New bioelectrical modulation techniques are constantly improving the spatial resolution of electronic extra- and intracellular biointerfaces using different micro and nanomaterials. Although substrate bound micro and nanoelectrodes are extremely useful, they are limited in the sense of delivering bioelectrical modulation to cells that are inside a 3D tissue construct, or in vivo. Thus, many leadless technologies are being developed. One of the most promising approaches for leadless electrical modulation with high spatial resolution is the use of optoelectronic nanomaterials that can transduce optical illumination to an electrical output. Free standing silicon nanowires (SiNWs) with coaxial p-i-n junction are ideal for minimally invasive intracellular biointerface as they are soft, flexible, and thus can spontaneously internalize into many different cell types. They have been used by us and others to deliver extra- and intracellular bioelectrical modulation to neurons, oligodendrocytes, cardiomyocytes, cardiac myofibroblasts and more. However, the underlying mechanism of how SiNWs transduce the optical energy to an electrical modulation was not yet fully determined and is still under debate. In this context, the optical effect may be photothermal via capacitive membrane currents or transient membrane poration. On the other hand, the optical modulation induces a photoelectrochemical response which may produce reactive oxygen species (ROS) that can trigger local calcium release from neighboring organelles (ER or mitochondria). Alternatively, the photoelectrochemical response can generate a local change in the cytosol electrical potential which may induce an ionic response via voltage gated ion channels. Clearly, to disseminate this technology within the relevant scientific community, it is essential to decipher the underlaying mechanisms that govern SiNWs based optical response.

In this study we used different approaches to assess the potential contribution of the proposed mechanisms. First, we used p-i-n and n-i-p coaxial core-shell SiNWs which possess photoelectrochemical properties to investigate the effect of opposing anodic/cathodic biointerfaces. Moreover, we used similar core-shell i-i-i SiNWs to test the contribution of photothermal effect without any photoelectrochemical response. We used calcium imaging and a tailored made algorithms to quantify the calcium flux in response to the modulation. We found that both p-i-n and n-i-p diode junctions resulted in comparable optical responses which were significantly higher than the i-i-i photothermal response. This suggests that the photoelectrochemical effect is dominant over photothermal response.

To investigate whether the calcium source is internal or external, we used Thapsigargin to deplete intracellular calcium stores. Alternatively, we used calcium free media to eliminate any extracellular calcium and compared the cellular responses to optical modulation. We found that the eliminating intracellular calcium abolished any optical response, while extracellular calcium elimination had no apparent effect. Thus, we conclude that intracellular calcium stores are the source for the intracellular modulation.

To investigate the contribution of ROS, we used ROS sensitive dyes to monitor changes in ROS upon optical modulation. Although a small ROS increase was observed in cells baring internalized SiNWs, intracellular ROS did not change upon optical modulation. This suggests that local ionic response is the dominant mechanism for inducing intracellular calcium release from organelles.

To further understand this phenomenon, we will use different specific channel blockers to identify the channels that play a role in calcium release upon optical modulation. We believe that the understanding of this mechanism will facilitate the dissemination of this technology into bioelectronic research and open new avenues for studying bioelectronic communication in 3D microenvironment and in vivo.

Advancements in Spinal Cord Research Using Organic Mixed Ionic–Electronic Conductors for Enhanced Neural Interfacing *Salim ElHadwe, Ruben Ruiz-Mateos Serrano, Alejandro Carnicer Lombarte, George G. Malliaras and Damiano Barone; University of Cambridge, United Kingdom*

Background: *Advancements in bioelectronics and Organic Mixed Ionic–Electronic Conductors (OMIECs) are propelling spinal cord research into new frontiers. These developments have led to electrodes with low impedance and high charge storage capacity, enhancing electrochemical performance and minimizing tissue trauma. Building on this progress, we have designed a groundbreaking flexible device that can be conformably wrapped around the spinal cord. This device leverages the functional anatomy of the spinal cord for precise, high-fidelity neural interfacing, representing a significant innovation in spinal cord interfacing.*

Methods: *We evaluated our device's efficacy and versatility through implantations in diverse models. Initial tests were conducted on rodents to assess basic functionality and safety, followed by trials in porcine models to evaluate adaptability and performance. Additionally, trials on human cadavers were performed to simulate clinical applicability and anatomical integration.*

Results: *The device demonstrated successful implantation and high-resolution interfacing with the spinal cord in rodent and porcine models. It enabled precise, muscle-specific controlled movements in anesthetized animals, indicating effective targeted stimulation. Additionally, the device facilitated high-fidelity recording of neural activity from the spinal cord of freely walking rodents. These neural recordings were combined with evoked stimuli and kinematic analysis of the animals' movements, allowing for the precise localization of spinal cord loci associated with specific functions.*

Conclusion: *Our research represents a substantial advancement in spinal cord interface technology. The device's successful performance across diverse models highlights its adaptability and potential applications in spinal cord research and clinical settings.*

SESSION SB02.06: Sensing and Screening
Session Chairs: Farbod Amirghasemi and Luisa Torsi
Wednesday Morning, December 4, 2024
Hynes, Level 1, Room 102

9:00 AM *SB02.06.01

Soft Electronic Materials, Sensors and Their Bioelectronic Applications *Zhenan Bao; Stanford University, United States*

In this talk, I will present recent progress related to soft bioelectronic materials, sensors and applications.

9:30 AM SB02.06.02

On-demand Advanced Manufacturing of Metal-Organic Framework-Integrated Textiles for Enhanced, Reversible, and Rapid Gas Sensing Applications *Reza Montazami, Maedeh Ahmadipour and Nursultan Turdakyn; Iowa State University of Science and Technology, United States*

Metal-organic frameworks (MOFs) have emerged as promising materials due to their tunable properties, high surface area, and excellent porosity, with applications spanning from gas sensing to catalysis. Integrating MOFs into textiles for soft electronics offers a versatile approach for addressing chemical agents by enabling selective adsorption and catalytic breakdown of toxic compounds. In this presentation, we will demonstrate the fabrication of MOF-integrated textiles using solution-phase electrohydrodynamic jet printing (e-jet printing), which allows for precise, scalable, and on-demand deposition of activated MOFs on various non-conductive textile substrates. Specifically, we formulated an ink of ionic liquid-activated $Cu_3(HHTP)_2$ MOF material suitable for e-jet printing on textiles. The resultant smart textiles exhibited excellent chemiresistive sensing capabilities towards nitric oxide (NO) gas, demonstrating significant and reversible sensitivity across a wide range of concentrations (5 ppm to 300 ppm). The integration of 1-Ethyl-3-methylimidazolium trifluoromethanesulfonate (EMIM-Otf) ionic liquid into the MOF structure significantly enhanced gas sensitivity and reversibility compared to MOF-integrated textiles without the ionic liquid and those fabricated through conventional approaches. The structural integrity of the printed MOF-integrated textiles was maintained after gas exposure, confirming their robustness and reusability. This work highlights the potential of e-jet printing for the fabrication of functional MOF-integrated smart textiles with tunable properties, paving the way for advanced applications in gas sensing and filtration.

9:45 AM SB02.06.03

Conductive Peptide-Based MXene Hydrogel as a Piezoresistive Sensor *Dana Cohen-Gerassi, Or Messer, Gal Finkelstein-Zuta, Moran Aviv, Bar Favelukis, Yosi Shacham-Diamand, Maxim Sokol and Lihi Adler-Abramovich; Tel Aviv University, Israel*

Wearable pressure sensors have become increasingly popular for personal healthcare and motion detection applications due to recent advances in materials science and functional nanomaterials. In this study, a novel composite hydrogel is presented as a sensitive piezoresistive sensor that can be utilized for various biomedical applications, such as wearable skin patches and integrated artificial skin that can measure pulse and blood pressure, as well as monitor sound as a self-powered microphone. The hydrogel is composed of self-assembled short peptides containing aromatic, positively- or negatively charged amino acids combined with 2D $Ti_3C_2T_z$ MXene nanosheets. This material is low-cost, facile, reliable, and scalable for large areas while maintaining high sensitivity, a wide detection range, durability, oxidation stability, and biocompatibility. The bioinspired nanostructure, strong mechanical stability, and ease of functionalization make the assembled peptide-based composite MXene-hydrogel a promising and widely applicable material for use in bio-related wearable electronics.

10:30 AM *SB02.06.04

Conductive Hydrogels and Elastomer Nanocomposites for Soft Bioelectronics *Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)*

Recent advances in soft bioelectronics have garnered significant attention, largely due to their potential applications in personalized, bio-integrated healthcare devices. The mechanical mismatch between conventional electronic devices and soft human tissues or organs often presents various challenges, such as low signal-to-noise ratios in biosensing, inflammation or excessive immune responses near implanted devices, and inadequate electrical or chemical stimulation in feedback therapies. To address these issues, novel materials for ultra-flexible and stretchable electronic devices have been developed, as their mechanical and material properties are more compatible with in vivo cellular environments, and these devices hold great potential for solving the aforementioned challenges. Particularly, in the development of such bioelectronic devices, nanomaterials and *their composites with hydrogels and elastomers have been actively researched. This talk presents unconventional soft electronic materials and device fabrication strategies, as well as their applications to diagnosing and treating major diseases including cardiovascular diseases. The integration of two different types of soft conductive materials and the incorporation of wireless power supply technologies in the unconventional bioelectronic platform offer additional opportunities. Key challenges in the future technological roadmap and potential technological solutions will also be briefly discussed. These efforts in developing unconventional materials and bioelectronic devices are expected to contribute significantly to addressing unresolved issues in clinical medicine.*

11:00 AM SB02.06.05
Real-Time Monitoring of Endoleak in Abdominal Aortic Aneurysm Stent Implants Using Flexible Coplanar Capacitor Sensors *Sun Young Park, Soo Hyun Kim and Yei Hwan Jung; Hanyang University, Korea (the Republic of)*

One of the treatment methods for abdominal aortic aneurysms is stent implantation. However, within five years post-procedure, there is a potential risk of recurrence due to endoleak. These leaks do not present characteristic symptoms upon onset, making it necessary to detect their occurrence solely through imaging techniques such as CT or MRI. This necessitates regular follow-up visits, imposing a significant burden on patients. To overcome the temporal and spatial limitations that hinder effective patient risk monitoring, real-time detection technology is crucial. We propose a non-invasive, flexible sensor capable of detecting Type I endoleak, which poses the highest risk. This serpentine-shaped coplanar capacitor sensor is designed to be attached to the exterior surface of the stent, continuously monitoring blood leakage. Fabricated with microscale thickness, this sensor does not impede vascular movement and can wirelessly provide real-time data on the location and extent of leaks. By overcoming major challenges associated with the transfer of flexible electrodes, the sensor maintains consistent performance even after repeated cycles of expansion and contraction. This technology enables real-time monitoring of the patient's condition, allowing for timely intervention. Consequently, it significantly improves treatment outcomes for patients with aortic aneurysms and reduces the complications that can arise post-procedure. The sensor represents a breakthrough in the management and treatment of aortic aneurysms, providing a means to minimize risks and enhance patient care through advanced monitoring capabilities.

11:15 AM SB02.06.06
Designing the Electrochemical Aptamer-Based Biosensor with Antifouling Properties for Therapeutic Drug Monitoring *Su Yeong Kim and Steve Park; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

As the aging society emerges, the market for point-of-care (POC) devices that can quickly and efficiently diagnose diseases and monitor patient-specific responses to drug delivery is rapidly expanding. Implantable electrochemical biosensors within the body enable rapid and continuous detection and facilitate prompt personalized medical treatments. Recent research has focused on flexible wire or chip-based implantable biosensors coated with nanostructured conductive materials. This innovation addresses the degradation of the signal-to-noise ratio caused by the mechanical mismatch between the biosensor and the surrounding tissues. By overcoming this challenge, these biosensors enable accurate and continuous monitoring of biomarkers and drug delivery over extended periods. However, electrochemical biosensors face several obstacles in detecting target biomarkers within tissues. These include (1) degradation of sensing performances (i.e., sensitivity, specificity) and shelf-life of the biosensor due to non-specific binding and biofouling of various biomolecules, (2) false positive and negative increment during diagnosis, and (3) potential inflammation caused by the low biocompatible nanomaterials. Addressing these challenges is crucial for the successful development of effective electrochemical biosensors for clinical applications and personalized precision diagnostics.
Here, we designed the electrochemical aptamer-based biosensor by coating it with a highly porous and thin

antifouling nanocomposite composed of cross-linked bovine serum albumin (BSA) and gold nanowires (AuNWs). Conventional antifouling coatings, such as the blocking layer with BSA, PEG hydrogel-based coating, cross-linked BSA/AuNWs coating, and self-assembly monolayer with alkylthiolate molecules, still face problems of high electrochemical impedance, low biocompatibility, and degradation of aptamer performances. These problems arise because of the thick and insulated coating and high cytotoxicity of cross-linker, like glutaraldehyde. Unlike these coatings, we optimized the composition of cross-linker, or genipin (GP), to contain high porosity and durability while maintaining the biocompatibility of the antifouling matrix. Coated through a solution process on gold chips, this coating showed a surface area higher than conventional cross-linked BSA/AuNWs coating and provided the micro-level electrochemical signal. It also exhibited 1.7-fold higher antifouling property than conventional cross-linked BSA/AuNWs coating under serum conditions. This electrochemical biosensor was used to confirm the continuous detection of tobramycin with a dynamic concentration range starting from micromolar to millimolar level. In addition, we demonstrated the in-vitro stability of this sensor by detecting tobramycin with constant sensitivity in the presence of various nonspecific substances from the serum. Moreover, we demonstrated the reduced cytotoxicity of the nanocomposite and improved durability of the aptamer itself in serum. As a result, this highly durable electrochemical biosensor enables various applications of implantable biosensing and customized diagnosis and treatment with high sensitivity and selectivity.

11:30 AM SB02.06.07

Development of a Fully Implantable Mechano-Electrocardiogram (MECG) Sensor for Comprehensive Cardiac Monitoring *Joosung Oh, Ik-Soo Kim, Woosung Cho, Huisim Moon and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)*

To accurately diagnose heart disease, it is important to monitor both the electrical and mechanical aspects of the heart simultaneously. Previously, these aspects have been assessed separately using electrocardiogram (ECG) and medical imaging techniques. Newly developed implantable devices named mechano-electrocardiogram (MECG) sensors now allow simultaneous measurement of mechanical electrocardiogram (MCG) and ECG. The device uses permeable electrodes on a flexible nanofiber mat to rapidly adhere to tissue. Strain-insensitive electrodes are used for ECG and strain-sensitive electrodes are used for MCG. When implanted over the rat heart, the MECG sensors demonstrated that MCG amplitude correlated with blood pressure changes induced by a vasoconstrictor (phenylephrine), whereas ECG peak intervals more closely matched heart rate fluctuations. These results highlight the clinical importance of MECG devices for continuous and comprehensive monitoring of both electrical and mechanical cardiac properties.

SESSION SB02.07/SB04.08: Joint Session: Sensing and Screening
Session Chairs: Charalampos Pitsalidis and Sihong Wang
Wednesday Afternoon, December 4, 2024
Hynes, Level 1, Room 102

1:30 PM *SB02.07/SB04.08.01

Transforming Antigenic Portable Technologies into Highly Dependable Screening Devices *Luisa Torsi; Università degli Studi di Bari Aldo Moro, Italy*

The emerging field of ionic and electronic devices for biosensing applications, holds promise for advancing the development of innovative diagnostic technologies. The endeavor to screen asymptomatic organisms, *encompassing humans, animals, and plants, through the utilization of point-of-care-testing (POCT) technologies boasting high diagnostic accuracy is both visionary and promising. Efficient surveillance necessitates the development of user-friendly, cost-effective, and highly reliable in-vitro diagnostic devices that are ultra-portable and readily deployable as needed. While such devices are not yet commercially available, there are encouraging advancements at readiness-level 5, notably the Clustered-Regularly-Interspaced-Short-Palindromic-Repeats (CRISPR) lateral-flow-strip tests and the Single-Molecule-with-a-large-Transistor (SiMoT) bioelectronic palmar devices.*

These technologies embody essential features as stipulated by the World Health Organization for POCT systems, exhibiting a minimal occurrence of false-positive and false-negative errors (<1-5%) and ensuring diagnostic selectivity and sensitivity (> 95 – 99 %). Furthermore, they offer a low limit of detection for various markers. The CRISPR-strip functions as a molecular assay, capable of detecting even a few copies of DNA/RNA markers in blood, while the SiMoT test can identify single oligonucleotides, protein markers, or pathogens in a minute sample of blood, saliva, or olive sap.

SiMoT single-sensor prototype, comprising a palmar electronic-reader and a disposable bioelectronic-cartridge, will reach TRL7 in a couple of years at most through a clinical-trial kicked-off in February 2024 involving 1.500 assays of peripheral-fluids (urine/plasma/serum) from oncological patients. This effort is conducted within the Apulian Regional Innovation-Center for Single-Molecule Digital-Assay (www.singlemolecule.center), chaired by Torsi, at the "Giovanni Paolo II" Scientific Institute for Research, Hospitalization, and Healthcare, the main oncological hospital in Bari.

The SiMoT technological breakthrough hold the potential to enable systematic and dependable surveillance of asymptomatic individuals prior to the aggravation or spread of illnesses, thereby facilitating timely diagnosis and prognosis. This proactive approach could establish a healthcare ecosystem that delivers effective treatments to all living organisms, fostering widespread well-being at manageable costs.

2:00 PM SB02.07/SB04.08.02

Graphene-Based Photothermal Nerve-on-a-Chip Device for Studying Thermal Sensation *Koji Sakai[1,2], Yujiro Tanaka[3,2], Riku Takahashi[1,2], Toichiro Goto[1,2], Yosuke Mizuno[1,2] and Masumi Yamaguchi[1,2]; [1]NTT Basic Research Laboratories, Japan; [2]NTT Bio-Medical Informatics Research Center, Japan; [3]NTT Device Technology Laboratories, Japan*

Thermal sensation is an essential function for animals to sense external temperatures, regulate body temperature, and avoid noxious stimuli. The peripheral nerve plays a major role in thermal sensation by receiving temperature, converting it into an electrical signal, and transmitting it to the central nervous system. The discovery of *temperature-sensitive ion channels has significantly advanced basic research on the molecular and cellular mechanisms of temperature reception. To examine the cellular responses to local temperature increases, light-sensitive nanomaterials have emerged as promising transducers for high spatiotemporal heat stimulation. However, it is still challenging to investigate how the received temperature is converted into electrical signals and then transmitted in axons due to the difficulty of simultaneously performing heat stimulation and electrical recording on the same axon. In this study, we fabricated a graphene-based nerve-on-a-chip device that enable us to record the electrical signals evoked by thermal stimulations in axon bundles of cultured sensory neurons.*

The device was fabricated by combining a microelectrode array that had both electrodes and heating elements with a polydimethylsiloxane-based culture chamber. The culture chamber had 8 microchannels that guide axon sprouting. Eight recording electrodes were aligned at each microchannel to record extracellular potentials from the guided axons. The heating elements were also positioned between the electrodes to measure the responses to the thermal stimulations upon the axons. To avoid stimulation artifacts caused by resistive heating, the stimulation was performed photothermally using a laser. To fabricate both the electrodes and the heating elements simultaneously, we used a spin-coated layer of graphene dispersion in cyclohexanone/terpineol because of its excellent electrical surface properties and photoabsorbance. The layer was patterned by photolithography and etching with O_2 *plasma to form 50 × 50 mm electrodes and 100 × 100 mm heating elements. A laser with a wavelength of 785 nm was focused on the heating elements to deliver local heat to the axons. Temperature measurements using a thermal camera in the air confirmed that the temperature was locally increased and then saturated less than 1 sec after applying the laser. Moreover, the saturated temperature was almost linearly increased by raising the laser power. For example, continuous laser irradiation in the range of 50 to 150 mW increased the temperature in the range of 12°C to 83°C. After confirming the photothermal properties of the heating elements, we seeded primary rat sensory neurons on the fabricated device and tested photothermal stimulation upon the axons. The stimulation was applied in a power range of 10 to 50 mW. At 44 mW, the electrodes aligned with the stimulation site recorded the evoked action potentials. The peak timing of the action potential was delayed in accordance with the distance from the stimulation site and the recording site, demonstrating that the evoked action potential propagated along the axons. Furthermore, calcein-AM staining indicated that there was no apparent laser-induced damage to the axons at 44 mW. In contrast, the axons were ablated, and glial cells were dead on the heating element at a higher laser power of 50 mW. Thus, we have successfully demonstrated that the nerve-on-a-chip device enables us to visualize the generation and propagation of action potential in response to local photothermal stimulation in axons. The device will be helpful in understanding how the sensory axon processes thermal information at the cellular level.*

2:15 PM SB02.07/SB04.08.03

Scalable, Lithography-Free Fabrication of Stretchable Microneedle Electrode Arrays for Electrophysiological Sensing *Qinai Zhao[1], Ekaterina Gribkova[2], Jilai Cui[2], Rhanor Gillette[2] and Hangbo Zhao[1]; [1]University of Southern California, United States; [2]University of Illinois at Urbana-Champaign, United States*

Microneedle electrode arrays have been a widely used technological platform for biomedical applications including electrophysiological sensing and electrical stimulation. They can penetrate surface layers of tissues, thereby allowing probing of physiological signals and electrical stimulation of the interior or deep tissues in a minimally invasive manner. Stretchable microneedle electrode arrays (SMNEAs) are highly desirable as dynamic bioelectrode interfaces to tissues or organs as they can follow tissue deformations, leading to enhanced recording signal quality and reduced tissue damage. However, current fabrication approaches for SMNEAs have limitations in achieving high device stretchability, high fabrication scalability, and low cost. Here we present lithography-free fabrication of SMNEA devices for localized electrophysiological sensing in deep tissues. This hybrid fabrication scheme combines 3D printing, physical vapor deposition, and transfer printing, which enables scalable fabrication *of SMNEAs with over 100% stretchability. A vat photopolymerization process creates polymeric microneedle arrays with custom geometries connected by a thin layer of serpentine filaments, followed by transfer printing onto a stretchable elastomer and metallization for electrical connection. The customizable electrode geometry, high device stretchability, and fabrication simplicity make our SMNEA a promising platform for sensing or stimulation in the interior of 3D biological tissues, such as the dermis layer, muscle tissues, and cardiac tissues.*

***Sustainable Bioelectronic Sensors** Martin Kaltenbrunner; Johannes Kepler Universität Linz, Austria*

Soft bioelectronic devices provide unique opportunities in our quest for a more sustainable future. Their adaptive and responsive nature renders them especially attractive as wearables in health monitoring. Among the key issues to overcome for successful market adoption are untethered operation, high performance green materials and end-of-lifetime considerations in complex (soft) systems. This talk introduces solutions for indoor light harvesting to power flexible and lightweight bioelectronic devices. We here utilize stable and ultrathin perovskite photovoltaic cells with record specific power for battery-free sensor patches. Whenever (sun)light is not available, battery powered solutions remain in high demand due to their relatively high power and energy densities. We here introduce stretchable, yet degradable and printable forms of batteries for wearable bio-sensors. Pushing the boundaries of sustainable electronics, we demonstrate new concepts for advanced fungal mycelium skins as biodegradable substrate material. With reduced surface roughness and improved mechanical stability, these naturally grown flexible circuit boards offer solutions for next-generation green bioelectronic systems.

4:00 PM SB02.08.02
***Wearable Multimodal Sensors for Health Monitoring** Juliane R. Sempionatto-Moreto; Rice University, United States*

The constant miniaturization of electronics and the development of powerful data processing tools have enabled the fast advance of wearable technology. The successful demonstration of wearable devices for sports monitoring has already been made. Although such outstanding technology has shown great performance, some important features are still missing. Nowadays, wearable devices are limited to monitoring physical parameters such as motion, temperature, heart rate, steps, etc, while important (bio)chemical information, such as metabolites (glucose, lactate, alcohol) and electrolytes (sodium, potassium) levels can only be accessed via blood analysis. My research focus on bridging the gap between physical wearable sensors and biosensors by developing multimodal platforms for the early diagnosis and prediction of diseases. I developed the first multimodal non-invasive wearable sensor platform able to simultaneously measure chemical analytes concentrations and blood pressure values to monitor cardiometabolic syndrome (CMS), a disorder characterized by abdominal obesity, insulin resistance, impaired glucose tolerance, and hypertension.

This was the first time that metabolic variations and corresponding hemodynamic parameters were monitored together. This novel device represents great opportunity for understanding the effects of cardiometabolic biomarkers in the development of CMS, such information was not previously available, and it can open doors to new insights of diseases enabling guided actions toward a healthier and safer lifestyle. CMS is characterized by obesity, insulin resistance, impaired glucose tolerance, hypertension, and hyperlipidemia. Untreated, patients are at high-risk for major adverse cardiovascular events, including stroke, myocardial infarction, and cardiovascular-related deaths. There is no standard methodology for the treatment or prevention of CMS. The current approach relies solely in the control of the risk factors that includes mainly hypertension and diabetes. This new wearable platform allows early diagnosis CMS toward timely intervention. The chemical-blood pressure platform can be adapted to measure different analytes in sweat and interstitial fluid, including nutrition (vitamins, amino acids), cholesterol, and lipidic (LDL, HDL) biomarkers that also correlate with cardiovascular health. The transition of self-monitoring devices from blood to other body fluids provides noninvasive, and continuous personalized healthcare holding considerable promise for successful remote and telemetric medicine. This work was published in Nature Biomedical Engineering (2021) and highlighted in Nature Reviews Materials.

*In addition, I have published a multimodal sweat patch capable of stress monitoring and classification. We combined eleven different sensors including different modalities into a single platform and used machine learning to find correlation of each biomarker signature with their respective stressor (2024-**Nature Electronics**). The stress patch was developed to study diseases that does not have specific biomarker such as the one related to mental health, where a simple questionnaire is used to diagnose. With the concept of biomarker signature, we hope to generate a comprehensive analysis of chronic and acute diseases, either improving the accuracy of the diagnosis or making it possible in an objective and measurable manner.*

4:15 PM SB02.08.03

A Stretchable and Durable pH Sensor for In Vivo Digestive System Monitoring *Jiawei Tan[1], Yichao Zhao[1,2], Kaiji Zhang[1], Mahammadreza Bahramian[1], Xuanbing Cheng[1], Jialun Zhu[1], Junjie Fang[1], Zoe Pepper[1], Andre Li[1], Murtadha Al Msari[1], Eva Shlyakhovaya[1], Katherine Lim[1] and Sam Emaminejad[1]; [1]University of California, Los Angeles, United States; [2]Massachusetts Institute of Technology, United States*

Monitoring pH levels in biological systems is crucial for understanding and maintaining physiological balance. For example, in the digestive system, pH imbalances can lead to a range of issues such as peptic ulcers, indigestion, and altered gut flora. The intricate structure of the digestive tract, characterized by curves and folds, maximizes surface area for efficient digestion and nutrient absorption, necessitating precise pH monitoring across various segments. This environment features extreme pH conditions, like the highly acidic stomach necessary for protein breakdown and pathogen control.

However, conventional pH sensors, often based on brittle materials like iridium oxide (IrOx), struggle with durability in soft tissue environments, compromising sensor longevity and biosafety in implantable applications. To address these challenges, we developed a stretchable pH sensor capable of robust performance in complex biological environments.

Our approach utilizes a sandwich design that decouples the brittle IrOx interfacial layer from the soft conductive substrate by integrating a vertically conductive stretchable layer in the middle. This structure, comprising a silicone-based conductive stretchable trace sealed with a silicone-based vertically conductive layer, was fabricated through e-beam deposition of Cr/Au, followed by Pt/IrOx electrodeposition. Under strain, the brittle IrOx layer fractures, while remaining *islands connect to vertical pathways in the lower stretchable traces.*

In vitro characterization confirmed that our pH sensor maintains its sensing capabilities under strains up to 100%, essential for dynamic biological environments. Robust cycling tests demonstrated its ability to withstand active movements within the digestive system, while stability tests indicated resistance to corrosion, ensuring long-term functionality.

Moving forward, our next steps involve in vivo testing in a rat model to evaluate the sensor's performance for implantable pH monitoring in both the intestine and stomach. The sensor's soft and stretchable nature facilitates smooth adhesion to the intestinal wall, promising stable real-time pH recordings in the stomach over extended periods. Integration of the sensor with a wireless module will allow untethered, continuous in-vivo monitoring, enabling the unraveling of the dynamics of digestive system diseases.

4:30 PM SB02.08.04

Long-Term Stable Biochemical Sensing Platform in Complex Biological Environment *Yihang Chen[1,1], Kaiyu Fu[2] and Hyongsok T. Soh[1,1,1]; [1]Stanford University, United States; [2]University of Notre Dame, United States*

Continuous monitoring of specific clinically-relevant analytes in situ would offer exciting capabilities for fundamental research and clinical medicine. However, achieving this capability has proven difficult due to biofouling, probe degradation and signal drift that often occur within complex biological environments. Our solution leverages the nanoporous biosensors (npAu), and demonstrated its ability to sustain prolonged small molecule sensing both in vitro and in vivo while mitigating fouling and signal degradation. We believe the nanostructure design could provide the foundation for a new generation of long-term stable biosensors.

4:45 PM SB02.08.05

Bio-Integrated Soft Electronic Surgical Mesh Implant and Wound Dressing for Soft Tissue Reinforcement and Wireless Sensing *Rajaram Kaveti[1], Suk-Won Hwang[2] and Amay Bandodkar[1]; [1]North Carolina State University, United States; [2]Korea University, Korea (the Republic of)*

Advancements in surgical mesh implants and wound dressings have largely focused on traditional designs and material synthesis, leaving room for innovation in multifunctional devices. Regeneration of damaged or diseased tissues and organs represents a major medical need as they pose significant risks such as postoperative complications, amputation and mortality. Current treatments are often costly, intricate, and only moderately effective. Herein, we present a bioresorbable electronic surgical mesh (BESM) and a water-powered, electronics-free dressings (WPEDs) for hernia repair and chronic wound healing, respectively. The BESM offers significant mechanical strength over extended periods, enables wireless postoperative pressure monitoring, and provides on-demand drug delivery to aid tissue repair and functionality. This mesh's design includes bioresorbable dielectric composites with a porous, pyramidal structure, enhancing the sensitivity of a wireless capacitive pressure sensor for intra-abdominal pressure monitoring. Integrated resistive microheaters with inductive coils facilitate a thermo-responsive drug delivery system for antibacterial agents. In vivo evaluations confirm the mesh's reliable, durable performance and its effectiveness in treating abdominal hernia defects, significantly reducing complications such as adhesions and infections. In parallel, WPED provide electro-therapy and offer a novel, cost-efficient, and practical solution for chronic wound healing, even under harsh environments. These dressings utilize a magnesium-silver/silver chloride battery and stimulation electrodes that generate a radial electric field upon hydration. Studies in diabetic mice have demonstrated that WPEDs can expedite wound healing by enhancing epidermal thickness, regulating inflammation, and encouraging angiogenesis. In preclinical models, WPED-treated wounds closed more rapidly than those treated with conventional methods, showing results comparable *to those achieved with expensive biologics or complex electronics. These innovations highlight the effectiveness and potential of soft electronics and tissue reinforcement in improving surgical outcomes and postoperative wound care.*

5:00 PM SB02.08.06
Microfluidic Sweat Patch Integrated Smartwatch for Non-Invasive Photonic Continuous Glucose Monitoring
Sunah Cheong and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

Managing diabetes is a chronic challenge and requires continuous glucose monitoring (CGM) for timely insulin delivery to maintain the homeostasis of blood glucose levels. Instead of blood sampling, CGM is based on the glucose monitoring in the body fluids such as sweat, tear, saliva, interstitial fluid, and so on. Wearable sweat sensor is a promising approach for CGM, but there are several challenges including stable sweat collection and sustainable reusability of glucose sensors. Here, we present a photonic sweat glucose patch sensor incorporating a Tesla valve-based microfluidic system designed for continuous sweat flow without evaporation. The Tesla valve microfluidic structure promoted unidirectional flow with minimal backflow, improving sweat acquisition efficiency. The performance of Tesla valve was validated by flow experiments with methylene blue and methyl red indicators. Glucose sensing was achieved by using glucose-responsive hydrogels immobilized in a microfluidic reservoir containing an oxygen-sensitive phosphorescent dye and glucose oxidase. The green LED of a smartwatch was used to sequentially excite the sensing hydrogel and the fluorescence intensity change was measured by a photodetector to monitor glucose levels. In vitro tests confirmed the successful monitoring of glucose levels ranging from 0.01 mM to 1 mM. Additionally, human trials showed the strong correlation between sweat and blood glucose levels before and after meals. Taken together, we could confirm the feasibility of microfluidic sweat patch integrated smartwatch for photonic CGM applications.

Direct Printing of Soft Intraspinal Electronics for Durable Restoration of Locomotor Function *Yong Won Kwon, Sanghoon Lee and Eunmin Kim; Yonsei University, Korea (the Republic of)*

Spinal cord injury (SCI), particularly in the lumbar region, often results in irreversible lower limb motor impairment. While spinal cord stimulation (SCS) shows promise for restoring motor function, conventional epidural and intraspinal approaches are limited by rigid materials that cannot adapt to spinal cord movement. Herein, we present a bio-integrated, customized intraspinal interface that accommodates dynamic spinal cord movements through tissue-adaptable direct printing of liquid metals, forming soft electronic neural interfaces. This system comprises soft intraspinal liquid-metal electrodes and interconnections printed directly onto the spinal cord surface. The intraspinal electrodes of liquid metals are printed with tailored lengths and diameters to target specific motor neurons within the gray matter. Liquid-metal interconnections adapt seamlessly to spinal cord movements, reducing mechanical stress on electrodes and interfaces. Utilizing Support Vector Machine (SVM) algorithms, our electronic neural interface optimizes stimulation parameters to elicit biomimetic locomotor patterns in rats with complete SCI. Extensive in vivo studies demonstrate the safety, biocompatibility, and long-term functionality of our system.

Photopatternable Skin Adhesive and Gel Electrolyte Integrated Microneedle Sensor for Enhanced Continuous Glucose Monitoring *Joohyuk Kang[1,2], Kyung Yeun Kim[1], Seungwan Kim[3], Byeong-Soo Bae[3], Seung-Kyun Kang[2] and Wonryung Lee[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Microneedle-based electrochemical biosensors are crucial for continuous monitoring of glucose levels in patients with chronic diseases. These sensors require soft materials like gel electrolytes and skin adhesives to integrate electrically and physically with the skin, ensuring stable and continuous measurements. However, current patterning methods for these soft materials are labor-intensive, time-consuming, and have low compatibility with various device types, especially three-dimensional microneedles. This poses a challenge for widespread application in different devices.

We present a conformable microneedle sensor utilizing a novel photopatternable gel electrolyte and skin adhesive, specifically designed for reliable glucose monitoring. The photopatternable materials enable precise and direct deposition onto the microneedle substrate, overcoming previous limitations. Our study employs oxygen inhibition photolithography to pattern the gel electrolyte and modifies a thermocurable adhesive for positive photolithography. The gel electrolyte was patterned with a resolution of 400 μm, and the skin adhesive achieved a resolution of 500 μm, ensuring precise application and integration with the microneedle substrate. This approach allows for the creation of stable, free-standing patterns directly on the microneedle substrate, enhancing the device's integration with the skin.

The resulting microneedle sensor exhibits a stable electrical and physical interface with the skin and demonstrates high sensitivity across a broad range of glucose concentrations. The sensor's performance was validated through continuous glucose monitoring in an anesthetized rat model, successfully diagnosing hyperglycemia. The sensor maintained stable impedance and adhesion over extended periods, confirming its practical application for continuous monitoring. It also showed noise-free results during glucose monitoring, ensuring accurate and reliable measurements. Our findings indicate that the integration of photopatternable soft materials significantly improves the fabrication efficiency and functionality of microneedle sensors. This advancement has the potential to accelerate the development of wearable biomedical devices, offering a cost-effective and reliable solution for continuous glucose monitoring.

SB02.09.03

A Flexible Inkjet-Printed Three-Dimensional Microelectrode Array Enables Neural Recordings in a Locust Ganglion *Hu Peng[1,2], Jianing Yang[3,4], Oleksandr Berezin[2,5], Lukas Hiendlmeier[1,2], Defne Tüzün[1,2], Xue Li[3,4], Zhengtuo Zhao[3,4], Gil Westmeyer[2,5] and Bernhard Wolfrum[1,2]; [1]TUM School of Computation, Information and Technology, Germany; [2]Technische Universität München, Germany; [3]CAS Center for Excellence in Brain Science and Intelligence Technology, China; [4]Shanghai Center for Brain Science and Brain-Inspired Intelligence Technology, China; [5]Institute for Synthetic Biomedicine, Germany*

Microelectrode arrays (MEAs) are widely used for electrophysiological studies, but conventional planar MEAs lack capabilities for penetration into 3D biological systems. In this work, we fabricated an inkjet-printed 3D MEA on a flexible thin film. The bottom structure of the MEA, including pads and traces, was fabricated by standard lithography in a clean room. Subsequently, silver shanks were inkjet-printed on top of the planar structure, followed by the deposition of parylene-C for insulation. Tips were opened using laser or focus ion beam (FIB) technology for accurately defining the electrode positions. Gold galvanization on the electrodes was employed to

avoid tissue exposure to silver ions. We achieved a high aspect ratio (> 30), and the laser-ablated shanks showed an impedance of around 100 kΩ at 1 kHz after gold galvanization. FIB-generated microelectrodes on the tips show better insulation properties of parylene on exposed silver electrodes compared to laser-ablated tips due to the highly defined ablation process. As a proof of principle, we implanted the device in a locust ganglion, which controls the movements of the legs. Our 3D MEA allowed the recording and stimulation of neuronal activity, demonstrating that this platform facilitates studies in small animal models.

SB02.09.05

Wireless, Battery-Free and Fully Implantable Neural Recorder for Non-Human Primates *Saehyuck Oh[1,2], Janghwan Jekal[1,2] and Kyung-In Jang[1,2]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of)*

Recent advances in brain neural interfaces including wireless, battery-free, and fully implantable device with optimized wireless power transfer technology have led to extensive applications in neuroscience research. However, most neuro-engineering studies have been limited to small-animal models such as rodents. It poses significant technical challenges to design an all-in-one miniaturized neural recorder for non-human primates (NHPs) that concurrently captures real-time brain signals, stores data on a remote server, and integrates multiple device functions such as efficient wireless power reception, wireless communication, and device control, as well as multimodal signal acquisition. To address these challenges, we introduce a new concept of a wireless neural recorder with unique functional thin layers operates by receiving wireless power from magnetic coupled double coils based wireless power transfer system with multi-channel flexible neural probe for studying instinctive behavior in primates.

The integration of wireless, battery-free technologies in neuroscience research has ushered in a new era of neurobehavioral analysis, particularly in the study of instinctive behaviours in non-human primates (NHPs). Our neural recorder, designed for deployment under the scalp of awake, freely moving NHPs, exemplifies this shift. This device, notable for its low power consumption (~25 mW), facilitates the real-time monitoring of neural signals from deep brain structures. Coupled with a custom smartphone application, it enables the synchronous collection of neurobehavioral data, transforming these signals into meaningful biomarkers through advanced signal processing and artificial intelligence (AI). This process not only enriches our understanding of the brain's functional dynamics but also opens new avenues for identifying digital biomarkers that are crucial for deciphering complex neurobehavioral states.

The neural recorder itself is a testament to the advancements in flexible bioelectronics, featuring a long, flexible neural probe with 32 electrodes capable of delving into the brain's depths to capture neural activity. Its architecture is meticulously designed to ensure minimal invasiveness and optimal signal quality, thanks to a novel combination of materials and structural innovations. The system's ability to harness wireless power and communicate data wirelessly eliminates the need for cumbersome batteries and wires, ensuring the device's seamless integration into the subject's natural movements. Furthermore, the sophisticated power transfer mechanism extends the operational range, allowing for uninterrupted data collection even in dynamic and unrestricted environments. This level of technological integration not only facilitates continuous monitoring of NHPs' natural behaviours but also significantly reduces the potential for stress or discomfort that could skew the collected data.

Our approach goes beyond mere data collection; it leverages AI to analyze and classify neurobehavioral states, providing a deeper understanding of the physiological underpinnings of behaviours like eating. By analyzing neural and acceleration signals, we can dissect the various phases of eating behaviour, shedding light on the neural *circuitry involved in these instinctive actions. This methodology not only validates the functionality of our neural interface but also offers a blueprint for future research aimed at unraveling the complex interplay between neural activity and behaviour. The potential applications of this technology extend far beyond academic inquiry, offering promising insights for the development of novel diagnostics and therapeutic strategies in neurology and psychiatry.*

SB02.09.06

Enzyme-Mediated Quantum Material Phase Transition Enables Proton-Driven Neurotransmitter-Specific Signal Amplification *Jinmin Kim[1], Minguk Jo[1], Yewon Seo[2], Hyunjin Kim[1], Jounghun Kim[1], Donghwa Lee[1], Junwoo Son[2] and Seungsoo Oh[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)*

In medical diagnostics, current biosensors often struggle with sensitivity and selectivity due to molecular interference, especially when analyzing easily obtainable patient specimens. To address these challenges, we developed a novel approach for the real-time detection of biomarkers with exceptional selectivity and sensitivity. We synergistically integrated an enzyme, which produces protons by specifically recognizing ultra-low concentration biomarkers, with a phase-transition oxide capable of generating a one-million-fold resistance change upon proton penetration. Our innovative design enhances the biosensor's performance, offering highly efficient and artifact-less detection of neurotransmitters. As a proof-of-concept, we systematically integrated the neurotransmitter-specific enzyme for selective proton production with the quantum dioxide for proton-driven insulator-to-metal phase transition. The miniaturized enzyme-oxide heterojunction device actualized a novel target-selective proton-driven electric signal amplification mechanism. Our device outperformed all types of previously reported biosensors, demonstrating an extremely low limit of detection (~ 10^{-17} M), an ultra-fast response time (50 msec), and a significantly high amplification ratio (> 100), along with the exceptionally high specificity even with one droplet of solution. Moreover, we actualize real-time monitoring of targets at live mouse neurons.

SB02.09.07

Chemo-Photodynamic Glioma Treatment Using Implantable Micro-LED and Drug Delivery System *Jun Seo Lee[1], Jeongrae Kim[2], Tae-il Kim[1] and Kwangmeyung Kim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of)*

Nano-sized drug delivery systems have been developed for targeted delivery of anticancer drugs, yet their systemic administration efficacy remains limited. To enhance targeting efficiency and minimize toxicity, we developed a combined approach utilizing a tumor-implantable micro-syringe chip (MSC) with a needle-type implantable micro-LED device for glioma treatment. The MSC, equipped with a 2μL drug reservoir, enables precise intratumoral delivery of pro-apoptotic anticancer prodrugs (SMAC-P-FRRG-DOX) encapsulated in optimized liposome nanoparticles (ApoLNPs), ensuring uniform drug distribution and enhanced tumor targeting. Complementing this, the micro-LED device, consisting of four small LEDs at the needle tip, can be implanted into the glioma core without craniotomy, delivering deep-tissue light irradiation. This approach overcomes the challenge of inadequate light penetration, crucial for photodynamic therapy. The device activates cathepsin B-responsive prodrug nanoparticles (PNPs) composed of doxorubicin, verteporfin, and a cathepsin B-cleavable peptide linker. PNPs remain inactive under normal conditions but release therapeutic agents specifically in cathepsin B-overexpressed glioma tissues. In vitro cellular assays showed that irradiated PNPs exhibit synergistic cytotoxicity in cancer cells while sparing normal cells. In vivo studies in tumor-bearing mice demonstrated high tumor accumulation of PNPs due to the enhanced permeation and retention effect. Micro-LED mediated light irradiation significantly inhibited tumor growth, showcasing remarkable therapeutic efficacy. This integrated approach offers a minimally invasive, *highly effective strategy for glioma treatment, combining precise drug targeting with efficient photodynamic therapy, resulting in reduced systemic toxicity and superior therapeutic outcomes.*

SB02.09.08

Fibrillary Gelation of PEDOT:PSS Nanofiber for Organic Electrochemical Transistors in Wearable Bioelectronics

Youngkwang Shin and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

PEDOT:PSS, a conductive polymer commonly used in organic electronics and bioelectronics, offers high electrical and ionic conductivity, solution processability, and biocompatibility. In this study, we present a novel method to enhance PEDOT:PSS fiber with high conductivity. Moreover, a robust and breathable nanofiber mat electrode with a large surface area could be demonstrated.

