

When the re-oxidation performances of the dual-perovskites were compared, it was found that the LSMA6446-LCMF6482 dual-perovskite retained 66.86% of its first cycle efficiency value. This composition was followed by LSMA6455-LCMF6446 (61.35%) and LSMA6464-LCMF6482 (57.14%) dual-perovskites, respectively. Here, it was understood that LCMF-containing dual perovskites maintained their efficiency at a higher rate.

Unassisted Polymer Electrode Membrane–Photoelectrochemical Cell with a Transparent Porous Conductive Substrates for Solar-Driven Overall Water Splitting with Humid Air

Benjamin Goldman, Nicolas J. Diercks and Kevin Sivula; École Polytechnique Fédérale de Lausanne, Switzerland

Photoelectrochemical (PEC) water splitting using humid air is a favorable option to scale up solar H_2 production in regions limited by freshwater feedstock. A Transparent Porous Conductive Substrate (TPCS) made with quartz fibers melted together and coated with FTO is a promising support for photoelectrodes and PEC water splitting in the gas phase instead of the classic gas diffusion layer or FTO glass. Inspired by the natural photosynthesis process of a leaf, an unassisted PEM-PEC cell using an organic BHJ semiconductor-based photocathode (PBDTTTPD:PNDIHDT) and an inorganic oxide-based photoanode ($BiVO_4$) was developed on TPCS, and a stable 1 mA/cm^2 was observed under vapor feeding conditions. This work makes a first step to validate unassisted water splitting using a PEM-PEC cell architecture with humid air, and further research will advance this technology toward practical applications.

EN01.11.24

Advanced Hierarchical S-Scheme Heterojunctions of O-Doped g-C_3N_4/N-Doped Nb_2O_5 for Superior Photocatalytic CO_2 Reduction

Fahim A. Qaraah[1], Samah A. Mahyoub[1] and Turki N. Baroud[2,2]; [1]king Fahd University of Petroleum & Minerals, Saudi Arabia; [2]King Fahd University of Petroleum & Minerals, Saudi Arabia

The strategic design and engineering of optimal hierarchical photocatalysts have gained significant attention for enhancing CO_2 photoreduction to fuel production. In this study, we present an innovative 3D O-doped g-C_3N_4/N-doped Nb_2O_5 (OCNNb) S-scheme heterojunction, synthesized through controlled surface charge-induced heteroaggregation for photocatalytic CO_2 reduction (PCR). The optimized OCNNb sample demonstrates significantly higher CO_2 conversion rates (combined production rates of CO and CH_4) compared to individual components, O-doped g-C_3N_4 (OCN), and N-doped Nb_2O_5 (NNBO). The superior photocatalytic efficiency is attributed to the effective suppression of photogenerated charge carrier recombination by the S-scheme heterojunction, along with the high specific surface areas and plentiful active sites. Work function measurements, in situ irradiated X-ray photoelectron spectroscopy, and electron paramagnetic resonance (EPR) studies validate

the S-scheme charge transfer mechanism. This research provides a valuable approach for developing highly efficient heterojunction photocatalysts for solar fuel conversion.