Designed to ensure skin adaptability and stability through theoretical mechanical analysis, this nanofiber mat electrode maintains impedance stability under daily use, thereby addressing durability issues for long-term applications. Its breathability, high surface area, and reduced interfacial impedance allow for continuous use even under significant and repeated skin deformation.

*This PEDOT:PSS nanofiber electrode exhibits an impressive electrical conductivity of approximately 200 S*cm^(-1) and a volumetric capacitance of approximately 80 F*cm^(-3), making it highly suitable for organic electrochemical transistors (OECTs). Utilizing the nanofiber mat electrode, we fabricate an OECT with a transconductance of 10 mS in depletion mode, demonstrating its potential for continuous sweat ion sensing applications. These results indicate that PEDOT:PSS nanofiber has significant potential as a reliable component for noninvasive skin electronics, especially sweat sensors and other wearable bioelectronic devices.*

SB02.09.09

A Superabsorbent Chronic Wound Healing Gel Patch with Ultrahigh Ion Conductivity for Electrical Stimulation Therapy

Jihong Kim[1], Sung Gyu Shin[2], Won Hyuk Choi[1], Jae Hyun Jeong[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of)

Electrical stimulation (ES) therapy has emerged as a promising therapeutic modality to expedite wound healing, offering a compelling adjunct to traditional wound care. By mimicking the endogenous electric field that naturally facilitates skin regeneration, this approach provides a more efficient and direct method for wound healing therapy compared to conventional treatments such as dressing, compression bandaging, and hyperbaric oxygen therapy. However, conventional stand-alone ES devices, typically based on metal materials, face significant challenges due to mechanical mismatch with the skin, limiting their ability to maintain conformal contact. Additionally, these metal-based stand-alone ES treatment struggle to provide a beneficial antibacterial and anti-inflammatory microenvironment, thereby restricting their overall healing efficacy. In response to these limitations, there has been a growing interest in developing soft conductors based on hydrogels for ES therapy. Hydrogels, with their high water content and superior ionic conductivity, present a promising alternative. Despite these advantages, hydrogels face a critical limitation in bioelectronics due to their dehydration, ultimately challenging their long-term stability and functional reliability.

Here, we propose a biocompatible ion conductor, based on a hydration gel wound dressing composed of a choline-based ionic liquid (IL) embedded in a gelatin matrix, which maintains a moist, antibacterial environment with high ion conductivity to accelerate tissue regeneration through exogenous ES. This hydrophilic IL with low vapor pressure hydrates by water, which are retained within the gelatin's triple-helix structure, resulting in high ion and water content without dehydration. In addition, this IL-water interaction dissociates ion pairs into free ions, significantly increasing ion conductivity compared to conventional iongels. The resulting hydration gel, with its high *water content, possesses a low Young's modulus similar to human skin. Furthermore, the intrinsic Arg-Gly-Asp (RGD) sequence in the gelatin enhances cell adhesion, mobility, and proliferation, promoting adhesion and conformal contact with the skin. Consequently, we have developed a soft(~70kPa), anti-dehydration(over 1 year), and highly ion-conductive(>30ms/cm) ES patch that effectively promotes wound regeneration. We believe our long-term stable hydration gel serves as a blueprint for developing the next-generation wound healing management system.*

SB02.09.10

Wireless Optical Biomarker Monitoring Using an Ultraflexible Organic-Inorganic Integrated Device *Kyung Yeun Kim[1,2], Hojeong Jeon[1], Jae-Hoon Han[1] and Wonryung Lee[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)*

Wireless communication systems for ultrathin organic electronics are essential for highly sensitive health monitoring. Organic electrochemical transistors (OECTs) are emerging as powerful amplifiers with high transconductance and can be used in wearable sensors to amplify biological signals. However, implementing wireless communication with OECTs presents significant challenges. Additional wireless communication systems are required for applications in continuous health monitoring, and conventional wireless communication circuits based on inorganic integrated chips face limitations in conformability due to the thick and rigid integrated circuit chips. Here, we present an ultraflexible organic-inorganic integrated wireless optical communication device with high conformability, which integrates OECT biochemical sensors and near-infrared (NIR) inorganic micro light-emitting diodes (μLEDs). The channel current of the OECT varies with biomarker concentration, which alters the irradiance of the μLED. The integrated device enables wireless optical monitoring of biomarkers, such as glucose, lactate, and pH. The OECT exhibits high transconductance and excellent flexibility, while the μLED demonstrates outstanding stability and electrical characteristics. The conformable system integrates an OECT and the μLED on a thin parylene substrate. Consequently, a 4-micrometer-thick ultrathin integrated device enables reliable data amplification and transmission while maintaining high conformability. To validate the wireless transmission ability, the integrated device was fabricated as a wearable patch powered by an elastomeric battery circuit, and wireless sweat glucose monitoring was performed. Furthermore, the utility of the system was demonstrated through NIR image analysis. The simple circuit structure and low-power operation of the integrated device suggest its potential use in various circuit applications. Furthermore, due to the biological application of OECTs and skin transmittance of NIR μLEDs, this system holds promise for various wearable and implantable device applications.

SB02.09.11

Inkjet-Printed Nafion Gated Graphene Field-Effect Transistors for Bioelectronic Applications *Van Ky Nguyen and WiHyoung Lee; Konkuk University, Korea (the Republic of)*

Inkjet printing technology has emerged as a promising tool for fabricating bioelectronic devices, offering scalability and accessibility in device manufacturing processes. In this study, we explore the application of inkjet-printed Nafion-gated graphene field-effect transistors (NF-GFETs) for bioelectronics applications. With the exceptional conductivity and biocompatibility of Nafion, NF-GFETs serve as ion-to-electron transducers, enabling precise control over electronic signals and ion transport. We extend our investigation to encompass varying relative humidity levels, mirroring biological conditions, and demonstrate enhanced device performance under humid environments.

SB02.09.12

Flexible Electrodes as a Companion Digital Diagnostic for Dysphagia—Needs Assessment Drives Innovation in Biomaterials *Anthony Cino; Lehigh University, United States*

Dysphagia, or difficulty in swallowing, can be the result of several etiologies such as stroke, neuromuscular disorders, blunt force trauma, or extrinsic compression of the esophagus. Patients presenting with dysphagia are at severe risk of sequelae, such as aspiration and malnutrition, which present a severe risk of mortality. Neuromuscular electrostimulation (NMES) is utilized by speech language therapists to aid in swallow function. It has been shown that NMES therapy promotes neuroplasticity, angiogenesis, and skeletal muscle hypertrophy and repair through tetanic muscle contraction. Concurrently, the ability to collect biofeedback signals that measure swallowing quality could provide a complementary and objective means to assess the efficacy of electroceutical therapy. There exist commercial devices that employ both NMES and surface electromyography (sEMG); however, the labyrinth of wires, harsh adhesives, and lack edge computation capabilities prevents their clinical application especially for remote rehabilitation settings. There remains an unmet clinical need to engineer electronic epidermal smart electrodes that mitigate iatrogenic skin injuries, skin erythema, and non-specific cathodal vasodilation and mitigate the use of wires to provide a wearable and unobtrusive therapeutic means to treat and monitor dysphagia severity for patients to ultimately ease patient burden. There exists an unmet engineering need for the development of a soft flexible wearable electroceutical electrode that facilitates delivery of electroceutical therapy for long-term applications coupled with a signal processing algorithm that quantifies swallowing quality and function. The development of flexible electrodes with low through thickness impedance, necessary biocompatibility, and long-term adhesion leveraging foundations in polymeric nanocomposite technology are required to address current shortcomings. Herein, this work will bridge clinical needs with engineering experimentation in evaluating the structure property relationship of a polymeric nanocomposite for surface stimulation applications towards treating dysphagia. Future work will seek to integrate sEMG capabilities towards creating the first electronic epidermal smart electrode (EESE) for dysphagia.

SB02.09.13

Addressing Impedance and Comfort Challenges in Through-Hair Electroencephalogram with Pyramid-Based Temperature-Responsive Ionic-Biogel Electrodes *Ankan Dutta[1,1], Arantza Moreno Calva[1,2], Ethan Gerhard[1], Md Abu Sayeed Biswas[1], Abu Musa Abdullah[1] and Huanyu Cheng[1]; [1]The Pennsylvania State University, United States; [2]Universidad Iberoamericana, Mexico*

Several invasive treatments for epilepsy have been studied to help drug-resistant patients manage or even prevent seizures. However, long-term, non-invasive electroencephalogram (EEG)-triggered transcranial alternating current stimulation (tACS) for preventing and controlling epileptic seizures is still in its infancy. Current EEG and tACS devices are uncomfortable for long-term usage, suffer from signal distortion, and degrade over time, limiting their use to a few hours. Therefore, biocompatible, adhesive, wearable, and scalp-conforming closed-loop electrodes for continuous EEG recording and tACS are crucial.

Long-term EEG recordings using dry electrodes are often hindered by high skin-contact impedance, whereas wet-gel-based electrodes face comfortability issues due to hair. Achieving direct scalp contact necessitates small electrode areas to bypass hair obstruction. However, reducing the electrode contact area inherently increases skin contact impedance, creating a trade-off between impedance and comfort. To address this, we developed a novel hollow-based pyramid electrode design capable of buckling through congested hair to achieve direct scalp contact. The electrodes use a temperature-responsive conductive gel that flows through hair guided by these pyramids, increasing the contact area only when contacting the scalp. This design leverages the buckling mechanism and conductive material to achieve low skin-contact impedance without hair interference.

Our approach combines PEDOT:PSS and 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMIM-TFSI) based ionic liquid with a gelatin-glycerol matrix to form a synergistic ionogel-hydrogel composite. The composite maintains high ionic conductivity, electrochemical stability, and anti-dehydration properties of the ionogel while retaining the inherent biocompatibility of the hydrogel. The ionic-biogel exhibits a high storage

modulus (1.5 kPa) and loss modulus (0.3 kPa) at scalp temperature (35°C), which transitions to a low modulus of 0.4 kPa at the transition temperature of 45°C. The skin-contact impedance of the ionic-biogel remains consistent (3 kΩ @ 4kHz) across the applied temperature range (40-50°C), with an electrical impedance of 200 Ω in the thickness direction. The high electrochemical stability of the ionogel-hydrogel composite enables long-term, high charge injection capacity compared to non-ionic biogels. The ionic biogel retains almost 99% of its content at 50°C, whereas non-ionic biogels retain only 93%, inhibiting long-term use. Additionally, the signal-to-noise ratio of the ionic biogel increases with applied temperature, showing a consistent signal-to-noise ratio of 36 dB at room temperature.
The improved electrode design and material combination offer a promising solution to the impedance-comfort trade-off in long-term EEG recordings.

SB02.09.14
Eco-Friendly Organic Bioelectronic Devices for Skin *Hyeonjun Na[1], Il-Young Jo[1], Sungrok Wang[1], Hong YeongBeom[2], Seunghyeon Lee[2], Won-June Lee[1], Mohammad Boshir B. Ahmed[1], Bong Sup Shim[2] and Myung-Han Yoon[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Inha University, Korea (the Republic of)*

In this research, we proposed a material technology for eco-friendly electronics based on organic active channels, passivation/insulators and substrates. For this purpose, organic mixed ionic-electronic conductors and inorganic clay nanostructures were combined to induce insect eating and microbial decomposition, leading to biodegradation with minimal environmental pollution issues. Furthermore, active channel materials were patterned on cellulose substrates with silver ink-based electrodes for modest-performance organic electrochemical transistors and their application to skin biosensors.

SB02.09.15
NIR-Laser Induced Fast Self-Healing Micro-Supercapacitor Based on Aniline-Trimer Based Polyurethane
Seojin Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

With increased demand for miniaturized wearable devices, there has been active research on wearable energy storage devices for integration into a single patch device. Among various energy storage devices, supercapacitors have appeared to be promising owing to high power density, fast charge/discharge time, and simple structure in addition to safety, compared to batteries. Considering the frequent movements of the wearers, those wearable devices including supercapacitors are required to be flexible/stretchable, leading to fabrication based on soft polymer materials. Thus, those soft devices are vulnerable to damages due to the deformations. As a result, extensive efforts on self-healing devices as well as materials have been recently made for extending the lifespan. In this study, we report on a laser-induced fast self-healing micro-supercapacitor (MSC) based on our novel synthesized aniline-trimer-based photothermal polyurethane (AT-PU). A room temperature self-healing interdigitated current collector of polyether-thioureas with triethylene glycol (TUEG3)-capped Au nanosheets, and MXene-based electrode are patterned on the AT-PU film using CO_2 laser patterned polyimide mask. By incorporating the same AT-PU into the ionic liquid ([EMIM][TFSI]) electrolyte with Li salt, laser-induced self-healing between the AT-PU film and the electrolyte can be achieved. AT-PU based electrolyte showed over 84% of self-healing efficiency in terms of ionic conductivity via 3 min NIR-laser induced self-healing. The fabricated MSC recovers the electrochemical performance after 808 nm NIR laser irradiation for 3 min on the bisected interface, exhibiting the full-device self-healing owing to the use of all self-healing component materials. This work demonstrates that the deliberate selection of self-healing materials and device architectures opens a new way of developing high performance full-device self-healing supercapacitor as a durable soft energy storage device with longevity.

SB02.09.16

Flexible Neural Probe with a Bioresorbable U-Beam Insertion Shuttle for Deep Brain Decoding in Non-Human Primates *Janghwan Jekal, Saehyuck Oh and Kyung-In Jang; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

Flexible neural probes, which closely mimic the mechanical properties of brain tissue, significantly mitigate immune responses and reduce astrocyte and microglia activity compared to rigid neural probes during long-term implantation. This compatibility enhances the stability of chronic neural recordings, which is critical for brain decoding. Despite these benefits related to immune response, the flexibility of these probes complicates their insertion into the brain regions of non-human primates (NHPs). This is because the force necessary to penetrate the white matter and properly position the probe in the brains of NHPs significantly exceeds that required for rodent models. This discrepancy has resulted in limited research on the use of flexible neural probes in primates, compared to the extensive methodologies developed for rodents. Despite this, non-human primates (NHPs) remain crucial for pre-clinical research. Their complex neural connectivity and resemblance to human brain anatomy make them invaluable for advancing our understanding of neurological disorders and testing new treatments. In this study, we introduce a bioresorbable U-beam shaped insertion shuttle-assisted flexible neural probe with porous electrodes, designed for AI-enhanced deep brain decoding in NHPs.

The shuttle, crafted from a disaccharide-based material, is engineered with a U-beam shape to minimize brain tissue invasion. It offers a transiently high moment of inertia and a buckling force of 90 mN. This design enables the insertion of neural probes up to several centimeters in length into the primate brain without risk of buckling. Moreover, the U-beam configuration optimizes the moment of inertia while minimizing contact area, resulting in minimal brain tissue damage after 4 weeks of implantation.

Upon insertion, the shuttle rapidly resorbs to expose the underlying dual-layer neural probe, which features 32 porous electrodes. These electrodes are electroplated with platinum(Pt) / iridium oxide(IrOx) and incorporate a 3D nano-porous structure using nanobeads, achieving a low impedance of approximately 40 kΩ. This configuration enables a high signal-to-noise ratio (SNR) neural signal capture.

To validate the probe's efficacy, it was implanted in the lateral hypothalamic area (LHA) of NHPs, an area associated with food consumption. We integrated a custom wireless neural recording system into the probe for in vivo testing. Local field potentials (LFPs) were recorded from the LHA during phases with and without food exposure over a period of four weeks. The LFPs were processed using a 4th order Butterworth band-pass filter to eliminate noise, followed by conversion into scalograms for visual analysis. The scalogram data revealed increased gamma activity during food presence. Utilizing this data, a convolutional neural network (CNN) classifier with three convolution layers and two dense layers, optimized with the Adam algorithm, was employed to decode the neural patterns, achieving a classification accuracy of 90.3% in distinguishing the feeding phases.

In conclusion, the deployment of a minimally invasive, biodegradable shuttle has addressed the limitations of flexible neural probes for deep brain recording in NHPs. The probe enabled effective, month-long wireless recording of LFPs, which were subsequently decoded using a CNN-based classifier to determine eating behaviors. These results underscore the potential of such technologies in advancing brain circuit research and electroceutical development.

SB02.09.17

Direct Combined Determination of Ion Transport and Exchange in Organic Bioelectronic Devices Aneta

Marková[1], Donghak Byun[2], Martin Weiter[1], Johannes Bintinger[2] and Martin Vala[1]; [1]Brno University of Technology, Czechia; [2]Linköping University, Sweden

Organic bioelectronic devices such as organic electronic ion pumps or organic electrochemical transistors are small electronic devices with a high potential for, for example, stimulation and correction of nervous activity (treatment of Parkinson's disease, suppression or complete cessation of epileptic seizures, regeneration of damaged nerve connections), detection and influence of cellular tissues (cardiac pacemaker, heart rate monitor, sweat or blood composition), and, last but not least, the targeted dosing of medicine in time and space (treatment of cancer, depression, diabetes), i.e. with significant minimization of side effects. Both of these devices are based on ion exchange and ion transport in organic semiconductors and ion-selective materials, which are mostly polymeric substances with the unique ability to conduct ions in addition to electrons, unlike classical devices, they are thus capable of much more efficient information transfer between living tissue and devices than the devices commonly used today.

However, despite significant progress in research, the disadvantage of these new bioelectronic devices is still their relatively low sensitivity, repeatability, and biocompatibility, which prevents their mass use in everyday life. Moreover, the understanding of ion transport and ion exchange is derived mostly based on nonspecific or non-real-time detection methods (e.g. mass spectrometry or purely electrical readouts). However, a precise understanding of the role of ions (e.g. drift and especially diffusion and its effect on electronic mobility) is therefore critical for understanding the principle of operation of organic (bio)electronic devices.

Nevertheless, the overall extent of the exchanged ions (especially the number of exchanged ions) is still not fully elaborated. Here, we report on a new approach based on direct combined determination of ionic transport and exchange using optical, electrical, and pH detection. We use absorbance measurement of the pH indicator (fluorescence of ion-selective fluorescent probe) to monitor a change in the concentration of protons (specific ions) that are transported/exchanged and correlate this change with electrical output. To support this measurement, a pH change is continuously measured in the case of proton transport and is correlated with the optical and electrical readout. Through the correlation of electrical output, pH, and data from optical measurements, we can calculate the delivered proton concentrations. Determining the amount of transported/exchanged ions is important not only from the point of view of characterizing new organic semiconductors or ion-exchanged membranes but also for studying the mechanism of interaction of bioelectronic devices with cells and living tissues and thus for the development of new bioelectronic devices and new drug development.

SB02.09.18

An Adsorption Dominated Miniaturized Multifunctional Biosensor Based on In Situ Functionalized MXene and Laser Induced Graphene Based Electrodes for Health Monitoring

Abu Musa Abdullah[1], Md Abu Sayeed Biswas[1], Ankan Dutta[1,1], Shuvendu Das[1], Arantza Moreno Calva[1,2] and Huanyu Cheng[1]; [1]The Pennsylvania State University, United States; [2]Universidad Iberoamericana, Mexico

The advancement of multifunctional wearable, flexible, and stretchable sensors plays a crucial role in precisely monitoring human health biomarkers. However, high-performing sensors require highly sensitive, stable, and miniaturized electrodes. In this study, we introduced an in-situ Functionalized Ti-MXene and Laser-Induced Graphene (LIG) composite (FMLIG) electrode-based biosensor for monitoring body glucose using human sweats. The two-step direct laser printing contributed to the surface reduction of MXene onto LIG electrodes, which shifted the electrochemical reaction from diffusion-controlled to adsorption-controlled. The shift has been confirmed through both simulative and experimental approaches. The FMLIG electrochemical sensor exhibits exceptional glucose sensitivity of 2751.3μA/mM.cm^2 with a miniaturized electrode area of 0.0079 cm^2 and a low limit of detection of 0.3μM for sweat detection, along with excellent stability maintaining over 90.53% sensitivity for 21 *days in ambient conditions. Furthermore, the sensor demonstrates high consistency in body glucose measurement across multiple human subjects. The miniaturized electrodes can further be implemented to fabricate highly sensitive multi-functional biosensor for space-constraint areas. The miniaturized size of the sensor enables seamless integration with VR-integrated health monitoring systems. Moreover, the FMLIG electrodes, when utilized as a humidity sensor, showcase impressive performance with a high sensitivity of 20197.01 pF/RH, a low response time of 27.57 s, and a rapid recovery time of 3.18 s. Additionally, the FMLIG composite electrodes exhibit remarkable capabilities in capturing skeletal muscle movements during grasping, with an observed increase in EMG amplitude by 167% compared to pristine LIG electrodes, even in the presence of sensible sweat, while maintaining an excellent signal-to-noise ratio. The sensors were further integrated with a VR mask to monitor physical and mental health. These devices show promising possibilities in health monitoring during VR mask usage*

SB02.09.19

Needle-Like Multifunctional Biphasic Microfiber for Minimally Invasive Implantable Bioelectronics *Gi Doo Cha; Chung-Ang University, Korea (the Republic of)*

Implantable bioelectronics has attracted significant attention in electroceuticals and clinical medicine for precise diagnosis and efficient treatment of target diseases. However, conventional rigid implantable devices face challenges such as poor tissue-device interface and unavoidable tissue damage during surgical implantation. Despite continuous efforts on utilizing various soft materials to address such issues, their practical applications are still limited. Here, we report a needle-like stretchable microfiber comprised of a phase-convertible liquid metal (LM) core and a multifunctional nanocomposite shell for minimally invasive soft bioelectronics. The sharp tapered microfiber can be stiffened by freezing like a conventional needle to penetrate the soft tissue with minimal incision. Once implanted in vivo where the LM melts, unlike conventional stiff needles, it recovers soft mechanical properties facilitating a seamless tissue-device interface. The nanocomposite incorporated with functional nanomaterials can both exhibit low impedance and detect physiological pH, which confers biosensing and stimulation capabilities. The fluidic liquid metal embedded in the nanocomposite shell enables high stretchability and strain-insensitive electrical properties. This multifunctional biphasic microfiber conforms to the surface of the stomach, muscle, and heart and offers a promising approach for electrophysiological recording, pH sensing, electrical stimulation, and radiofrequency ablation in vivo

SB02.09.20

Modeling the Impact of Electromagnetic Fields on C3 Plant Cellular Metabolism Using Helmholtz Coils *Vittal Harith[1] and Salah Badjou[2]; [1]Gordon College, United States; [2]Wentworth Institute of Technology, United States*

Low-frequency Electromagnetic Fields (EMFs) have been explored for several years for their ability to inhibit the growth of cancer cells by altering cell signaling networks involving cell division and regulating proliferation. Cancer cells, known for uncontrollable growth and impaired apoptosis, could potentially be affected by electromagnetic interference. This research aimed to measure and investigate the effects of electromagnetic fields on the metabolic rate of spinach leaf cells using the Helmholtz Coil System. Understanding how EMFs can affect cellular metabolism may inform new strategies for cancer treatment that exploit cancer cells' dependency on energy production, which may present the opportunity, for instance, to develop a targeted therapy to interrupt tumor development that is non-invasive to health cells.

Fresh tree leaves were put inside a sealed bottle with a CO2 sensor attached facing the direction of EMFs and placed between the two coils. The ring-shaped coils were connected to the function generator to produce different EMF frequencies. In addition, this experiment was performed in a room with no lights to isolate external factors such as sunlight. Electric fields (16Hz-100kHz) produced an average metabolic rate reduction of -12.24%, while controls increased by a +17% increase. Correspondingly, the exposure to *magnetic fields (0-60Hz) resulted in a decrease of -43% as compared to +17% in the control group. Overall, these results suggest that the electric and magnetic fields are capable of reducing the metabolic rate and inducing stress at a cellular level that can weaken the cells. The purpose of this research was accomplished as it showed that electric and magnetic fields decreased the metabolic rate of tree leaves. This occurs due to the potential generation of eddy currents within the magnetic field and internal AC from the electric field which may interfere with ion transport and mitochondria function. In addition, the increase in controls shows evidence of CO2 build-up, which is a byproduct of cellular respiration. For future research, plant tumor models like the tobacco and tomato plants infected with Agrobacterium tumefaciens will be employed to understand these effects. These models will be placed in Helmholtz coils to observe effects on tumor development. This approach potentially offers a solution to understanding EMFs for new methods of cancer treatment.*

SB02.09.21

Graphene Quantum Dot Integrated Polyaniline Nanofibers for Applications in Cortisol Biosensors *Cesar Sanchez[1], Ashwin James[2] and Victoria Padilla[1]; [1]The University of Texas at Rio Grande Valley, United States; [2]University of Texas Rio Grande Valley, United States*

Cortisol, a key hormone involved in stress response, metabolism, and immune function, is a vital biomarker for diagnosing various health conditions. Rapid and cost-effective cortisol detection is important for clinical and medical applications, but traditional methods can be slow and expensive. In this study, we developed a novel cortisol biosensor using porous polyaniline (PANI) nanofibers integrated with nitrogen-doped graphene quantum dots (N-GQDs), offering a highly sensitive, flexible, and low-cost solution for cortisol monitoring.

Polyaniline is a conductive polymer with excellent electrical properties, making it suitable for biosensor development. To synthesize high-molecular-weight PANI, the reaction mixture was cooled to -40°C for an extended period, which enhanced the conductive properties of the polymer. The resulting PANI was then dissolved in dimethyl sulfoxide (DMSO) and mixed with polyethylene oxide (PEO). This composite was processed via electrospinning, a technique that allows for the production of continuous nanofibers with controlled diameter and morphology.

The electrospun PANI-PEO nanofibers were then washed in water to dissolve the PEO, leaving behind a porous network of PANI fibers. This porous structure is critical, as it increases the surface area available for further modification and enhances sensor performance. To improve conductivity and create more binding sites for the anticortisol enzyme, nitrogen-doped graphene quantum dots (N-GQDs) were incorporated into the pores of the PANI nanofibers. N-GQDs are highly conductive, biocompatible, and have a large surface area, making them ideal for boosting the sensor's sensitivity.

The integration of N-GQDs into the porous PANI fibers served multiple functions: it enhanced the electrical properties of the nanofibers, allowing for more efficient signal transduction, and it provided a larger surface area for the immobilization of the anticortisol enzyme. This combination of enhanced conductivity and surface area greatly improved the sensor's ability to detect cortisol.

The composite PANI-N-GQD nanofibers were fabricated into biosensor electrodes and tested in a dilute solution of cortisol in water. The sensor's performance was evaluated based on its response to varying cortisol concentrations, and it showed excellent sensitivity. Compared to control sensors made from plain PANI fibers, the N-GQD-integrated fibers demonstrated significantly improved detection capabilities. This improvement can be attributed to the synergistic effects of the porous structure and the N-GQDs, which together enhanced the *conductivity and enzyme attachment, leading to a more sensitive biosensor.*

In addition to its application in cortisol detection, the PANI-N-GQD composite offers several advantages for a wide range of biosensing technologies. The nanofibers are highly conductive, flexible, and cost-effective, making them ideal for wearable and portable biosensors. Moreover, the electrospinning process used to fabricate these nanofibers is scalable, enabling large-scale production of sensor components. These characteristics make the PANI-N-GQD platform a versatile and attractive solution for various biosensor applications.

Future work will focus on further optimizing the integration of N-GQDs into the PANI fibers and improving the sensor's long-term stability and reproducibility. Additionally, the potential to use these fibers for detecting other biomarkers and chemicals will be explored, as their versatility and ease of fabrication make them a promising platform for a wide range of sensing applications.

In conclusion, the integration of nitrogen-doped graphene quantum dots into porous PANI nanofibers provides a powerful approach for developing highly sensitive, flexible, and low-cost cortisol biosensors. This innovative platform has the potential to be adapted for other biosensing applications, offering a scalable, efficient, and cost-effective solution for future sensor technologies.

SB02.09.22

Effect of Liquid Metal on PEDOT: PSS Organic Electrochemical Transistors *Qian Zhou, Huanan Zhang, Austin Eiting and Deisy Fernandes; The University of Utah, United States*

Organic electrochemical transistors (OECTs) play an important role in neural interfaces, as well as in bio- and chemical sensing, due to their high efficiency, flexibility, and compact size. Currently, most OECTs are based on the conductive polymer PEDOT: PSS, which is primarily used as the channel material in the depletion mode. However, the depletion mode requires a high static gate voltage to be applied during operation, leading to device instability in aqueous electrolyte environments because of the parasitic reactions with water and oxygen. In this work, we introduced a liquid metal gallium-indium alloy (EGaln) to reduce the doping of PEDOT: PSS and crosslink PEDOT: PSS into the hydrogel. Preliminary studies have shown that OECTs with an EGaln crosslinked PEDOT: PSS hydrogel channel can operate stably in the accumulation mode. Additionally, the PEDOT: PSS hydrogel is printable and can be prepared in various shapes, showing great potential for the mass production of PEDOT: PSS OECTs.

Anions Doping Induced Reversable Threshold Voltage Modulation for Organic Electrochemical Transistors
Zhongliang Zhou and Wei Lin Leong; Nanyang Technological University, Singapore

Controlling the threshold voltage in organic electrochemical transistors (OECTs) has been considered as a promising approach for customizing transistors to meet specific application requirements. By tuning the threshold voltage, OECTs can switch effectively in both accumulation mode and depletion mode, providing researchers with *greater flexibility in circuit design. In this work, we propose anion doping induced threshold voltage modulation in OECTs for bioelectronics applications. By altering the doped anions (varying radius) in the aqueous liquid electrolyte, the threshold voltage of pgBTTT based OECTs can be shifted from -0.15 V (under 0.1 M NaCl) to 0.3 V (0.1 M NaTFSI). This wide range is sufficient for pgBTTT based OECTs to function as both accumulation and depletion mode transistors. To demonstrate their feasibility in various operating modes, we first employed pgBTTT-based OECTs doped with TFSI$^-$ to construct a zero-gate biased ECG amplifier. This amplifier exhibited high amplification (23.3 μA), and the high transconductance at 0 V indicates that it requires only one power supply, significantly reducing power consumption. Next, we implemented a complementary logic circuit using the pgBTTT-based OECT doped with Cl$^-$ as a pull-up transistor. The proposed complementary inverter exhibits high gain (59V/V) and a high noise margin with full rail-to-rail swing. Furthermore, we combined the features of both these two transistors (doped with Cl$^-$ and TFSI$^-$) to create organic electrochemical nonlinear devices (OENDs). The exhibited S-shaped negative differential resistance (S-NDR) curve demonstrates oscillation functionality, similar to other spiking neurons but with a reduced transistor type, which is particularly useful for future multi-layer spiking neurons. In summary, the easily tunable threshold voltage of pgBTTT-based OECTs under different anions offers a simpler approach to customizing transistors for specific requirements, paving the way for further advancements in low-power bioelectronics.*

Enhancing the Performance of N-Type Organic Mixed Conductors by Blending Polymers with Alkyl and Oligoglycol Side Chains *Seth Jackson, Garrett Collins, Perry Martin, Jolene Keller, Emily J. Dalley and Connor G. Bischak; The University of Utah, United States*

Conjugated polymer organic mixed ionic electronic conductors (OMIECs) are promising materials for bioelectronics, neuromorphic computing, and energy storage. Compared to their p-type counterparts, n-type are typically not as stable and have significantly lower figures of merit. Naphthalene diimide (NDI) based n-type OMIEC copolymers with hydrophobic alkyl and hydrophilic oligoglycol side chains show stability in water. In this work, we investigate the performance of blends of p(gNDI-gT2) and N2200. We employ nanoscale infrared imaging with photoinduced force microscopy (PiFM) to interrogate how p(gNDI-gT2) and N2200 phase separate at the nanoscale. We also use a combination of grazing incidence wide-angle X-ray scattering (GIWAXS) and UV-vis spectroelectrochemistry to monitor polaron formation and ion movement in these blended films. To determine whether the polymer blends boost organic electrochemical transistor (OECT) performance, we fabricate OECTs with active layers consisting of different ratios of p(gNDI-T2) and N2200. We find enhanced OECT performance when we add small amounts of N2200 to p(gNDI-T2). Overall, this study emphasizes that blending two n-type materials can result in enhanced device performance.

9:30 AM SB02.10.03

Fast and High-Transconductance Organic Electrochemical Transistor for Implantable Peripheral Nerve Recording System *Seong Jun Park, Yongwoo Lee and Sungjune Jung; Pohang University of Science and Technology, Korea (the Republic of)*

Organic bioelectronics is an emerging field that leverages the unique properties of organic semiconductors in interfacing with cells, tissues, and biological systems. Organic electrochemical transistors (OECTs), in particular, are promising for wearable and implantable electronics due to their low operating voltage, high transconductance, stability in aqueous environments, and biocompatibility. The operation of OECTs is characterized by ion penetrating into the polymer channel for electrochemical doping/dedoping through applying gate voltage bias. However, OECTs face a significant challenge due to an inherent trade-off between transconductance (gm, defined as $\partial I_D/\partial V_G$) and transient characteristics, which limits their range of sensing applications. In our study, we *addressed this issue by modifying the channel structure to micro/nano structure using conventional lithography and reactive ion etching process. We hypothesized that the introduction of micro/nano structures into the channel architectures will allow more efficient ionic penetration from electrolytes to all sides of the channel, significantly increases the surface-to-volume ratio, thereby reducing the effective path of ions. The transient response of the micro/nano structured channel OECT showed that as the size of the patterned structure decreases, the effective path of ions for doping/dedoping process is reduced, and consequently enhance the operation speed of OECT. We also controlled the OECT channel structure precisely and uniformly, which makes it highly scalable for various application. Our results show that micro/nano structured channel OECTs achieve improved response times compared to conventional structures maintaining high transconductance about 10 mS. Subsequently, we developed our micro/nano structured channel OECT arrays as an implantable nerve cuff for monitoring peripheral nerve signal. This array was utilized to be wrapped around the peripheral nerve of the anesthetized rat to monitor neural signals induced by external mechanical stimulation. We envision that these results will provide valuable insights for kinetics of OECTs operation and the fields of neuroprosthetics and neurological diseases.*

Exploring the Role of the Electrolyte and Nanoscale Morphology on the Performance of Organic Mixed Ionic-Electronic Conductors *Garrett Collins, Seth Jackson and Connor G. Bischak; The University of Utah, United States*

Organic mixed ionic-electronic conductors (OMIECs) have emerged as powerful materials for bioelectronics applications because of their ability to conduct both ionic and electronic species. The performance of these materials strongly depends on couplings between ionic motion, electron transport, and structural dynamics. Understanding the design rules that dictate these coupled dynamics is challenging because of (1) the need to characterize these materials in a liquid environment, (2) the inherently nanoscale morphology of these materials, and (3) the large parameter space that impacts OMIEC performance (e.g. electrolyte identity, processing conditions). In this talk, I will show how our group has developed a high-throughput robotic system to interrogate OMIEC performance as a function of electrolyte identity and OMIEC processing conditions. I will also demonstrate how we use nanoscale infrared imaging with photoinduced force microscopy (PiFM) to map the location of ionic and electronic species in the OMIEC polymer matrix. By combining high-throughput studies and nanoscale imaging, we aim to understand dynamic processes in OMIECs over a wide range of length scales and timescales.

Aerosol Jet Printed Ion Selective Organic Electrochemical Transistors for Non-Invasive Detection of Neural Health *Anoushka Ganguli, Yuchen Shao, Catlin Letendre and Manisha Gupta; University of Alberta, Canada*

Monitoring nerve function is important to understand and treat many prevalent neural diseases. An effective and non-invasive way of doing so is by monitoring ion concentration in bio-fluids such as sweat. It is believed that there are normal and subnormal thresholds for ion concentrations in sweat that can be directly correlated with the health of the nervous system and can be used for early detection of diseases such as neuropathy. By monitoring sodium concentrations, which are the most abundant ion in sweat, correlations will be made for predictive analysis of diabetic neuropathy. Traditionally, potentiometric sensors are used for this application. However, it is often difficult to fabricate and miniaturize the necessary reference electrode and such sensors face issues of high output impedance. The proposed system does not encounter these challenges and uses organic electrochemical transistors (OECTs) with an ion selective membrane (ISM) functionalized channel for real-time measuring, up to 30 minutes at a time.

Initial characterizations of the ISM were based on redox potentials determined by cyclic voltammetry (CV). This *process involved recording voltammograms for interfering and primary analyte ions with a Na^+ selective membrane to ensure selectivity for primary ions in a repeatable and reliable way. Gold electrodes were printed using an Optomec Aerosol Jet 5X printer were used for the CV testing. These devices were coated with a drop-casted layer of poly(3,4-ethylenedioxythiophene): polystyrene sulfonate (PEDOT:PSS), acting as the ion-to-electron transducer, and a layer of ISM solution. Given that the average redox peak for PEDOT:PSS was found to be 1.15 ± 0.03V, the measured values showed an obvious and repeatable selectivity for Na^+ when compared to K^+ of the same concentration. The average redox peak potential for 0.1M NaCl was found to be 1.24 ± 0.03V and for 0.1M KCl, it was found to be 1.16 ± 0.02V. This difference in redox peak potential allows for clear selectivity towards Na^+ ions. An OECT will be used to increase the signal to noise ratio, thus reducing the need for signal amplification and thereby improving sensitivity. This device is fabricated on a flexible Kapton substrate, using aerosol jet printed gold and PEDOT:PSS as the electrode material and the device channel respectively. The ISM solution is drop-casted on the channel as well. Kapton is used to ensure that the form-factor is biocompatible both in terms of wearability and material composition. The proposed sensor is designed to not only distinguish between varying concentrations of Na^+ but also different ions. So far, the devices have been tested against K^+, Ca^{2+} and Mg^{2+} ions and has shown reliable selectivity such that minimal current responses are produced when these ions are introduced. The chosen concentrations for the Na^+ selective device range from 0.005M to 0.5M which is adequate to measure ion concentrations in human sweat which are between 0.08M and 0.128M [1,2,3]. Detailed CV and OECT results from the ion sensor will be presented.*

***Self-Powered, Bioresorbable Optoelectronic Devices** Yamin Zhang; National University of Singapore, Singapore*

Programmable engineering platforms for active control of medical devices include power sources, delivery mechanisms, communication hardware, and associated electronics, most typically in forms that require surgical extraction after a period of use. In this talk, I will introduce our self-powered optoelectronic platforms that bypasses key disadvantages of these systems and enables miniaturized devices for drug delivery and electrotherapy, with constituent materials being bioresorbable that naturally degrade after a period of stable operation in the human body. Bioresorbable batteries serve as power supplies. Studies of various bioresorbable electrode materials define the key considerations and guide optimized choices in designs. Programmability relies on the use of external light sources to illuminate wavelength-sensitive phototransistors via wavelength-division multiplexing strategy. In vivo demonstrations of programmed release of lidocaine and multi-site cardiac pacing in small and large animal models illustrate the functionality in the context of drug delivery and electrotherapy. This platform can be readily adapted for a broad range of additional applications.

***Wireless Smart Microneedle Patches for Real-time Continuous Glucose Monitoring of Diabetes** Inhoo Choi, Kwanghyeon Park and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)*

Microneedles (MN) have been widely investigated for biomedical applications with the unique capability of reaching dermal interstitial fluid (ISF) in a minimally invasive way. The analysis of glucose concentrations in ISF with MNs can benefit diabetic patients with facile and pain-free diagnosis compared to the conventional continuous glucose monitoring (CGM) devices. However, CGM using MNs has many limitations including slow response time, low mechanical strength and low stability of glucose monitoring. Here, we developed a wireless, highly sensitive CGM MN system to electrochemically detect glucose with bimetallic nanocatalysts and glucose oxidase using the glucose sample of ISF transferred through the mesoporous polyvinyl alcohol (PVA) and polyvinyl pyrrolidone (PVP) hydrogel MNs. The mesoporous structure of MNs reduced the response time by facilitating the rapid diffusion of analytes from ISF to the sensing interface. Chronoamperometry measurements showed that the MN system had high sensitivity, a low detection limit, minimal hysteresis, and remarkably short response times at the glucose concentration from 1 mg/dL to 200 mg/dL. Mechanical tests conducted using the Instron and porcine skin confirmed the sufficient mechanical strength for skin penetration and sensor functionality. The integrated wireless smart microneedle patches will be presented for the real-time glucose monitoring of diabetes.

11:15 AM SB02.10.08

Soft Tissue-Adhesive Epicardial Bioelectronics for Chronic On-Site Signaling Yewon Kim and Donghee Son; *Sungkyunkwan University, Korea (the Republic of)*

Soft bioelectronics for stable and multifunctional cardiac implants have been developed. However, using inorganic materials through wavy/buckled structural designs for stretchability and softness cannot perfectly match the tissue deformations of the heart under the dynamic contraction-relaxation cycles. Therefore, intrinsically stretchable bioelectronics for epicardial interfacing have been paid remarkable attention to make stable tissue-device interface on the epicardium for reducing tissue deformations of the heart due to applied pressure. In addition, tissue adhesion is needed for avoiding suture, conventional fixation methodology, which causes bleeding, continuous shear stress and an inflammation in the stitched regions. However, the bioadhesive devices still remain challenges due to instability of adhesion, non-uniform coverage on the curved tissue, and the breakdown of the fatigue-accumulated electrodes. In this work, we report soft and stretchable cardiac patch with instantaneous adhesion on the tissue. This patch composed of three layers: a tissue-adhesive catechol-conjugated alginate (Alg-CA) hydrogel, an electrospun fibre-interlocked viscoelastic network-type polymer substrate, and an electrically durable liquid metal nano-/micro-particles composite electrode. The patch immediately adheres to the curved tissue with spontaneous modulus matching according to no need for external stimuli or long time for adhesion and an efficient strain adaptation of SHP (Self-healing polymer). Especially, fibrous network structure mechanically enhances not only the stress relaxation property of the polymer itself but also the tissue adhesiveness of the patch through interlocked interface via penetration of the Alg-CA into the micropores on the substrate. Also, compared to the composite of solid-state conductive fillers, liquid-state of the EGaIn (Eutectic gallium-indium) particles is suitable for reducing the issues related to fatigue-induced electrical malfunctions during long-term cardiac monitoring. Lastly, the chemical coordination between carboxylate and catechol groups in adhesive hydrogel and metal ions on the oxide layer of the liquid metal particles in electrode enables precise electrical stimulation besides stable ECG (Electrocardiogram) signal recording even in rodent with myocardial infarction (MI) and drug-induced bradycardia-/arrhythmia-triggering model. Therefore, the approach can be of potential use in precise diagnostics and feedback treatment for patients with cardiovascular diseases.

1:30 PM *SB02.11.01
Soft and Stretchable Neural Electrodes Based on Gold Nanowire Composites *Klas Tybrandt; Linköping University, Sweden*

Two-way communication between electronics and neural tissue is key for advancing diagnosis and therapies for neurological diseases and disorders. Establishing such neural interfaces is a major challenge, as the tissue response to implants can have a detrimental effect on the signal quality and functionality of the implant. Matching of the mechanical properties of the electronic implant to the soft interfaced tissue can reduce the tissue response and improve the long-term performance of the device. This requires soft and stretchable conductors, which typically are composed of elastomer/hydrogels and conductive fillers. However, the tough materials requirements on biomedical implants, including material chemistry, mechanical and electromechanical properties, and long-term stability, disqualifies most of the developed stretchable electronic materials for such applications. Here I will present our efforts in developing inert soft neural electrodes based on stretchable gold nanowire composites, covering aspects ranging from nanomaterial synthesis, material formulation and processing to device design and in vivo applications.

Patterning Electronically Conductive Features Within Soft Hydrogel Substrates for Bioelectronics and Tissue Engineering Applications *Lorenzo Lucherini, Esther Amstad and Stephanie P. Lacour; École Polytechnique Fédérale de Lausanne, Switzerland*

Hydrogels, highly hydrophilic polymeric networks, have gathered significant attention in the biomedical field due to their exceptional water-retention capability, biocompatibility, and anti-biofouling properties. The mechanical properties of hydrogels can be tuned with their composition, and type and degree of crosslinking. Moreover, hydrogels exhibit excellent ionic conductivity due to their ability to swell to many times their dried volume in aqueous solutions. The synergy of these two features makes hydrogels ideal for mimicking natural soft tissues. However, their lack of electronic conductivity limits their applicability in bioelectronics. Moreover, many applications in bioelectronics would strongly benefit not only from the electrical conductivity in the hydrogel, but from the ability to pattern it, a feature that has not been demonstrated at the sub-μm length scale thus far.
In this presentation, I will introduce a method to fulfill these requirements. Exploiting two-photon direct laser writing (DLW), we trigger the in-situ synthesis of noble metal nanoparticles (NPs) through photoreduction. Thereby, we generate electrically conductive 50-250 μm wide tracks within both synthetic and natural hydrogels possessing Young's moduli as low as 20 kPa, matching the mechanical properties of soft natural tissues.
We envision this method could be used for the fabrication of hydrogel-based devices and functional substrates for tissue engineering. Lastly, the introduction of spatially-controllable electronic conductivity within hydrogels would open new possibilities for interfacing soft materials with electronic equipment.

2:15 PM SB02.11.03
Soft Multimodal Optoelectronic Devices for Cardiac Interfacing *Luyao Lu; The George Washington University, United States*

Recent advances in new materials, electronics, and assembly techniques have allowed the design and application of soft optoelectronic systems to integrate with living organisms for a wide range of biological and biomedical applications. In this talk, I will discuss several of our recent examples of soft bioelectronic devices enabled by new concepts in materials science, microfabrication, and microsystem integration. Those functional devices contain one or multiple components of transparent microelectrodes, microscale light sources, and photodetectors in flexible formats and allow for stable, high-fidelity, electrical and optical mapping and modulation of cardiac activity both ex vivo and in vivo. We envision those soft optoelectronic microsystems will open new windows to understand important biological processes, such as studying heart function, transforming biology and medicine.

2:30 PM SB02.11.04

Soft and Transient Bioelectronics from MXene Hydrogels *Raghav Garg[1], Stefano Ippolito[2], Prastuti Upadhyay[2], Spencer R. Averbeck[1], Yury Gogotsi[2] and Flavia Vitale[1]; [1]University of Pennsylvania, United States; [2]Drexel University, United States*

Biological tissues, such as cardiac and neural tissues, are inherently soft and exhibit viscoelastic behavior. Monitoring and modulating such tissues through bioelectronic implants can enable real-time diagnosis and adaptive therapies for a growing and diverse number of disorders. Current bioelectronic interfaces are composed of mechanically rigid materials that trigger stiffness-related inflammatory and toxic reactions. Hydrogels have emerged as promising materials for soft and flexible bioelectronic interfaces due to their similarities with mechanical properties of biological tissues. Existing hydrogel-based bioelectronics are designed to facilitate chronic operation and require surgical extractions when necessary. Biodegradable bioelectronics might circumvent the need for surgical extraction; however, their material library and interface geometry has been limited to two-dimensional metal and polymeric thin films.

Here we leverage liquid-phase processing of two-dimensional $Ti_3C_2T_x$ MXene to fabricate MXene-based hydrogels for soft and transient bioelectronics. We directly crosslink individual MXene flakes using transition metal ions to achieve soft matrix-free hydrogels high electrical conductivity of up to 790 ± 150 S/m. The high capacitance and surface area of $Ti_3C_2T_x$ MXene flakes allows us to fabricate electrodes that exhibit electrochemical impedance as low as 540 ± 130 Ω at 1 kHz (2 mm diameter), thus facilitating their application in low-noise electrophysiological recordings with high signal-to-noise ratio. $Ti_3C_2T_x$ hydrogel electrodes further exhibit up to 50-fold greater high charge storage capacity and up to 7-fold greater charge injection capacity than conventional Pt-based rigid electrodes of the same size. By optimizing the structure and degree of cross-linking of the gelatin-based encapsulation and $Ti_3C_2T_x$ conductive hydrogel, we have fabricated a biodegradable electrode array. Our unique approach facilitates safe delivery of therapeutic electrical stimulation and recording of electrophysiological signals from target tissues. Our results underscore the application of MXene-based soft hydrogel bioelectronics in studying neural function and disease pathologies, as well as developing transient electroceutical approaches.

2:45 PM SB02.11.05

Enhancing the Scalability and Functionality of Soft Bioelectronic Materials Through Emulsion-Based Techniques *McKayla L. Torbett[1], Aida Fica[2], Samuel West[2], Manish Kumar[2] and Stephen A. Sarles[1]; [1]The University of Tennessee, Knoxville, United States; [2]The University of Texas at Austin, United States*

Despite significant progress in recent decades, fundamental differences between biological tissues and conventional electronics create challenges in material design and manufacturing for the next generation of bioelectronics. For example, the human body comprises a diverse array of soft tissues with variable mechanical properties and high water content, while most commercially available and lab-level bioelectronic devices primarily use stiff, dry electronic components like silicon and metals. Additionally, natural tissues are hierarchal in structure, whereby cells act as building blocks for larger networks of tissues and organs, but traditional *bioelectronic devices are often monolithic, resulting in spatially homogeneous devices with limited regional control of functionalities. Droplet-based assembly techniques, such as the Droplet Interface Bilayer, harness the natural compartmentalization observed in cells, offering precise spatial control and modular manipulation of chemical and biological processes, along with selective transport across their membrane interfaces, enabling functionalities such as signal processing and molecular detection. Current strategies for constructing droplet-based materials involve the dispensing and positioning of individual droplets, which is time-consuming and demands meticulous coordination of timing and spatial precision. Also, while a liquid-in-liquidfilled structure more closely models the uniquely wet environment of natural tissues, it lacks the mechanical robustness needed in many applications. Thus, an alternative approach is necessary for the rapid and scalable assembly of soft, compartmentalized bioelectronic materials. This study introduces a novel protocol utilizing emulsification and centrifugation to enhance the scalability of soft compartmentalized tissues. In this approach, lipids or amphiphilic block copolymers such as poly(Butadiene)-b-poly(ethylene oxide) (PBPEO) act as emulsifiers to stabilize a water-in-oil emulsion. By emulsifying an aqueous buffer, a selective oil solvent, and the surfactant, individual compartments (5-50 μm) are formed, each stabilized by a monolayer of the surfactant and connected with their neighbor via a biomimetic bilayered hydrophobic membrane. Centrifugation then removes excess oil and condenses the surfactant-coated droplets into a densely packed network of interconnected aqueous compartments. The resulting tissue-like material has a suitable consistency for 3D bioprinting in that it has shape-holding abilities but is viscous enough to be extruded at low pressures. Additionally, the presence of biomimetic membranes allows for the incorporation of transmembrane proteins and ion channels. For example, the voltage-gated ion channel, Alamethicin, can be reconstituted into the hydrophobic membranes, providing discrete control of ionic current. The overall mechanical, electrical, and selective transport properties of the emulsions are not yet well-defined, though. Thus, a comprehensive examination of the material is performed herein. Rheological measurements are obtained to evaluate the material's viscoelasticity and self-healing abilities. Electrophysiology is used to reveal equivalent circuits and characterize membrane selectivity, and the print fidelity is assessed across various 3D geometries. Overall, this innovative protocol offers a rapid and scalable approach for creating compartmentalized tissue-like materials. The compartmentalized architecture enhances the functionality of bioelectronic devices by enabling precise spatial control and customization of individual compartments. Ionic conductance can be regionally manipulated via selective channels to enable localized filtration, absorption, and/or secretion of distinct species, holding great promise for applications such as advanced biosensing, drug delivery, and biohybrid systems.*

Standalone Stretchable Device Platform for Biomedicine *Huanyu Cheng; The Pennsylvania State University, United States*

Conventional electronics today form on the planar surfaces of brittle wafer substrates and are not compatible with 3D deformable surfaces. As a result, stretchable electronic devices have been developed for continuous health monitoring. Practical applications of the next-generation stretchable electronics hinge on the integration of stretchable sustained power supplies with highly sensitive on-skin sensors and wireless transmission modules. This talk presents the challenges, design strategies, and novel fabrication processes behind a potential standalone stretchable device platform that (a) integrates with 3D curvilinear dynamically changing surfaces, and (b) dissolves completely after its effective operation. The resulting device platform creates application opportunities in fundamental biomedical research, disease diagnostic confirmation, healthy aging, human-machine interface, and smart Internet of Things.

UV-Assisted Spinning of Tough, Stretchable and Resilient Ionotronic Fibers for Stable Signal Transmission

Lingtao Fang, Zijian Zheng and Qiyao Huang; The Hong Kong Polytechnic University, Hong Kong

The development of tough and stretchable ionic conductors, particularly hydrogels in fiber shape, has facilitated the operation of ionotronic devices under various deformation scenarios by leveraging a hybrid circuit of mobile ions and electrons. However, the production of ionic conductive hydrogel fibers still encounters significant challenges, including the development of efficient fabrication techniques and ensuring long-term durability and reliability, especially in harsh environmental conditions. Herein, we present a continuous and cost-effective UV-assisted spinning method that utilizes deep eutectic solvents (DESs) as substitutes for water in the fabrication of ionic conductive gel fibers, which exhibit remarkable mechanical resilience, conductivity, and exceptional stability under varying temperatures and humidities. The resulting gel fibers display a high ionic conductivity of 0.896 S/m and Young's modulus of 8.7 MPa, rivaling the performances of most hydrogels. Notably, these fibers exhibit exceptional durability, retaining their mechanical and electrical integrity over 365 days of ambient storage without discernible degradation. Moreover, we demonstrate the utility of these fibers in the creation of ionic cables that can reliably transmit high-quality signals even under strain, highlighting their potential for long-term ionotronic applications, including wearable devices and health monitoring systems.

Environmentally Stable and Stretchable Polymer Electronics Enabled by Surface-Tethered Nanostructured Molecular-Level Protection

Yu Zheng[1,2] and Zhenan Bao[2]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States

Soft and stretchable bioelectronics made of polymeric materials are envisioned to be promising platforms for next-generation wearable and implantable applications, enabling real-time health monitoring, timely medical diagnosis/treatments, smart prosthetics, and brain-machine interfaces. However, the environmental instability of polymer semiconductors (PSCs) remains to be a long-standing concern that hinders their practical deployment. Previous reports of addressing the challenge are mainly focused on encapsulation of the entire electronic device with stretchable polymer coatings, which usually have high water permeability and thus exhibit poor protection effect due to large free volume. In this work, we developed a simple and effective molecular protecting method to improve PSC operational stability in organic field-effect transistors, which involved covalent functionalization of fluoroalkyl-chains onto stretchable PSC film surface to form densely packed nanostructures. The fluorinated molecular protection layer (FMPL) with nanometer thickness exhibited orders of magnitude lower water permeability than that of various stretchable elastomers and dense plastics, and even on par with some inorganics. More importantly, the FMPL maintained its protecting function under mechanical deformation. Utilizing multiple nanoscale characterization tools, we quantitatively elucidated that the FMPL's remarkable ability to block water absorption and diffusion was attributed to its hydrophobicity and high surface fluorination density. The FMPL's protection effect outperformed various thick stretchable polymer encapsulants, leading to a stable PSC mobility of ~1 cm^2 V^{-1} s^{-1} in harsh environments such as in 85-90 % humidity air for 56 days and water or artificial sweat for 42 days. This strategy can be potentially implemented into a wide range of devices such as sensors, organic light-emitting diodes, solar cells, and batteries, building highly integrated stretchable electronics with prolonged operation lifetime.

4:30 PM SB02.11.10

Monolithic Silicon for High Spatiotemporal In Vitro and In Vivo Optoelectronic Modulation

Pengju Li and Bozhi Tian; The University of Chicago, United States

Leadless flexible bioelectronics that mimic the body's natural bioelectrical signaling can offer innovative electrophysiology platforms and treatments for neurodegenerative and cardiac diseases.[1] Optically mediated genetic systems provide high spatiotemporal resolution and tunability, allowing for precise cellular and tissue stimulation. For clinical applications, recent non-genetic photodiode-based optoelectronic devices, which convert light into electrical currents, have shown efficiency in modulating cells and tissues at optical-power levels like those used in optogenetics.[2] Here, we reported nanoengineered monolithic silicon devices for high spatiotemporal and multiscale biological modulation in in vitro cultured rat cardiomyocytes, ex vivo rat heart tissues and in vivo ischemic rat heart models.[3] Through rational design of nanostructures, we screened various silicon-based diodes and achieved nanoporous single crystalline silicon capable of injecting highly-localized photocurrents – a property promising for random-access and multisite photostimulation, enabled by minority carrier depletion and diffusion restriction in nanopores. We demonstrate reliable multisite cardiac control using millisecond-duration light pulses in a live pig heart experiment under clinical open-thoracic conditions. Additionally, we showcase closed-thoracic pig heart stimulation with a custom endoscopic operation system, underscoring its translational potential. This procedure offers new solutions for temporary heartbeat regulation following open-heart surgeries, which are performed on over two million patients worldwide each year.
Further efforts have focused on developing low-power, wearable, and long-term solutions for deep tissue modulation, which current optoelectronic devices cannot achieve.[4] Inspired by neurons, new materials and neuromorphic designs bridge the gap between optically accessible depths and deeper tissues. This approach reduces the required irradiance for optical tissue stimulation by two to three orders of magnitude and ensures stable functioning in fully implanted, long-term applications.

Evaluating the Effects of Variability on the Mechanical Performance of Nanocellulosic Fibers *Daniel Soderberg, Damien Pierce, Mu-Rong Wang, Anastasia Riazanova, Korneliya Gordeyeva and Tomas Rosén; KTH Royal Institute of Technology, Sweden*

There have been significant research efforts on the topic of fabricating continuous fibers (filaments) from nanocellulose with impressive mechanical properties[1-3]. To use these in engineering applications such as e.g. fiber-reinforced composites, there are several additional requirements apart from the mechanical properties, such as stiffness and strength. One example is to understand and control the presence and effects of defects, the variability in internal structure and diameter, or the fiber-matrix interphase that provides the connection between the bulk fiber and bulk polymer matrix in the composite. In addition, the effects of ambient conditions such as humidity are of interest since they influence the performance of the fibers as well as fabricated composites.

To understand and quantify these effects, a significant effort has been made to carefully characterize nanocellulosic fibers spun using the micro-fluidic concept of flow-focusing[4] and evaluate the effects of, e.g., variability on mechanical performance. Several routes have been pursued to try to couple failure to variability and process conditions: laser diffraction to provide 3D tomograms representing the surface of the spun filaments, X-ray scattering for characterizing the internal variability, as well as effects of humidity and temperature during fabrication and in the use phase. The results are put in the context of conventional reinforcement fibers such as natural, glass, and carbon fibers.

Mechanisms of Fracture of Cellulose Products—From Network Structure to Strength *Md Nishan Parvez and Catalin R. Picu; Rensselaer Polytechnic Institute, United States*

Paper is a network material composed of cellulose fibers. The relationship between the structure of the fiber network and the properties of various types of paper has been studied extensively. Despite this interest, the mechanism of failure and the relation between structure, strength, and toughness are not entirely understood. In this work, we aim to establish the functional dependence of the strength and toughness of a quasi-two-dimensional network of fibers on the architecture and parameters of the fiber assembly. We investigate two failure mechanisms – controlled by bond failure and controlled by fiber failure, respectively and determine the parametric regime in which one mechanism dominates over the other. Further, we explore and observe strong effects of structural parameters such as density, fiber length, and volume fraction on the mesoscale failure mechanism exhibited as a transition from brittle to ductile failure of the material under tension. This, in turn, affects the effective strength and toughness of the material. We summarize these observations as a phase diagram that relates the structural parameters and material properties of interest. Our findings not only contribute to the fundamental understanding of failure mechanisms in fibrous network materials but also provide practical insights for the development of advanced paper products with tailored mechanical performance.

11:45 AM SB03.01.03

Flocculation in Cellulose Nanofiber Films for Biocompostable Food Packaging *Patience N. Abugu and James Elliott; University of Cambridge, United Kingdom*

Flocculation refers to the formation of dense fiber clusters, known as flocs, in suspensions of high aspect ratio materials like cellulose nanofibers (CNFs). These flocs form mainly through mechanical entanglement, causing inhomogeneities in fiber suspensions and products. In CNF suspensions, the kinked fibers create strong flocs through mechanical linkages and frictional resistance at contact points, which prevents redispersion. This significantly impacts CNF suspension properties such as yield stress, gel-point concentration, and rheological behavior. However, it is less well understood how flocculation in CNF suspensions affects thin films and membranes (nanopapers) and how this complicates property comparisons. Our research aims to investigate how flocculation influences the bulk properties of CNF films, focusing on properties which are relevant to food packaging applications: physical (thickness, porosity, transparency), mechanical (stiffness, strength, extension at break), and gas barrier (water vapor and oxygen).

Flocculation in CNF suspensions is described by the crowding number theory (CNT), where the crowding number (N) indicates fiber density in a given volume. Four concentration thresholds with unique crowding numbers are identified: dilute (N = 1), gel-point (N = 16), rigid (N = 60), and volume arrested state (N = fiber aspect ratio, A), each indicating a transition in suspension properties. CNT relates N to volume concentration (Φ) and fiber aspect ratio (A) by: $N = 2/3\Phi A^2$.

To study flocculation in CNF films, nanopapers with controlled basis weights were prepared by vacuum filtration from different initial suspension concentrations of CNFs with the same aspect ratio, corresponding to the four thresholds (N = 1, 16, 60, and A). This approach ensures that the same amount of CNFs is dispersed in decreasing suspension volumes, showing increasing flocculation. The physical, mechanical, and barrier properties of the resulting films were then compared.

We found that while film physical properties are related to dimensions and basis weight, mechanical strength, elongation, and gas barrier properties correlate with the initial fiber suspension concentration. Thus, flocculation in suspensions affects nanopaper properties. Films from mid-connectivity suspensions (N = 16 and 60) had significantly better properties than those from non-connected (N = 1) and over-connected (N = A) suspensions. This trend was consistent for uncharged CNF samples from different plant materials and produced by varying mechanical treatments. This indicates that flocculation and the crowding number theory can predict and control CNF nanopaper properties, regardless of CNF source and production method. With a known fiber aspect ratio, optimal concentrations for desired properties can be selected using the crowding number equation above. The concentration range for optimal properties is modulated only by the uncharged fiber aspect ratio.

The study also indicates that properties of CNF films made from the same concentration of fibers which have different aspect ratios cannot be directly compared. Adjustments in CNF suspension concentration, directed by fiber aspect ratio, are necessary to accurately compare film properties from different CNF samples. Understanding these differences will help researchers and industry guide property trends in CNF materials, facilitating their use as biocompostable food packaging alternatives.

SESSION SB03.02: Fundamental Understandings II

Insights into Wood Nanoscale Structure from Neutron Scattering Techniques *Hugh M. O'Neill; Oak Ridge National Laboratory, United States*

The plant cell wall is an intricate hierarchical structure that is primarily composed of the biopolymers, cellulose, lignin and hemicellulose. Understanding how the plant cell wall is assembled and also the changes that occur when it is deconstructed, either by chemical or biochemical approaches, to produce fuels, chemicals and materials is of critical importance for the development of a sustainable bioenergy economy. Although there has been significant progress towards these goals, the molecular level interactions between the component biomass polymers remains poorly understood. Neutron scattering has emerged as a versatile tool to investigate the structure and dynamics of biomass and related model materials to obtain information that is unattainable by other means. In this presentation we will discuss some recent examples from the Biological Small-Angle Neutron Scattering instrument (Bio-SANS) at Oak Ridge National Laboratory that focus characterization of the properties different biomass systems with altered cell wall properties. One example that will be discussed is the investigation of transgenic poplar trees with biosynthetically altered lignin properties which resulted in an altered plant cell wall structure that is less recalcitrant than wild-type trees. In this case, significant changes were observed in cellulose microfibril organization that could be correlated with decreased lignin content in these trees. Another example is the mechanism of action of microbial expansin-related proteins on the organization and morphology of structural biopolymers in lignocellulosic materials. This work examined how different expansin-like proteins changed cellulose-microfibrils correlations in holocellulose substrates. The final example will describe how neutron scattering can be used to characterize advanced biomaterials such as transparent wood revealing the intimate associations between wood and polymer that confer its unique properties. These examples will demonstrate how neutron scattering with can enhance our knowledge of the plant cell wall structure and the underlying processes that occur that change biomass morphology for biofuels or bioproduct production.

2:00 PM SB03.02.02
Adhesion Between Nanocellulose and Pectin Predicted Using Molecular Dynamic Simulation *Xiawa Wu; The Pennsylvania State University Behrend, United States*

The existence of interaction between nanocellulose and pectin is under debate and the current experimental measurements show conflicting findings. This work proposes to use a computational tool, molecular dynamics simulation, to study the nanoscale adhesion between nanocellulose and homogalacturonan pectin. Two cellulose nanocrystals are modeled in direct contact, and a pectin molecule is embedded at the interface. The resulting *adhesion is compared between systems with and without pectin molecules to analyze the effect of pectin. In addition, the charge density of pectin, the hydrophilicity of nanocellulose, and the water and ion solution are studied for their influence on the interfacial adhesion between nanocellulose. The model-predicted results reveal the atomistic level interaction between nanocellulose and pectin, which shines light on experimentally conflicting observations and provides essential information for understanding the structure of primary plant cell walls.*

2:15 PM SB03.02.03

Distinct Roles of Different Nanocellulose Superstructures in Determining Performance of Urea-Formaldehyde Based Adhesives *Ebru Sarioglu[1] and Erkan Senses[1,2]; [1]Koç University, Turkey; [2]Koc University, Turkey*

The inherent ability of cellulose chains to self-assemble at the nanoscale through hydrogen bonding creates hierarchical structures, forming cellulose nanocrystals (CNCs), cellulose nanofibrils (CNFs), and cellulose microfibrils (MFCs). These self-assembled structures have been widely incorporated into petroleum-derived adhesive formulations to mitigate their environmental and health impacts. However, the effects on adhesion strength are often contradictory due to a lack of fundamental understanding of the microstructure-rheology relations. In this study, we investigated the dispersion, stability, phase behavior, rheology, and curing behavior of urea-formaldehyde (UF) adhesives modified with wood-derived cellulose nanoparticles, including CNCs, CNFs, and MFCs. Our results show that CNC- and CNF-containing suspensions were homogeneously distributed in the UF solution, whereas MFCs agglomerated due to a higher degree of entanglements. Rheological measurements revealed that all nanocellulose forms increased the viscosity and moduli of the UF solution, albeit with significant differences in magnitude. Highly viscous composite adhesives with MFCs were unsuitable for spraying and hindered homogeneous spreading and wetting on wood surfaces. In contrast, CNFs caused negligible improvement in rheological properties due to their inherent flexibility and tendency to form isolated bundles. Remarkably, the addition of CNCs to UF resin allowed for precise tuning of the flow properties of the composites with filler content, affecting the properties over several orders of magnitude at concentrations as low as a few percent. Composites with low CNC concentrations (1, 2, and 3 wt%) were homogeneously dispersed in the UF solution, forming a network between negatively charged CNCs and the UF matrix. However, adhesives with higher CNC concentrations (4 and 5 wt%) disrupt the long-range particle network and caused clustering in the UF-CNC mixture and promote gel formation- an undesirable form for practical applications. These physicochemical characteristics reflect well in the adhesion behavior as characterized by lap-shear and tact-tests.

2:30 PM SB03.02.04

Enhancement of Piezoelectricity and Mechanical Properties in Cellulose-Based Elastomers Via Slide-Ring Polyrotaxane Crosslinkers Moonseok Jang, Bitgaram Kim and Jihun Seo; Korea University, Korea (the Republic of)

Cellulose, a bio-based material with high crystallinity, has great potential in the field of piezoelectricity. However, its low processability and poor mechanical robustness limit its use as an additive such as nanoparticles and nanofibers. In this study, a mechanically robust, cellulose-based piezoelectric elastomer with enhanced piezoelectric performance was developed by crosslinking cellulose with polyrotaxane (PR). The effects of cross-linking on the mechanical properties and crystalline structures of the resulting elastomers were investigated. By incorporating slidable polyrotaxane into the cellulose network (eHPC$_{25}$PR$_{75}$, 20.4 MJ m^{-3}), the mechanical toughness increased by up to 2.7 times compared to the pure cellulose network (eHPC$_{100}$, 7.57 MJ m^{-3}). In addition, the ferroelectric and piezoelectric properties were evaluated from their polarization hysteresis loops and voltage generation characteristics, with eHPC$_{25}$PR$_{75}$ showing a power density 4.2 times higher (1.34 μW cm^{-2}) than *eHPC100 (0.321 μW cm^{-2}). The crystallinity and crystalline structure of the fabricated elastomers were analyzed using X-ray Diffraction (XRD), Small Angle X-ray Scattering (SAXS), and Transmission Electron Microscopy (TEM), and their correlation with piezoelectric performance was investigated. Finally, eHPC$_{25}$PR$_{75}$ exhibited notable sensitivity to bending and vibrational motions, indicating its potential for use in mechanically robust, flexible piezosensitive devices.*

2:45 PM SB03.02.05

Compatibilizing Degradable Polymer Blends for Recycling Applications Using Nanocellulose *Damien Crowley[1], Brianna Zheng[2], Yiwei Fang[3], Miriam Rafailovich[3], Allen Bethancourt[3] and Katherine Martinez[4]; [1]Wantagh High School, United States; [2]BASIS Independent Silicon Valley, United States; [3]Stony Brook University, The State University of New York, United States; [4]Suffolk Community College, United States*

Mixed sorting of plastics at recycling facilities limits the capacity for recycling, because many synthetic organic compounds are incompatible with others at the molecular level, resulting in high interfacial tensions and immiscible blends. Consequently, less than 9% of United States plastic is recycled annually.[1] While research has displayed blend enhancement by organoclays, phyllosilicates functionalized with organic molecules, and silica-coated cellulose nanofibers (sCNF) and microfibers (sCMF), phase separation in nanocomposites still poses extensive limitations for recycling competence.[2] Thus, this study aims to understand the mechanical and interfacial impact of adding organoclay, clay combined with resorcinol bis(diphenyl phosphate) (RDP), which is a flame retardant, sCMF, and sCNF to commonly recycled nanocomposite blends, exploring potential solutions to polymer incompatibility. We hypothesized that organoclay application would decrease interfacial tension while sCNF and sCMF treatment would enhance mechanical strength and flame retardance.

50-gram blends of 35 g polylactic acid (PLA) and 15 g polystyrene (PS) were composited with various copolymers (e.g., C-20A, C-30B, acryl-sCMF, sCMF, RDP-clay) at various concentrations (1%, 3%, 5%) in a Brabender at 180°C for 10 minutes and molded into necessary formats for experimentation (rectangular prisms, dogbones, notched for impact strength testing). Differential scanning calorimetry was initially conducted on the control, C-20A, and C-30B samples, revealing slight convergence in polymer glass transition (T_g) temperature: C-20A induced a -0.41°C alteration in Tg difference between PLA and PS compared to the control while the C-30B displayed a -1.13°C change, two statistically-insignificant modifications. Dynamic mechanical analysis revealed that C-30B also boosted amalgam elasticity. Transmission electron microscope (TEM) imaging qualified these results, however, because C-20A was found at the PLA-PS interfaces more than C-30B, which was commonly in the PLA domain. Sample impact strength findings demonstrated that clay increased composite brittleness, while sCMF and sCNF affected impact strength insignificantly within error. Tensile testing imitated these conclusions: Incorporating 3% acryl-sCNF in the PLA:PS resulted in ultimate tensile strength of 37.16 MPa and Young's modulus of 1.37 MPa compared to 37.96 MPa and 1.33 MPa for the control sample. Similarly, including 3% acryl-sCMF in PLA:PS blends insignificantly altered tensile results.

Similar compounding of 35 g PLA and 15 g polycaprolactone (PCL) occurred next, and impact strength testing revealed the PCL sample's superiority in this category. The inclusion of cellulose nanotubes (sCNF) in PLA:PCL blends consistently increased blend impact strength. However, we found that the incorporation of 5% sCNF into the PLA:PCL blends improved impact strength most significantly (+95.5 ± 15.13 (J/m)). Tensile testing also displayed PCL's augmentation of PLA ductility

In order to understand the improved performance of 5% sCNF PLA:PCL blends, further studies are planned of the interfacial structures between the different nanocomposites, using TEM on thin cryo-microtome sections, as well as contact angle measurements to correlate the results to the force of adhesion and its modification using the different nanoparticles. Finally, the impact of flame retardance on the blends will be measured using the UL-94 testing protocols.

We would like to thank the Louis Morin Charitable Trust for supporting this research. We also gratefully *acknowlege Professor Young-Soo Seo and Sejong University, South Korea, for providing the CelluloSys utilized during this study.*

***Equilibrium Water-Mediated Isolation of Lignocellulosic Nanofibrils via Esterification Reaction** Feng Jiang; The University of British Columbia, Canada*

Lignocellulosic nanofibrils (LCNFs) isolation is recognized as an efficient strategy for maximizing biomass utilization. Nevertheless, achieving a 100% yield presents a formidable challenge. Here, an esterification strategy mediated by the equilibrium moisture in biomass is proposed for LCNFs preparation without the use of catalysts, resulting in a yield exceeding 100%. Different from anhydrous chemical thermomechanical pulp ($CTMP_{0\%}$), the presence of moisture (moisture content of 7 wt%, denoted as $CTMP_{7\%}$) introduces a notably distinct process for the pretreatment of CTMP, comprising the initial disintegration and the post-esterification steps. The maleic acid, generated through maleic anhydride (MA) hydrolysis, degrades the recalcitrant lignin-carbohydrate complex (LCC) structures, resulting in esterified $CTMP_{7\%}$ ($E\text{-}CTMP_{7\%}$). The highly grafted esters compensate for the mass loss resulting from the partial removal of hydrolyzed lignin and hemicellulose, ensuring a high yield. Following microfluidization, favorable $LCNF_{7\%}$ with a high yield (114.4 ± 3.0%) and a high charge content (1.74 ± 0.09 mmol/g) can be easily produced, surpassing most previous records for LCNFs. Additionally, $LCNF_{7\%}$ presented highly processability for filaments, films, and 3D honeycomb structures preparation. These findings provide valuable insights and guidance for achieving a high yield in the isolation of LCNFs from biomass through the mediation of equilibrium moisture.

4:00 PM *SB03.03.02
***Engineering Nanocellulose 3D Printed Materials—From Controlled Anisotropic Structures to a Platform for Living Materials** Gilberto Siqueira[1,2], André R. Studart[2] and Gustav Nyström[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland*

Shaping polymer-based nanocellulose materials into complex architectures is challenging but desirable in many applications. One of the main challenges is the design of inks that combine viscoelastic responses and high dispersion degree of the anisotropic nanocellulose particles in varied solvents or monomers.
In our group, we investigate the development of polymer-based inks containing cellulose nanocrystals (CNCs) and/or nanofibers (CNFs) which act as both reinforcing elements and as organic biodegradable rheological

modifiers in the systems. In this direction, we demonstrate how to create stiff, soft or porous 3D printed cellular-structures, as hydrogels and aerogels, and how to fine-tune their mechanical properties taking advantage of the shear-induced orientation resulting from the anisotropic components in the inks. In another research front, we explore the encapsulation of microorganisms, such as microalgae, within multifunctional hydrogels that supports the growth and proliferation of those cells by designing a set of inks and printing platforms that allow shaping them in complex functional 3D structures.
The simplicity and universality of our approaches makes them highly attractive for applications that require tailored mechanical properties or cell-protected environment for the production of functional materials or devices for sensing, structural and thermal purposes.

4:30 PM SB03.03.03
3D-Printed Nanocellulose-Based Aerogel for Thermal Managment in Portable Electronics *Chenming Liu[1], Ossi Laitinen[1], Janne Lauri[1], Ari Seppälä[2] and Henrikki Liimatainen[1]; [1]University of Oulu, Finland; [2]Aalto University, Finland*

Nanocellulose aerogels are emerging as a fascinating material that features sustainability, light weight, and low thermal conductivity, promising widespread prospects in the realm of heat insulation, electric magnetic interference, and biomedical. However, the construction of the mechanical robust aerogels with rational designed architectures aiming for the application in portable electronics remains a major challenge. Here, 3D constructed nanocellulose-based aerogels reinforced by aramid fibers possessing programmed geometries and engineered mechanical properties are created via additive manufacturing. More importantly, the customized lightweight aerogels show a low thermal conductivity (0.032 $W\,m^{-1}\,K^{-1}$), enabling precise heat insulation for portable electronics. In addition, they display outstanding adjustable insulation performance in harsh environment (-50 °C-100 °C). The present work represents a promising direction for flexible thermal management devices and other potential applications through the design and rapid fabrication of cellulose aerogels.

SESSION SB03.04: Cellulose Based Functional Materials

Microencapsulation of Phase Change Material by Assembly of Polysaccharide Colloidal Particles at Oil-Water Interface *Shuaib Mubarak, Gulbahar Bahsi Kaya and Yunsang Kim; Mississippi State University, United States*

The assembly of lignocellulosic particles and fibrils into macroscopic load-bearing elements in biomass is ubiquitous in nature. Given the inherent amphiphilicity of many polysaccharide particles and their ability to form aqueous colloidal dispersions, the assembly of plant-derived colloidal particles at the oil-water interface can lead to the construction of hierarchical superstructures for advanced nanostructured materials. In this work, cellulose nanofibrils (CNF)-based Pickering oil-in-water (O/W) emulsions are used to encapsulate a paraffin-based phase change material (PCM). The CNF-based microcapsules containing PCM are further modified with chitin nanofibers (ChNF) through electrostatic interaction. Characterization of the CNF-ChNF based emulsions is conducted to determine their size and distribution, PCM loading, shell tightness, and stability over environmental changes *including temperature, pH, and ionic strength. It is shown that the addition of ChNF increases the shell tightness of the CNF-PCM O/W emulsions, resulting in improved overall stability without a significant change in the emulsion size. The influence of ChNF addition on the thermal energy performance of CNF-PCM O/W emulsions is also presented, along with a discussion of potential applications of hierarchical structures fabricated from the assembly of plant-derived colloidal particles.*

9:15 AM *SB03.04.02

Nanocellulose Thin Films—A Versatile Material for Optical, Conductive and Electromechanical Properties

Ana Villares[1], Celine Moreau[1], Olivier Chauvet[2], Benoit Guiffard[3] and Bernard Cathala[1]; [1]Institut national de la recherche agronomique, France; [2]Université de Nantes, CNRS, IMN, UMR 6502, France; [3]Université de Nantes, France

Cellulose is an abundant, renewable and non-toxic polymer used in countless materials. Due to its multi-scale hierarchical structure, it can be used in a variety of ways, notably in the form of nanocrystals (CNC) or nanofibers (NFC). Depending on their botanical origin, production method or chemical modification, these nanoparticles can present a wide range of structural variability offering a large panel of structure for material fabrication. These nanoparticles exhibit good colloidal stability and acicular morphology, completed by self-assembly properties or interaction capacities with different polymers or other nanoparticles. All together, these features can be used to build thin films with a wide variety of structures, from which advanced properties can emerge. In this presentation, elaboration of nanocellulose-based thin film displaying optical properties, electrical conductivity and piezoelectric and flexoelectric effects will be presented.
-The first type of thin film was produced by a layer-by-layer method combining adsorption and spincoating and by alternative deposition of cellulose nanocrystals and xyloglucan, leading to the formation of very low-roughness thin films generating structural colors caused by an interferential process. Entirely made up of biopolymers, these films are sensitive to enzymatic hydrolysis, which leads to a change in color allowing easy and fast enzymatic activity detection. These materials have been used to create miniaturized, ultra-sensitive and versatile enzymatic activity detection devices. 1-4
-The second type of thin film presented consists of CNCs associated with single wall and multiwall carbon nanotubes (SWCNT and MWCNT). We have demonstrated that cellulose nanocrystals can disperse carbon nanotubes in water under the action of ultrasound, forming CNC-CNT complexes. The mechanisms of nanotube dispersion were investigated by a parametric and structural study demonstrating a difference in mechanism between SWCNT and MWT. The complexes were then incorporated into multilayer by films, which showed good electrical conductivity. 5-7
- The last category of films studied were made from chemically modified NFCs and cellulose fibers. We evaluated the flexoelectric μ31 and transverse effective piezoelectric e31,f coefficients of cellulose films allowing to separate the flexoelectric from the piezoelectric contribution. TEMPO-oxidized cellulose films exhibited the highest flexoelectric coefficients (almost 7 times higher than those of synthetic polymer dielectrics), demonstrating that the presence of polar groups and surface charges stimulated both flexoelectricity and piezoelectricity in electrically unpolarized cellulose films. 8

Exploring Carbon Nanocellulose as a Novel Alignment Layer in Liquid Crystal Display Technology *Ye Zhang[1], Jay Doherty[2], Aaron D. Franklin[2] and Ioannis Kymissis[1]; [1]Columbia University, United States; [2]Duke University, United States*

This study introduces a novel Liquid Crystal Display (LCD) structure employing carbon nanocellulose as the alignment layer in a twisted nematic configuration, replacing traditional materials such as polyimide. Derived from wood-based fibers, carbon nanocellulose is a sustainable and eco-friendly material noted for its high tensile strength, good transparency, and low birefringence, making it a good candidate for aligning liquid crystals. The LCD cell was fabricated using carbon nanocellulose as the alignment layer through spin coating followed by mechanical rubbing. Following characterization and evaluation demonstrated its functionality, including uniform alignment of liquid crystals and stability under various operating conditions. The results underscore the potential of carbon nanocellulose as a functional alignment layer in LCDs, offer a recyclable and non-toxic alternative to traditional materials, and pave the way for new opportunities in the circular economy of liquid crystal display technology.

10:30 AM *SB03.05.01

From Forrest to Electronic and Biomedical Applications *Elvira Fortunato, Tomás Pinheiro, Sara Silvestre and Rodrigo F. Martins; NOVA School of Science and Technology, Portugal*

According to the United Nations University's Global e-waste monitor, a record of 62 Mt of electronic waste was generated worldwide in 2022, which represents a record in human history, up 21% in only five years. The report also predicts that global e-waste will reach 82 Mt by 2030. This makes e-waste the world's fastest-growing domestic waste stream, powered mainly by higher consumption rates of electric and electronic equipment, short lifecycles, and few options for repair. Sometimes it is mentioned that "e-waste is a toxic waste stream where valuable finite resources are lost".
The global consumption of electronics is forecast to double by 2050. In this context, printed electronics and 3D printing are an interesting alternative to conventional manufacturing methods and materials, reducing the weight of electronic components and offering more energy-efficient and sustainable solutions.
Therefore, electronics, including flexible printed circuits are facing a critical challenge: How to balance, decreasing supplies with growing volumes of e-waste? In part: by using new sustainable approaches, either in terms of materials and technological processes!
Here we propose the use of a new manufacturing technology supporting flexible and organic/inorganics electronics by exploring single laser processes for direct generation of conductive structures on biodegradable substrates. By means of different kind of laser sources, conductive carbon nanostructures can be generated on

carbon-based precursor materials and substrates via a thermo-photo pyrolysis: the so-called Laser Induced Graphene (LIG). One of the main advantages of the LIG process is that the precursor materials and the substrates themselves can be bioderived and biodegradable, thus allowing new opportunities for sustainable electronics, avoiding the need to use scarce and difficult-to-recycle metal materials and be reused, in addition to costly and time-consuming processes.
In this presentation we will demonstrate the use of the LIG process to a set of devices ranging from electronic to biomedical applications.

11:00 AM SB03.05.02
Biomass-Derived Electrode and Electrolyte for Green Supercapacitors *Ridwan T. Ayinla; Mississippi State University, United States*

Supercapacitors, known for their high-power density and rapid charge-discharge capabilities hold immense promise for addressing the growing demand for sustainable energy storage solutions. This research presents a sustainable approach to the development of green supercapacitors by utilizing biomass-derived materials for both electrodes and electrolytes. The sustainable nature of these materials aligns with the global drive towards green energy technologies and the circular economy. Herein, we developed green supercapacitors by utilizing biomass-derived materials for both electrodes and electrolytes. Activated carbon prepared from pine bark using acid (H_3PO_4), base (K_2CO_3), and salt ($ZnCl_2$) as activation agents at different activation temperatures (600, 800, and 1000 C) were used as the active material of the electrodes. Cellulose nanofiber was also derived from wood pulp and crosslinked with mobile Cu2+ ions as the electrolyte. The surface area and porosity of the prepared activated carbon showed an increasing trend with increasing activation temperature for all activation agents. Real supercapacitors were fabricated with excellent energy and power densities. This research underscores the importance of sustainable and environmentally friendly alternatives in the transition towards a greener and cleaner energy future.

11:15 AM SB03.05.03
High-Speed Fabrication of Intrinsically Flexible Perovskite Optoelectronics on Diverse Substrates (Cellulose Paper, Textiles, etc.) Using Printing and Handwriting *Junyi Zhao and Chuan Wang; Washington University in St. Louis, United States*

Flexible optoelectronic devices on deformable substrates hold significant promise for applications in wearable electronics, soft robotics, deformable displays, and more. Despite extensive research into halide perovskites for high-performance light-emitting diodes (LEDs), existing fabrication techniques that use rigid substrates fail to meet the growing demand for flexible display electronics. This study introduces two all-solution-processed fabrication strategies for high-throughput production of intrinsically stretchable perovskite LEDs (PeLEDs), printing and handwriting. We firstly developed a highly scalable multi-material inkjet printing approach, each device layer, from the bottom anode to the top cathode, is directly patterned on elastomer such as PDMS.

Beyond elastomers, common materials such as cellulose paper and textiles show potential as platforms for next-generation flexible and wearable electronics. We introduce a novel fabrication methodology termed "handwriting," which is versatile, scalable, and sustainable. This method enables the direct drawing of multicolor PeLEDs (covering the entire visible spectrum) and perovskite photodetectors (PePDs, in both vertical-photodiode and planar-photoconductor configurations) on various unconventional substrates (including cellulose paper, textiles, plastic, rubber, metal, and 3D objects) in an ultra-fast and mask-free manner. This innovation leverages everyday ballpoint pens filled with specially formulated inks containing conductive polymer blends, metal nanowires, and perovskite/polymer composites for light emission and absorption.

To address the challenge of rough surface morphology on cellulose fiber networks, particularly to achieve uniform printed film thickness and minimal leakage current, we incorporated an ionic polymer, poly(ethylene oxide), into the inks. The rheology and viscosity of these formulated inks were meticulously adjusted to replicate an authentic writing experience. Furthermore, the handwriting method sets a new benchmark for the rapid production of high-performance perovskite optoelectronic devices, enabling the fabrication of a batch of samples within just 10 minutes—significantly faster compared to the hours or days required by conventional microfabrication processes. Notably, the entire process is conducted under ambient conditions without the need for specific moisture and temperature control. The PeLEDs produced via the handwriting method exhibit a brightness of up to 15,225 cd/m^2, a current efficiency of 6.65 cd/A, and a turn-on voltage of 2.4 V. The PePDs demonstrate an on/off ratio exceeding 10^4 and a response time of less than 15 ms. Benefiting from the exceptional flexibility of each functional layer, the LEDs written on cellulose paper substrates can be bent to an extreme curvature radius of 1 mm for over 5000 cycles without any performance degradation. In summary, this work lays the foundation for the practical application of perovskite optoelectronics in cost-effective and large-area scenarios, such as E-textiles, E-paper, smart packaging, disposable electronics, and wearables.

Stabilizing Nickel-Rich Cathodes in Aqueous Process via Nanochannel Water Confinement *Hongli Zhu and Ying Wang; Northeastern University, United States*

Based on the two manuscripts provided, here is a possible abstract that summarizes the key findings:

Nickel-rich LiNi0.8Co0.1Mn0.1O2 (NMC 811) cathodes offer high voltage and capacity for high energy density lithium-ion batteries, but their manufacturing via aqueous electrode processing remains challenging due to material decomposition caused by the proton exchange reaction with water. This work addresses this issue by developing a protective nanocellulose coating on NMC 811 particles through electrostatic interactions. Wide-angle X-ray scattering measurements and atomistic simulations demonstrate that the nanochannels between nanocellulose chains can effectively confine interlayer water, preventing it from reaching the NMC surface. Density functional theory calculations predict that the functional groups of the nanocellulose exhibit stronger binding to the NMC surface than water molecules, suppressing Li+ surface segregation. As a result, nanocellulose-protected NMC electrodes prepared via aqueous processing exhibit higher capacity (133 vs. 59 mAh/g at 6C) and initial coulombic efficiency (83% vs. 62% at 0.1C) compared to unprotected electrodes. The optimized water-processed NMC electrodes also demonstrate superior rate capability and cycling stability compared to conventional NMP-based electrodes. This sustainable aqueous electrode manufacturing approach utilizing an in-situ formed nanocellulose barrier enables the realization of high-performance nickel-rich cathodes for next-generation lithium-ion batteries.

SESSION SB03.06: Lignin Based Materials and Applications

High-Consistency Lignin Nanoparticles for High-Performance Phenol-and Formaldehyde-Free Adhesives

Ievgen Pylypchuk, Federica Ferruti and Mika H. Sipponen; Stockholm University, Sweden

The quest for sustainable materials has steered significant interest towards lignin, a major component of wood and a byproduct of the pulp and paper industry, as a potential resource for developing eco-friendly adhesives. This study focuses on the nanoengineering of lignin to create high-performance, phenol- and formaldehyde-free adhesives, addressing fundamental challenges in the handling, and processing of lignin for industrial applications.

We have developed a novel method to synthesize high-consistency lignin nanoparticles in a water-based system, enhancing their adhesive properties without the need for chemical modifications. The resultant lignin-based adhesives exhibit superior mechanical strength, thermal stability, and water resistance, positioning them as viable alternatives to traditional petroleum-based adhesives. Additionally, this system allows for high lignin loading and good penetration into the wood, making it suitable for producing plywood prototypes.

We analyze the mechanical properties of lignin-based adhesives and also study how they interact with wood substrates to understand their performance. We have successfully produced this scalable solution at a scale of 5 kg.

The development of lignin-based adhesives not only helps reduce the carbon footprint but also promotes the efficient use of lignin, supporting the principles of a circular bioeconomy. Our approach integrates green and energy-efficient processing methods to ensure the sustainability and scalability of lignin-based adhesive production.

This research is part of the TREECURE project, aiming to develop 100% bio-based adhesives free from formaldehyde and phenol, promoting environmental sustainability and safe built environments. TREECURE project has received funding from the Knut och Alice Wallenbergs Stiftelse under the Wallenberg Launch Pad (WALP) Proof-of-Concept initiative.

2:45 PM SB03.06.02

Lignin-Derived Hydrogels for Green and Sustainable Agriculture *Nataliia Fihurka and Tetyana Budnyak; Uppsala University, Sweden*

The world agricultural sector is looking for new technologies to enhance crop yields as more than 800 million people lack food. There are several factors affecting the productivity in agriculture, irrigation and utilization of fertilizers are among the most important. In the 1970s scientists confirmed that super-adsorbent hydrogels reduce the sensitivity of plants to water shortage, and promote their growth, particularly under water deficiency conditions. Further investigations showed that these hydrogels are able to slow release of fertilizers. Up-to-date, synthetic super-adsorbent polymers are widely used for agriculture applications. Although effective for water remediation and fertilizer delivery, these materials are synthesized from non-renewable resources. The resulting hydrogels are non-biodegradable, and thus sustainable alternatives need to be developed. Biomass-derived hydrogels based on naturally occurring polymers are more sustainable and cost-effective compared to the abovementioned options

Large quantities of lignin, as a by-product, are yearly available from numerous pulping processes such as paper and biorefinery industries. Instead of being burned, lignin could be used for various environmental and biomedical applications as lignin macromolecules contain available sites for chemical modification.
This work presents an easy and effective synthetic approach to semisynthetic hydrogels with a lignin content of up to 70wt%. Spectroscopic and thermal analyses were used to confirm the hydrogel structure. An investigation of performance characteristics, i.e., swelling capacity, water retention in the soil, and biodegradability, confirmed that developed hydrogel materials possess properties comparable with industrial polymers. Moreover, obtained hydrogels are able to the prolonged release of urea making them promising candidates for producing the fertilizers formulations.
Thus, novel lignin-based hydrogels possessing super adsorbent properties could be a sustainable and environmentally-friendly alternative to industrial agriculture hydrogels based on synthetic crosslinked polymers.

3:00 PM BREAK

3:30 PM *SB03.06.03
Towards Printed Zinc-Lignin Batteries *Reverant Crispin; Linköping University, Sweden*

Printed electronics involves using printing technologies as a mass production tool to integrate electronic circuits, sensors, and wireless communication on a flexible label, making any kind of object interactively connected to the internet. This is the "Internet of Everything," which is expected to connect billions of electronic labels to the internet. Powering these devices with conventional batteries presents a sustainability challenge in terms of material recycling and expensive maintenance. Today, bulky batteries are increasingly being replaced by low-power energy harvesters (e.g., thermoelectrics, solar cells, piezoelectrics) that charge thin batteries without the need for maintenance. The technical specifications for these types of thin batteries include high cyclability, high power, green materials, low cost, and compatibility with printed technologies, rather than the high energy density required in other sectors such as mobile phones.

The greenest materials come from biomass. Lignin is of particular interest because it is an aromatic biopolymer that carries catechol groups capable of storing charges through electrochemical reactions. First, we explore the design of lignin electrodes by compositing with carbon or conducting polymers [1,2]. Second, a new class of electrolyte operating in the "water in polymer salt electrolyte" regime is considered to enable aqueous organic batteries with low self-discharge behavior [3-6]. Finally, we integrate these materials into a robust and promising zinc-lignin battery [7].

Lignin-Based Materials for Potassium Batteries Anodes and Electrolytes *Sabrina Trano, Carlotta Francia, Silvia Bodoardo and Federico Bella; Politecnico di Torino, Italy*

In the framework of of SuN2rise ERC project, different materials applicable as electrodes and electrolytes for current energy technologies have been developed, starting from electrochemical nitrogen reduction.
Rechargeable batteries are a key technology in the world rush toward the energy transition. Li-ion batteries (LIBs) have reached unprecedent targets of performance and safety, nevertheless it is not logical thinking that the LIB technology alone is able to provide for the whole world electrification, given lithium scarcity (0.0017 wt% in the Earth crust) and its uneven distribution. In this scenario, it is not surprising the increasing attention coming from the research community on potassium-based batteries.
Our groups have carried out the preparation of two main components of this battery (i.e., anode and electrolyte) starting from a widely abundant and sustainable biosourced precursor: lignin.
On one side, we have worked on the design, synthesis and characterization of a lignin-based membrane by crosslinking lignin matrices matrix with pegylated crosslinkers [1], obtaining gel polymer electrolyte with different properties in terms of specific capacity, long-term stability, and self-rapairability.
In parallel, carbonaceous anodes were prepared by pyrolityic processes starting from Kraft lignin. Different materials with turbostratic disordered structures and very low graphitization degree (i.e., ideal for K-ion insertion) were obtained.
The resulting lignin-based potassium prototype cell is the answer to the quest of an exponentially increasing electrification and large stationary storage demand, but it also fulfills the responsibility for sustainable and low-cost industrial production. Among the most intriguing applications, the integration of these batteries with ammonia power plants and electrochemical reactors would lead to a sustainable and green-powered chemical industry.

Lignin Valorization—Fungal Laccase Modification of Industrial Lignin with Antimicrobial Activity *Lan Heung Wong and Haozhong J. Xin; The Hong Kong Polytechnic University, Hong Kong*

Lignin is the second most abundantly available natural source after cellulose and the annual industrial lignin production has exceeded 70 million tons. Although lignin exhibits enormous potential as a sustainable feedstock, there is less than 5% native lignin being valorized to advanced products like industrial materials and fine chemicals. The recalcitrant lignin structure with complicated network exhibits significant resistance to chemical and biological degradation. In recent years, biocatalysis is proposed to depolymerize lignin with mild operating conditions, high selectivity of enzymatic catalysts and broad range substrate production. Laccase is a multi-copper containing oxidoreductase enzyme widespread in plants and fungi, which perform the redox reaction of the copper ions and catalyze the oxidation of various substrates by reducing oxygen to water. Although this versatile biocatalysis has been introduced for lignin conversion, potential challenges in biological lignin valorization still *exist because of insufficient information on the laccase-catalyzed products.*

This study aimed to provide a novel insight on developing lignin-derived antimicrobials under bioconversion. Fungal laccase treatment is an ecological and bio-based approach for producing value-added products, which is proposed for lignin conversion. The research project started with the laccase-mediated oxidation on kraft lignin, followed by fractionation to separate the small molecular fractions from bulk lignin chain. A series of analytical tools were applied to identify and quantify the degraded products after enzymatic treatment. UV-visible spectroscopy was first applied to evaluate the degradation through laccase-catalyzed treatment. UV analysis confirmed the loss of the original peak from kraft lignin, indicating the breakdown of aromatic content of lignin to small components. The molecular weight distribution of the sample was then screened by gel permeation chromatography (GPC) and the chemical composition of the sample was identified nuclear magnetic resonance (NMR) with the assist of fourier transform infrared (FTIR) spectroscopy. Further GPC, NMR and FTIR results revealed that laccase could catalyze lignin with possible changes in the chemical composition. Liquid chromatography (LC) offered non-volatile analysis on separating and identifying the isolated lignin derivatives after enzymatic modification. Products included acetovanillone, vanillic acid, isovanillin and vanillin could be detected from the lignin fraction. The antimicrobial performance of the isolated lignin derivatives was examined by the antimicrobial susceptibility test (AST) using agar dilution method. The minimum inhibition concentration (MIC) of lignin derivatives against gram-positive bacteria Staphylococcus aureus (S. aureus) and gram-negative bacteria Escherichia coli (E. coli) were observed at 1mg/ml and 3mg/ml respectively, which exhibited great antibacterial performance compared with the untreated lignin. In summary, enzymatic lignin degradation not only offered an environmentally friendly approach without environmental pollutants and hazardous waste, but also facilitated effective method to upcycle recalcitrant lignin content and developed advanced functional chemicals under mild reaction condition.

Innovative Three-layer Particleboards—Non-Toxic Bio-Adhesives and Nanoparticle Reinforcement for Sustainable Building Materials *Derrick Mirindi; Morgan State University, United States*

Three-layer particleboards are essential components in the building industry, used in furniture, cabinetry, and flooring. However, stakeholder demand and prices for wood-based materials are increasing rapidly, while climate change is affecting our planet. This review takes a critical look at the progress made in making new three-layer particleboards that are safer for your health than traditional formaldehyde-based glues and better at their mechanical and physical functions. The study focuses on particleboards fabricated using non-toxic, bio-based adhesives derived from renewable sources such as soy protein, lignin, tannin, and starch. These eco-friendly alternatives to urea-formaldehyde resins not only mitigate health concerns but also promote sustainability in the building industry. Furthermore, researchers are exploring the incorporation of nanoparticles such as cellulose nanofibers, nanoclay, and graphene oxide as reinforcing agents to enhance the particleboards' strength, stiffness, and dimensional stability. International standards such as ANSI A208.1, EN 312, JIS, and ABNT NBR 14810 *evaluate the performance of these innovative three-layer particleboards, classifying them into different grades based on their physical (water absoption and thickness swelling) and mechanical properties (modulus of rupture and modulus of elasticity) and end-use applications. The findings demonstrate that particleboards fabricated with non-toxic bio-adhesives and nanoparticle reinforcement exhibit superior properties compared to conventional formaldehyde-bonded boards, making them suitable for various applications ranging from lightweight interior furniture to high-density structural panels. This review highlights the potential of these sustainable and high-performance particleboards to revolutionize the building industry while addressing environmental and health concerns, ultimately contributing to the development of safer and more eco-friendly building materials.*

Integrated Nanofibrillation and In Situ Polymerization of Biomass-Deep Eutectic Solvent System—A One-Pot Approach *Udyani A. Weerasinghe[1,2], Tingting Wu[1] and Dan Kai[2,1,1]; [1]Agency for Science, Technology and Research, Singapore; [2]Nanyang Technological University, Singapore*

The employment of natural polymers such as cellulose in the synthesis of advanced materials, utilizing environmentally conscious approaches, represents a promising trajectory towards a sustainable future. Deep Eutectic Solvents (DESs) act as an emerging green solvent system with numerous capabilities in biomass pretreatment and polymer synthesis owing to its vast tunability in the selection of hydrogen bond donor and acceptor systems. In this study, a ternary DES system (choline chloride, citric acid, and acrylic acid) is utilized to facilitate the acidic condition for biomass nanofibrillation with subsequent polymerization using the acrylic monomers in one-pot approach. This process eliminates the extra steps and waste produced during commercial cellulose nanofiber generation and enables the assembly of nanofibers to generate eutectogel material. The selected novel polymerizable DES system produces cellulose nanofibers with diameters in the range of 1-30 nm while preserving its crystalline structure. Stable dispersions of the biomass-containing system were evident with the esterification of the cellulose hydroxyl groups after the DES treatment. The addition of biomass allows the composite to exhibit a yield point and achieve shear-thinning behavior, which is necessary for direct ink writing (DIW) 3D printing applications. This procedure opens up new possibilities for environmentally friendly processing of biomass materials with printable properties.

SB03.07.04

Nanocellulose Bio-Vitrimer Materials *Enrico Boschi[1,2], Gilberto Siqueira[1], Gustav Nyström[1], Dambarudhar Parida[1] and Lea Rapp[1,3]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]University of Copenhagen, Denmark; [3]ETH Zürich, Switzerland*

Plastics have been used extensively in a myriad of industries due to their excellent properties, yet their use has created significant environmental challenges. Predominantly produced from depleting fossil fuel, conventional thermoplasts and thermosets are resistant to biodegradation, contributing to pollution. While thermosets dis-play exceptional mechanical properties, they cannot be recycled or remolded due to extensive crosslinked networks. Conversely, thermoplastics, which are recyclable, often lack the mechanical robustness of thermosets. In this context, vitrimers have garnered considerable attention because of their outstanding mechanical prop-erties like those of thermosets, while maintaining recyclability as thermoplastics. This is achieved by incorpo-rating dynamic covalent bonds along the polymer chain.

Herein, we propose the synthesis of a distinct bio-vitrimer. In this system, we explore transesterification based dynamic covalent bonds by combining sebacic acid and epoxy modified vanillic acid. To further improve the mechanical properties of the material, different nanocellulose types (e.g. cellulose nanofibers (CNF) and cellulose nanocrystals (CNC)) were integrated to the synthetized vitrimer matrix. This system, based on three bio-based components, leverages the ability of the epoxy group to form covalent bonds with the two carboxylic groups of the

sebacic acid and the hydroxyl groups present on the nanocellulose. Our research reveals the impact of surface modified nanocelluloses to achieve covalent adaptable networks, as well as the effect of the transesterification catalyst when reprocessing the composites.
Throughout our research we investigate the recycling, thermal stability and mechanical properties of the numerous composites, focusing on the impact that the various bio-based materials have on those properties. We highlight the potential of recyclable bio-vitrimers to substitute currently used fossil-based polymers. Chemical modification of nanocellulose with covalent adaptable networks, offers new opportunities for the application of bio-based advanced materials in the field of adhesives, food packaging and 3D printing.

SB03.07.05
Harvesting Pickering Emulsion Properties for Cellulose Nanocrystal Functionalization *M Bachir Messikh and Kenneth R. Carter; University of Massachusetts Amherst, United States*

Cellulose nanocrystals (CNCs) are a bioavailable and cost-effective material known for having a high hydrophilicity, a highly functionalizable surface, and the ability to form stable Pickering emulsions. The chemical modification of the CNC surface is often leveraged to enhance the properties of the Pickering emulsion and to expand their applications in fields such as pharmaceuticals and cosmetics. However, to the best of our knowledge, no one has taken this property to surface functionalize the CNCs themselves an oil/water interface and covalently attach water-insoluble species on the CNC surface, which would be difficult or impossible to graft using conventional methods. Herein, we utilize this property as well as our previous work on attaching amino acids onto nanocellulose to install water-insoluble species on its surface using thiol-ene Micheal addition. We demonstrate the versatility of our method by grafting three different species: a small fluorescent molecule (9-vinyl carbazole), an elastomer (polybutadiene), and a semiconducting polymer (poly (9,9-dihexyl fluorene)). We investigate the covalent nature of the grafting using FTIR, 13C CPMAS NMR as well as photoluminescence. This work expands the number of species that can be grafted onto CNCs, removing the barrier of solvent and allowing expanded application in electronics, mechanical reinforcement, or sensing.

Nature-Based Polymeric Electrolytes Towards Sustainable Applications *Diana Gaspar[1,2], Bárbara Carmo[2], Elvira Fortunato[2], Rodrigo F. Martins[1] and Luis Pereira[1,2]; [1]AlmaScience, Portugal; [2]Universidade Nova de Lisboa, Portugal*

The present global scenario drives the need for efficient energy storage systems, with special emphasis on electrochemical devices. Due to the widespread use of critical and toxic materials, the research community has begun prioritizing next-generation materials based on various factors, including greener availability, low-impact, recyclability, biodegradability, cost-effectiveness, and eco-friendliness. A large share of the electrolytes reported in the literature encompasses significant drawbacks such as complicated synthesis, use of ionic liquids, toxic composition, restricting their development for applications and posing environmental problems for their disposal. In contrast, biopolymer-based electrolytes meet all of the aforementioned criteria and can play an important role in energy applications. Having this in mind, this work focused on the selection of highly available, rapid regeneration natural materials (lignin, cellulose, alginate) to prepare polymer electrolyte systems.
These natural polymers are particularly interesting due to their chemical structure differences, influencing the ionic conductivity of the electrolytes. In the present work, two approaches were pursued: creating a biopolymeric electrolyte and preparing biopolymer matrices that act as the host polymer that might incorporate the electrolyte and various ionic dopants to increase their ionic conductivity further.
Different host polymer matrices were prepared and impregnated with lignin-based electrolytes with ionic conductivities in the order of 10^{-4} – 10^{-3} Scm^{-1}.

SB03.07.07

Development of Flexible Methylcellulose/Cellulose Acetate-Based Triboelectric Nanogenerators with AlFe2O4 and CuMnO2 Nanoparticle Coatings for Enhanced Energy Harvesting

Ashwin James[1,2,2], Elizabeth Varughese[1,2,2], Fernando Viesca[1,2,2], Swati Mohan[1,2,2] and Mohammad J. Uddin[2,2,2]; [1]The University of Texas at Rio Grande Valley, United States; [2]University of Texas Rio Grande Valley, United States

Wood is one of the most used materials in the world, from its applications in building structures, furniture, food flavorings, to even the paper this is printed on. One of the earliest usages of wood by man was energy generation by combustion. As time passed, and mankind developed, we turned to other sources of energy, such as coal, natural gas, and nuclear energy, which happen to be the three main sources of energy production in the USA. However, these predominantly used energy generation methods contribute a lot to wastewater/air pollution and greenhouse gas production. In order to prevent this, and to reduce the amount of greenhouse gas emissions and pollution, many alternative energy resources have been investigated. One of these alternatives discovered during the last decade are triboelectric nanogenerators, commonly referred to as TENGs . As these devices were investigated and studied, a list known as the triboelectric series was formed, based on the ability of various materials to gain or donate electrons. Cellulose, a wood-derived polymer, happens to fall near the middle of this list, slightly to the positive side. In this study we investigated both cellulose and its derivatives, methylcellulose and cellulose acetate, in combination with CuMnO2 delafossite and AlFe2O4 spinel to manufacture a TENG device.

TENGs are devices composed of two layers with opposing charges, one negatively charged and one positively charged, that produce electricity when the two layers contact each other. This voltage is produced by the triboelectric effect and electrostatic induction. The former is when different materials become charged after coming in contact with another through friction. One will gain electrons and the other will lose electrons, which creates a current. The latter is when materials with different charges separate, in this case charges created by the triboelectric effect, and create an electric potential difference which generates a current once more. This is why TENGs produce voltage upon both contact and separation. By maximizing the charge difference and surface area of the two layers, more voltage can be produced.

Cellulose is considered a slightly positive material, which means it tends to lose electrons, based on its chemical structure. However, in order to maximize voltage production, we synthesized methylcellulose and cellulose acetate, the former being more negative than standard cellulose, and the latter more positive. These derivatives were then used to make hydrogel films,. Metals are highly conductive and durable materials, and have high electron mobility, traits essential to a good TENG. By depositing metallic nanoparticle compounds onto the surface of the cellulose derivative films, the charge difference, surface area, and electron mobility of the respective films can be enhanced. Copper and manganese are relatively negative on the triboelectric series, meaning they are likely to gain electrons. On the other hand, aluminum and iron are more positive, and easily donate electrons.

Given this we synthesized CuMnO2 delafossite and AlFe2O4 spinel nanoparticles using hydrothermal process, that when deposited onto the methylcellulose and cellulose acetate films respectively, will enhance their negative and positive charge respectively as well as their contact surface area. Once complete, a TENG device surrounded by a 3D printed chassis is produced, and then connected to an oscilloscope and triboelectric testing commences. The produced TENGs generated a much higher voltage than our control TENGs made of plain cellulose, plain methylcellulose and cellulose acetate, and plain cellulose deposited with AlFe2O4 and CuMnO2. Further studies must be conducted in order to investigate the capacitance properties of these cellulose derivatives, as well as their ability to conduct electricity. Nonetheless, the usage and application of cellulose derivatives seems to be a promising and unique direction for future TENG research.

SESSION SB03.08: Wood Structured Materials and Applications
Session Chairs: Elvira Fortunato and Yuanyuan Li

8:30 AM *SB03.08.01

Wood as Hygromorphic Actuators *Lining Yao[1], Danli Luo[2], Teng Zhang[3], Shu Yang[4], Guanyun Wang[5] and Tucker Rae-Gran[6]; [1]University of California, Berkeley, United States; [2]University of Washington, United States; [3]Syracuse University, United States; [4]University of Pennsylvania, United States; [5]Zhejiang University, China; [6]Carnegie Mellon University, United States*

Natural wood has well-studied hygromorphic properties and is an abundant, environmentally friendly structural material. Compared to other biodegradable, water-responsive materials like spider silk, bacterial spores, engineered silk film, pollen paper, and naturally derived hydrogels, wood offers a superior modulus (about 10 GPa) and can be processed on a large scale (centimeters to meters). However, the high modulus also limits wood-based actuators to a small initial curvature (<10 m−1) and a small range of curvature changes (<30 m−1). To tackle this challenge, we developed a five-step process involving both chemical washing and mechanical molding to transform bulk wood into a tight hygromorphic actuator. With this technique, we can turn wood veneer into highly stiff (about 4.9 GPa when dry and about 1.3 GPa when wet) hygromorphic bending or coiling actuators with an extremely large bending curvature (1,854 m−1), 45 times larger than values reported in the literature. We design and fabricate self-drilling seed carriers [1] and versatile wood-based actuation materials and applications [2] with this process.

9:00 AM SB03.08.02

All-Wood Electrochemical Transistor and Energy Storage Electrodes from Electrically Conducting Wood *Isak Engquist[1], Van Chinh Tran[1], Gabriella Mastantuoni[2], Marzieh Zabihipour[1], Lengwan Li[2], Lars Berglund[2], Qi Zhou[2], Jonas Garemark[3], Christopher Dreimol[3], Xin Wang[4], Renee Kroon[1] and Magnus Berggren[1]; [1]Linköping University, Sweden; [2]Royal Institute of Technology, Sweden; [3]ETH Zürich, Switzerland; [4]Research Institutes of Sweden, Sweden*

Using suitable pretreatment, wood serves as an excellent template for electronic and ionic conductivity. To utilize this possibility, we treated wood with the conducting polymer PEDOT:PSS to achieve a conductivity of 69 S/m, while maintaining the good mechanical properties of the balsa wood veneers that served as raw material. SEM and SAXS measurements indicate a thin film of PEDOT:PSS coating the inner surface of the lumen, with slight penetration of conducting polymer in between the wood fibers, while the inner volume of the lumen remains accessible for an ion-conducting electrolyte. Three pieces of this conducting wood were used to create an all-wood, double-gate electrochemical transistor where all three electrodes (drain, source, gate) and the transistor channel were made from the same material. The electric current in the 1 mm thick transistor channel could be modulated with an on/off ratio of up to 50.
Conductive wood also has potential to serve as electrodes for capacitive energy storage. Using a similar

procedure, we prepared such electrodes using pine veneers, where the pretreatment was designed to maintain a portion of the wood-native lignin. The lignin increases energy storage capacity due to the redox-based charge storage capacity of its catechol groups. To access lignin inside the wood cell wall, where PEDOT:PSS has limited reach due to its particle size, an additional step was used where the conducting polymer S-PEDOT was in situ polymerized inside the wood. Confocal Raman spectroscopy was used to map the distribution of the two different polymers inside the wood. The synergistic use of these two polymers increased the electrode capacitance by a factor of 7 compared to samples with only PEDOT:PSS, and by a factor of 2 compared to only S-PEDOT, reaching a maximum specific capacitance of 315 mF/cm^2.

9:15 AM SB03.08.03

Sustainable Hierarchical Wood/ZnO Piezoelectric Nanogenerators for Green Energy Harvesting *Madalena Roque[1], Elvira Fortunato[1], Rodrigo F. Martins[1], Diana Gaspar[2,1] and Luis Pereira[2,1]; [1]Universidade Nova de Lisboa, Portugal; [2]AlmaScience, Portugal*

The increasing demand for sustainable and renewable energy sources has triggered significant research efforts in the field of energy harvesting. Among these technologies, low-cost and biodegradable piezoelectric nanogenerators have emerged as promising candidates for a wide range of applications.

Nowadays, a growing demand has urged materials to be able to play an imperative role in sustainable energy harvesting, namely in piezoelectric mechanical energy conversion, since it is an attractive approach for mechanical energy harvesting. In response, wood, an abundant piezoelectric biomaterial, emerges as a promising sustainable material for harvesting mechanical energy, owing to its renewable origin, advanced hierarchical and porous structure, easy multi-functionalization and favourable mechanical properties.

This work aims to contribute to the (r)evolution of Wood/ZnO nanohybrids by strategically modifying and tailoring wood substrates. This will open up new opportunities for expanding its performance into new advanced applications. The process involves delignification to increase wood porosity, followed by an oxidation process. It was observed that the oxidation process plays a crucial role in the performance of the devices. Hence, it can negatively charge the wood surface, allowing the accessibility to Zn^{2+} ions, leading to the growth of ZnO through a hydrothermal process at low temperatures.

Combining the unique properties of wood with advanced nanomaterials leads to devices with output voltages above 9 V. In the work developed it was possible to maintain wood's hierarchical structure and mechanical robustness after the fabrication of wood/ZnO composites with efficient mechanical energy conversion.

9:30 AM SB03.08.04

Multiscale Wood Bonding Enabled by Recoverable Cellulose-Dissolving Ionic Liquid *Shiying Zhang, Shennan Wang and Lauri Rautkari; Aalto University, Finland*

The growing adoption of mass timber in the construction industries highlights the need for high-quality adhesives. Ensuring that adhesive joints in engineered wood products possess strength and durability comparable to the wood itself is essential for overall performance and longevity. Although petroleum based adhesives are extensively used in the engineering timber products, they raise environmental and health concerns. Recent efforts to develop renewable bio-based adhesives address these issues, but commercializing these adhesives has been challenging due to their complex and time-consuming synthesis, poor bonding strength, and low water resistance. Although Cross-linkers like isocyanate and epichlorohydrin have been introduced, but their toxicity and cost limit large-scale production.

Ionic liquid (IL) has emerged as a recoverable and green solvent for lignocellulosic materials, and the dissolved *cellulose can readily regenerate by introducing antisolvents. In this work, we propose a feasible multiscale wood bonding system employing an ionic liquid-cellulose solution as the bonding agent. The bonding mechanism involves the diffusion of IL-cellulose solution into two wooden adherends from their joint interface, where they interact with wood cell wall components, forming new hydrogen bonding networks among cellulose chains after regeneration in water. This approach achieves bonded wood remained its orignial chemical composition with excellent bonding integrity and water resistance. The shear strength of the bonded wood interface reaches up to 22 N/mm^2, attributed to the cell wall interlocking, which is threefold higher than the commercial formaldehyde resin, effectively addressing the challenges associated with petroleum and bio-based adhesives. The overall results indicate a novel wood bonding mechanism with a promising potential for sustainable production of mass timber.*

9:45 AM SB03.08.05

Characterization of Copper Based Nanoparticles in Treated Wood *David F. Bahr, Temitope Aminu and Mohamad Zbib; Purdue University, United States*

There are multiple industrial processes capble of incorporating malachite green particles in wood; the copper continaing compound serves as a preservative from microbial damage to wood products. However, they use a variety of pressure, environments, and temperature for getting the copper-carbonate into the structure of the wood, which may alter the structure and location of the copper-containing compounds between lumens and cell walls. This study aimed to investigate how three wood processing methods impact the incorporation of malachite green particles in wood. We examine both the the crystal structure and long-range order of the copper-containing compounds as well as particle morphology. Three different types of commercially available treated wood, as well as a novel patented processed wood were examined for copper compounds, structure, and location. Electron microscopy revealed particulate features and chemicals in the wood that chemically matched malachite, but in general x-ray diffraction demonstrated an absence of the crystalline malachite structure upon infiltration in the wood post high pressure processing. The amorphoization of copper carbonate appears to occur both when "micronized" powders are infused into the sturcutre, or when copper and carbonate environments are used to precipitate the copper carbonate in situ. This suggests that the pressure and temperatures used to infiltrate wood with copper containing compounds, or the pressure and chemistry swings needed to precipitate the copper may alter formation pathways or of malachite. While all methods examined show similar copper chemistries, the location and distribution of copper including particles does show differences between the processes in relationship to the nanoparticle positioning in early to late wood.

Micromechanics of Plant Growth Under Healthy and Salt Stress Conditions for Bioinspired Design *Anamika Prasad and Salman Jamal; Florida International University, United States*

Nature has offered much inspiration to design bio-inspired based efficient composites. Abstraction of the hidden *cues of the hierarchical organization, principles and underlying structure-function relations are some of the critical approaches of bioinspired materials design. However, significant effort has been focused on rigid natural composites such as bone, wood, and bamboo for designing structures optimized for strength, toughness, and density. In this study, we investigate the vascular tissue of a fast-growing plant sunflower (Helianthus annuus) to gain insights into changes in cell wall mechanics from early stages with a soft pliable structure to later stages with tough lignified mass. Our focus lies on the cell wall as these components play a vital role in maintaining cell growth for structural integrity during development.*

To conduct the study, we grew sunflowers in the lab under healthy and salt-stressed conditions and compared the response from the early stages of 4 weeks to 12 weeks. We employed the depth-sensing nanoindentation technique (Hysitron T1 980) to map the elastic and viscous properties and Raman spectroscopy to analyze the composition changes and evaluated the structure mechanics and composition connected among the stages due to salt presence. Combining these results provided a comprehensive understanding of the micromechanics of cell-wall structure from primary to secondary growth. The results are presented in the context of functional composite design. Overall, this research sheds light on the importance of examining the mechanical properties of cell walls during different growth stages and provides valuable data for developing bioinspired materials with enhanced functionalities and optimized composite interfaces.

10:45 AM SB03.09.02

***Leaves for Transpiration Driven Hydrovoltaic Generators** Ramesh Adhikari and Neha Viradia; Colgate University, United States*

Water covers two-thirds of the earth's surface and stores a huge amount of energy available from the sun as well as geothermal and human activities. Tapping this energy could help with not only addressing the growing demand for energy but also help identify a sustainable source of energy for a cleaner future. Hydrovoltaic generators are composed of two electrodes that sandwich laminar and porous materials that allow water molecules to pass through as they evaporate. The difference in ion concentration during this process results in streaming and evaporation potential and current which can transmitted, stored, or used for low-power applications. Leaves are abundant natural resources that are readily available in the regions with plant coverage. The architecture of leaves allows for water to transpire through its surface as a natural mechanism which allows for plants to maintain their internal temperature. Using this property of the leaf and the evaporation of water, here we report development of leaf-based hydrovoltaic generator that can continuously produce significantly high open source voltage (>1 V) and short circuit current (>1 mA) with maximum power density (>150 μWcm^{-2}) which are values much higher compared to the hydrovoltaic generators that have been reported so far. We will present our study on the mechanism of hydrovoltaic electricity generation in these devices, the optimization process of such devices, and demonstrate their potential application. The use of natural water evaporation mechanism along with the use of leaves as bio-based and biodegradable active material for high-power density hydrovoltaic devices presents an environmentally friendly and sustainable alternative option for developing electric power generators for low-power electronic applications.

11:00 AM SB03.09.03

***Wood Nanostructure Control for Efficient Energy Conversion** Yuanyuan Li; KTH Royal Institute of Technology, Sweden*

Research focuses shift back to biomaterials ascribing to the increasing energy crisis and environmental concern. Sustainable energy conversion and storage is one of the most influenced fields. Wood is attractive in this context due to its advanced hierarchical structure including anisotropic multi-scale pores benefiting directional diffusion. However, the wood structure is not optimized. E.g. micro meter scale pores are not efficient for maximized surface *interactions. Therefore, more effort should be put into wood structure tailoring. In this presentation, wood structure tailoring strategies will be introduced for efficient energy conversion including hierarchical catalyst synthesis*[1] *for water splitting and wood cell wall nanostructure reconstruction for hydrovoltaic energy harvesting*[2,3]*. The wood structure development during the treatments as well as further applications will be discussed in detail.*

One-Step Amination on Porous Wood Aerogel for Direct CO2 Capture from Atmosphere *Man Qi and Jiayin Yuan; Stockholm University, Sweden*

Given the substantial emissions of carbon dioxide (CO_2) into the atmosphere, currently at a level of over thirty billion metric tons annually, there is a critical need of effective CO_2 adsorbents at scale, ideally derived from abundant natural resources as sustainable materials. In this work, sustainsble wood was used to fabricate structured wood aerogel as porous support via solvent dissolution and regeneration process, followed by surface modification with a series of amino silane coupling agents to produce aminated wood aerogel as CO_2 adsorbent. The as-synthesized optimal adsorbent exhibited a high CO_2 sorption capacity of up to 1.5 mmol/g and 1.3 mmol/g at 0 °C and 25 °C at 1 bar, respectively. Notably, in-depth analysis showed that the adsorbent achieved an impressive capacity of CO_2 uptake of 0.65 mmol/g at 25 °C at an exceptionally low CO_2 pressure of 0.4 mbar, i.e., under ambient CO_2 pressure. It implies its potential use as adsorbent both for the traditional point-source capture and the direct air capture as an emerging negative emission technology. This study underscores the environmentally friendly, cost-effective, and biosourced attributes of aminated wood aerogel as a compelling alternative for carbon capture, contributing to global initiatives combating CO_2 emissions and stressing the key role of sustainable materials in tackling this global environmental challenge.

11:30 AM SB03.09.05

Molecular Dynamics Study of Wood-Inspired Polymeric Composite Interactions with Water *Dominique Derome*[1]*, Ali Shomali*[2]*, Wenqiang Liu*[1]*, Brigitte Chabbert*[3]*, Eleonor Schofield*[4]*, Benoit Coasne*[5] *and Jan Carmeliet*[2]*;* [1]*Université de Sherbrooke, Canada;* [2]*ETH Zürich, Switzerland;* [3]*Institut national de la recherche agronomique, France;* [4]*Mary Rose Trust, United Kingdom;* [5]*Université Grenoble Alpes, France*

In this study, we analyze the hygromechanical behavior of composite consisting of amorphous cellulose, xylan, lignins reinforced or not with crystalline cellulose and treat the composites with polyethylene glycol as consolidant. Atomistic simulations is used to mimic water adsorption and desorption in amorphous polymers, allow observations on mechanical behavior like swelling and shrinking, mechanical softening in compression and shear, and on the stick-slip behavior of the stiff fibrils pulled out of the matrix. To better understand the hygro-mechanical behaviour of biopolymer composites, Molecular Dynamics combined with Grand Canonical Monte Carlo simulations [1] is used to model sorption and sorption-induced deformation and determine the mechanical properties of wood-inspired biopolymer composites and a system approaching S2 configuration.

Atomistic modeling is an insightful tool for the in-depth study of the coupled effects of water sorption on hygric and *mechanical properties of different polymeric components. Molecular modeling can contribute to support and complement experimental methods which yield, most frequently, indirect structural information. With molecular modeling, there is a freedom of investigating unlimited possibilities of configurations, ranging from individual wood polymer materials to composite structure resembling subunits of wood S2 cell wall. This presentation includes recent methodological developments towards good practices for such simulations and the recent insights on wood cell wall S2 layer hygromechanical behavior [2].*

Composites show swelling-induced sorption and a mechanical weakening upon sorption. Due to the reinforcing effect of the crystalline cellulose fibre, the swelling and weakening of composites in longitudinal direction is supressed. Additional sorption is found to occur in the porosity created by the misfit between crystalline cellulose fibre and matrix, leading to a reduction of the pullout shear strength due to breakage of matrix-fiber hydrogen bonds by the water molecules. Adding polyethylene glycol to composites results in filling the gap between crystalline cellulose and matrix, leading to a reduction of the volumetric swelling and sorption, and an enhancement of the pullout shear strength.

We observed hysteresis not only in water sorption but also in mechanical properties. This hygromechanical behavior can also be observed in particular from the breaking and reforming of hydrogen bonds.

This work in inspired by wood, an orthotropic cellular biomaterial. As a plant and as a building material, water impacts the behavior of wood and particularly the cell wall material. As water molecules are adsorbed by the hydrophilic composite that makes up the cell walls, the induced fluid-solid interaction forces result in swelling of cell walls. Thus, this process, at the origin of wood-moisture relationships, lies at the nanoporous material scale. A second inspiration of the work is the treatment of waterlogged archaeological wood of shipwrecks, like the Varsa and Mary Rose, with PEG for its consolidation and stabilization, where PEG molecules replace the water making wood at museum conditions less susceptible to changes in humidity and able to sustain mechanical load.

11:45 AM SB03.09.06

Directional, Silanized Plant-Based Sponge for Oil Collection *Jongbeom Kim[1], Jingyu Deng[2], Nam-Joon Cho[2] and Seung Min J. Han[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Nanyang Technological University, Singapore*

Porous materials that are used for oil absorption to combat marine pollution suffer from the unwanted release of microplastics or nanoparticles from their synthetic components, which ironically raises environmental concerns. In this study, a sustainable and reusable pollen sponge derived from eco-friendly pollen grains and fabricated using a directional freeze-drying method is introduced. These grains undergo a defatting process followed by a controlled hydrolysis process, transforming them into a pollen microgel made of sporopollenin, the primary constituent of a pollen grain's outer layer. The directional freeze-drying technique is used to fabricate porous structures with controlled orientation using the pollen microgel. The application of a chemical vapor deposition with dodecyltrimethoxysilane (DDTS) grants sponge hydrophobic properties, making it ideal for selective oil *absorption. This modified pollen sponge boasts superior absorption capacities (15–59 times its weight) compared to most natural sponges. Additionally, its excellent durability and ability to recover up to 65% of deformation even after 60% strain compression are remarkable with the silanization process tripling the recoverability of pollen sponges. Remarkably, the silanized directional pollen sponge (SDPS) retains this resilience after 100 compression cycles. Therefore, the SDPS emerges as an eco-conscious solution for repeated and selective oil absorption tasks.*

SESSION SB03.10: Sustainability

Wednesday Afternoon, December 4, 2024
Hynes, Level 1, Room 111

1:30 PM *SB03.10.01
***Integrative Life Cycle Modeling for Sustainable Design of Biomass-Residue-Based Materials** Yuan Yao; Yale University, United States*

The use of residue biomass, such as forest and agricultural residues, for producing value-added materials and products is garnering increasing interest. Traditional practices like prescribed burning or leaving residues in the field contribute to greenhouse gas (GHG) emissions and climate change. However, converting this waste biomass into bio-based materials is not always environmentally sustainable or cost-effective. To design climate-beneficial and cost-competitive materials from residue biomass, a comprehensive assessment across the material's life cycle is essential.

Systems analysis tools such as life cycle assessment (LCA) and techno-economic analysis (TEA) are widely used to evaluate the environmental and economic performance of biomass-derived materials. However, previous studies have predominantly focused on engineering systems without adequately considering ecosystem dynamics, which are influenced by complex spatial and temporal factors (e.g., land management, climate, and soil conditions) and significantly impact the overall environmental and economic costs of these materials. Conducting LCA and TEA is also challenging for early-stage material development due to the lack of large-scale operational data and limited knowledge of system-wide effects.

This presentation will introduce several life cycle modeling frameworks designed to address the challenges of assessing biomass-based materials. Our framework couples LCA and TEA with advanced modeling techniques such as ecosystem modeling, system dynamics, supply chain analysis, and geospatial analysis. This talk will present examples demonstrating how these integrated systems analyses can enhance engineering, process, supply chain, and policy design for sustainable biomass-based materials. Specifically, we will highlight products derived from wood residues, such as bioenergy and biochar (a carbon-negative technology). We will discuss the potential of lignocellulosic materials in mitigating climate change and identify key processes, supply chains, and socioeconomic factors that influence these potentials. Additionally, the presentation will explore strategies for the sustainable co-design of material manufacturing, supply chains, and land management.

2:00 PM SB03.10.02
***Engineering Solid Biofoams to Replace Plastics** MIkko Alava, Isaac Miranda-Valdez, Kourosh Mobredi, Aref Gharmi, Maryam Roza Yazdani-McCord, Juha Koivisto and Tero Mäkinen; Aalto University, Finland*

Mimicking natural biological structures is a route for developing novel, bio-based materials to substitute plastics. Based on a process of creating a solid cellular foam structure similar to natural wood we create extremely lightweight anisotropic structures with a strong direction 40 times stronger than the soft direction (M. Reichler et al., Sci. Reports 11,1 (2021)). We explore the material property landscape exploiting Bayesian Optimization automatically highlighting the relevant control parameters and measurables from multidimensional data reducing the number of measurements over 50 % (Miranda-Valdez et al. Submitted for publication). We report on successful attempts to speed up the material design, for acoustic properties control and for applications to energy storage materials exploiting phase-change material components (Miranda-Valdez et al., J. Energy Storage 73, 1 (2023), and to water and humidity resistant foams, as true plastics replacements (Miranda-Valdez et al., Adv. Eng. Materials, accepted). These properties and techniques are essential for novel materials to become cheaper and easier to use replacing oil-based alternatives in packaging, textile and construction sector.

2:15 PM SB03.10.03

Sustainable Dual-Network Cellulosic Bioplastics with Tunable Mechanical Properties and Biodegradability via Ring-Opening Polymerization *Jiyu Kim and Jinkee Hong; Yonsei University, Korea (the Republic of)*

The global advancement of bioplastics development as an alternative material for traditional petroleum-based plastics is driven along with the emphasis on sustainable society. Cellulose, the most abundant natural polysaccharide, is a wood-derived renewable biopolymer widely used for sustainable materials. However, most cellulose-based bioplastics hinder their practical use because highly ordered structure of cellulose from extensive hydrogen bonding are difficult to process. To overcome these limitations, designing advanced materials by tailoring the structure and properties of cellulose requires innovative approaches and a deeper understanding beyond current knowledge. Furthermore, further studies are still needed to effectively balance and correlate biodegradability with mechanical properties of bioplastics. Our promising strategy is the fabrication of cellulose-based biopolymers using a dual-network via ring-opening polymerization, which allows precise tuning of mechanical properties and biodegradability for various applications. Dual-network bonds effectively dissipate energy under stress, enhancing toughness and fracture resistance, while providing a balance between rigidity and flexibility.

In this study, we report a straightforward approach to control the mechanical properties and biodegradability be utilizing a cellulose network as the primary structure and incorporating the Y-junction network as the secondary structure. In the Y-junction network, lipoic acid and 2-hydroxyethyl acrylate engage in ring-opening polymerization to regulate the mechanical properties, while glycerol carbonate modulated biodegradability. We developed two types of dual-network bioplastics: dynamic bond bioplastic (DBP) and permanent bond bioplastic (PBP), both designed to control physical properties and biodegradability effectively. DBP is synthesized via thermal ring-opening polymerization and PBP is produced through radical-assisted ring-opening polymerization. Dual-network bioplastics using ring-strained disulfides have been shown to undergo ring-opening polymerization, resulting in the formation and linear disulfide crosslinking and can be further complemented by permanent reactions with alkenes to control network properties.

Overall, our findings indicate that the ultimate tensile strength and elongation at break of these dual-network bioplastics can be finely tuned within the ranges of 8.8 to 193 MPa and 3.3 to 32.5%, respectively. Moreover, these bioplastics exhibit rapid biodegradability, achieving approximately 60% degradation within 2 weeks. Remarkably, our bioplastics demonstrate compatibility with plant growth, suggesting their potential to coexist with the ecosystem without disruption during the biodegradation process. This research provides a promising strategy to developing advanced bioplastics that meet sustainability goals while offering tunable performance characteristics.

In summary, ring-opening polymerization and dual-network structures enable the creation of bioplastics with customized mechanical properties, tailored biodegradability, improved thermal stability, and enhanced *processability. This versatility makes them suitable for a wide range of applications while addressing sustainability goals. This study not only contributes to the fundamental understanding of cellulose-based dual-network bioplastics but also paves the way for the development of high-performance, sustainable materials that align with the environmental and economic goals of a sustainable society.*

Real-Time Biosignal Monitoring in In Vivo and In Vitro 3D Tissues with Organic Printed Electrochemical Transistors *Sungjune Jung; Pohang University of Science and Technology, Korea (the Republic of)*

This talk explores the development of printed organic electrochemical transistors (OECTs) for interfacing with in vivo and 3D in vitro tissues. Initially, we present tunable organic active neural probe enabling near-sensor signal processing. By utilizing additive inkjet printing technology, we seamlessly integrated multiple OECTs with passive components to detect neural signals from the somatosensory cortex, achieving high gain and low noise performance. We then introduce a pioneering 3D tissue-integrated ion-sensing platform using OECTs. For the first time, inkjet-printed large-area OECTs were integrated with 3D-bioprinted lung tissue models. This platform effectively monitors changes in tissue tight junctions during long-term air-liquid culture and successfully detects disruptions caused by H1N1 influenza virus infection, demonstrating its potential in disease modeling and drug efficacy evaluation. This presentation highlights the synergy between organic electronics and biological systems, highlighting the transformative potential of organic bioelectronics in medical diagnostics, therapeutic interventions, and personalized medicine.

11:30 AM SB04.01.02

Live Monitoring of Cellular Respiration at Cell/Gate Nanogap Electrical Interface *Toshiya Sakata; The University of Tokyo, Japan*

Ionic or biomolecular charges induce a change in potential at the electrolyte solution/electrode interface. As a type of potentiometric biosensor, biologically coupled gate field-effect transistors (Bio-FETs), which are originally based on solution-gated FETs, are attracting attention worldwide. This is probably because various types of biomolecules with charges can be directly detected as electrical signals with the Bio-FETs in a label-free and real-time manner, and various semiconductive materials can also be applied to biosensing [1].

A general cell culture medium includes various ions and chemicals such as serum and glucose. In such a medium, the shielding effect caused by counter ions is a problem because Bio-FETs are very insensitive to the changes in the density of molecular charges based on biomolecular recognition events on the gate electrode in the cell culture medium, although the diluted measurement solution can be used for reducing the shielding effect by counter ions. In other words, nonspecific electrical signals can be prevented from interfering with species in the cell culture medium because some proteins contained in it have been nonspecifically adsorbed on the gate electrode during preculture. Then, what specific targets are detected by the Bio-FETs under this condition? Hydrogen ions, in particular, which have the smallest size, induce changes in pH. Actually, in our group, cellular respiration activities were easily and continuously monitored for any living cells (e.g., cancerous, autophagic, and normal cells, extracellular matrix production of chondrocyte, and embryo and sperm activities) using Bio-FETs with an oxide gate electrode in the cell culture medium [2–8]. Some proteins in the cell culture medium are adsorbed at the oxide gate surface during preculture, resulting in the adhesion of cells at the substrate. These macromolecules prevent targeted ionic charges from coming into contact with the gate, but hydrogen ions can easily attach to the oxide gate surface, where the equilibrium reaction between hydroxyl groups and hydrogen ions contributes to the change in the charge density at the oxide gate electrode. Moreover, hydrogen ions are concentrated in the closed nanogap space between the cell membrane and the oxide gate electrode [4,6]. This detection mechanism is very simple, that is, living cells are simply cultured on the oxide gate electrode of the original solution-gated FET (i.e., pH-responsive ion-sensitive FET) for monitoring cellular respiration. In addition, the cell culture medium with high ionic strength contributes to the reduction in the effect of other ionic and biomolecular charges on the output signal by minimizing the Debye length. This is a straightforward mechanism in the pH-responsive FET. Thus, it is also important to reconsider the intrinsic features of Bio-FETs, which allow the stable monitoring without additional modifications of the gate electrode. In this talk, we would like to introduce the above fundamental characteristics of the cell-coupled gate FETs and their applications.

Biomimetic Tunable Electroactive Surfaces for Bone-on-Chip *Amaia Ortega[1], Elisabet Henell[1], Jose G. Martinez[1], Emilio Hara[2] and Edwin Jager[1]; [1]Linköping University, Sweden; [2]Okayama University, Japan*

Conjugated polymers such as polypyrrole (PPy) are interesting materials for bio-applications due to their low redox *potentials (1<V), biocompatibility, and can be operated in any aqueous electrolytes, including full blood and cell culture medium. Previously, we demonstrated that chondrocyte-derived plasma membrane nanofragments (PMNFs) initiate bone formation in vivo and can be used to fabricate biomimetic bone microenvironments in vitro. Using coupling chemistry, we now covalently immobilised the PMNFs onto the PPy surface. By alternating the redox potential, we can dynamically control the presentation of the attached PMNFs. This influences the biological activity and thereby the mineralisation of bone on the surface. The different redox states resulted in different morphologies of the bone minerals on the surface, which in turned showed to influence the viability of bone marrow cells. Such biomimetic tunable electroactive surfaces are a valuable tool for dynamically altering the biofunctionality of the surface to study cell-cell and cell-matrix interactions or develop a more optimized artificial stem cell niche.*

SESSION SB04.02: Bioelectronics for In Vitro Cell Models II
Session Chairs: Roisin Owens and Anna-Maria Pappa
Monday Afternoon, December 2, 2024
Hynes, Level 3, Room 309

1:30 PM SB04.02.01
Highly Sensitive and Quantitative Monitoring of Adenosine Receptor Activities in Nonsmall Cell Lung Cancer Cells Using Carbon Nanotube-Based Hybrid Devices *Yoonji Choi[1], Jin-Young Jeong[2] and Seunghun Hong[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)*

We report a method for highly sensitive and real-time monitoring of adenosine receptor activities in nonsmall cell lung cancer (NSCLC) cells through a carbon nanotube device. In this work, NSCLC cells expressing adenosine receptors were immobilized on a carbon nanotube field effect transistor (CNT-FET) via an extracellular matrix protein to build a hybrid device. Our device could be utilized to sensitively detect adenosine down to 1 fM and selectively discriminate adenosine among other nucleosides. Additionally, we could use the device to evaluate adenosine in complicated environments such as human serum. Importantly, our hybrid device allowed us to quantitatively monitor pharmacological effects between adenosine and other drugs, including dipyridamole and theophylline, even in human serum samples. In this respect, the NSCLC cell-hybridized CNT-FET can be a practical strategy for the evaluation and screening of drug-candidate substances, providing broad opportunities in biological and pharmaceutical industries.

1:45 PM SB04.02.02
The Gut-Immune Axis—A Bioelectronic Approach for Studying IBS, Diet and Intestinal Inflammation
Alexandra Wheeler-Enslin, Sophie Oldroyd, David Bulmer and Roisin Owens; University of Cambridge, United Kingdom

Irritable bowel syndrome (IBS) is a chronic bowel disorder associated with abdominal pain and altered bowel movements, broadly classified as diarrhea- or constipation-predominant or mixed. Altered intestinal permeability and immune function have been linked to subsets of IBS(1). Intestinal immune cells play a pivotal role in regulating intestinal homeostasis and are key role players in inflammatory responses and maintenance of barrier integrity(2). Understanding the intricate interplay between the intestinal epithelium and immune cells is therefore important in broadening our understanding of IBS as well as intestinal inflammation and its modulation by diet. Traditional in *vitro intestinal models often focus on the epithelial layer to study barrier function and transport processes, however it is becoming increasingly recognized that incorporation of immune cells in these models is crucial for improving our understanding of inflammation and immune responses(3).*

Methods

We introduce a novel in vitro model of the gut-immune and gut-immune-vasculature interface, offering a more physiologically-relevant platform to investigate the effects of IBS and the dynamics of intestinal inflammation. The model integrates key components of the gut microenvironment, including epithelial and immune cells, contained within a collagen-based hydrogel, with or without vascular endothelial cells. We use this model to explore the effects of hallmarks of healthy (short chain fatty acids) and western (long chain fatty acids) diets as well as faecal supernatants from patients suffering from IBS, pre- and post-dietary intervention, and their healthy household controls. To do this we focus on monitoring changes in intestinal barrier integrity using both a conventional transepithelial electrical resistance (TEER) monitoring approach relying on chop-stick electrodes and a novel Parylene C and PEDOT:PSS based conformable device(4).

Results & Discussion

Our findings demonstrate that barrier integrity changes in response to both pro-inflammatory and anti-inflammatory stimuli can be measured electrically. Additionally, we show that TEER changes induced by incubation with faecal supernatants from IBS patients can be effectively measured, including changes post dietary intervention. Our results indicate that our conformable devices are more sensitive and capable of detecting these changes compared to conventional methods.

Conclusion

The study confirms that dietary metabolites and IBS faecal supernatants impact the gut-immune and gut-immune-vasculature interfaces, and that these effects can be effectively monitored using novel conformable devices. This provides a valuable platform and monitoring technique for IBS and metabolic research, allowing for detailed study of the effects of diet and disease states on intestinal barrier integrity.

From Ion Channels to Brain Organoids—Bioelectronics for Actuation and Sensing Across Length Scales

Marco Rolandi; University of California, Santa Cruz, United States

Cell-to-cell communication is key for the functioning of biological systems and life itself. This communication involves the exchange of chemical and electrical signals mediated by ion channels and intermembrane proteins that control the motion of charges across the cell membrane. The ability to connect into this communication with bioelectronic devices can be used to augment the performance of electronic devices and develop bioelectric therapies. Here, I will present three examples of bioelectronic interfaces across length scales spanning from ion *channels, cells, and organoids. The first is an ion conducting interface with a supported lipid bilayer that is capable of directly recording ionic currents from natural and synthetic ion channels. The second is a closed loop system that sets the membrane voltage (Vmem) in stem cells to drive them towards a specific fate. The third is a plug and play ion pump that easily interfaces with cell culture well plates and allows tuning of neuronal excitability in brain organoids. I will then conclude this talk how these technologies can be translated in vivo to develop new treatments.*

2:30 PM SB04.02.04

Electrochemical Early Intervention Through Microscaffold-Based Models for Rapid Bacterial Sepsis Detection *Manleen Kaur; Indian Institute of Technology, India*

Sepsis is a dysregulated inflammatory response leading to multiple organ failure. Current methods of sepsis detection are time-consuming, involving nonspecific clinical signs, biomarkers, and blood cultures. Hence, efficient and rapid sepsis detection platforms are of utmost need for immediate antibiotic treatment. In the current study, a noninvasive rapid monitoring electrochemical sensing (ECS) platform was developed for the detection and classification of plasma samples of patients with liver cirrhosis by measuring the current peak shifts using the cyclic voltammetry (CV) technique. A total of 61 hospitalized cirrhotic patients with confirmed (culture-positive) or suspected (culture-negative) sepsis were enrolled. The presence of bacteria in the plasma was observed by growth kinetics, and for rapidness, the samples were co-encapsulated in microscaffolds with carbon nanodots that were sensitive enough to detect redox changes occurring due to the change in the pH of the surrounding medium, causing shifts in current peaks in the voltammograms within 2 h. The percentage area under the curve for confirmed infections was 94 and that with suspected cases was 87 in comparison to 69 and 71 with PCT, respectively. Furthermore, the charge was measured for class identification. The charge for LPS-absent bacteria ranged from -400 to -600 μC, whereas the charge for LPS-containing bacteria class ranged from -290 to -300 μC. Thus, the developed cost-effective system was sensitive enough to detect and identify bacterial sepsis.

2:45 PM SB04.02.05

Engineering Conductive Hydrogels with Tissue-Like Properties—A 3D Bioprinting and Enzymatic Polymerization Approach *Changbai Li[1], Sajjad Naeimipour[1], Fatemeh Boroojeni[1], Tobias Abrahamsson[1], Xenofon Strakosas[1], Yangpeiqi Yi[1], Rebecka Rilemark[2], Caroline Lindholm[1], Venkata Perla[1], Chiara Musumeci[1], Yuyang Li[1], Hanne Biesmans[1], Marios Savvvakis[1], Eva M. Olsson[2], Klas Tybrandt[1], Mary J. Donahue[1], Jennifer Gerasimov[1], Robert Selegård[1], Magnus Berggren[1], Daniel Aili[1] and Daniel Simon[1]; [1]Linköping University, Sweden; [2]Chalmers University of Technology, Sweden*

Hydrogels are promising materials for medical devices interfacing with neural tissues due to their similar mechanical properties. Traditional hydrogel-based bio-interfaces lack sufficient electrical conductivity, relying on low ionic conductivity, which limits signal transduction distance. Conducting polymer hydrogels offer enhanced ionic and electronic conductivities and biocompatibility but often face challenges in processability and require aggressive polymerization methods. Here, we demonstrate in situ enzymatic polymerization of p-conjugated monomers in a hyaluronan-based hydrogel bioink to create cell-compatible, electrically conductive hydrogel structures. These structures were fabricated using 3D bioprinting of hyaluronan-based bioinks loaded with conjugated monomers, followed by enzymatic polymerization via horseradish peroxidase. This process increased the hydrogels' stiffness from about 0.6 kPa to 1.5 kPa and modified their electroactivity. The components and polymerization process were well tolerated by human primary dermal fibroblasts and PC12 cells. This work presents a novel method to fabricate cytocompatible and conductive hydrogels suitable for bioprinting. These hybrid materials combine tissue-like mechanical properties with mixed ionic and electronic conductivity, providing new ways to use electricity to influence cell behavior in a native-like microenvironment.

3:30 PM *SB04.03.01
Building Hybrid Technology Platforms to Mimic the Nervous System Christina M. Tringides[1,2]; [1]Rice University, United States; [2]ETH Zurich, Switzerland

Biomaterial scaffolds have emerged as a tool to build 3D cultures of cells which better resemble biological systems, while advancements in bioelectronics have enabled the modulation of cell proliferation, differentiation, and migration. Here, we first describe a porous conductive hydrogel with the same mechanical modulus and viscoelasticity as neural tissue. Electrical conductivity is achieved by incorporating low amounts (<0.3% weight) of carbon nanomaterials in an alginate hydrogel matrix, and then freeze-drying to introduce a highly porous network. The mechanical and electrical properties of the material can be carefully tuned and used to modulate the growth and differentiation of neural progenitor cells (NPCs). In addition to forming neurite networks that span the material in 3D, the NPCs can differentiate into astrocytes and oligodendrocytes. With increasing hydrogel viscoelasticity and conductivity, we observe the formation of denser neurite networks and a higher degree of myelination. Application of exogenous electrical stimulation can then be applied to the scaffolds to further promote NPC differentiation. To investigate the functionality of neurite networks in 3D, we begin by placing a polydimethylsiloxane (PDMS) microstructure on an underlying multielectrode array (MEA), as previously described. We then explore different materials and techniques to integrate hydrogels into the PDMS microstructures, such that the hydrogel can facilitate neurons to form 3D networks while still confined by the PDMS. This platform is compatible with various methods to assess neuronal functionality (e.g. MEA electrical recordings), and can be used to understand the effect(s) of hydrogel properties on the resulting neuronal networks. Both described biomaterial platforms can support the growth of neuronal cells for over 100 days, and could facilitate the development of biohybrid electronic devices to understand neuronal development and disease.

4:00 PM *SB04.03.02
Transparent Neuroelectronics for Multimodal Neural Interfacing Vasiliki Giagka[1,2]; [1]Delft University of Technology, Netherlands; [2]Fraunhofer IZM, Germany

Interacting with the human body using a range of modalities (i.e., electricity, light, ultrasound), holds great potential in increasing the resolution and specificity of neuromonitoring and neuromodulation. Neuroelectronic interfaces that are compatible with more than a single modality can serve as a valuable tool for neuroscientific research. This talk will describe recent research in the development of such multimodal neural interfaces. The first part of this talk will discuss the wafer-level fabrication and performance of optically transparent and MRI-compatible graphene-based in vivo and in vitro neural interfaces. Such interfaces enable concurrent optogenetic stimulation and electrophysiology, as well as two-photon imaging during electrical stimulation. The devices discussed here are fabricated using a unique transfer-free process which leads to a multi-layer graphene with the highest charge storage capacity among all reported CVD-graphene electrodes to date. During the second part, this *talk will focus on the development of ultrasound-compatible neuroelectronics to enable systematic studies to elucidate the mechanisms of ultrasound neuromodulation.*

4:30 PM SB04.03.03

In Vitro Recording of Intracellular Action Potentials of Cardiomyocytes Using Printed Electrolyte-Gated Polymer Field-Effect Transistors *Adrica Kyndiah[1], Giulia Zoe Zemignani[1,2], Luca Sala[3], Carlotta Ronchi[1], Aleksandr Khudiakov[3], Giuseppina Iachetta[1], Rosalia Moreddu[1], Stefano Chiodini[1], Gabriele Tullii[1], Fabrizio A. Viola[1], Peter John Schwatrz[3], Gabriel Gomila[4], Francesco De Angelis[1], Maria Rosa Antognazza[1] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Istituto Auxologico Italiano, Italy; [4]Institute for Bioengineering of Catalonia, Spain*

Excitable cells such as cardiomyocytes exert their function through a complex interplay of ion channels that regulate selective ion fluxes across the membrane. This process generates Action Potentials (APs), which are rapid changes in the membrane voltage that occur spontaneously or as a consequence of an electrical stimulus. The shape, duration and amplitude of the AP convey relevant information about the physiological state of the cell. Currently, most electrophysiology tools for probing intracellular action potentials are either invasive or require complex manufacturing processes. There is a high demand for minimally invasive, high-throughput technologies capable of scalable recording of intracellular action potentials in electrogenic cells. To facilitate a cost-effective and non-invasive probing platform, based on devices that can be effortlessly fabricated and processed from solution using large-area printing techniques, we propose planar Electrolyte Gated Field-Effect Transistors based on solution-processed carbon based semiconductors. Remarkably, despite the planar geometry of the device, we could demonstrate the spontaneous recording of intracellular action potentials from a monolayer of human induced pluripotent stem cells derived Cardiomyocytes. The effect of drugs on the AP shape, duration and frequency was investigated. The device's simplicity and high signal-to-noise ratio pave the way for low-cost, reliable, and flexible biosensors and arrays, enabling high-quality parallel recording of cellular action potentials.

4:45 PM SB04.03.04

Magnetically Reshapable 3D Multi-Electrode Arrays of Liquid Metals for Electrophysiological Monitoring of Brain Organoids *Enji Kim, Eunseon Jeong, Inhea Jeong, Junghun Kim, Seungwoo Cho and Jang-ung Park; Yonsei University, Korea (the Republic of)*

Brain organoids have emerged as a miniaturized substitute for the human brain to investigate the electrophysiological developments and mechanisms in three-dimensional (3D) neural network circuits. To comprehend the volumetric neural connectivity of a brain organoid, it is crucial to monitor the spatiotemporal electrophysiological signals within the organoid, known as intra-organoid signals. However, previous methods risked damaging the 3D cytoarchitecture of organoids, either through sectioning or inserting rigid needle-like electrodes. Also, the limited numbers of electrodes in fixed positions with non-adjustable electrode shapes were insufficient for examining the complex neural activity throughout the organoid.

Herein, we present a magnetically reshapable 3D multi-electrode array (MEA) using direct printing of liquid metals for electrophysiological analysis of brain organoids. The adaptable distribution and the softness of these printed electrodes facilitate the spatiotemporal recording of intra-organoid signals. The height of these liquid 3D probes is controllable to monitor electrophysiological signals from entire 3D spatial points in the organoid. Furthermore, the unique capability to reshape these soft electrodes within the organoid using magnetic fields allows a single electrode in the MEA to record from multiple points, effectively increasing the recording site density without the need for additional electrodes. This multi-spot detectable MEA can be advantageous for the 3D mapping of intra-organoid neural networking circuitry, and it offers a promising solution to overcome the limitations of previous methods and providing elaborate insights into the electrophysiological volumetric networks of brain organoids.

SESSION SB04.04/SB09.03: Joint Session: Cell Systems Integration I
Session Chairs: Donata Iandolo and Achilleas Savva
Tuesday Morning, December 3, 2024
Hynes, Level 3, Room 309

***Nanostructured Piezoelectric Polymers as Soft Electromechanical Interfaces for Biology** Sohini Kar-Narayan; University of Cambridge, United Kingdom*

The mechanical and electrical environment of a cell is crucial in determining its function and the subsequent behavior of multicellular systems. Platforms through which cells can directly interface with mechanical and electrical stimuli are therefore of great interest. Piezoelectric materials are attractive in this context because of their ability to interconvert mechanical and electrical energy, and piezoelectric nanomaterials, in particular, are ideal candidates for tools within mechanobiology, given their ability to both detect and apply small forces on a length scale that is compatible with cellular dimensions. Properties of piezoelectric polymers at the nanoscale can be significantly different to their bulk properties. [1] The ability to engineer material properties at the nanoscale can give rise to a wide range of applications of these materials in fields such as biomedicine and energy harvesting. Our research involves understanding structure-property and functionality relationships in novel polymer-based piezoelectric nanostructures, with a focus on the role of phase, crystallinity and morphology on their functionality. At the same time, these nanomaterials can also be integrated into electromechanical devices for biology. For example, we show that poly-l-lactic acid nanotubes, grown using a melt-press template wetting technique, can provide a "soft" piezoelectric interface onto which human dermal fibroblasts readily attach. [2] Interestingly, by controlling the crystallinity of the nanotubes, the level of attachment can be regulated. Through detailed nanoscale characterization of these nanotubes, we show how differences in stiffness, surface potential, and piezoelectric activity of these nanotubes result in differences in cellular behavior. We also demonstrate the use of advanced microscale additive manufacturing techniques to create soft functional interfaces based on piezoelectric polymer nanostructures for both sensing and stimulation of cells, and also to enhance and control piezoelectricity in aerosol-jet printed structures based on collagen [3] for possible applications in tissue engineering.

***Investigating Cell-Substrate Interactions Using Fib-Sem in Neuroelectronics Application** Claudia Latte*

Bovio[1,2] and Francesca Santoro[1,3,4]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Naples Federico II, Italy; [3]RWTH Aachen University, Germany; [4]Forschungszentrum Jülich GmbH, Germany

In tissue engineering, understanding the interaction between cells and substrates is crucial for the development of neuroelectronic devices[1,2]. Focused Ion Beam – Scanning Electron Microscopy (FIB-SEM) has emerged as a powerful technique to investigate these interactions, particularly as we transition from 2D to 3D environments. This study highlights the use of FIB-SEM in examining the electromechanical coupling between primary cortical neurons and biomimetic microelectrodes. Utilizing advanced techniques like two-photon lithography and "salami slicing" for precise milling and imaging, the study preserves neuronal integrity through ultra-thin plasticization[3–5]. This method enables high-resolution 3D reconstructions, revealing how neurons conform to microelectrode topographies. The findings demonstrate that neuron membranes deform inward around nanoscale protrusions more readily than outward around invaginations, influencing the cleft width between cell membranes and substrates. This deeper understanding of cell-material interactions has significant implications for the design and functionality of medical implants and biosensors, advancing the field of neuroelectronics.

9:15 AM SB04.04/SB09.03.03

Scalable Fabrication of 3D Structured Microparticles Using Induced Phase Separation *Sohyung Lee[1,2] and Dino Di Carlo[3]; [1]Harvard University, United States; [2]Brigham and Women's Hospital, United States; [3]University of California, Los Angeles, United States*

We introduce a high-throughput method to manufacture 3D structured microparticles at rates of greater than 40 million/hour using a parallelized step emulsification device and temperature-induced phase-separation of polymerizable polyethylene glycol/gelatin aqueous two phase system. The resulting particles are spatially patterned with gelatin, which enables selective cell attachment in the cavity of particles and local capture of secreted molecules. We demonstrate its application as a high-throughput single cell analysis platform.

Microparticles with defined 3D shapes and spatially-tailored chemical functionality enable new opportunities in biotechnology at the scale of cells and tissues. The current approach to manufacture these shaped particles requires precise injection of multiple polymer precursors into a flow focusing microfluidic device which has a limited scalability. Further, these previous approaches lacked the ability to spatially pattern different chemical functionalities, limiting the flexibility of the platform. In this report, we introduce a new induced-phase separation concept to overcome tradeoffs between particle complexity and fabrication throughput for the manufacture of *microparticles with tunable localized surface chemistry and shape.*

Phase separation of polyethylene glycol (PEG) and gelatin is dependent on the temperature of the system due to the conformational change of gelatin upon cooling. Using a microfluidic droplet generator, we constructed two isothermal binodal curves, corresponding to which PEG and gelatin undergo phase transitions at 4 and 22 °C respectively. By using compositions of the PEG/gelatin solutions located at points between the two binodal curves a transition is enabled from a miscible solution to a phase-separated state induced by the temperature change. Using the conditional phase separation of PEG and gelatin, photocrosslinkable PEG and gelatin ATPS droplets were generated and crosslinked with UV light to form uniform microparticles. The morphology of the droplets and resulting particles were controlled by changing the composition of PEG/gelatin solution. We used fluorescein isothiocyanate (FITC)-conjugated gelatin to demonstrate the particles were selectively functionalized on their inner cavities with higher densities of gelatin, which we showed was beneficial for their application as a platform for cell-carriers and reaction vessels to perform single-cell assays.

We manufactured hydrogel microparticles at rates of greater than 40 million/hour with localized surface chemistry using a parallelized step emulsification device and temperature-induced phase-separation. The localized gelatin on the cavity promoted deterministic attachment of cells only within the cavities via integrin binding. Cells adhered to nanovials could be sorted using standard fluorescence activated cell sorting (FACS) and higher cell viability was achieved for cells attached to nanovials compared to unbound cells, implying that these nanovials provide protection from fluid shear stresses during the sorting process. Localized gelatin was modified with different biomolecules to capture secretions from encapsulated cells. Secretion assay with human IgG producing chinese hamster ovary (CHO) cells demonstrate the ability to capture secretions on particles containing cells without crosstalk to neighboring particles.

We overcome previous barriers to achieve scalable production of hydrogel microparticles with localized surface chemistry using a parallelized step emulsification device and temperature-induced phase-separation. The engineered particles was utilized as individual cell carriers modified to run assays on single cells, opening of numerous applications in functional screening of cells at throughputs of 100,000s of single cells.

9:30 AM *SB04.04/SB09.03.04
In Vivo Development of Organic Conductors—Bridging the Mismatch in Bioelectronics *Xenofon Strakosas; Linköping University, Sweden*

The field of Bioelectronics aims to integrate electronics with biology, offering promising opportunities across various domains. A significant challenge in this field is the mechanical mismatch between rigid electronics and the soft nature of living tissues. To address this, soft and flexible bioelectronic devices are being developed using microfabrication and printing techniques. In contrast, biological processes polymerize small molecules to create intricate micromachines. Inspired by these biological processes, we utilize thiophene-based monomer systems and enzymatic processes for the in vivo development of organic conductors. By harnessing the advantages of this approach, we successfully achieved the in situ formation of conducting polymer gels within living organisms. These gels exhibit mechanical properties that closely resemble those of natural tissues. Furthermore, we demonstrate the enzymatic construction of organic conductors in various tissues and their application as active materials in organic electrochemical transistors. Our approach offers a solution to the limitations of conventional methods, providing opportunities for the development of novel, soft, and biocompatible electronic interfaces. This advancement in Bioelectronics opens new avenues for healthcare, bioengineering, and beyond.

Peptidic and Polymeric Phototransducer Biomaterials for Modulating Cardiac Form and Function *Herdeline Ann Ardoña; University of California, Irvine, United States*

The cellular machinery of excitable cells, such as cardiomyocytes, processes a myriad of biophysical cues from its local environment that influence tissue morphogenesis and normal tissue functionality. This presentation focuses on the development of peptidic and polymeric biomaterials capable of modulating cellular signals and their corresponding tissue function via the transduction of optical and electrical phenomena at the interface of excitable cell-material in vitro. The molecular makeup of these biomaterials is carefully designed with self-assembling, organic pi-conjugated networks to endow them with unique optoelectronic properties that dynamically interact with electroactive living units. We utilize peptide conjugation to these materials for presenting bioadhesive epitopes to the cells, as well as for facilitating non-covalent interactions (i.e., energy donor-bearing peptides and their complementary acceptor-bearing sequence) resulting in hierarchically ordered structures that maximize transport efficiency. The peptide chains also provide a functional handle for covalently stabilizing the transducer units in topographically defined substrates, altogether offering several advantages for the tunability of the resulting bioscaffolds. To date, our biomaterial designs have yielded scaffolds that are photocurrent generating and can be micropatterned on surfaces as bioscaffolds to induce cardiac tissue anisotropy. In the future, we envision that this class of bioscaffold that induces light sensitivity to native (or gene modification-free) excitable cells when interfaced with them will offer advancements in promoting regenerative and maturation processes for electroactive tissues with high spatiotemporal resolution.

11:00 AM SB04.04/SB09.03.06

Cytomorphic Double Network Hydrogel for Molecular Biosensing *Amar Zouboye, Baris Kumru and Filipe A. Cardoso; Delft University of Technology, Netherlands*

In the past decade, there has been an increasing interest in real-time monitoring signals from in-vitro cells to learn how they interact. Of particular interest is the molecular communication between cells. Molecular biosensors must specifically detect molecules in complex biological environments containing multiple biomolecules and cells that can interact with the device in an undesirable way. Among these interactions, the non-specific adsorption of biomolecules to the sensor surface and the blockage of the bioreceptors by the cells (biofouling) are the most impactful on the sensor performance and lifetime [1].

To reduce these unwanted interactions, researchers have coated biosensors with additional materials. Hydrogels are excellent materials for reducing biofouling in biosensors due to their controlled porosity. The hydrogel's pores function as a semipermeable filter, only allowing relatively small biomolecules to diffuse through the hydrogel structure to the active sensing site and blocking larger biomolecules or cells. Hydrogels also allow bioreceptor integration, enabling selective molecular biosensing [1]. Another interesting approach relies on supported lipid bilayers with transmembrane proteins that allow only specific biomolecules to pass to the sensor's surface [2]. However, both hydrogel-based filters and lipidic bilayers may inhibit the performance of the bioreceptor (e.g., aptamers) at the biosensor's surface because of steric hindrance.

To solve this limitation, we propose a device that mimics the functioning of a cell, the best biosensor ever created in nature. Cells have a membrane that separates the interior and outer world. The cell membrane selectively allows specific molecules to pass to the interior, where the biorecognition and metabolic processes happen. In this work, we propose to mimic the cell structure to improve biosensing by using a double hydrogel network, which we call the cytomorphic double network hydrogel (CDNH). This CDHN comprises a structural hydrogel semi-sphere to mimic the inner cell cytoskeleton and an outer shell to mimic the cell membrane. For the inner network, we used a poly (ethylene glycol) diacrylate (PEG) hydrogel with a large pore size that allows the diffusion of the *target molecules to the receptors. It also aims to reduce the steric hindrance, giving enough space for the target analyte to bind to the receptors. Binding bioreceptors (i.e., aptamers) to the structural PEG hydrogel is also possible via chemical free radical polymerization. The outer shell is implemented by a copolymer polyacrylamide hydrogel network with a very dense mesh (nanopores), allowing only small molecules to pass. This CDNH is then attached to Au electrodes to perform electrochemical biosensing. In this paper, we will demonstrate the filtering ability of the CDNH with confocal microscopy, show preliminary results of electrochemical biosensing and SEM images of the CDNH.*

11:15 AM SB04.04/SB09.03.07
Conductive Thiophene-Based Fibers Assembled by Living Cells as Novel Bioelectronic Materials *Ludovico Aloisio[1,2], Giuseppe Maria Paternò[1,2], Francesca Di Maria[3], Mattia Zangoli[3], Filippo Monti[3], Guglielmo Lanzani[2,1] and Zeev Valentine Vardeny[4]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Consiglio Nazionale delle Ricerche, Italy; [4]The University of Utah, United States*

In recent years, it has been observed that living cells can be employed as active synthesis platforms for the assembly of intrinsically biocompatible bioelectronic materials. This process, which lies at the interface between living and non-living matter, is of fundamental interest since self-assembly in-vivo could allow circumvention of the blood-brain barrier, enabling the delivery of large aggregates or even devices to the brain. Within this context, thiophene-based compounds are pivotal materials for organic bioelectronics, owing to their biocompatibility and their capability for both electronic and ionic conduction.
Here, we report on the cell-mediated assembly of semiconductive nanofibers composed entirely of dithienothiophene-S,S-dioxide (DTTO) aggregates. This molecule spontaneously penetrates the cell membrane, and fibers originate inside cells with the aggregation of the DTTO. These fibers grow "through" cells, reaching and piercing the plasma membrane in one cell to penetrate the adjacent cell, without causing cell death. We extensively characterized the photophysics of DTTO molecules during the various stages of fiber production through steady-state and time-resolved spectroscopy. We observed that the fibers are formed entirely from DTTO aggregates, which dictate the conductivity of the nanostructured material, and described the interaction between DTTO molecules and the protein scaffold. By complementing the spectroscopic data with theoretical calculations, single crystal X-ray diffraction and electrical conductivity measurements, we discovered an extended polymorphism of DTTO in the solid state. Our results suggest that the aggregation occurring in living cells is somewhat unique to the biotic phase, involving at least part of the cell machinery. As the fibers exhibit electrical conductivity, they present a method to directly stimulate cells or to induce artificial gap junctions between cells, potentially affecting signal propagation as occurs in cardiomyocytes, or in general, influencing cell population behavior.
Further studies on the fiber production process are in progress, aiming to pave the way for a wide range of new cell-mediated syntheses of materials or devices.

11:30 AM *SB04.04/SB09.03.08
Neuromorphic Biomaterials for Cell Interfacing *Francesca Santoro; Forschungszentrum Jülich/RWTH Aachen University, Germany*

In the field of organic neuroelectronics, the use of organic polymers shows promising results for the application in biological interfaces, because of their biocompatibility and mixed ionic and electrical conduction. These devices were shown to have neuromorphic properties emulating the synaptic plasticity of biological neuronal networks. Furthermore, they exhibit the ability to be integrated with cells and show response to neurotransmitters. However, they do not exhibit the 2.5D/3D features, characteristic of neuronal cells.
We identified different geometries for the structures that resemble dendritic spines and whole neuronal morphology made of soft and rigid composition. These have been produced via two photon polymerization and electrodeposition of PEDOT-based blends. Thin shapes spines that can initiate contacts with presynaptic terminals, crucial in the early stages of spinogenesis; mushroom shapes that result from the plastic and dynamic reshaping of neuronal circuits during synaptic development; and stubby forms.
Our results show that microelectrodes and in general surface topography can impact directionality and influence neural network remodeling on bioelectronic devices, particularly affecting the growth cone phase, causing a shift from pausing to a resting state. Importantly, we have demonstrated that the growth cone rate changes in response to different pitch configurations. Our research has revealed that biomimetic topographical cues can quickly affect membrane adhesion proteins and enhance efficiency, as shown through the 3D reconstruction integrated into an electrical equivalent model. Looking toward future applications in controlling signal dissipation, this work has the potential to improve the recording of electrogenic cells towards seamless recognition and integration of artificial neuronal electrodes into biological neuronal networks in vitro and in vivo.

SESSION SB04.05: Cell Systems Integration II
Session Chairs: Anna-Maria Pappa and Xenofon Strakosas
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 309

1:30 PM *SB04.05.01
Organic Bioelectronics Grown onto Cells and in the Brain *Magnus Berggren; Linköping University, Sweden*

An array of different thiophene-based monomers and trimers has been synthesized that combines electronic, chemical, and pharmaceutical functions. These materials have been applied onto and into various cell and tissue systems to form seamless bioelectronics that is amalgamated with biology. Selectivity to specific biological components and structures enables us to form well-defined electroactive structures and devices that promise for radically new tools to record and stimulate biological functions, such as neuro-signaling. Our goal is to apply this new bioelectronic toolkit to different disease models, such as neurodegenerative diseases.

2:00 PM SB04.05.02
Programmable Multifunctional Microrobots for Cell Patterning *Sambeeta Das; University of Delaware, United States*

The field of micro-robotics has emerged as an intriguing new area of research that has the potential for significant applications in biomedicine, both in vitro and in vivo, taking advantage of the untethered actuation and small size of the microrobots. Examples of applications of microrobots include targeted cargo delivery, microsurgery, and cellular manipulation. Of particular interest are multi-modal actuated microrobots which potentially offer greater adaptability, robustness, and capability to perform a variety of tasks. Additionally, modular microrobots provide *exciting possible applications due to their ability to reconfigure into various shapes, create structures that may be difficult to fabricate as one whole unit, and be assembled on-site. Here, we present a microrobot that is actuated by both magnetic and acoustic fields and forms modular microstructures of various shapes. We demonstrate the use of these microrobots for cellular manipulation by creating patterns of cells on a surface.*

Osmotic-Capillary Principle Inspired Epidermal Biofluid Sampling and Continuous Sensing *Tamoghna Saha; University of California, San Diego, United States*

The current market for biosensor-based health monitoring is continuously rising. The demand for biosensors is proportionally rising majorly due to the following two reasons: (a) Biosensors as either wearables, or in-situ point-of-care (POC) testing platforms allow rapid, on-site monitoring of several disease biomarkers under decentralized settings, (b) Such platforms can allow continuous tracking of one's health status non-invasively and without the intervention of trained medical professionals. Despite the research progress with alternative (to blood) biofluids as essential candidates for disease biomarker detection, a majority of these remain difficult to be accessed continuously.[1] As an alternative, sweat can be generated continuously on-skin via physical exertion and is an useful repository for disease biomarkers. However, conventional sweat-based devices function with active perspiration (sweat on skin prior testing), which makes them inoperative under exertion-free low sweat rate conditions. We demonstrate a new principle for the design of wearable patches which are capable of extracting sweat under both resting and actively perspiring conditions using osmotic pressure difference for pumping, and evaporation for liquid disposal.[2] Our patch is composed of silicone, hydrogel, and a paper microfluidic conduit with a site of evaporation at the end (evaporation pad). The hydrogel (pump) is equilibrated with a high concentrated solution to build up the desired osmotic strength to extract sweat from the skin under rest.[2] The sampled sweat analytes can be analyzed directly on the paper channel with both colorimetric[3] and electrochemical sensing[4] methods. The analyte amount also depends on the dimensions of the paper channel, hydrogel area and paper pore size. Human trials have shown the potential to extract sweat and analyze it for lactate, glucose, vitamin C, and levodopa under both resting and non-resting conditions. I will discuss their correlation with blood concentrations and even focus on how osmotically sweat derived glucose can be a valuable candidate (in addition to ISF) towards next-generation continuous glucose monitor development. Furthermore, the concept can even be used in a biofuel cell for continuous bioenergy harvesting at rest. Our group is currently investigating how this sweat sampling concept can be further integrated with microneedle patches for prolonged interstitial fluid (ISF) sampling (US Patent App #18/217392). Overall, the successful execution of such novel sampling methods to point-of-care and wearable platforms holds great potential in laying the foundation for next generation epidermal devices for personalized metabolic monitoring.

2:30 PM BREAK

3:00 PM SB04.05.04

Controlling Mammalian Cell Detachment via The PEDOT:PSS Redox Reaction *Caroline McCue[1], Sean M. Parks[1,2], Domitille Avalle[1] and Kripa K. Varanasi[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Michigan–Ann Arbor, United States*

Cell-based assays are some of the most common experiments for biomedical research across a wide range of fields. Many researchers perform cell culture tasks daily at large scale. Therefore, developing a fast, simple, enzyme-free, non-damaging and effective technology for on-demand cell detachment could improve the ability to culture delicate cell types, as well as enable new modalities for automating cell culture workflows. Here, we demonstrate the use of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) surfaces as a cell culture surface with excellent biocompatibility, and the ability to significantly decrease cell adhesion on demand. The application of AC voltage to PEDOT:PSS cycles a redox reaction which results in ion flux at the cell-surface interface, and disrupts cell adhesion, allowing cells to be more easily detached from the surface. The application of 5V resulted in cell cells becoming more rounded within minutes. At the same shear force (1.5nN), cell detachment can be increased from 1% to 95% by tailoring the frequency of the voltage applied. For this system, the optimal frequency was found to be 0.05 Hz. However, at higher frequencies (a frequency of 0.1 Hz and above), the redox reaction does not have time to fully complete, and the cell adhesion is not significantly impacted. Cell viability was not significantly impacted by the use of PEDOT:PSS as a cell culture material or by the application of voltage to the surface, with viability >90%. In all, this suggests that PEDOT:PSS could be used as a cell culture material that allows for on demand cell detachment via a simple voltage application.

3:15 PM SB04.05.05

Supra- and Sub-Threshold Intracellular-Like Recording of 2D and 3D Neuronal Networks Using Nanopillar Electrode Arrays *Shivani Shukla[1], Joshua Schwartz[1], Callum Walsh[2], Wen Mai Wong[2], Vrund Patel[1], Melody Hsieh[1], Chichi Onwuasoanya[1], Shaoming Chen[1], Andreas Offenhaeusser[3], Gert Cauwenberghs[1], Francesca Santoro[3], Alysson Muotri[1], Gene W. Yeo[1], Sreekanth Chalasani[2] and Zeinab Jahed[1]; [1]University of California, San Diego, United States; [2]Salk Institute, United States; [3]Forschungszentrum Jülich GmbH, Germany*

Nanoscale bioelectronic sensors which harness the cell/nanomaterial interface have recently emerged as a promising in vitro approach to correlate single cell behavior to network activity. Probing and manipulating cells within semi-native environments requires nanomaterials that do not cause immediate stress or ultimate degeneration. Typical gold standard electrophysiological techniques, such as patch clamp or calcium imaging, have enabled neuroscience breakthroughs, but today present limitations related to scalability, temporal resolution, and invasiveness.[1] One solution offered by previous researchers has been multiplexed, intracellular-like electrophysiology using nanostructured electrode arrays (NEA). These arrays of nano-scale vertical conductive or non-conductive structures leverage the malleable nature of a cell's plasma membrane to create a region of high-seal resistance, allowing for tight electrical coupling between the electrode and cell.[2–4] Upon a brief electrical pulse, the membrane is temporarily permeabilized, allowing the electrode to gain intracellular access. While the nature of these intracellular signals is poorly understood, an ensemble of integrins and curvature-sensitive proteins allow the plasma membrane to adhere to the underlying nanostructures through curved adhesions.[5] With these devices, signals obtained from cellular networks can be used to evaluate novel drugs,[6] monitor maturation over time,[2] identify cellular subtypes,[7] and even transfect single cells.[8] A critical gap in NEA technology is the optimization of various nanostructures to target different kinds of cell sizes, morphologies, and structures. Here, we optimize the electrode size, chemical functionalization and device packaging to achieve intimate contacts with neurites and somata in diverse neuronal cultures. Using these optimized NEAs, we show that intracellular-like signals can be recorded from primary neurons, iPSC-derived neuronal networks, and brain organoids. We also use pharmacology to confirm the validity of these recordings. Furthermore, we present a novel spike detection algorithm for characterizing diverse spiking datasets, which include extracellular field potentials, extracellular action potentials, intracellular postsynaptic potentials, and intracellular action potentials. We believe that our findings will lead to biological discoveries relating subthreshold synaptic activity to neuronal network behavior, elucidate the role of excitatory-to-inhibitory imbalances in neurological disorders, and pave the way for analyzing *diverse spiking datasets within neural signal processing.*

An Electro-Mechanical Perspective for Microphysiological Systems *Massimo Mastrangeli; Delft University of Technology, Netherlands*

Microphysiological systems (MPS) aim to capture in-vitro the native (patho)physiology of living tissues and organs. They stand out from traditional cell cultures thanks to the provision of tailored topography, multi-physical stimulation and dynamic cues to synthetially recapitulate a realistic microenvironment. Additionally, MPS should enable continous and potentially real-time monitoring of cell and tissue conditions to facilitate long-term culturing and track responses to endogenous (e.g., phenotypical maturation) and exogenous processes (e.g., drug administration). Whereas the current main driving force behind the development of MPS is the potential of improving the quality and speeding up the conclusion of drug development processes, the longer-term promise lies in more comprehensive, bottom-up understanding of organismal physiology alongside personalized medicine. Here we argue that an electro-mechanical perspective is particularly convenient to address standing technological challenges in the way of further development of MPS. These challenges include integrated stimulation and sensing of cell and tissue cultures, convenient and industrially-compliant upscaling of device fabrication, and co-existence of partly-conflicting requirements from fit-for-purposeness and standardization - traits which recent MPS developmental roadmaps have indicated as critical. To articulate the feasibility and benefits of the proposed perspective, we present a set of MPS fabricated using a consistent toolbox of multi-material, wafer-level microfabrication technologies and addressing a variety of microphysiological purposes: MPS for engineered heart tissues with integrated microelectrodes for electric pacing and capacitive recording of cardiac contractile dynamics; MPS with integrated charge and field-potential sensing of cell electrophysiology; MPS with arrays of three-dimensionally stacked and electrically-addressable microelectrodes for spatial tracking of inter-neuronal signaling; a microfluidic MPS with integrated electrodes for 4-point transendothelial electrical resistance sensing. Furthermore, the concept of the smart mutli-well plate is introduced to demonstrate how fit-for-purpose MPS can be subsumed into a standardized, modular and easy-to-use technology platform compatible with existing microfluidic standards and laboratory workflows and suitable for large-volume industrial production. Grounded in decades of technological advancements and informed by mature experience in the microelectronic *domain, the electro-mechanical perspective may deliver comparable benefits and outlines of progress to bring MPS to the widest adoption.*

4:00 PM SB04.05.07
Optimizing Magnetic Hyperthermia Parameters—Enhancing Cell Viability for Neuromodulation *Shahar Shalom and Dekel Rosenfeld; Tel Aviv University, Israel*

Magnetic Hyperthermia exploits magnetic nanoparticles (MNPs) to locally increase the temperature in cell surroundings while exposed to external alternating magnetic fields (AMFs). MNPs in size of 20-22 nm demonstrate hysteresis behavior under AMFs, resulting in heat dissipation. The low electromagnetic attenuation in the body's tissues enables AMFs penetration to deep organs. Moreover, coupling the properties of the applied AMFs with the MNPs' properties allows efficient heat dissipation.
With the development of such applications for cancer hyperthermia and neuromodulation, there is a high demand to verify the approach's safety and eliminate damage to cells and surrounding tissues. To this end, we assessed cell viability while exposed to magnetothermal stimulation in vitro in two-dimensional and three-dimensional cultures. We examined the AMFs' parameters, e.g. stimulation duration and field amplitude, and MNPs properties. Furthermore, we conducted thorough examinations of different heating rates, and different MNPs concentrations to determine the requirement for enhancing cell viability.
Our research contributes to a more profound understanding of magnetic hyperthermia, providing insights for establishing appropriate infrastructures and conducting experimental procedures. Our results enhance the translational potential of magnetothermal stimulation for neuroscience and tissue engineering.

4:15 PM SB04.05.08
Innovative Approaches in Tumor-Treating Fields—The Impact of Electric Field Orientation on GBM Organoid Dynamics *Kian Kadan-Jamal; University of Cambridge, United Kingdom*

Tumor-Treating Fields (TTFs) are a therapeutic modality that has been approved by the FDA for the treatment of glioblastoma (GBM), a type of brain cancer known for its poor survival rates. This approach utilizes low-intensity, intermediate-frequency alternating current (AC) electric fields to disrupt the cellular activities of actively dividing tumor cells. This study specifically examines the impact of multi-directional electric fields on GBM organoids using advanced multi-electrode configurations. The focus of the research is to understand how the orientation of the electric fields affects the growth patterns of the organoids, including their size, shape, and thickness. The study combines experimental methods with computational modeling to predict and analyze the biophysical effects of the electric fields at different orientations. The findings of this research aim to improve our understanding of the mechanism of action of TTFs and suggest that manipulating the orientation of the electric fields could lead to improved therapeutic outcomes. The ultimate goal of this research is to propose enhancements in device design that could facilitate broader clinical adoption and improved efficacy in treating GBM.

Cellular Signalling Pathway Regulation via Polyelectrolyte-Graphene Oxide Ionic Bipolar Junction Transistor

Yixin Zhang, Konstantin G. Nikolaev, Jia Hui Bong, Konstantin S. Novoselov, Vitaly Sorokin and Daria V. Andreeva; National University of Singapore, Singapore

Calcium homeostasis is essential for a wide range of physiological functions, from muscle contraction and neurotransmitter release to bone health and blood clotting. Abnormal calcium release from sarcoplasmic reticulum also results in arrhythmias and hypertension. Spheroid formation is a process where cells aggregate and self-organize into three-dimensional spherical structures in a low-attachment surface. The device fabricated with poly(diallyldimethylammonium chloride) (PDADMAC) coated graphene oxide (GO) membrane works as an ionic bipolar junction transistor (IBJT) with $CaCl_2$/PDADMAC as the emitter and $MgCl_2$/PDADMAC as the collector, regulating calcium ion flows under various collector-emitter voltage (V_{CE}) and base-emitter voltage (V_{BE}). It is observed that vascular smooth muscle cells (VSMC) were more compactly aligned after voltage stimulation, accompanied by a significant uprush of calcium ionic current. Also, the slight condensation of spheroids overtime and an increase of fluorescence intensity are observed, indicating stronger cytoplasmic protein activities. Our device demonstrated its potential in regulating cellular metabolism by providing ionic signals such as calcium and magnesium via external electrical stimulations. The device paves the way for in vitro Ca^{2+}-disease modeling for cardiovascular diseases like hypertension, cardiac arrhythmias and atherosclerosis.

SB04.06.02

ECIS-Based Multi-Well Array Impedance Biosensor for the Comparison of Apoptosis Responses with Various Drug Testing

Sugwon Nam, Seok-Kyu Kim, Seong-bin Yeon and Moongyu Jang; Hallym University, Korea (the Republic of)

ECIS (Electric Cell-Substrate Impedance Sensing) based biosensors monitor physiological changes in cells by measuring electrical impedance in real-time, and have been actively utilized in various recent studies [3]. This non-invasive method requires no preprocessing and minimizes cell damage while providing highly sensitive and accurate data. The ECIS-based multi-well array impedance biosensor can analyze multiple samples simultaneously, making it suitable for high-throughput screening. Previous studies have developed and validated the reliability of this multi-well array impedance biosensor. The sensor features a 2x2 array pattern with independent environments, overcoming the limitation of traditional single-sensor single-sample measurements [1]. Additionally, the array impedance pattern allows the study of various drug responses at different concentrations and can be mass-produced at low cost through semiconductor processes.

In this study, four anti-biotic drugs, Cycloheximide, Actinomycin D, Zeocin, and G418, which cause apoptosis and programmed cell death in NIH/3T3 cells, were monitor the cell-drug reaction for each drug, respectively. To prove the reliability of the sensor, Puromycin, a type of protein synthesis inhibitor, was used to induce cell death, which was accurately reflected through the impedance signal [2]. Based on this results, we conducted experiments on Cycloheximide, Actinomycin D, Zeocin, and G418, which have different biological mechanisms of action on NIH/3T3 cells. Cycloheximide blocks translation elongation by interfering with the movement of both tRNA and mRNA associated with the ribosome, Actinomycin D binds to DNA and blocks the production of RNA, Zeocin binds to DNA and induces double-strand breaks in DNA, and G418 binds to a subunit of the ribosome and stops translation of mRNA to protein, and in this way each drug induces cell death. We first defined a baseline of drug concentrations to be administered for comparative analysis with existing data for each drug. After setting the baseline concentration of each drug, the experiment was conducted by administering four concentrations with a certain ratio from the baseline concentration, and as a result, the cell death rate of different concentrations was accurately reflected through the impedance signal. In addition, the impedance signal accurately reflected the mechanism by which each drug induces cell death and the difference in cell behavior and death rate depending on

the concentration, and the difference in cell death rate of each drug was quantitatively confirmed through mathematical analysis. Compared to JuLi Br, a real-time cell monitoring device, each impedance data accurately reflected the actual cell death behavior. Thus, the multi-well impedance biosensor accurately reflected the differences in cell behavior by concentration of four drugs with different biological mechanisms, which shows promise as a new drug development platform through drug compatibility evaluation to screen drugs and concentrations suitable for cancer patients in the future.

Role of Brownian Force for Molecular Translocation in Nanopores *Won Yong Lee[1,2], No-Won Park[1], Min-Sung Kang[1] and Sang-Kwon Lee[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Uppsala University, Sweden*

Based on the previous experiments, detecting fast nanopore translocating analytes requires a high-frequency measurement system that guarantees a time resolution of better than 1 μs. This limitation may still make it uncertain whether all translocation events are unambiguously captured, as the challenge effectively shifts from increasing the sampling bandwidth to dealing with the rapidly increasing noise at frequencies typically above 10 kHz. In this work, we introduce a numerical simulation model as an alternative to discern translocation events under different experimental settings: pore size, bias, analyte charge state, salt concentration, and electrolyte viscosity. The model allows simultaneous analysis of the forces acting on a large analyte cohort along their individual trajectories, which are responsible for the analyte movement that ultimately leads to nanopore translocation. By following the analyte trajectory, it is found that the Brownian force dominates the analyte movement in the electrolyte until the last moment when the electro-osmotic force determines the final translocation act. The mean dwell time of analytes mimicking streptavidin decreases from ~6 to ~1 ms with increasing the bias voltage from ±100 to ±500 mV. The simulated translocation events are in qualitative agreement with our experimental data using streptavidin. The simulation model is also useful for the design of new solid-state nanopore sensors.

SB04.06.05

Breaking the Biofilm—Magnetic Nanoparticles for Cleaning Surfaces in Marine Environment *Payel Biswas and Irene Andreu; University of Rhode Island, United States*

Marine biofilms, which are formed by the growth of various organisms, can significantly compromise underwater equipment especially for devices like sensors and camera lenses, by obscuring sensor readings and camera clarity. They can also escalate fuel consumption and corrosion on ships by altering hydrodynamics. These persistent biofilms necessitate costly removal and maintenance, posing a challenge to marine operations. Removing bacterial biofilms early on can prevent the attachment of harmful macro-organisms. This project proposes using magnetic nanoparticles (MNPs) to remove marine biofilms under alternating magnetic fields. Spherical iron oxide MNPs (diameter ~20 nm) were synthesized by the hydrothermal method, and their morphology, crystallinity, and magnetic properties were evaluated by electron microscopy, X-ray diffraction, and static and dynamic magnetometry. The synthesized MNPs have a polyethyleneimine coating, a positively charged polymer with antimicrobial properties. The integrity of these coatings was verified and quantified using Transmission Electron Microscopy (TEM), Z-potential measurements, Energy Dispersive X-ray Spectroscopy (EDS), and Electron Energy Loss Spectroscopy (EELS). The MNPs were internalized within lab grown C. marina biofilms and placed under alternating magnetic fields. Several high-frequency alternating magnetic fields, in the hundreds

of kHz range were tested. This frequency range is designed to promote MNP heating for the MNP morphology and composition. Also, the MNPs were placed in a low-frequency magnetic field, which caused the particles to rotate due to their interaction with the magnetic field. This rotation generates mechanical torque that can disrupt the biofilm physically, augmenting the MNP's ability to disturb and displace the biofilm matrix. The morphology of the biofilm and viability of the bacteria before and after alternating magnetic field treatment were evaluated by fluorescence microscopy and crystal violet absorbance. The study investigated the most effective MNP treatment regime and the effects of mechanical or thermal excitation on biofilm and bacterial physiology. The proposed research holds potential for providing a new and effective approach to addressing the problem of marine biofilms and could be used to treat biofilm caused by antibiotic-resistant bacteria strains.

Advancing Glioblastoma Treatment—Aptamer-Mediated, Long-Circulating, Cationic, PEGylated Hybrid Liposomes with Bavachalcone

Ashwini Y. Chandane; Abhinav Education Society, India

Background: *Glioblastoma, a formidable brain tumor, poses a significant therapeutic challenge. Current treatments face limitations due to the infiltrative nature and resistance of glioblastoma cells.*
Aim: *To explore the brain-targeting efficacy of cationic, long-circulating, targeting PEGylated liposomes incorporating transferrin, folate vitamins, and cationic albumin as aptamers (hybrid-liposomes). These liposomes are entrapped with poly (lactic-co-glycolic acid) (PLGA) nanoparticles containing the anticancer ligand Bavachalcone (BCN), with the goal of advancing therapeutic strategies for glioblastoma.*
Materials and Methods: *PLGA nanoparticles were formulated to encapsulate Bavachalcone. Characterization involved TEM, FE-SEM, FT-IR, XRD, TGA, particle size, and zeta potential analysis, confirming successful formulation. Liposomes were prepared via the ethanol-injection method and characterized using a particle size analyzer, zeta potential, TEM, and CSM. In silico studies encompassed network pharmacology, docking, and simulation for efficacy assessment. In vitro cell line studies utilized U87MG, LN-229, and T98G to evaluate cytotoxic effects. In-vitro drug release study evaluate by franz diffusion method.*
Results: *In silico studies unveiled the potential inhibitory effects of BCN on glioblastoma growth. Prepared NPs exhibited a particle size of 99 ± 0.5 nm, zeta potential of -12 mV, and drug entrapment efficiency of 89.33 ± 0.5%. Liposomes displayed a favorable particle size of 201 ± 0.29 nm with a positive surface charge of 8.72 ± 0.53 mV. Encapsulation efficacy was measured at 77.8 ± 0.61% for BCN. In vitro drug release studies demonstrated significantly higher cumulative release rates of BCN over 82 h. Hybrid liposomes exhibited superior cytotoxicity and accelerated apoptosis in glioblastoma cell lines (U87MG, LN-229, and T98G) through MTT assays. Cellular uptake studies, flow cytometery study confirmed enhanced internalization in glioblastoma cells. Cell viability assays demonstrated improved cytotoxic effects on glioblastoma cells.*
Conclusion: *Bavachalcone exhibited promise against glioblastoma, supported by in silico and in vitro studies. Hybrid liposomes offer an innovative approach for enhanced drug delivery, addressing BBB challenges. This approach sheds light on the potential of natural compounds and nanotechnology for enhanced glioblastoma treatment.*

SB04.06.07

High Resolution Size Exclusion Chromatography (SEC) Purification and Isolation of Small Vesicles in Ovarian Cancer Cell Lines

Michael Callahan, Jordan E. Pagliuca, Olivia Collins and Milana C. Vasudev; University of Massachusetts Dartmouth, United States

Small vesicles are spherical membrane bound packets 30-150 nm in diameter which contain DNA, RNA, lipids, and proteins that are used for signaling and transport of cargo between cells. It is known that cancerous cells alter the molecular composition of small vesicles. Thus, detection of different types of cancer can be performed by *molecularly comparing secreted small vesicles of malignant cells to those of healthy cells through various detection methods such as Polymerase Chain Reaction (PCR) and Surface Enhanced Raman Scattering (SERS). Currently, there are multiple methods being investigated to extract vesicles. Ultrafiltration (UF) in combination with size exclusion chromatography are more readily transferred to a clinical lab setting due to lower cost and faster exosome isolation compared to the predominately used method of ultracentrifugation (UC) currently used in research settings. The isolation and purification of small vesicles were extracted from the SKOV3 cell line, a high-grade serous ovarian carcinoma (HGSOC) using ultrafiltration (UF) and high-resolution size exclusion chromatography (SEC). The vesicles were extracted on an AKTA 25 protein purification SEC system using a 1 cm diameter by 30 cm long high resolution Tricon column which was packed with Sepharose CL-6B resin. High-resolution SEC coupled with UF allows for lower levels of contaminating proteins and other biomolecules in vesicle containing media and tighter vesicle size distribution than low resolution SEC that is predominately used for SEC vesicle isolation. The isolated SKOV3 exosomes were characterized by dynamic light scattering (DLS), field emission scanning electron microscopy (FE-SEM), Protein analysis, and Bead-based flow cytometry to determine size, morphology, protein levels, and semi-quantitative vesicle concentration, respectively. Bead based flow cytometry was used to identify proteins on the surface of the exosomes with emphasis on the tetraspanins, molecular scaffolds which are known to be overexpressed in small vesicles of cancerous cells. Exosomes extracted from fetal Bovine Serum (FBS), which have high levels of lipids and lipoproteins which are also prevalent in human blood and serum samples was used to further elucidate the capability of high-resolution SEC to purify samples with tighter vesicle size distribution. The SKOV3 cell line exosomes were harvested for eventual integration on a novel photonic array design currently in development for SERS detection of malignant exosomes.*

SB04.06.08

Optimization of Piezoelectric Gamma-Phase Glycine Biocrystal Formation Using Electroanalytic Methods for Production of a Bone Healing Polymer-Nanomaterial-Glycine Composite *Bijay Dhungana[1], Craig J. Neal[1], Jiajie Sui[2], Elayaraja Kolanthai[1], Joselyn Gutierrez[3], Xudong Wang[2] and Sudipta Seal[1]; [1]University of Central Florida, United States; [2]University of Wisconsin-Madison, United States; [3]Boise State University, United States*

Piezoelectric materials find use in a broad array of technologies: functioning as actuators, transducers, and sensors. Further, piezoelectric materials have been developed with mechanical properties from low to high modulus: allowing incorporation into devices undergoing substantial deformation (e.g., for biomedical applications such as bone growth, wound healing). However, traditional materials still see limitations on their use due to economic and application-specific constraints. Biomaterials, such as γ-phase glycine biocrystals, exist as biocompatible, biodegradable, renewable, and low-cost alternatives with tunable mechanical properties compliant to biomechanical forces. The presented study was designed to further characterize/optimize a coordinative interaction between aqueous glycine and poly(vinyl alcohol)-associated hydroxyl groups which is implicated in the nucleation and preferred interfacial growth of γ-phase glycine biocrystals. The relative coordinative behaviors of select organic moieties (-R), present as end-groups of (gold) electrode-modifying self-assembled monolayers (SAMs; alkane thiol derivatives: $HS\text{-}(CH)_n\text{-}R$), were studied via electroanalytical methods. Glycine adsorption was studied in situ through continuous measure of electrode potentials, along with voltametric measures of related transient/charging currents. Electrochemical impedance spectroscopy was similarly performed in situ, as well as at discrete time points throughout the crystallization process to assess film crystallinity. Results from these studies were fit to relevant physicochemical models (e.g., adsorption isotherms, equivalent circuit models); related to crystal formation processes/behaviors; and utilized in the synthesis of low modulus, high-efficiency piezoelectric polymer/γ-glycine composites. These materials were further modified with antioxidant cerium oxide nanomaterials and utilized to induce growth and differentiation of bone cells, in vitro.

SB04.06.09

Quantification of Skeletal Muscle Fatigue in Biohybrid Actuating Systems *Emily Trotto, Daniel Ranke, Inkyu Lee, Mengdi He, Ashlee Liao, Maria Stang, Victoria Webster-Wood, Adam Feinberg and Tzahi Cohen-Karni; Carnegie Mellon University, United States*

Incorporation of biohybrid materials into soft robotics actuation systems leverages the beneficial characteristics of in vivo muscle actuation, such as tuned force output, energy efficiency, self-healing ability, and adaptability. This offers a promising alternative to synthetic-compliant materials such as shape memory alloys or pneumatics. Although proof-of-concept studies have demonstrated small-scale biohybrid actuating systems, many aspects of the system require further optimization before the desired longevity and force output can be achieved. One such aspect is mitigating performance challenges related to muscular fatigue. Metabolic biomarkers such as lactate can be correlated to contractile mechanisms which determine muscular force output. Therefore, integration of a real-time lactate sensing component into a biohybrid actuator could improve system performance by informing stimulation parameters to reduce fatigue. Here we show the development of a sense and actuation platform for skeletal muscle cells, in which two-dimensional (2D) and three-dimensional (3D) skeletal muscle constructs are electrically stimulated. A nanostructured carbon-based electrochemical sensor is used to measure the varying concentration of lactate over time, allowing for system fatigue level determination and control using varying stimulation patterns. The electrochemical sensing device presented here provides a promising alternative to more invasive methods of quantifying fatigue levels in skeletal muscle systems, such as utilizing force gauges to measure changes in output capabilities. The prospective applications of this device into a minimally invasive device for long-term continuous lactate detection could be of great assistance in development of soft robotic systems, as well as in other fields such as clinical care and diagnoses.

SB04.06.10

Flexible, Wearable and Implantable Passive Bioelectronic Sensors for Continuous Biological Signal Monitoring *Seyedamin Hashemi, Saman Ebrahimibasabi, Mostafa Sajjadi, Maryam Golshahi, Hamed Arami, Saeed Zeinolabedinzadeh and Layla Khalifehzadeh; Arizona State University, United States*

Continuous wireless monitoring of physiological variables holds the potential for transformative breakthroughs in our understanding of human health and disease, offering numerous biomedical applications. By providing real-time data on cellular and physiological processes, this technology can significantly enhance our ability to diagnose, monitor, and treat various medical conditions with unprecedented precision. Wireless pressure sensors are essential tools for recording biological signals and detecting abnormalities in areas such as blood flow, intraocular pressure, and haptic feedback in robotics. These bioelectronic devices are commonly categorized into active and passive types. Active pressure sensors involve more complex circuitry and require significant space to accommodate the circuit components and the antenna for communication or power harvesting. In contrast, passive sensors are more compact and include types such as resistive, piezoelectric, optical, and capacitive sensors. Capacitive sensors, in particular, offer advantages in sensitivity, flexibility, accuracy, and temperature independence. These sensors consist of a structured dielectric elastomer stacked between two identical spiral antennas, forming an LC tank. The dielectric material is crucial in determining the characteristics of a pressure sensor, including sensitivity, hysteresis, and resolution of the recorded biological data. In this study, we developed an elastomeric-electronic pressure sensor that autonomously monitors minute pressure changes. Leveraging advances in flexible electronic materials, we designed a wearable and implantable bioelectronic device that continuously measures, records, and transmits these changes. Our focus is on developing a scalable system of wearable and implantable passive sensors integrated with a wireless detection platform for continuous pressure monitoring. We fabricated passive pressure sensors with pyramid-shaped dielectric elastomers. We analyzed the material properties of Polyurethane and Styrene-Ethylene-Butylene-Styrene dielectric elastomers using a scanning electron microscope and Fourier-transform infrared spectroscopy to evaluate their performance as dielectric *layers in capacitive pressure sensors. The sensors were then encapsulated using Polydimethylsiloxane, followed by parylene coating, and their performance was compared with non-encapsulated sensors in terms of sensitivity. The initial capacitance and its changes due to applied force were measured using an LCR meter. Additionally, we designed a novel radio frequency pickup probe to wirelessly receive resonance frequency data at a maximum distance, using a vector network analyzer. A MATLAB code was developed to detect the resonance frequency and translate it into real-time pressure data. Finally, both encapsulated and non-encapsulated sensors underwent cytotoxicity tests to evaluate their biocompatibility in various scenarios. Detailed comparisons and analyses of the elastomers will be presented.*

SB04.06.11

Engineering a Reverse Thermo-Responsive Injectable Liquid Embolic Agent for Brain Aneurysm Treatment

Dhruva Bhat[1], Leah Abrahams[2], Shira Fisher[3], Joshua Mu[4], Catherine Suo[5], Kimberly Wang[6], Sarah Yagudayev[3], Robert Wong[7], Miriam Rafailovich[7], Aaron Sloutski[7], Ziv Peselev[7], Daniel Cohn[7] and Chander Sadasivan[7]; [1]Foothill High School, United States; [2]The Frisch School, United States; [3]Yeshiva University High School For Girls (Central), United States; [4]Illinois Mathematics and Science Academy, United States; [5]Hong Kong International School, Hong Kong; [6]Jericho Senior High School, United States; [7]Stony Brook University, The State University of New York, United States

Current treatments for brain aneurysms, such as metallic coiling, suffer from drawbacks including mass effect symptoms and coil compaction. A new method uses F88 Pluronic polymer Functionalized with dimethacrylate groups (F88DMA), the polymer crosslinks, which forms stable soft coil structures to embolize aneurysms, eventually degrading along with the dilated vessel. This project aimed to engineer an injectable liquid embolic agent (LEA) from F88DMA with the appropriate mechanical, chemical, and biological properties for aneurysm treatment.

To determine the fundamental properties of the uncrosslinked gels, rheological analysis was conducted. At approximately 24.6°C, viscosity increase indicated micelle formation and differential scanning calorimetry confirmed this micelle formation at the same temperature. A negative relationship between concentration of F88DMA and average micellization temperature was established.

Crosslinking with 1% ammonium persulfate (APS) and 3.5% tetramethylethylenediamine (TEMED) was performed to analyze the crosslinked gel mechanics. Rheological analysis revealed a linear correlation, with an R2=0.94 where lower concentration of F88DMA led to longer crosslinking times after adding APS and TEMED. Therefore, linear regression can be used to guide selection of F88DMA concentration based on desired crosslinking time.

Swelling experiments were conducted on crosslinked F88DMA samples to investigate the effects of concentration, Iohexol addition, static vs. flow conditions, and crosslinking temperatures. Mass swelling ratios were determined, and rheology was performed to correlate shear modulus with time. Initially, all gels swelled rapidly for three hours, then contracted over several days. Higher F88DMA concentrations led to greater swelling, while higher Iohexol concentrations reduced swelling. A combination of high Iohexol and low F88DMA caused the gels to contract over time. Gels exposed to flowing saline (simulating blood flow) and those crosslinked below the micellization temperature showed reduced swelling. A reduced level of swelling would enhance safety by minimizing the risk of aneurysm rupture.

To mimic cell adhesion in blood vessels, F88DMA hydrogels were immersed in a fibrinogen solution before plating human umbilical vascular endothelial cells, which were then observed over several days. Cell adhesion and proliferation were quantitatively measured using Alamar Blue assay, while EVOS microscopy provided detailed imaging. The fibrinogen-treated hydrogels exhibited significantly more properly-shaped, adherent cells and supported higher proliferation, with an average proliferation ratio of 4.54 on day 7, compared to 1.16 for the untreated gels. These results suggest that fibrinogen enhances cell compatibility and proliferation on polymer gels, making them promising for aneurysm treatment.

A stable procedure was developed to test the injectability of the polymer by attaching a syringe to a catheter, and injecting it into a model aneurysm. The F88DMA solution crosslinked through the catheter and formed a strand-like gel when exiting. The impact of Iohexol on F88DMA in the catheter was recorded as well. Blood flow was tested using water in the model to depict how the gel would act over time under the realistic setting of a blood vessel. The results showed consistent gel strands inside the aneurysm, indicating a successful procedure and suggesting that this method may be an effective and sustainable treatment for brain aneurysms. Future work will involve research on the long-term sustainability of the polymer coils in vivo.
We gratefully acknowledge funding from the Louis Morin Charitable Trust.

Innovative Organoid Assessment Incubator—Comprehensive Monitoring of Pressure and Electrophysiology in Brain Organoids with Applications in Electrotherapy Evaluation *Inhea Jeong, Jakyoung Lee, Eunseon Jeong and Jang-ung Park; Yonsei University, Korea (the Republic of)*

Brain organoids, derived from human induced pluripotent stem cells (hiPSCs), serve as advanced three-dimensional in vitro models mimicking human brain architecture and functional. To employ this aspect of brain organoids for neurodevelopmental studies, regenerative medicine, and personalized disease modeling, accurate evaluation of organoids is essential, which necessitates a tracking of their status in multi-perspective over time. However, comprehensive and chronic monitoring remains challenging due to the limitations of conventional analysis techniques, which are often invasive and disrupt the integrity of organoids. Here, we introduce an organoid assessment incubator (OAI) system, a novel platform designed for long-term monitoring of both the cellular status and neural functionality of brain organoids, while maintaining their intact structures. The OAI system employs mass density distribution as a new parameter to evaluate organoid integrity and viability, utilizing ultra-sensitive pressure sensors combined with machine learning-based 3D reconstruction. By integration of liquid metal-based multi-electrode arrays (MEAs) for minimally invasive recording of neural activity within organoids, the OAI system reliably monitored multi-aspects of brain organoids during their maturation. Furthermore, the effects of temporal interference stimulation (TIS) on brain organoids were assessed by the OAI system, demonstrating its efficacy in promoting cell proliferation, neuroplasticity, and reducing central necrosis. By enabling multi-faceted monitoring and therapeutic interventions of brain organoids, the OAI system represents a significant advancement with broad applications in neurological research and therapeutic development.

SESSION SB04.07: Optoelectronic Systems for Cells Stimulation and Recordings

Session Chairs: Dimitra Georgiadou and Charalampos Pitsalidis

Porosity-Based Silicon Nanowires for Optoelectronic Modulation *Tania Assaf, Nadi Hathot and Menahem Y. Rotenberg; Technion–Israel Institute of Technology, Israel*

Nanoscale photoelectrochemical modulation holds great potential for intracellular bioelectric interrogation, offering significant insights into cellular function. Silicon nanowires (SiNWs) are promising candidates for this purpose, as they can be engineered to exhibit photoelectrochemical and photothermal effects through methods such as doping-based homojunctions and porosity-based heterojunctions. Additionally, SiNWs can spontaneously

internalize into various cell types, providing versatility in morphology, surface functionalization, and composition. As a result, SiNWs serve as leadless probes for intracellular electrical and mechanical measurements, enabling the induction of calcium fluxes and monitoring of cellular mechanical forces. However, to facilitate the widespread use of SiNWs as leadless intracellular bioelectronic probes, their optoelectronic performance must be enhanced to enable optical modulation at feasible power densities. Furthermore, the underlying mechanisms of nanoscale optoelectronic modulation are not well understood, limiting their broader applicability. To fully utilize SiNWs as tools for intracellular investigation, it is crucial to resolve this underlying mechanism. The complex relationship between photoelectrochemical devices and their surrounding medium must be studied in the context of their nanoscale size. In this regard, optoelectronic modulation may involve photoelectrochemical, photothermal, and/or ROS-mediated mechanisms; however, the exact mechanism remains unclear.

Traditionally, doping-based heterojunction SiNWs are created using chemical vapor deposition (CVD), which generates deep traps in silicon and reduces electron-hole charge separation. In This study, we used top-down methods for producing perfectly single crystallin SiNWs with porosity-based heterojunctions, employing nanosphere lithography and stain etching, which offers advantages at the biointerface. The porous layer modulates the band structure in situ, enabling an efficient photoelectrochemical response and reduces stiffness, which minimizes mechanical mismatch with biological cells. Moreover, the single crystallinity of both the bulk and pores-silicon eliminates the deep traps within polysilicon. The resulting SiNWs have uniform diameters and consistent outcomes. To induce intracellular calcium fluxes, SiNWs were allowed to spontaneously internalized. and cells were then loaded with calcium dye, and a Spinning Disk Confocal was used to optically stimulate and record calcium fluxes simultaneously. When comparing the two fabrication methods, cells exhibited higher calcium velocity due to stimulation with the top-down method, showing less reduction in cell reaction over prolonged duration of up to 5 days. Regarding the intracellular calcium mechanism, our results show that stimulating n-i-p and p-i-n SiNWs (producing photoelectrochemical and photothermal effects) led to higher dF/F values and higher calcium propagation velocities compared to i-i-i SiNWs (thermal effects only). This suggests that the photoelectrochemical reaction was the dominant effect. Additionally, depleting intracellular calcium storage with 5μM Thapsigargin eliminated calcium fluxes in response to optical modulation of p-i-n SiNWs, confirming the internal source of calcium transients. Furthermore, both Cell-SiNW hybrids and SiNW-free cells showed elevated oxidative stress levels with and without stimulation, indicating baseline oxidative stress due to the presence of nanowires regardless of their type. SiNWs exhibit promising potential in optoelectronic biointerfaces, highlighting the need for SiNWs in bioelectric interrogation and studying intracellular cell activity.

8:45 AM SB04.07.02

3D Optoelectronic Scaffold with Impregnated Silicon Nanowires for Leadless Bioelectrical Modulation with Sub-Cellular Resolution *Menahem Y. Rotenberg and Nadi Hathot; Technion-Israel Institute of Technology, Israel*

Bioelectricity is gaining more and more interest due to its ability to modulate tissue regeneration and function. However, although substrate bound micro and nanoelectrodes are extremely useful for bioelectronic modulation of cells cultured in vitro in 2D monolayers, they lack the ability to interface cells that are inside a 3D engineered tissue construct. Thus, many leadless technologies are being developed. One of the most promising approaches for leadless electrical modulation with high spatial resolution is the use of optoelectronic nanomaterials that can transduce optical illumination to an electrical output. Free standing silicon nanowires (SiNWs) are ideal for minimally invasive intracellular biointerface as they are soft, flexible, and thus can spontaneously internalize into many different cell types. However, introducing theses silicon-based leadless probes into the inner volume of an engineered tissue without disrupting its integrity is challenging.

To address this challenge, we developed an electronic scaffold (e-scaffold)- a novel 3D macroporous scaffold from alginate and/or collagen, with impregnated optoelectronic SiNWs. The e-scaffold can be comprised of different ratios of alginate and collagen, so that cellular interactions can be enhanced towards cell-scaffold (high *collagen low alginate) or cell-cell (high alginate low collagen) interactions. Moreover, by using high alginate e-scaffolds and coating impregnated SiNWs with fibronectin, cell-Si interactions may be enhanced. During the development of engineered tissue constructs, the SiNWs within the soft and biodegradable scaffold are free to interface with the cells and form extra- and intracellular biointerfaces. Thereafter, a spinning disc confocal with integrated FRAP modulus can be used to apply local optoelectronic modulation of cells baring or interfacing SiNWs.*

We found that cells grown within the e-scaffold were able to integrate and proliferate within the 3D environment. Moreover, the cells were interfaced with SiNWs regardless to their volumetric locations. On the other hand, when SiNWs were seeded onto cells in regular scaffolds, only the superficial cells (top, bottom and perimeter of the scaffold) were interfaced with SiNWs, while intra-volumetric cells were not interfaced.

When intracellular SiNWs were optically modulated, cells exhibited an immediate intracellular local electrical response as indicated via calcium imaging. This demonstrates the utility of the e-scaffold as a platform for 3D engineered tissue with bioelectronic interrogation capabilities that is free standing, 3D accessible, spatially and temporally precise, and versatile. Moreover, when using standard bioelectronics, a finite number of electrical interrogation sites must be hard wired and their locations must be pre-determined during fabrication. However, the use of free standing SiNWs without any hard wire requirements, allows us to homogenously distribute the SiNWs within the e-scaffold so that numerous bioelectronic interfaces are formed without any limitation on the number or locations of the biointerfaces.

Interestingly, cells were found to electrically couple to one another, as electrical modulation of a specific cell, resulted in calcium flux from the stimulated cell to neighboring cells. Thus, we decided to approach a long-lasting debate of whether cardiomyocytes and myofibroblast form heterocellular electrical coupling in the heart. We have previously tackled this question in vivo, by modulating a single myofibroblast within a viable contacting heart ex vivo. Interestingly, we found that such coupling was not established, opposing our in vitro 2D monolayered cells in which they did couple. In this study we investigated whether they electrically couple in a 3D engineered cardiac tissue and found no such electrical coupling. These findings suggest that the 3D engineered cardiac tissue is much better and comprehensive model of the cardiac tissue than 2D monolayered cells.

Optical Control of Intracellular Redox Balance in Cardiovascular Cells by Conjugated Semiconducting Polymers

Camilla Marzuoli[1], Gabriele Tullii[1], Miryam Criado-Gonzalez[2], Carlotta Ronchi[3], Paola Lagonegro[1], Marco Malferrari[4], Stefania Rapino[4], David Mecerreyes[2] and Maria Rosa Antognazza[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of the Basque Country, Spain; [3]Humanitas Clinical and Research Center, Italy; [4]Università di Bologna, Italy

In cell physiology, the term "redox homeostasis" refers to the balance between oxidizing and reducing agents and is recognized as a core concept governing the entire cell cycle. An imbalance in cellular redox status is intrinsically linked to the onset and progression of numerous diseases[1]. Specifically, Intracellular Reactive Oxygen Species (ROS) concentration plays a crucial role in the control and fine tuning of several physiological functions, from cell proliferation to differentiation, from migration to metabolic activity, to specific functionalities[2]. As a consequence, there has been a growing interest in the emerging field of 'redox medicine' over the past few years[3].

Currently available treatments to modulate the cell redox balance rely on the employment of chemically controlled methods. However, this strategy often fails to achieve accurate spatial and temporal control, is not reversible and is unsuitable for finely-tuned control of sub-cellular organelles. Employing optical excitation as a stimulus to precisely modulate intracellular ROS concentration at non- toxic levels offers the opportunity to overcome these limitations, but requires the development of novel, photoelectrochemically active transducers.

To support the development of new tools for precise, non-toxic, non-invasive and on-demand modulation of intracellular ROS concentration it is therefore necessary to develop new biocompatible materials, characterized

by highly tunable electrochemical efficiency and good stability in a biological environment[4]. Moreover, stimulation protocols should be as minimally invasive as possible.
Here, we propose a novel strategy, based on the use of ad-hoc chemically functionalized semiconducting polymers, with enhanced opto-electrochemical properties[5,6]. We investigate the phototransduction process, highlighting how photoelectrochemical reactions occurring at the polymer/electrolyte interface can modulate ROS concentration on-demand.
We successfully employ extra- and intracellular delivery strategies, respectively based on polymer thin films and NPs, to achieve ROS increase within the eustress dynamic range in relevant cardiovascular cell models. We demonstrate that photoelectrochemically active organic semiconductors developed in this work potentially satisfy all the requirements for innovative in-vivo redox-based therapies, potentially advancing clinical applications in the redox medicine field.
So, we investigate the possibility to exploit photo-activated ROS to activate redox-dependent biochemical pathways with pivotal roles in cardiovascular cells, such as calcium dynamics, nitric oxide modulation, angiogenesis process[8,9].
These results open up unexplored possibilities for wireless, geneless, and optically driven regenerative therapies in the cardiovascular domain, targeting the restoration of endothelial tissue functionality, the normalization of hypervascularization stages, and over a longer perspective the optical pacing of cardiac cells.

Advanced Imaging Techniques Reveal the Dual Function of a Thiophene Based Compound to Modulate Cell Behaviours

Marika Iencharelli[1], Giuseppina Tommasini[2], Graziano Preziosi[1], Silvia Santillo[1], Nicol Spallacci[1], Mattia Zangoli[1], Soraia Flammini[1], Vittorio De Felice[1], Francesca Di Maria[1], Angela Tino[1], Maria Moros[1], Maria Antonietta Ferrara[1] and Claudia Tortiglione[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Instituto de Nanociencia y Materiales de Aragón, Spain

Living systems possess the unique capacity to produce complex structures starting from "molecular building blocks". Exogenous compounds internalized into the cell may interact with metabolic machinery and produce hybrid structures with novel properties. We previously demonstrated the capability of cells and whole animals to produce fluorescent and conductive biofibers starting from a thiophene based compound, named DTTO [1, 2]. Here, by confocal microscopy and holotomography techniques we show the diverse function played by the compound when present as monomer or following in vivo self-assembling into microfibrils. In fact, following short pulses of photostimulation the cell death was induced by the monomer, while the microfibers strongly protected the cells from the death pathway. By merging data from non invasive label free holography and detection of reactive oxidative species (ROS) we could relate the cell death to the ROS production and study the dynamic of this process. Electrophysiological recordings and in vitro assays confirmed the different cell behaviour induced by *the monomer and its self assembled form. This differences is likely due to a combination of a reduced surface area exposed by the fibers and a variation of the energy levels of the aggregated form, suggesting a DTTO dual role as photosensitizer and as novel building block for conductive materials.*

Photoelectroceuticals—Current Advances and Future Developments *Bozhi Tian; The University of Chicago, United States*

Our lab has coined the concept of photoelectroceuticals within the bioelectronics community. In this talk, I will explore the latest advancements in this field, particularly the photoelectrochemical modulation of cells and tissues. This technology enables precise control over intracellular membraneless organelles and opens new avenues for neural and cardiac modulation at the cellular level. I will present the latest materials and device concepts developed to support these applications. Additionally, I will discuss the potential translational applications of photoelectroceuticals, emphasizing their promise in clinical settings. These applications hold significant potential for targeted treatments and personalized medicine. Toward the end of my presentation, I will outline the future directions for this burgeoning field, stressing the importance of advanced materials science research to address current challenges and enhance the clinical applicability of these technologies.

10:30 AM *SB04.07.06
Intra Membrane Molecular Phototransducers *Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy*

Life-machine interfacing has broad applications in regenerative and therapeutic medicine, robotics and life enhancing technology. There are several approaches to obtain a functional abiotic/biotic interface that allows control by external stimuli. In this communication I will show that intra membrane molecular transducers have a potential in cell opto-stimulation, alternative to both the genetic strategy and the covalent engineering. I will show a class of molecular phototransducers and their specific working mechanism. In general, amphiphilic molecules bear natural affinity for the plasma membrane and successfully partition into it. The phototransducers absorb light and transform it into an electrical signal. Shining light onto those cells that incorporate the phototransducers results in their stimulation. By chemical engineering we obtained different phototransducers that act differently on the cell membrane, essentially modulating the membrane electrical properties: capacitance, conductance, surface charge. Results obtained in different cell types will be shown, together with a simple modeling of the mechanism. These results represent a new rationale for designing photo-responsive systems that operate via simple non-covalent affinity to biotargets and can be of importance for future life-machine integration.

11:00 AM SB04.07.07
Organic Semiconductor Photomodulation Enhances Maturation of PSC-Derived Cardiomyocytes *Camilla Galli[1], Nicolò Salvarani[1], Carlotta Ronchi[2], Gabriele Tullii[2], Camilla Marzuoli[2], Marco Malferrari[3], Stefania Rapino[3], Elisa Di Pasquale[1] and Maria Rosa Antognazza[2]; [1], Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Università di Bologna, Italy*

Cardiomyocytes differentiated from pluripotent stem cells (PSC-CMs) hold a great potential for the study and the cure of cardiovascular disease; indeed they have been extensively used as platform for disease modeling and drugs testing, and represent a promising source of cells for regenerative therapies. However, the immature phenotype of these cells, which differ from adult cardiomyocytes for molecular, metabolic and morpho-functional properties, is a major hurdle for their full application. Recently, a new technology based on optical excitation of light-sensitive organic semiconductors (OS) has been shown to be able to modulate cell behavior of many cell types by targeting different cellular pathways, as proliferation, angiogenesis, neuronal firing and contractility. Here, we adopted a multidisciplinary approach based on morpho-functional, metabolic and transcriptional analyses to investigate the effect of OS-photoexcitation on PSC-CMs. Analyses were performed on PSC-CMs seeded on either glass (control) or a red-light sensitive OS polymer, namely Poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta [2,1-b;3,4-b]dithiophene)-alt-4,7(2,1,3-benzothiadiazole)] (PCPDTBT), in form of a thin film. Our results revealed a significant modulation of markers of CM maturation in PSC-CMs exposed to PCPDTBT and photomodulation, showing an increased size, altered membrane capacitance, a shift of their maximal diastolic potential (MDP) toward more negative values, and augmented Ca^{2+} transient amplitude. Moreover, by Scanning Electro-Chemical Microscopy (SECM) we found a decrease in glucose uptake and lactate release upon PCPDTBT light stimulation, potentially indicating a switch toward a more adult-like metabolism in stimulated PSC-CMs. Recently obtained RNA sequencing data are in line with these results, and will provide us with hints on the underlying molecular mechanisms.
In conclusion, our data are in support of a potential effect of polymer-mediated optical photoexcitation in boosting PSC-CMs toward a more mature phenotype. We believe that the proposed approach, with a relevant effect on PSC-CM maturation and functionality, will significantly promote their full applications toward personalized medicine applications.

11:15 AM SB04.07.08
Non-Invasive Label-Free Electrical and Optical Parrallel Recordings of Electrophysiological Action Potentials of hiPS Cardiomyocytes *Julien Hurtaud, Alessio Boschi, Giuseppina Iachetta, Michele Dipalo and Francesco De Angelis; Istituto Italiano di Tecnologia, Italy*

Among the many molecules tested every years as potential drugs, 90% fail to reach the market despite sometimes more than 12 years of development and over two billion individual cost. As rejections are often related to cardiovascular issues, some cell-lines such as hiPSC cardiomyocytes have been extensively used to model drug toxicity in vitro, translating efficiently to clinical trials afterward. However, at the current state of art, parameters such as mechanical contractility, electrophysiological signals and calcium fluxes have to be measured separately, on different types of device and often on different in vitro cultures. This makes the interpretation of results difficult and therefore reduce their relevancy. In that context, we developed a novel device that: i) is able to optically record electrophysiological signals in a label-free and non-invasive manner. ii) has embedded electrodes for direct recordings of field potentials and for cell stimulation at the electrode location iii) is transparent enough to enable calcium imaging using fluorescence microscopy. Moving beyond the simple sum of these data , the device couples these modes that can be used independently and simultaneously. Thus, it provides a platform on which relevant and time-efficient studies of cardiotoxicity can be performed. One can use electrodes to pace the surrounding cells and detect discrepancies in cardiac frequency due to assayed drugs. The cardiotoxic effect can be detected at the whole culture level using the high density optical sensors. In this work, we could observe for example the respective increase and reduction in action potential duration using E-4031 and Nifedipine drugs. To conclude, this device exploits and combines microfluidics, fluorescent dyes, complex nanofabrication and pass-through electrodes to transduce the cardiac action potentials into optical signals. Using the same structure, it can also perform basic electrical recordings and stimulation, allowing deep studies of drugs cardiotoxicity, necessary to *improve drug approval rates.*

11:30 AM SB04.07.09

Azobenzene-Substituted Poly-Thiophene Nanoparticles for The Photo-Stimulation of Living Cells *Fabio Marangi[1,2], Lorenzo Gambini[3,2], Matteo Moschetta[2], Mattia Zangoli[4], Nicol Spallacci[4], Soraia Flammini[4], Francesca Di Maria[4] and Guglielmo Lanzani[3,2]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Politecnico di Milano, Italy; [4]Consiglio Nazionale delle Ricerche, Italy*

The use of biocompatible exogenous materials for the stimulation of living organisms avoiding genetic manipulation has been extensively proposed as an effective strategy. Poly-thiophenes have been employed for in vitro and in vivo photo-stimulation in the past years. Polymer nanoparticles in close proximity to the cells can induce a perturbation in the membrane due to a charge displacement in the material, resulting in a physiological response. Similarly, azobenzene-based molecules, able to insert in cells' membrane, can induce modifications in the membrane which can be reverted through photo-switching between trans- and cis-isomer. At the same time, such photochromic molecules have also proved to be effective in interacting with bacteria.

Here, we report the synthesis of a poly-thiophene with simple azobenzene substituents and the fabrication of nanoparticles. The proposed material, in the form of nanoparticles, shows a good affinity with living cells and can also induce a physiological response upon light excitation of the isomerization band. Such a system enables the simultaneous utilization of two different stimulation paradigms which may allow more precise targeting in the case of particularly functionalized azobenzene substituents. In fact, excitation bands of the thiophene and azobenzene substituents are spectrally separated. Tuning of the absorption and selectivity may be obtained with more specific azobenzene derivatives. Combination of the two different stimulation mechanisms may result in increased response when required. Moreover, such approach enables increased spatial resolution due to light confinement and limits inflammatory response associated with more invasive techniques. The electronic and optical properties of those systems also make them interesting for sensing application, since the geometrical conformation of the azobenzene branches has been found to influence the optical characteristics of the poly-thiophene backbone.

11:45 AM SB04.07.10

Materials and Designs for Photoelectroceuticals In Vitro and In Vivo *Pengju Li and Bozhi Tian; The University of Chicago, United States*

Recent non-genetic optoelectronic devices, which convert light into electrical or electrochemical currents, have demonstrated efficiency in modulating cells and tissues in vitro, ex vivo, and in vivo.[1] The potential of photoelectrochemical modulation has been explored for its wireless and remote operation, minimally invasive procedures, high spatiotemporal resolution, and immunity to interference from strong electromagnetic fields, leading to the promising field of clinical therapeutic treatments termed "photoelectroceuticals." In this context, we report innovations in materials and designs for photoelectroceuticals using silicon-based photoelectrochemical devices. By employing rational nanoengineering of monolithic silicon membranes, we developed nanoporous single-crystalline silicon for highly accurate, precise, and localized injection of minority charge carriers (electrons).[2][3] This advancement enables high spatiotemporal and multiscale biological modulation in in vitro cultured rat cardiomyocytes, ex vivo rat heart tissues, and in vivo ischemic rat heart models. Furthermore, we demonstrated reliable multisite cardiac control using millisecond-duration light pulses in a live pig heart experiment under clinical open-thoracic conditions. Additionally, we showcased closed-thoracic pig heart stimulation with a custom endoscopic operation system, highlighting its translational potential. This procedure offers new solutions for temporary heartbeat regulation following open-heart surgeries, which are performed on over two million patients worldwide each year.

Further efforts have concentrated on developing low-power, wearable, and long-term solutions for deep tissue modulation, addressing limitations of current optoelectronic devices.[4] Inspired by neurons, new materials and neuromorphic designs bridge the gap between optically accessible depths and deeper tissues. This approach significantly reduces the required irradiance for optical tissue stimulation by two to three orders of magnitude, ensuring stable performance in fully implanted, long-term applications.

***Materials and Devices for Bacteria-Bioelectronic Interfaces** Agneta Richter-Dahlfors[1,2]; [1]Karolinska Institutet, Sweden; [2]KTH Royal Institute of Technology, Sweden*

Bacterial electrogenicity, which is the capacity of bacteria to release metabolically generated electrons extracellularly across the cell membrane to terminal acceptors or vice versa, is a crucial process for bacterial growth, respiration, and cooperation with the surrounding environments. Based on the discovery of bacterial electrogenicity, bidirectional electron exchange between the bacteria and electrodes has been exploited to created novel techniques in many bioelectrochemical systems, such as microbial fuel cells, microbial electrolysis cells, and microbial electrosynthesis. Focussing on the medical aspects, our group has demonstrated an essential role for extracellular charge transfer also in a range of clinically relevant bacteria like Salmonella, Escherichia coli, Pseudomonas, Klebsiella, and Staphylococci, as shown by bacterially produced small extracellular metabolites reducing PEDOT:PSS in a screen printed organic electronic sensor. Likewise, we show that Salmonella biofilm formation can be modulated by providing charged organic electronic surfaces as interface for attachment and growth. Biofilms represents the predominant lifestyle of all bacterial species. This lifestyle, also referred to as a sessile lifestyle, is known to enhance bacterial survival in wetted natural and artificial environments. Based on conjugated oligomers, we have developed optical sensors detecting components of the extracellular matrix formed by bacteria when forming biofilms. Our technique provides a unique tool that enables dynamic, real-time analytics of biofilm formation, in contrast to traditional indicators purely identifying bacterial load. Using a combination of bioelectronic interfaces and our optical sensors, we were the first to show a direct effect of electrical charge of bioelectronic-bacterial interfaces on the production of extracellular matrix. Our collective findings have revealed dual functions of bioelectronic-bacterial interfaces, as they are able to i) detect and track bacterial multiplication, ii) track colonization and biofilm formation, and iii) modulate attachment and production of extracellular matrix in order to sensitise biofilm forming strains to the effect of antibiotics and antimicrobial compounds. Collectively, our work demonstrates that conducting polymers are excellently suited materials to be used at bioelectronic-bacterial interfaces, as a wide variety of applications can be achieved due to the bidirectional activities of the material.

9:00 AM *SB04.10.02

Biomembranes on Chip—Nanomechanical-Alchemy of Dissecting Cells into Nanovesicles and Crafting Confluent Membrane Bilayers on Planar Surfaces for Studying Membrane Events *Anna-Maria Pappa; Khalifa University of Science and Technology, United Arab Emirates*

Despite their significance, cell membranes are still an underexplored target for studying the mechanisms of diseases or drug therapies. Cell-free commercially available technologies for cell membrane studies have been limited to synthetic membranes that lack the inherent complexity found in the membrane of the cell. A recent example of a bio-integrated electronic device, the BiOET, is based on polymeric semiconductor technology and is fabricated using nano/micro-fabrication methods in conjunction with synthetic biology approaches to incorporate hierarchically organized biological models of the cell membrane. In this talk I will describe a new method to create native cell membranes, using vesicles derived from live cells, on top of conducting polymer- based microfabricated electrodes. The activity of transmembrane proteins or the degree of lipid packing in response to different stimuli can be electrically monitored, offering a direct means to characterize biological events i.e., drug toxicity or potency at the critical first contact point: membrane interaction.

9:30 AM SB04.10.03

Photocontrol of Bacteria Bioelectric Language *Giuseppe Maria Paternò[1,2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy*

The possibility to control living matter with exogenous stimuli can have tremendous impact on synthetic biology, medicine and materials science, among others. For instance achieving control over cells behaviour remains a challenge at the interface between living and non-living matter, and would enable the development of new bio-mimetic and bio-enabled materials able to perform tasks. Within this context, bacteria have arisen as "active and actively-controllable materials", exhibiting neuro-like behaviour, extended bioelectric signalling and tunable assembly properties. In the last decade, it has been observed that the regulatory element of such an active behaviour is the electrical potential across the membrane, which governs bacteria electrophysiology, metabolisms and bioenergetics. Light can be a powerful tool in these regards, as one can control the membrane potential and, thus, cell function and behaviour remotely and with relatively high spatiotemporal precision.

Here, I will show that membrane partioning of azobenzenes in bacteria can render these organisms responsive to light, without any genetic modification. In particular, we found that the isomerization reaction at the membrane location induces either hyperpolarisation or depolarisation of the potential depending on the excited state deactivation pathways, within a bio-mimetic mechanism reproducing the initial fate of retinal. I show that bacterial opto-stimulation can trigger neuron-like bioelectric signalling and can highlight the role of previously uncharacterized ion channels in bacteria electrophysiology. Finally, I also show recent results on the light-modulation of antibiotic uptake, as well as perspectives on the photocontrol of bacterial motion and assembly behavior in consortia.

9:45 AM SB04.10.04

Temporal-Spatial Control of Potassium Ions Delivery via Bioelectronics Modulates Membrane Voltage and Growth Dynamics in Bacteria Biofilms *Yixiang Li[1], Harika Dechiraju[1], Colin Comerci[2], Le Luo[1], Sydnie Figuerres[1], Niloofar Asefi[1], Ansel Trevino[1], Alexie Barbee[1], Maryam Tebyani[1], Prabhat Baniya[1], Mircea Teodorescu[1], Gurol Suel[2] and Marco Rolandi[1,3,3]; [1]University of California, Santa Cruz, United States; [2]University of California, San Diego, United States; [3]University of California Santa Cruz, United States*

Bioelectrical signaling, or bioelectricity, is crucial in regulating cellular behavior in biological systems. This signaling, involving ion fluxes and changes in membrane potential (V_{mem}), is particularly important in the growth of bacterial biofilms. Current microfluidic-based methods for studying bacterial colonies are limited in achieving spatiotemporal control over ionic fluxes due to constant flow within the system. To address this limitation, we have developed an innovative platform that integrates biofilm growth with bioelectronic ion pumps that enable targeted delivery of potassium (K^+) ions, allowing for controlled manipulation of local potassium concentration. With deterministic delivery of K^+, we adjust the concentration of extracellular K^+ and affect both the biofilm membrane voltage and growth dynamics. In our study, we observe significant changes in V_{mem} and coordination within the biofilms. Changes in V_{mem} are influenced by K^+ level where higher K^+ concentration change results in more pronounced modulation of the V_{mem}. Furthermore, we investigate the impacts of spatially controlled K^+ delivery on bacterial biofilm growth patterns and dynamics. The elevated K^+ concentrations correlating with larger growth rates enable us to direct growth in desired directions and induce anisotropy in the biofilm. These findings demonstrate that localized K^+ delivery is highly effective in controlling biofilm expansion in a spatially targeted manner. These observations offer insights into the mechanisms underlying bacterial signaling and growth and suggest potential applications of bioelectronics in bioengineering, synthetic biology, and regenerative medicine, where precise control over cellular signaling and subsequent tissue growth is required.

10:30 AM *SB04.10.05
Electron and Cation Transporting Polymer Films as Multifunctional Bioelectronic Interfaces *Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia*

The ability to sense and react to environmental stimuli is a crucial material property to harness in the development of next-generation sensors, actuators, and robotics. In this presentation, I will introduce n-type conjugated polymers as multifunctional bioelectronic interfaces. I will demonstrate how these polymers can be tailored to establish favorable interactions with catalytic enzymes as well as lipid bilayers to build biosensors. While highlighting the unique characteristics of these devices, I will delve into the potential pathways through which the polymer film generates charges and address stability concerns. Subsequently, I will explore how these polymer films respond to visible and near-infrared light by generating voltage drops at the aqueous electrolyte interface. This system is then seamlessly integrated into an adaptable circuit with outputs controlled by various stimuli, effectively mimicking the function of a light-sensitive neuron. Finally, I will unveil a novel application of the n-type films, demonstrating their capacity to enhance stem cell maturation.

11:00 AM *SB04.10.06
Cell-Free Protein Synthesis Goes Electric—Measuring Transmembrane Ion Channel Activity Using Bioelectronic Circuits *Susan Daniel; Cornell University, United States*

The sensor elements of a biological cell are its transmembrane proteins (TMP). Housed in a lipid bilayer, these species carry out a variety of functions that let the cell interact and respond to its environment. Harnessing these functions for biosensing purposes that can lead to new diagnostics, drug screening platforms, and pathogen detection tools are just a few of the promising applications possible if TMP could be integrated with sensing platforms that have an easy readout. However, this class of proteins remains challenging to study. Progress has been hindered by the difficulty in synthesizing, isolating, and incorporating them and their membrane scaffolds into a sensing platform. Cell-free protein synthesis (CFPS) is an emerging technique for synthesizing TMPs directly into a membrane environment by using reconstituted components of the cellular transcription and translation *machinery in vitro, bypassing purification and reconstitution into a membrane. Our recent goals have been to leverage this approach to integrate TMPs into supported lipid bilayers coating conducting polymer electronic circuits. Specifically, PEDOT:PSS electrode arrays, which are both transparent and electrically conductive, can be coated with lipid membranes and enable the assessment of protein incorporation and activity by optical and electrical means. We use fluorescence microscopy and electrochemical impedance spectroscopy (EIS) to characterize the synthesized TMPs. In this talk, I will share our success in incorporating several TMP ion channels into biomembrane bioelectronic devices. By dramatically simplifying TMP incorporation into a platform capable of sensing their biological function, label-free, we envision a future where large libraries of protein variants can be easily synthesized and assayed using bioelectronic circuits. This kind of scale up is necessary to mimic and achieve the systems-level sensing used in nature.*

SESSION SB04.09/SB09.05: Joint Session: New Materials and Fabrication Approaches for Bioelectronics
Session Chairs: Filipe Cardoso and Anna Herland
Wednesday Afternoon, December 4, 2024
Hynes, Level 3, Room 309

3:30 PM *SB04.09/SB09.05.01
Exploration of Hybrid Carbon Materials Through Molecular Dynamics Simulations-Guided Engineering of Polymers *Sam Kassegne; San Diego State University, United States*

The current state-of-the-art research in neural probes predominantly concentrates on either increasing channel counts for electrophysiology, increasing longevity of the implanted microelectrodes, or increasing the voltammetric sensitivity of microelectrodes for neurochemistry applications. These siloed approaches that focus largely on only ***single modality*** *at a time have slowed down progress in understanding of large-scale brain circuitry, particularly in short- and long-term behavior studies. From a microelectrode material point of view,* *carbon-based electrodes, specifically glassy carbon (GC) and graphene (Gr), have been of significant interest in addressing the research needs described above. For example, GC microelectrodes have been shown to offer a compelling platform for detection of neurotransmitters such as dopamine and serotonin at record sensitivities (10 nM). However, there are still some key factors that continue to offer obstacles to increased innovations in these carbon materials like the single-atomic layer nature of graphene that renders handling and processing of devices difficult and relatively low electrical conductivity and slow charge mobility of glassy carbon* ***along with*** *non-uniform and sporadic distribution of chemically active functional groups in both Gr and GC that is needed to promote surface chemistry for biomolecule adsorption.*

Driven by the need for addressing these gaps through the discovery of newer materials, we introduce a new approach for engineering of electrical, electrochemical, and surface properties of carbon (particularly two of its allotropes, Gr and GC), through a molecular dynamic (MD) modeling of polymer precursors, with the specific target of synthesizing a ***hybrid material*** *that is made of flat graphene-like 6-member carbon rings (high conductivity and charge mobility) and 3D cage-like carbon nanostructures (high charge storage capacity. The modeling work is supported by synthesis of a hybrid material that exhibits enhanced conductivity, charge mobility, and charge storage capacity.*

4:00 PM SB04.09/SB09.05.02

A Novel Electrokinetic Membrane System for Efficient Nanoparticle Preconcentration and Separation *Ji Hyo Park[1,2], Jae Sung Yoon[1], Do-Hyun Kang[1], Yeong Eun Yoo[1], Heung Nam Han[2] and Kwanoh Kim[1]; [1]Korea Institute of Machinery & Materials, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)*

Efficient preconcentration and separation of colloidal nanoparticles are pivotal for various biomedical and pharmaceutical applications, especially as target substances decrease in size. In this work, we introduce an innovative electric field-assisted membrane system that integrates oversized-pore membranes with an electrokinetic particle retention mechanism. By generating the electric field directly from a Ti/Au-coated PTFE membrane, nanoparticles even smaller than the pores are electrokinetically isolated and retained with over 99% separation efficiency and a 1.7-fold concentration increase. Compared to conventional membrane processes, our approach significantly reduces transmembrane pressure and particle adsorption, providing advantages such as low driving pressure and enhanced particle recovery. Comprehensive experimental and theoretical analyses reveal that this method optimally balances drag and electrokinetic forces on the nanoparticles, thus improving its performance. This innovative technique offers an energy-efficient and high-yield tool for biomolecule purification and enrichment, with potential applications in point-of-care diagnostics, highly sensitive biochemical detection, and biomanufacturing.

4:15 PM SB04.09/SB09.05.03

Better Organic Semiconductors Through Liquid Purification *Alexander Giovannitti, Jessica Vasquez and Megan M. Westwood; Chalmers University of Technology, Sweden*

Organic semiconducting polymers often contain side products from synthesis that can alter the photophysical and electrochemical properties of polymers. Especially metal traces and organic compounds from synthesis (catalyst and ligands) often remain in the polymer with current purification methods, creating challenges to investigating the real properties of the organic semiconducting polymer. When these impure polymers are employed as the active electrode in heterogeneous electrocatalysis, the remaining metal ion impurities (Pd, Pt, etc.) can result in an overestimation of the electrocatalytic performance (1).

In my talk, I will show how we employ high-performance liquid chromatography (HPLC) to purify polymers by removing metal traces and other organic side products. When comparing the neat polymer to the purified polymers, we observe a clear trend for the electrocatalytic activity for the oxygen reduction reaction (ORR), where *a metal-free polymer undergoes the two-electron reaction, forming hydrogen peroxide (H_2O_2) as the main product, while Pd-containing polymers increase the selectivity towards the four-electron process to form water (H_2O). Finally, we fractionate polymers by molecular weight and show that polymers with higher molecular weight achieve higher electrochemical stability during continuous operation.*

4:30 PM SB04.09/SB09.05.04

3D-Printed, Biomimetic, Conductive MXene-Microfiber Hyaluronic Acid Composite Scaffolds Enhance the Axonal Growth-Promoting Characteristics of Electrical Stimulation in a Microarchitecture-Dependent Manner

Ian Woods[1,1], Dahnan Spurling[2], Sandra Sunil[1], Jack Maughan[1,1,2], Javier Guttierez-Gonzales[1,2,1], Tara McGuire[1,1], Adrian Dervan[1,1], Valeria Nicolosi[2] and Fergal O'Brien[1,1,2]; [1]Royal College of Surgeons in Ireland, Ireland; [2]Trinity College Dublin, The University of Dublin, Ireland

Neurotrauma is associated with losses in motor and sensory function and no effective reparative treatment exists. The complex pathophysiology of neurotrauma (including inflammation, scarring and poor neuronal regrowth) suggests that a multi-faceted approach may be required to direct effective repair. Electrical stimulation-based therapies exhibit multifunctional benefits (e.g. axonal growth, neuronal differentiation) and conductive biomaterials can enhance the delivery of electrical stimulation. However, existing conductive biomaterials suffer from significant trade-offs between neurocompatibility, poor processability, and limited conductivity. $Ti_3C_2T_x$ titanium carbide nanosheets, known as MXenes, are a class of highly conductive ($>10^7$ S/m) biocompatible 2D nanomaterials. It was hypothesized that functionalizing a 3D-printed polycaprolactone (PCL) microfiber scaffold with MXene nanosheets would produce highly conductive MXene-PCL microfiber architectures whose tunable electroconductive properties could be used to enhance tissue engineering scaffolds for neurotrauma repair applications

Melt-electrowriting was used to 3D print orthogonal PCL microfiber architectures of varying fiber densities (Low, Medium and High) which were coated with a $Ti_3C_2T_x$ MXene ink (1 mg/ml), resulting in composite MXene-PCL microfiber architectures. 2-probe conductivity measurements demonstrated that the bulk electrical conductivity of these microfibrous architectures could be varied in a controlled manner from approximately 0.081 ±0.053 S/m to 18.87 ±2.94 S/m - depending on the microfiber density and layer of MXene coating. The MXene microfiber architectures were filled with a previously developed biomimetic macroporous neurotrophic hyaluronic acid-collagen type-IV/fibronectin biomaterial, designed to mimic the stiffness and composition of neural tissues (Woods et al. 2022). Scanning electron microscopic analysis of the resulting MXene-HA composite scaffolds indicated a macroporous microstructure and uniaxial mechanical testing indicated the scaffolds exhibited biomimetic stiffnesses between approximately 587 Pa and 3.25 kPa, depending on MXene-PCL fiber density. Confocal microscopic analysis of immunolabelled neurons following 7 days of continuous electrical stimulation (200 mV/mm, 12 Hz) indicated that MXene-HA scaffolds enhanced the average maximum axonal length projected from neurons in a manner dependent on both the conductivity of the microfiber scaffolds ($p<0.05$) and microfiber density ($p<0.05$).

To assess the capacity of the MXene-HA scaffolds to deliver electrical stimulation within more complex multicellular systems, primary murine neural stem cells were cultured to form neurospheres containing mixed populations of neuronal and glial precursor cells. Confocal microscopic analysis of stimulated neurospheres indicated upregulation of βIII-tubulin, a key marker of neuronal differentiation, on the MXene-HA scaffolds compared to inert controls and “High” density MXene-HA architectures promoted enhanced axonal growth (approx. 2-fold increase) from the neurospheres compared to “Low” density MXene-HA scaffolds.

These results describe the development of highly tunable electroconductive scaffolds which combine the excellent electroconductivity of 2D MXene nanosheets with cutting-edge biomimetic tissue engineering scaffolds through microscale 3D printing. These composite MXene-HA scaffolds demonstrate that MXene-PCL microfiber architectures can enhance the delivery of electrical stimulation to neurons. Furthermore, the controlled spatial distribution of these conductive microfibers was shown to play a key role in directing the electrical stimulation. These biomimetic electroconductive MXene-microfiber hyaluronic acid composite scaffolds overcome existing challenges associated with the use of conductive biomaterials and hold significant clinical potential for neurotrauma repair.

4:45 PM SB04.09/SB09.05.05
Spatial Bioelectric Control of Live Tissue Dynamics with 3D Printed, Miniaturized Electrotaxis Bioreactors
Yubin Lin, Jeremy Yodh and Daniel J. Cohen; Princeton University, United States

Directional cell migration under a DC electric field, called as electrotaxis, is known to be critical in wound healing and embryonic development. Here, cells typically migrate from effective anode to cathode in naturally occurring ionic currents, relying on the electric field as a navigational cue. Manipulating this process offers great potential from guiding tissue growth to treating chronic wounds. However, the unique material challenges for injecting current into the salt solutions that typically surround living tissues mean that most electrotaxis apparatuses are often handmade, leading to low reliability and reproducibility across experiments due to assembly variations. These factors make results across studies difficult to compare due to varying platform designs, as well as reducing throughput and the ability to sweep parameters.
Here, we present high-throughput, modular stimulation inserts that enable precise spatial control of electric field delivery to program non-excitable tissues through electrotaxis. Our 3D printing approach integrates miniaturized salt bridges and Ag/AgCl electrodes into each insert and simultaneously allows independent stimulation of up to 8 biological samples using standard 24-well Petri plates—a significant advantage over conventional single-sample systems. Moreover, each insert is capable of delivering uniquely shaped electric fields through the ‘ceiling’ of the insert, and each field can be computationally designed and optimized prior to fabrication to allow stimulation with a range of different field geometries.
Using these interfaces, we have been able to optimize converging and diverging field geometries based on concentric electrodes that allow us to investigate accelerated wound healing. One recent finding indicates how the biomaterial properties of the healing tissue modulate its response to stimulation and how well a tissue ‘remembers’ past stimulation. We have also demonstrated unique tissue responses to mono-, di-, and quadru-polar point-source/sink anode/cathode combinations, inducing complex 2D and 3D cellular re-arrangements in live tissues. These rearrangements also cause patterns of stress and strain in the tissues that can guide their development and growth, offering an additional use of patterned electrical fields to mechanically pattern living biomaterials.
This device addresses the fundamental challenges of in vitro tissue-electronic interfaces by providing a standardized, flexible, and scalable solution. By advancing the field of bioelectronics for non-excitable tissues, this platform holds potential for both biomedical applications and novel device architectures.

SESSION SB09.01: Electroactive Materials at the Interface with Biology
Session Chairs: Anna Herland and Donata Iandolo

Monday Morning, December 2, 2024
Hynes, Level 2, Room 204

10:30 AM *SB09.01.01

Enhancing Tissue Regeneration Through Semiconducting Organic and Inorganic Materials *Claudia Tortiglione; Consiglio Nazionale delle Ricerche, Italy*

Regenerative medicine strives to identify the mechanisms underlying regeneration of missing structures or repair of damaged tissues with the final aim to control the cells that execute these programs, that is, the endogenous stem cells. In addition, genetic and biochemical factors, acting at cell and tissue levels, and physical stimulations (heat, electric fields, light irradiation) provide pivotal instructive roles for the coordinated behavior of large tissue regions healing the wound. In the last decade bioelectrical signaling has gained an important role as a biophysical master regulator, controlling cell behaviours and driving proliferation, differentiation, migration processes. An overview on the possibility to enhance these processes through diverse physical triggers, from magnetic to optical stimulation, will be provided, using as model a small invertebrate with unique regenerative potential, the freshwater polyp Hydra vulgaris [1]. The effects played by diverse nanoparticles, i.e. inorganic nanoparticles or based on conjugated polymers or carbon nanotubes will be described together with the dissection of the mechanisms underlying the cell responses to the nanoparticle actuating. These results open new perspectives for the development of wireless technologies based on nanomaterials for spatio temporal control of tissue regeneration.

11:00 AM SB09.01.02

Electrostimulation via a 3D-Printed, Biomimetic, Neurotrophic, Electroconductive Scaffold for the Promotion of Axonal Regrowth After Spinal Cord Injury *Liam Leahy[1,2], Ian Woods[1,2], Adrian Dervan[1,2] and Fergal O'Brien[1,2,3]; [1]Royal College of Surgeons in Ireland, Ireland; [2]Advanced Materials & Bioengineering Research (AMBER) Centre, Ireland; [3]Trinity College Dublin, The University of Dublin, Ireland*

Spinal cord injury (SCI) is a devastating neurotrauma, affecting up to 500,000 people annually, and typically results in lifelong paralysis. Electrostimulation can promote neuronal growth, but the formation of a lesion cavity post-SCI inhibits regrowth, limiting its efficacy. Bridging the lesion with a structured, electroactive substrate to direct electrostimulation to growing axons could support and drive regrowth to enable functional recovery. Through mimicking the architecture of the tissue, regrowing neurons could also be guided to meet their distal targets. However, to date, no such platform exists. This study describes the application of electrostimulation via an electroconductive 3D-printed scaffold, comprising an electroconductive polypyrrole/polycaprolactone framework filled with biomimetic & neurotrophic extracellular matrix, to induce significantly longer process extension in neurons.

Biomimetic polycaprolactone (PCL) scaffolds were 3D-printed (Allevi 2) to produce uniaxially aligned, interlocking cylindrical architectures, utilising several channel sizes to match the diameters of human lateral corticospinal cord axonal tracts. Polypyrrole (PPy) was polymerised in situ to form an electroconductive nanoparticle coating on the scaffolds, verified using FTIR and SEM imaging. Electroconductivity was measured via the 4-point probe method. A hyaluronic acid-based extracellular matrix (ECM) was directionally freeze-dried within scaffold *channels to provide a neurotrophic environment, and a physical guide to direct neuronal growth. Biocompatibility was assessed by growing neurons and astrocytes on 2D PPy/PCL films and measuring metabolic activity, cellular DNA and morphology. Neurons were electrically stimulated for 7 days on ECM-functionalised PPy/PCL and PCL scaffolds using an Ionoptix bioreactor and imaged to assess the effect of electrostimulation-induced neurite extension.*

PCL scaffolds with anatomically relevant channel sizes were 3D-printed and functionalised with PPy and ECM. The conductivity of the PPy coating was measured at 15±5 S/m, 30 times higher than native spinal cord tissue. PPy/PCL substrates displayed excellent biocompatibility – with both neurons and astrocytes colonising the surface with typical morphologies and no difference in metabolic activity or cellular DNA on PPy/PCL in comparison to PCL controls. The freeze-dried neurotrophic ECM formed aligned pore structures within scaffold channels, to guide neuronal neurite outgrowth. Scaffolds of varying channel sizes exhibited no difference in electrical properties or cell activity, showing scaffolds can be scaled to match native cord tracts without losing functionality. Electrostimulation induced significantly longer neurite outgrowth and average neurite length was significantly increased on stimulated PPy/PCL scaffolds compared to all other groups.

This work represents the development of a novel, biphasic electroconductive scaffold, which can direct electrostimulation to promote neurite growth through its longitudinal, ECM-filled channels. The data indicates that PPy/PCL is an excellent substrate for neural tissue engineering and can be developed into ordered structures that can be tailored to match the native tracts to direct neurite growth. Applying electrical stimulation via this electroconductive scaffold results in significantly longer neurite length through the ECM phase of the scaffold, demonstrating the potential of this system to direct and guide axonal growth post-SCI to restore connection and promote functional recovery.

Cellular Behaviors on 2D and 3D Crystalline PEDOT:PSS Scaffolds *Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)*

In this research, we investigated cellular behaviors on conducting 2D and 3D scaffolds based on crystallized poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS). The crystallized PEDOT:PSS films on plastic substrates exhibited excellent electrical/electrochemical/optical characteristics, long-term underwater stability without film dissolution/delamination, and good viability for primarily cultured cardiomyocytes and neurons over several weeks. Furthermore, the highly-crystallized PEDOT:PSS with nanofibrillar surface morphology enabled dramatically enlarged surface areas and electrochemical activities, which were successfully employed to modulate cardiomyocyte beating via direct electrical stimulation. In parallel, we prepared 3D conductive scaffolds based on crystallized PEDOT:PSS fiber mesh networks and examined cellular behaviors on top in comparison with those on thin PEDOT:PSS films.

The Faraday Scalpel—Using Low-Level Electrochemical Currents for Tissue Lesioning and Ablation *Eric D. Glowacki, Jiri Ehlich, Marie Jakesova, Jan Svec, Amedeo Ruggiero and Anna Tvrdonova; Central European Institute of Technology, Czechia*

Electrosurgery typically relies on high charge-density alternating currents, achieving tissue ablation via thermal dissipation or via irreversible electroporation mechanisms. These methods are relatively indiscriminate with respect to tissue type. We present the concept of using low-level direct currents to selectively ablate tissue via electrochemical reactions, as different cell types have different tolerances to various chemical species. We have assessed a range of possible cathodic and anodic processes. The main mechanism of interest, corresponding to the lowest current densities (10-100 μA/cm^2), is the oxygen reduction reaction (ORR). ORR can be tuned to proceed via a 4-electron process, giving hypoxia, or it can be engineered to follow the 2-electron pathway and yield hydrogen peroxide. Both pathways can irreversibly damage certain cell types. We show in vitro and in vivo examples of using microelectrode systems to create on-demand hypoxic and/or oxidative stress conditions. Higher cathodic current densities can rapidly damage tissue with alkalization, applicable to tissues highly resistant to hypoxia/ROS. On the anodic side, we have identified the chloride oxidation reaction, with hypochlorite as a product, as a potent mechanism of tissue damage. Organic electronic materials have proven as excellent candidates for reliable ROS delivery. We discuss the application of faraday scalpel concepts in various in vivo models in the context of neurosurgery, and also examples of potential efficacy in cancer treatment.

2:00 PM *SB09.02.02

Extending the Reach of Bioelectronic Implants *Christopher M. Proctor; University of Oxford, United Kingdom*

Significant advances have been made in the last two decades in interfacing electronic devices with the nervous system. To that end, research efforts are being pursued to develop minimally invasive, implantable bioelectronic devices integrating sensing, stimulating, and dynamic control of geometry. Here we report recent developments towards such multimodal devices for neural interfacing that take full advantage of the favorable properties offered by flexible electronics, conducting polymers and polymer substrates. It is shown that thin, flexible devices can incorporate microfluidic channels to enable new sensing and therapeutic functionalities. One such technology leverages the mixed conducting properties of conducting polymers for applications in ultra-low frequency stimulation for nerve regeneration. Furthermore, we show fluidic components can open the door to novel implantation strategies that can reduce the surgical footprint required for implantation of widely used bioelectronic devices. We anticipate this work will accelerate the development of a new generation of bioelectronic devices for diagnostics and therapy.

Nanofiber Based Janus Electrode with Stable Asymmetric Wettability for Long-Term Biosignal Monitoring

Tomoyuki Yokota; The University of Tokyo, Japan

To monitor the bio-signals with high accuracy for a long time, it is important to keep the skin and electrodes dry. Sweat can cause noise in the readings due to interactions with the electrode material. The Janus electrode, which is a type of dry electrode made from nanofibers, has a special property that lets it absorb sweat and move it to the outside, keeping the skin and electrode interface dry. This process is known as the wicking phenomenon. The Janus electrode can reduce noise from sweat and maintain stable contact with the skin. Janus electrodes are made from layers of hydrophilic (water-attracting) and hydrophobic (water-repelling) membranes, with the conductive part on the hydrophobic side, which touches the skin. The wicking effect happens due to the combined action of capillary and hydrostatic forces from the hydrophilic layer. However, it is challenging to make Janus electrodes that stick to the skin for days despite sweat. Common wet adhesives used for good skin contact can dry out over time and become unstable when exposed to water or sweat, reducing electrode adhesion and affecting bio-signal quality. Additionally, hydrophilic layers can dissolve in water, breaking their polymer chains.
Here, utilizing a Janus electrode, a stacked layer of ultrathin hydrophobic microporous Au-membrane, and water-durable hydrophilic nanofibers, asymmetric wettability can be realized and maintained for 7 days. Thus, it can create a spontaneous unidirectional sweat transport out from the skin surface, ensuring the skin-electrode interface keeps dry, especially during sweating. The ultrathin hydrophobic membrane facilitates self-adhesion with an adhesion energy of 50.7 μJ cm^{-2}, which creates a high conformal contact with the skin and self-adheres to the hydrophilic nanofibers. The hydrophilic nanofibers show excellent durability to continuous water immersion for up to 1 month. Additionally, a thin translucent polyvinyl alcohol (PVA) nanofibers frame assists the Janus electrode to achieve a highly conformable attachment on both dry and sweaty skin. By the overall porous structure as well as the fine thickness scale, the Janus electrode also exhibits excellent breathability and high mechanical stability. With all these properties, the Janus electrode can monitor a long-term electrocardiogram (ECG) signal after dynamic activities, including physical exercising, after awaking, after desk work, after meals, and after going out for 6 days while maintaining a stable signal-to-noise ratio (SNR) of ~18.8 dB.

9:45 AM SB09.04.02

A Quantitative Study of Extracellular Electron Transfer Kinetics in Electroactive Biofilm-Electrode Interface by Nonlinearly Fitting Discharging Current of Microbial Fuel Cells

Hao Ren; ShanghaiTech University, China

In this abstract, we present a quantitative kinetic modeling of the extracellular electron transfer (EET) in electroactive Geobacter sulfurreducens enriched biofilm-electrode interface for a series of biofilm growth stages and utilizing the kinetic equations to study kinetics parameters of EET through nonlinear fitting of discharging current profiles of microscale microbial fuel cells (MFC). The quantitative EET rate constants and the amounts of redox cofactors associated with individual EET steps are obtained for initial to fully-grown biofilms. The quantitative study reports the rate-limiting step in EET transitions during the biofilm growth. In early to mid-stage biofilms, having current densities of less than 2.2 Am^{-2} and between 2.2 and 3.1 Am^{-2}, respectively, the rate-limiting step transitions from irreversible acetate turnover to the electron transfer from inside exoelectrogen to extracellular redox cofactors (ERCs) within the biofilms. For fully-grown biofilms, having current density of more than 3.1 Am^{-2}, the rate-limiting step is the electron transfer from ERCs in biofilm to ERCs at the anode.

Microbial fuel cells (MFC) have been extensively studied in the past two decades to address the global warming and energy crisis. Although significant performance improvement has been achieved, the current and power densities are still lower than those of other power sources, such as lithium ion batteries. Further improving the performance of microbial fuel cells requires studying the bottleneck of current and power densities of MFCs. However, although many studies have studied the bottlenecks of microbial fuel cells by electrochemical or optical approaches, the bottlenecks are still not clear, which limits the further improvement of MFC performance.

The microscale MFC utilized to obtain discharging current has a chamber volume of 50 μL. We model the extracellular electron transfer (EET) on electroactive Geobacter sulfurreducens enriched biofilm-electrode interface for a series of biofilm growth stages by mathematical kinetic equations, and obtain the discharging current profiles by discharging the MFCs at different biofilm growth stages. Afterwards, nonlinear fitting is performed on the experimental discharging current profiles to obtain the quantitative EET rate constants and the amounts of redox cofactors associated with individual EET steps during different growth stages of biofilms. The results show that the rate-limiting bottleneck for EET changes as biofilm grows thicker. In early-stage biofilms, having current densities of less than 2.2 Am^{-2}, the rate-limiting bottleneck is the irreversible acetate turnover. In mid-stage biofilms, having current densities between 2.2 and 3.1 Am^{-2}, the rate-limiting bottleneck transitions from irreversible acetate turnover to the electron transfer from inside exoelectrogen to extracellular redox cofactors (ERCs) within the biofilms. For fully-grown biofilms, having current density of more than 3.1 Am^{-2}, and the rate-limiting bottleneck is the electron transfer from ERCs in biofilm to ERCs at the anode. The nonlinear fitting results provide important guidance on future work of improving the current generation capability of Geobacter sulfurreducens enriched biofilms: alleviating the bottleneck of electron transfer from ERCs in biofilm to ERCs at the anode will improve the current generation capability of Geobacter sulfurreducens enriched biofilms.

10:30 AM SB09.04.03
Reusable Self-Healing Electronics *Fabio Cicoira; Polytechnique Montréal, Canada*

Materials able to regenerate after damage have attracted a great deal of attention since the ancient times. For instance, self-healing concretes, able to resist earthquakes, aging, weather, and seawater are known since the times of ancient Rome and are still the object of research.

While several mechanically healable materials have been reported, self-healing conductors are still relatively rare, and are attracting enormous interest for applications in electronic skin, wearable and stretchable sensors, actuators, transistors, energy harvesting, and storage devices, such as batteries and supercapacitors.[1] Self-healable and recyclable conducting materials have the potential to reduce electronic waste by enabling the repair and reuse of electronic components, which can extend the lifespan of electronic devices. Furthermore, they can be used for wearable electronic and biomedical devices, which are often subject to mechanical stress causing damage to their components.

Conducting polymers exhibit attractive properties that makes them ideal materials for bioelectronics and stretchable electronics, such as mixed ionic-electronic conductivity, leading to low interfacial impedance, tunability by chemical synthesis, ease of process via solution process and printing, and biomechanical compatibility with living tissues. However, they show typically poor mechanical properties and are therefore not suitable as self-healing materials.

In our group, we produced several self-healing and stretchable conductors by mixing aqueous suspensions of the conducting polymer poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) with other materials providing the mechanical characteristics leading to self-healing, like for instance polyvinyl alcohol (PVA), polyethylene glycol, polyurethanes and tannic acid.[2-10] In this talk, various types of self-healing will be presented and correlated with the electrical ad mechanical properties of the materials. The use of the self-healing gels and films as epidermal electrodes and other devices will be also discussed.

Biosensing Interfaces and Parameters in Field-Effect Transistor-Based Biosensors *Toshiya Sakata; The University of Tokyo, Japan*

In developing a biosensor, we consider the design criteria based on its three components, namely, the biological target, signal transduction interface, and detection device. Among the detection devices, a platform based on an electronic device with field-effect transistor (FET) biosensors is suitable for use in miniaturized and cost-effective systems to directly measure biological samples because the FET biosensors allow the direct detection of intrinsic ionic and biomolecular charges in principle, which contributes to label- and enzyme-free biosensing. Such miniaturized electronic devices can be easily equipped with a wireless function and attached to the body, which is available for wearable biosensors to detect biomarkers in a blood-sampling-free manner (i.e., tears, sweat, and saliva). Here, it is very important to determine how the change in the density of charges based on biomolecular recognition events is directly transduced into electrical signals at the signal transduction interfaces, regardless of the wearability of FET biosensors. Such bio/device interfaces are chemically synthesized, physically and chemically structured, and biologically induced to control the biosensing parameters such as specificity, selectivity (S), binding constant (K_a), limit of detection (LOD), signal-to-noise ratio (S/N), and biocompatibility with respect to the biological target, although the chemically synthesized electrical interfaces are also useful as the signal transduction interfaces for the flexible wearable biosensors [1]. In particular, the increase in K_a for the target biological target, which results in the enhancement of S and LOD, becomes a key challenge for enzyme-free interfaces, and then biocompatible materials may be chosen for the signal transduction interfaces. On the other hand, various semiconductor materials have been recently applied as the channel of FET biosensors. Therefore, the diversity of signal transduction interfaces broadens the possibility of developing novel biosensing devices, in parallel with the development of new channel materials for the FET biosensors. The optimal biosensing parameters are effectively provided by the diverse signal transduction interfaces for the practical use of FET biosensors. In this talk, distinctive signal transduction interfaces for FET biosensors are introduced, categorized as chemically synthesized, physically structured, and biologically induced interfaces, focusing on the above biosensing parameters.

Triggering Protein Assembly On-Demand by Electroreduction *Eloise Masquelier, Sabrina Fojut, Xiaotian He, Xagros Faraji, Seren Tochikura, Lior Sepunaru, Mike J. Gordon and Daniel E. Morse; University of California, Santa Barbara, United States*

Proteins are the material central to cells, participating in virtually every process, from structural support and DNA *replication to catalyzing biochemical reactions. Their functions often stem from their hierarchical assembly, inherently dynamic over multiple scales providing highly responsive behaviors. Developing methods that can actively stimulate biological functions is necessary to recapitulate biology's ability to tune the biomolecular structures and functions in living systems. We have developed an electrochemical approach that uses an electric trigger to reduce charged amino acids in freely diffusing proteins. We demonstrate the applicability of our method on tau, an amyloid forming protein associated with neurodegenerative diseases. By combing electrochemistry with spectroscopy techniques (UV-absorbance, circular dichroism, dynamic light scattering), we are able to trigger and follow in real time tau's conformational change and assembly. By finely tuning the reductive potentials and electrolyte conditions, a gradient of behaviors is observed: from monomers to reversibly folded assemblies, and thence to the formation of irreversible β-rich fibrillar structures, closely parallel to the transition from physiological to pathological function of tau. This work highlights the potential of electrochemical methods as tools to achieve on-demand, rapid and spatially controlled assembly of proteins. We anticipate the applicability of this method to a wide range of other charge-controlled and amyloid-forming proteins.*

Cation-Doped IrO_2 Electrode for Improved Charge Storage Capacity in Bioelectronics Applications *Yi-Chieh Hsieh[1], Wai-Hong Cheang[1], Kuang-Chih Tso[2] and Pu Wei Wu[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Nara Institute of Science and Technology, Japan*

Bioelectrodes play a crucial role in bioelectronic sensing and neural therapy. The primary materials used for bioelectrode substrates include platinum, titanium nitride, tantalum pentoxide, and iridium oxide. Among these, iridium oxide has garnered attention for its low impedance and high charge storage capacity which is suitable for active bio-stimulation applications. Our laboratory has synthesized iridium oxide electrodes doped with Na^+, K^+, or Mg^{2+} on ITO substrate. We utilize XPS and XAS to confirm the changes in the iridium oxidation state post-ion doping, aiming to study the chemical structure alterations resulting from the doping process. CSC of cation ion doped IrO_2 electrode is determined by CV which showed excellent results, Na^+ doped IrO_2: 0.31 mC cm^{-2} nm^{-1}, K^+ doped IrO_2: 0.31 mC cm^{-2} nm^{-1}, Mg^{2+} doped IrO_2: 0.37 mC cm^{-2} nm^{-1}. After 1,000 CV cycles, the CSC of the IrOx thin films remained relatively consistent.

SB09.06.02

Conductive Polymer Substrates as Cardiac Tissue Culture Scaffolds *Sujin Jeon and Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)*

Myocardial infarction (MI) damages heart muscle, increasing its insulating properties and making the heart susceptible to arrhythmias and other diseases and the infarcted area that replaces the damaged tissue becomes electrically inactive, preventing the heart from maintaining a regular beat. In this research, we developed poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) microfiber mesh with high ionic conductivity to facilitate electrical signal propagation in cardiomyocytes. The PEDOT:PSS mesh enhanced the expression of *cardiac marker proteins such as Connexin 43 (Cx43), α-actinin, and cardiac Troponin T (cTnT) during cardiomyocyte culture on top. This increased protein expression improved electrical coupling between cardiomyocytes, allowing for more efficient interactions and synchronized contractions. Furthermore, the high Young's modulus of the PEDOT mesh provided significant mechanical support to cardiomyocytes, which was crucial for achieving both mechanical and electrical activation of the cells. We suppose that this study introduces a novel approach to the treatment of myocardial infarction toward a foundation for future clinical applications.*

SB09.06.03

Electric Potential-Induced Adhesion and Filamentation of Xylella Fastidiosa *Ayron A. Lima, Duber M. Munar, Antonio A. Zuben and Monica A. Cotta; Universidade Estadual de Campinas, Brazil*

Xylella fastidiosa is a plant photogenic bacterium responsible for various plant diseases, significantly impacting economically important crops such as grapevines, olive trees, and citrus plants. The adhesion of X. fastidiosa to surfaces is a critical step in biofilm formation, which is essential for its pathogenicity and persistence [1,2]. This study aimed to investigate the effect of electric potential on the adhesion of X. fastidiosa to dielectric-coated gold electrodes. Previous studies have indicated that Xylella fastidiosa exhibits a stronger adhesion affinity to gold compared to other abiotic and biotic substrates [3,4], which may be due to metal electronic structure; in our samples, we are able to modulate the potential at the surface of interdigitated gold electrodes coated with a dielectric layer. We explored the adhesion behavior X. fastidiosa on these electrodes at different electric potential differences ranging from 0 to 500 mV. The thin gold layers forming the electrodes were deposited by e-beam evaporation on SiO2/Si substrates, and subsequently coated with another SiO2 layer. X.fastidiosa growth was carried out in PW broth media. After a 24-hour growth period, we conducted analyses to observe specific behaviors at each applied electric bias. At 0 mV, adhesion occurred with single cells and small bacterial clusters, with X. fastidiosa cells maintaining their typical length of approximately 3-4 μm; similar behavior was observed for larger bias. However, at 300 mV, a significant presence of single filamented cells, reaching up to 10 μm, was noted, with no biofilms present in the samples. As bias increases to 500 mV, single cells were the most present on the surface, but with a larger dispersion in cell sizes, between 3 and 10μm. In terms of coverage area on the electrodes, the maximum coverage was observed at 0 mV, with a steady decrease as the applied electric potential difference increased. These results suggest a relationship between electric potential and cellular filamentation in the adhesion of X. fastidiosa to surfaces. Further studies are on the way to further the understanding and establish a clearer relationship between these phenomena.

Advancing Thin Film Implants for Spinal Cord Stimulation—Innovations in Electrode Design and Methodology from Industry Perspectives *Maria Vomero; NeuroOne Medical Technologies, United States*

The field of spinal cord stimulation (SCS) has not seen significant advancements in many years: electrode design and implantation methodologies have remained the same for a couple of decades. At NeuroOne, we are exploring a novel approach to developing thin film leads for SCS applications while integrating user feedback and creating a path to market. The proposed technology aims to revolutionize SCS therapy by introducing new electrode materials and designs without compromising user familiarity and comfort during the implantation process.
Traditional SCS electrodes typically use bulky materials and designs, which can limit flexibility and versatility of the implant location. In contrast, thin film technology offers advantages such as reduced size, increased biostability, and potentially new treatment options for the patients. Our approach focuses on leveraging these benefits through the development of advanced thin film electrodes that are not only smaller and more flexible but also capable of delivering precise stimulation patterns tailored to individual patient needs.
Key challenges addressed in this innovation include maintaining or improving upon the durability and reliability of current electrode designs, ensuring compatibility with existing SCS systems, minimizing disruption to established supply chains, and integrating user feedback. User feedback plays a crucial role throughout the development process, guiding the design iterations to ensure that the new technology meets the logistical and functional expectations of healthcare providers and patients.
Furthermore, the methodology for implanting these new electrodes will be discussed, emphasizing a seamless transition for clinicians accustomed to current implantation techniques. By aligning with familiar procedural protocols and leveraging advancements in surgical tools and techniques, the goal is to streamline the adoption of this new technology into clinical practice.
The integration of user feedback and supply chain considerations into the development of thin film electrodes for SCS represents a paradigm shift in medical device innovation. Here, the goal is to highlight the collaborative efforts between industry stakeholders, researchers, and clinicians to drive advancements that not only enhance therapeutic outcomes but also improve the overall user experience and accessibility of SCS therapy.

9:30 AM SB09.07.02

Area Selective Catalytic Etching for Opening Electrodes in Neural Implants *Nicolai W. Simon[1,2], Thomas Stieglitz[2,2] and Volker Bucher[1]; [1]Furtwangen University, Germany; [2]Universität Freiburg, Germany*

Neural implants are used to treat and diagnose a wide range of neuronal diseases by intervening in the body's nerve network via neuro-technical interfaces. The surfaces of these interfaces are protected with biocompatible insulating polymers except the microelectrodes. Area selective catalytic etching (ASCE) offers the potential to replace error-prone and cost-intensive lithography steps, as the opening of the electrodes can be achieved by catalytic etching. Oxygen diffuses through Parylene-C to dissociate atomically on the platinum electrode surface. The resulting reaction partner can etch the Parylene-C above it. In contrast to polyimide, Parylene-C can be deposited from the vapor phase, which provides an excellent basis for the production of 3D electrodes.

In this work, the conventional opening of the electrode surfaces by means of reactive ion etching (RIE) was compared with the method of ASCE. The focus of the study was set on the surface morphology of the etched Parylene-C and the structure of the etched side walls. Silicon wafers were coated with Parylene-C and then sputtered with a titanium/platinum layer, which were subsequently structured using lift-off. The structures were coated with another layer of Parylene-C, so that the structures were sandwiched between the two Parylene-C layers. A lithography process was carried out in which the mask was intentionally misaligned slightly so the mask opening was also minimally on the conductor tracks. One wafer was etched using conventional RIE process and *the other wafer was placed on a hot plate at 240 °C under ambient atmosphere for ASCE. The etched structures were examined using scanning electron microscopy (SEM).*

The SEM images of the RIE-processed wafer showed roughened sidewalls and a fissured surface of the Parylene-C next to the conductor tracks. The sidewalls of the wafer processed by ASCE were much smoother and have a more cauliflower-like surface. Furthermore, only the Parylene-C located above the platinum was etched. This allowed the misalignment error to be corrected by ASCE.

Using ASCE, new process paths for the production of neuro technical interfaces can open up, which would make wafer-bound processing obsolete.

Organic Semiconductors for Regenerative Medicine—Optical Modulation of the Cell Fate *Maria Rosa Antognazza; Istituto Italiano di Tecnologia, Italy*

Use of light for selective and spatio-temporally resolved control of cell functions (photoceutics) is emerging as a valuable alternative to standard electrical and chemical methods. Here, we propose the use of smart materials, and in particular of organic semiconductors, as efficient and biocompatible optical transducers in the field of regenerative medicine.
Devices able to selectively and precisely modulate the fate of living cells, from adhesion to proliferation, from differentiation up to specific function, upon visible light will be presented. Examples of practical applications, recently reported by our group, include optical modulation of the activity of both excitable and non-excitable cells, the control of essential cellular switches like transient receptor potential channels and mechanosensitive channels, as well as effective modulation of intracellular calcium signaling for precise control of cell metabolic processes.
In more detail, we critically discuss the reliability and efficacy of our approach by focusing on a couple representative examples:

1. Optical modulation of cell differentiation, migration and wound healing processes, by hybrid interfaces with epithelial cells and skin tissue models;[2]
2. Optical modulation of cardiovascular cells, namely endothelial cells[3] *and human induced pluripotent stem cells-derived cardiomyocytes (hPSC-CM). Novel materials to optically modulate angiogenesis*[4] *and to optically induce an anti-arrhythmogenic effect will be presented*[5]*. Interestingly, these results may represent a breakthrough, noninvasive approach to face the cardiovascular risk, in particular post-ischemic disease and arrhythmias.*

The two study-cases are among the very first reports on use of organic semiconductors for optical modulation of the cell fate, with disruptive perspectives in cell-based therapies and regenerative medicine.

10:45 AM SB09.07.04
Tuning Gold Nanoparticles for Deep-Tissue Photothermal Reactions *Saman Ebrahimibasabi, Jeremy Graunke, Jaxon Henderson, Jack Evans, Maryam Golshahi, Layla Khalifehzadeh and Hamed Arami; Arizona State University, United States*

Gold nanoparticles are widely used in various biomedical applications such as imaging, diagnosis, drug delivery, photodynamic therapy (PDT), and photothermal therapy (PTT). This broad range of applications is due to their *unique chemical and physical properties, such as chemical stability, biocompatibility, optical properties (e.g., surface plasmon resonance), and versatile synthesis. Naturally, gold nanoparticles exhibit significant absorption in the visible light range. However, visible light is inefficient for photothermal reactions in deep tissues, due to its low tissue penetration. Therefore, modifying gold nanostructures to absorb higher wavelengths with more tissue penetration (i.e., NIR range, 600-1400 nm) can expand their potential biomedical applications. Nanoparticles with higher specific surface areas (such as star-shaped and urchin-like nanostructures) can show enhanced absorption and resonance at such longer wavelengths. However, the pathway for their synthesis and running of their deep-tissue photothermal properties requires extensive experimental and theoretical investigations. Here, we will discuss various methodologies for synthesis and modification of gold nanostructures to optimize their NIR photothermal response for this specific purpose. We introduce a seedless method for making such and help to stabilize them in biological solutions and tissues using PVP (poly(N-vinyl-2-pyrrolidone) with different molecular weights (MW = 10,000, 40,000, 360,000 g/mol) as the capping agent. We used different concentrations of* H_2O_2 *(≈30% (v/v)) to modulate the kinetics of the nucleation and growth of the nanoparticles to tune the size, morphology, and NIR absorption of the nanoparticles. The morphology, size, and dispersibility of the synthesized nanoparticles were studied using scanning electron microscopy, DLS, and zeta potential measurement. Additionally, the NIR absorption and photothermal efficiency of the nanoparticles were investigated using UV-Vis spectroscopy and IR imaging of the nanoparticles irradiated with 780 nm (first NIR window) and 1064 nm (second NIR window) lasers, respectively. Our results showed that the deep-tissue photothermal response of the gold nanoparticles is dependent on the molecular weight and amount of the capping agents (e.g., PVP), reducing agents (e.g.,* H_2O_2*), and reactions solvents, such as DMF (dimethylformamide), HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) buffer, and their mixtures. These comprehensive results can be used as a general guideline for repeatable synthesis of gold nanostructures with tuned photothermal properties when irradiated with different wavelength lights.*

SYMPOSIUM SB05

Biomaterials for Regenerative Engineering
December 3 - December 5, 2024

Symposium Organizers
Gulden Camci-Unal, University of Massachusetts Lowell
Michelle Oyen, Washington University in St. Louis
Natesh Parashurama, University at Buffalo, The State University of New York
Janet Zoldan, The University of Texas at Austin

** Invited Paper*
+ JMR Distinguished Invited Speaker
*** Keynote Speaker*
^ MRS Communications Early Career Distinguished Presenter

SESSION SB05.01: Polymeric Biomaterials for Regenerative Engineering I

Session Chairs: Gulden Camci-Unal and Natesh Parashurama

Up-to-date as of November 14, 2024

Tuesday Morning, December 3, 2024
Hynes, Level 3, Room 312

8:30 AM *SB05.01.01
Regenerative Engineering *Cato T. Laurencin; University of Connecticut Health Center, United States*

Regenerative Engineering is defined as the Convergence of Advanced Materials Science, Stem Cell Science, Physics, Developmental Biology and Clinical Translation for the Regeneration of Complex Tissues and Organ Systems. Over the past 35 years work in the Laurencin Laboratories has focused on translating discoveries to people. The theme of the laboratory has been to "Explore, Discover, Treat, Cure, Teach, Repeat." The Cato T. Laurencin Institute, a cross university Institute at UConn has 6 pillars. Two are "Transformative Technologies for Humanity" and "Entrepreneurship and Economic Value Creation." It is through the use of principles of regenerative engineering, and employing the pillars, innovative technologies have been inspired helping millions of people throughout the world.

9:00 AM SB05.01.02
Unconventional Biomaterials for Regenerative Engineering *Gulden Camci-Unal; University of Massachusetts Lowell, United States*

Across different areas of regenerative engineering, there are limitations with controlling cell adhesion, viability, growth, differentiation, biocompatibility. Conversion of simple and abundant items to advanced cell culture substrates addresses some of the limitations in regenerative engineering. Departure from complex fabrication processes to the applications of unusual materials provides another dimension to the engineering of viable multifunctional tissue constructs and regenerative can increase access to regenerative engineering technologies on a global scale. In this work, we used unconventional biomaterials such as eggshells and paper for tissue regeneration.

We fabricated eggshell micro/nanoparticle (ESP) reinforced protein-based scaffolds to produce mechanically stable and biologically active three-dimensional (3D) scaffolds that can differentiate stem cells into osteoblasts. The ESP-reinforced constructs were then implanted in a rat model to determine their biocompatibility and degradation behaviors. In addition, these composite scaffolds were used to regenerate critical sized cranial defects in a rat model. We also used mineralized paper scaffolds with hydrogels through an origami-inspired approach to test their osteoinductivity and potential for tissue repair in in vitro and in vivo studies.[1-6]

The ESP-reinforced scaffolds enabled the differentiation of stem cells into osteogenic lineage. The constructs showed significant enhancement in mineralization by the cells. The ESP composites demonstrated superior mechanical properties and showed favorable in vivo responses by subcutaneous implantation in a rat model. The implants were easily accepted by the host, allowed for cellular infiltration and migration in 3D, and highly vascularized. Implantation of ESP-reinforced scaffolds into critical sized cranial defects in a rat model resulted in significant bone regeneration in 12 weeks. The resulting bone volume and bone density were as high as the native bone using these composite scaffolds as determined by micro-computed tomography assessment.

We also fabricated origami-inspired paper-based scaffolds for biomineralization. Material properties of the paper-based mineralized scaffolds were highly tunable. The tensile modulus of the scaffolds increased significantly after the mineralization process. Gene expression results for the osteogenic differentiation markers revealed the osteoinductivity of the mineralized paper scaffolds. Subcutaneous implantation of the samples in rats *demonstrated biocompatibility, vascularization, and integration in vivo.*

Unconventional scaffolds that are readily available and adapted from nature demonstrated biomimetic characteristics including porosity, structure, and bioactivity resulting in physiologically relevant constructs. The use of existing naturally derived materials in combination with hydrogels for regenerative engineering provides an inexpensive and sustainable approach that benefits the economy and environment while providing unique solutions to unmet clinical needs. Many of the unconventional biomaterials are overlooked and under-studied for biomedical applications, partly for their simplicity as mundane items.

9:15 AM *SB05.01.03

Bioactive Materials for Tissue Sealing and Repair *Kaushal Rege; Arizona State University, United States*

Complications associated with ineffective tissue repair including in slow or non-healing wounds, cost the US healthcare system ~$20 billion / year and amount to ~5% of the total cost of Medicare and Medicaid. In cases of surgical closure, lack of immediate tissue approximation, high potential for scarring, including in visible areas of the body, susceptibility to infection, and long procedure times necessitate new approaches for tissue repair especially for unmet needs where current approaches are suboptimal in performance. Light-activated tissue sealing is an emerging strategy that facilitates rapid, liquid-tight approximation of ruptured tissues, but the lack of effective biomaterials compromises efficacy of tissue repair. I will discuss our advances in the generation, characterization, evaluation, and of laser-activated sealant (LASE) biomaterials for the rapid sealing and repair of incisional wounds. Use of bioactive therapeutics that facilitate early tissue repair or combat infection further enhanced the efficacy of this approach. In addition to acute trauma, slow-healing and chronic wounds, including in diabetic and obese patients, are a significant cause for morbidity. Advanced biologics have shown some promise but have largely not succeeded in cases of intractable wound pathologies, and the last biologic approved for diabetic wounds was over 25 years ago. I will describe our new findings on the delivery of immunomodulating bioactive molecules e.g., histamine receptor agonists and silk-nanomaterials for kickstarting early stages of tissue repair, which are largely dysfunctional in diabetic wounds. I will also discuss new findings on the effect of polypeptide structure on immunomodulation and on transcriptional responses to silk treatment. An approach for temporal delivery in which, timing the delivery of growth factor nanoparticles to later stages of tissue repair led to early wound closure in healthy and diabetic obese mice will also be discussed. Novel biomaterials designed to stimulate histamine pathways for effective wound healing will also be discussed. Our approach on biomaterials innovation, light-activated sealing, and temporal bioactive delivery will lead to new therapeutic interventions for tissue repair and regeneration.

Growth and Characterization of In Vitro Vascular Tissues *Zhengpeng J. Wan, Marie Floryan, Jordan Whisler, Shun Zhang, Emad Moeendarbary and Roger Kamm; Massachusetts Institute of Technology, United States*

Introduction. Most organs in the body require a perfusable vasculature to deliver needed nutrients, eliminate waste, and maintain normal levels of gas exchange. This is accomplished by means of a hierarchical vascular tree from arteries to capillaries to veins, with the smallest caliber vessels having diameters on the order of 10 mm. To generate realistic in vitro models of healthy and diseased tissue, and for creating implantable organ systems, it is essential to develop the capability to grow microvascular networks (MVN) in our microphysiological systems that recapitulate in vivo morphological complexity and maintain perfusability for as long as needed to characterize and interrogate the model and to prepare systems designed for implantation. Multiple approaches have been tried having the potential to achieve the high cell densities and organ specific microstructure needed to accomplish complex organ functions in a fully-vascularized and perfusable system. Here we describe recent studies aimed at refining the methods employed to optimize the self-organization and self-assembly of a perfusable MVN with long-term viability and functionality.

Methods and Results. Our approach has been to focus on the vasculature first, then seek methods to increase organ-specific cell type and density, prolong functionality, and promote anastomosis with intra-organoid vascular structures. We currently use a broad repertoire of endothelial cells (EC) along with a variety of accessory cells, generally selected from the organ of interest. We most often start by suspending the cells in a fibrin gel solution at an optimized concentration (both gel and cells) and allow them to polymerize and self-organize into a 3D network. Polymerized gel moduli are typically in the range of 100-500 Pa initially, which rises to over 1 kPa within 2 weeks as measured by AFM. This stiffening is attributable to secretion of a broad collection of matrix proteins (assessed by mass spectrometry), notably from the collagen family, as well as to the generation of stromal cell-induced stresses (assessed by 3D traction force microscopy).
Methods have been developed to promote robust vascular network formation even when using EC or stromal cell combinations that are otherwise prone to poor vascular development. These methods include the use of interstitial flow (IF) during the initial formation of networks from cells suspended in fibrin gels, and the introduction of intravascular flow after network formation. One of the mechanisms of action with IF is the transient elevation of MMP-2 secretion by the EC during vessel formation, creating conditions that reduce the dependence on stromal cells. Intravascular flow also promotes long-term (> 1 month) viability of the networks, reduced dependency on added growth factors, and a suppression of the initial inflammatory response often observed in in vitro vascular networks.
Recent experiments have also shown that iPS cell-derived EC generated by transient induction of ETV2 expression produce exceptionally high yields of endothelial cells with short-term differentiation protocols that form functional vascular networks in co-culture with various types of stromal cell. Transcriptomic analysis of these endothelial cells indicates strong EC marker expression with few of the epithelial signatures seen in previous iPSC-derived ECs, suggesting wide applicability in numerous model applications.

Conclusions. High quality and durable microvascular networks can be reliably formed from a variety of EC/stromal cell combinations for a range of applications. The ECs can be derived from iPSC sources using simple, short-duration protocols and remain viable with good functionality for periods more than one month. These attributes make them excellent candidates for uses in disease models or regenerative medicine applications.

10:45 AM SB05.01.05
Enhancing Neural Tissue Engineering Through Gradient Printing of Surface-Bound Laminin Protein *Ayesha Budhwani, Omid Dadras-Toussi, Sheereen Majd, Chandra Mohan and Mohammad Reza Abidian; University of Houston, United States*

To regenerate damaged nerves after injury, it is essential for the axons and neurites to receive guidance cues for *their outgrowth. Laminin is a surface-bound protein found in the extracellular matrix that can serve as a chemoattractant to guide the neurite outgrowth. The printing of laminin gradients can guide the axons in the desired direction. Several research groups have leveraged various approaches to fabricate these gradients, however enabling these gradients to cover large nerve gaps (>10mm) has remained a challenge. Here, we introduce a novel micro-printing technique for the printing of long gradients with various profile shapes (I.e., linear, exponential, hill) to potentially direct axonal regeneration.*

Laminin gradients were first printed on the surface of an agarose hydrogel slab (thickness: 4mm) with the help of controlled X-Y-Z stages and a nano-syringe pump. Laminin solution (50 ugml-1) was loaded into the syringe and vertical lines of laminin were printed next to each other (vertical and horizontal distances of 5mm and 200µm, respectively) while varying the velocity with each line. The printed laminin patterns were then stamped to the surface of a glass coverslip which was previously treated with poly-L-lysine (PLL) for 10 minutes. The immobilized laminin gradients were then visualized and quantified using immunofluorescence staining.

Various laminin gradients (I.e., linear, exponential, and hill) were printed, stamped, and quantified. The linear gradient consisted of 25 lines (5mm long) with a solution concentration of 50 ugml-1 and each line was printed for an increasing interval of 10, 20, and 30 seconds. The results demonstrate that this technique can be used to obtain a wide range of long and high-resolution laminin gradient profile shapes, and the neurite outgrowth response to each gradient will be assessed to record the optimum gradient profile for better axonal regeneration.

11:00 AM SB05.01.06

In Vitro Validation of PEDOT:PSS 3D Printed Conductive Hydrogels as Promotors of Angiogenesis and Wound-Healing in Diabetic Foot Ulcers (DFU) *Andrea D. Madrigal, Atzin Alcaraz, Alexandra Huerta, Tania S. Hernandez, Laura S. Cardenas and Luis M. Lozano; Tecnológico de Monterrey, Mexico*

Diabetic foot ulcers (DFUs) represent a significant healthcare challenge worldwide for patients with diabetes Mellitus. These wounds are associated with poor glycemic control, vascular disease, and underlying neuropathies. Alongside impaired wound healing and bacterial infection biofilms, DFUs often become a chronic disease that can lead to severe complications such as osteomyelitis and lower limb amputations. In this research project, we propose an innovative therapeutic strategy, applying polymeric conductive 3D-printed hydrogels to promote angiogenesis and improve wound healing in DFUs. These hydrogels, composed of biocompatible polymers, offer a combination of electrical conductivity and mechanical properties suitable for wound healing applications. The conductive properties of the hydrogels facilitate electrical stimulation at the wound site, promoting cell proliferation, angiogenesis, tissue regeneration, and inhibiting bacterial growth. The antimicrobial activity of the hydrogel is of high relevance, as progressed polymicrobial biofilms become drug-resistant and can lead to treatment failure. Additionally, the 3D printing technology allows for precise customization of the hydrogel scaffolds, ensuring optimal fit and coverage of the ulcerated area.

At this stage, the project aims to investigate the efficacy of conductive 3D-printed hydrogels in promoting wound healing and preventing complications associated with DFUs through in vitro experiments in hyperglycemia conditions. Additionally, biocompatibility and long-term safety assessments will be conducted to evaluate the feasibility of clinical translation. The outcomes of this research can potentially translate into improved therapeutic approaches in the management of DFUs, offering a promising addition to the current standard treatment and improving the quality of life for diabetic patients.

This research project has been supported by the Challenge Research Funding Program of Tecnologico de Monterrey.

11:15 AM SB05.01.07

Enhancing Drug-Induced Tissue Regeneration via a Polydopamine-Based Delivery System *Hyeju Han, Bongkyun Kang, Yuejin Kim and Kyueui Lee; Kyungpook National University, Korea (the Republic of)*

A drug known as 1,4-dihydrophenonthrolin-4-one-3-carboxylic acid (1,4-DPCA), which acts as a PHD (prolyl hydroxylase) inhibitor, has demonstrated the ability to promote tissue regeneration by enhancing metabolic activity through the upregulation of Hif-1α. This study introduces a novel approach to designing a drug delivery system aimed at optimizing the regenerative effects of 1,4-DPCA. By encapsulating 1,4-DPCA within polydopamine (PDA), which induces the production of reactive oxygen species (ROS), the combined effects of Hif-1α upregulation and the activation of cellular antioxidant defenses by localized ROS can significantly accelerate tissue regeneration. The hydrophobic properties of 1,4-DPCA make it suitable for encapsulation in the PDA carrier through a series of steps: initially, the drug forms aggregates due to its hydrophobic nature in the reaction solution, and subsequently, PDA components (dopamine hydrochloride) assemble around these aggregates, incorporating the drug into the core of PDA nanocarriers. This encapsulation process was validated using SEM, TEM, and XPS analyses. The ROS-generating capability of the developed drug delivery system (DDS) was confirmed via peroxide analysis. Further RT-qPCR and ELISA analyses showed that the released ROS and 1,4-DPCA contributed to the upregulation of antioxidant genes and Hif-1α, respectively. The synergy between these effects resulted in significantly enhanced bone tissue regeneration, as evidenced by a mouse calvarial defect model, where the bone regeneration was approximately six times greater than that of the untreated control group. Additionally, hemolysis and CCK-8 assay results indicated that the developed DDS is safe for in vivo injection, suggesting its potential for non-invasive applications. Considering that the tissue regeneration mechanisms activated by this DDS can be applied to various types of tissues, its applicability extends beyond bone defect-related conditions to other disease models requiring accelerated tissue regeneration.

SESSION SB05.02: Polymeric Biomaterials for Regenerative Engineering II
Session Chairs: Michelle Oyen and Janet Zoldan
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 312

1:30 PM *SB05.02.01

Biomaterials to Promote Endogenous Tissue Regeneration *Shyni Varghese; Duke University, United States*

Regenerative medicine is an interdisciplinary field that has significant promise for treating compromised tissues and organs. In our laboratory, we use a number of tools including biomaterials, organoids, quantitative modeling, and animal models to gain new fundamental understandings and identify therapeutic targets. In this talk, I will first discuss our efforts in creating synthetic analogs of the extracellular matrix to identify molecular mechanisms new therapeutic targets. Next, I will discuss how these understandings can be leveraged to develop therapeutic interventions to promote endogenous tissue repair and mitigate pain.

2:00 PM *SB05.02.02

Polymer Engineering for Pulsatile Release of Biologics *Ana Jaklenec; Massachusetts Institute of Technology, United States*

Engineering translatable technologies to help global population has been met with various challenges related to infrastructure, patient access and adherence. I will present how polymers can be leveraged with engineering design to develop solutions for global health. For example, the innovation of the SEAL (StampEd Assembly of polymer Layers) technology that allows controlled pulsatile release of biologics days to months after injection or implantation, for single-injection self-boosting vaccines, cancer immunotherapy and post-surgical therapy for tissue regeneration will be discussed.

2:30 PM SB05.02.03

Dipeptide Nanotubes Reinforced Hydrogels for Neural Injuries *Jordan E. Pagliuca[1], Parthiv Ravikumar[1], Alecsander DaSilva[1], Prathyushakrishna Macha[1,2] and Milana C. Vasudev[1]; [1]University of Massachusetts Dartmouth, United States; [2]Molecular Devices, Danaher, United States*

The study of self-assembled, nanomaterial scaffolding has become a rapidly-growing area of biomedical research, particularly in the realm of regenerative medicine and tissue engineering applications for neurological injuries and diseases. Currently, there are limited self-repair strategies and treatments for central nervous system deficits, as the process of neurite growth is often slow, complex, and occurring in inhibitory environments, ultimately leading to permanent nerve damage. Preliminary findings from our team support the efficacy of PECVD deposited, vertically-aligned, dipeptide-based nanotube substrates for stimulating neural cell proliferation and differentiation. Peptide-based building blocks are utilized as they have the capacity to self-assemble into highly organized nanoscale structures that possess key functional properties such as biocompatibility, biodegradability, molecular recognition, high aspect ratios, semi- conductivity, and stiffness. The lingering issue is the need to successfully develop a vehicle to introduce these nanostructures into targeted regions of the body for in-vivo testing while retaining their structure, orientation, and organization. One potential solution involves combining these nanotubes with hydrogels for noninvasive, ease of implantation.

Within this study we aim 1) to fabricate a dipeptide nanotube reinforced-hydrogel with optimized structural properties for cell adhesion, proliferation, and differentiation, 2) to investigate the in vitro effects of human neural stem cells cultured within the scaffold, and 3) to explore the logistics of incorporating a 3D printable, bioresorbable, electrical stimulation circuit. We hypothesize that incorporation of semiconductive, dipeptide-based nanotubes into a hydrogel scaffold can positively impact the regeneration capacity of nerve and support cells via mechanical cues as well as via electrical stimulation. In essence, these functionalized scaffolds will create tissue mimics that can encourage repair along short sections of injured neurons. Peptides containing tryptophan-tyrosine residues are of particular interest due to their well-characterized redox potential and their multiple roles in neurotransmitter synthesis. Gelatin and sodium alginate will be the natural polymer bases for the hydrogel component of the biomaterial, as they have been linked to numerous salutary advantages for central nervous system repair, including tunable degradation rates, slow release of bioactive factors, and low immunogenicity. Nanotubes synthesized through solution phase self-assembly mechanisms are incorporated in concentrations ranging from 0-1 mg/mL to circumvent issues with cell viability and accelerated degradation reported at higher concentrations. Examination of physiochemical characteristics, biological interactions, cellular proliferation, gene expression, and cytotoxicity at the cell-scaffold interface via various imaging techniques and cell culture analyses will reveal whether this option is a worthy investment for neurological research.

The nanocomposite will be further 3D bioprinted to create scaffolds that can be predesigned to custom fit to an individual's unique site of nerve injury, thus, constraining exogenous/endogenous neurite growth and recreating developmental neurogenesis. Furthermore, the scaffolds inherent electrical properties can be harnessed for neurological activation and repair, introducing potential gradients through periodic voltage treatments that induce membrane depolarization and impact the functionality of enzyme-activated and ion-transport membrane proteins.

Thus far, the idealized parameters for bioprinting while maintaining maximum cell viability has been achieved and initial morphological and in-vitro analyses of these samples have commenced.

2:45 PM SB05.02.04
Targeted Electrospun Fiber Formation and Cellular Response for Cardiac Patch Applications *Alexi Switz, Darryl Dickerson and Anamika Prasad; Florida International University, United States*

Overview*: A common thread in regenerative medicine is mimicking the underlying architecture of the tissue being replaced. This is particularly challenging in heart tissue given the thick fibrous architecture and flexibility to match the dynamic environment during the cardiac cycle. Electrospinning and electrospinning-based technologies such as melt and near-field electrospinning are increasingly used in fiber formation for regenerative medicine, but challenges remain in controlling fiber morphology, integrating matrix within fibers, and creating structures to support cellular activity. These, in turn, also require innovation in electrospinning technologies. Our work has focused on developing affordable electrospinning devices, using the device for targeted fiber formation, and evaluating the cellular activities on the generated patches in the context of the structure and mechanics of patch-to-cell response.*

Methods and Results: *The material of choice for fiber formation was polycaprolactone due to its proven biocompatibility and use in cardiac tissue applications. Fibers were targeted to have an aligned and helically coiled architecture to mimic coiling present in many natural systems, including the heart and to provide strength along with dynamic stability. A range for fibers with variable fiber morphology was prepared, and its mechanics response was characterized via image analysis and tensile testing. Fiber formation was dictated by the electrospinning parameters, specifically the flow rate of the polymer solution through the syringe and the tip-to-collector distance. Porosity was one key parameter being controlled to provide space for cardiomyocyte activity. The biocompatibility and cellular response of these fiber scaffolds were tested by encasing the fiber scaffolds in a hydrogel comprised of gelatin glycidyl methacrylate with fibronectin added to this hydrogel to increase biocompatibility and aid in cardiomyocyte growth. Multiple such patches were produced resulting in a range of fiber diameter and structure porosity.*
The hydrogel-fibrous mat structure was seeded with cardiomyocytes and placed on a holder made of PDMS to provide mechanical stimulus to the cardiomyocytes. These holders were placed in a 6-well plate, and the cardiomyocytes seeded in the cardiac patch scaffold were incubated for 28 days. Cell media was regularly changed to provide the cells with nutrients. Cell growth, viability, and cardiomyocyte function were monitored and compared across patches with a final deduction on the most suitable design for the patch delivery.

3:00 PM BREAK

3:30 PM SB05.02.05
Flow Enabled Tissue Engineered Testbeds for Cancer Metastasis *Kalpana Katti[1], Preetham Ravi[1], Sharad V. Jaswandkar[1], Quyen Huang[1], Shrinwanti Ghosh[1], Parth Vyas[2], Jiha Kim[1] and Dinesh R. Katti[1]; [1]North Dakota State University, United States; [2]Sanford Hospital, United States*

Bone metastasis of breast cancer and prostate cancer to bone results in over a million deaths each year in the world. Even larger number of patients suffer from skeletal complications affecting the quality of life. In the event of bone metastasis the inefficacy of available anticancer drugs results from the increased drug resistance of the migrated cancer. The lack of availability of patient samples and the failure of animal models results in an acute need for robust in vitro models of cancer metastasis. We report the design of a tissue-engineered bone scaffold seeded with patient-derived cancer cell lines co-cultured with appropriate tumor microenvironment duplicating *cells such as cancer-associated fibroblasts and epithelial stromal cells to create realistic bone metastasis testbeds of breast and prostate cancer bone metastasis. The bone scaffold is made using nanoclay polymer composites seeded with human mesenchymal stem cells, recreating the remodeling stage of fetal bone. Further, we have developed a novel horizontal flow bioreactor that mimics the interstitial fluid flow in the scaffolds. The bioreactor also has the ability to mimic the migration of cancer cells in fluid flow to the metastatic bone site. This fluid flow-enabled metastasis testbed is used for screening drugs and the discovery of new markers of metastasis. Thus, by mimicking both the accurate tumor microenvironment of the bone site of metastasis, as well as the migration of cells and their adhesion at the bone site using flow-based bioreactor, the novel testbed presented here is a useful in vitro system for the development of new therapies of metastasis as well as providing methods for personalized medicine.*

3:45 PM SB05.02.06
Generative Modeling, Design and Analysis of Spider Silk Protein Sequences for Enhanced Mechanical Properties *Wei Lu[1], David L. Kaplan[2] and Markus J. Buehler[1]; [1]Massachusetts Institute of Technology, United States; [2]Tufts University, United States*

Spider silks are remarkable materials characterized by superb mechanical properties such as strength, extensibility and light weight features. Yet, to date, limited computational models are available to fully explore sequence-property relationships for analysis and design. We propose a generative modeling, design and analysis technique applied to create novel spider silk protein sequences for enhanced mechanical properties. The model, pretrained on a large set of protein sequences, is fine-tuned on 1,033 major ampullate spidroin (MaSp) sequences for which associated fiber-level mechanical properties were measured. This process represents an end-to-end forward and inverse generative strategy. The dataset is established by curating a published silkome dataset. Performance is assessed through: (1) novelty analysis and protein type classification for generated spidroin sequences through BLAST searches, (2) property evaluation and comparison with similar sequences, (3) comparison of molecular structures, and (4) detailed sequence motif analyses. We generate silk sequences with property combinations that do not exist in nature and develop a deep understanding of the mechanistic roles of sequence patterns in achieving overarching key mechanical properties (e.g., elastic modulus, strength, toughness, failure strain). Other research that will be discussed includes applying this approach to expand the silkome dataset by using a combination of generative modeling and molecular simulations, thereby facilitating further sequence-structure analyses of silks, and establishing a foundation for synthetic silk design and optimization.

4:00 PM SB05.02.07
Fabrication of Poly (ε-caprolactone) Scaffolds with Cyclic Compressional Stability for Bone Tissue Engineering *Meenal Agrawal and Rajiv K. Srivastava; Indian Institute of Technology Delhi, India*

The traditional method of grafting to address chronic tissue injury is severely constrained by the risk of disease transmission, immunogenic rejection, and constrained availability of donor sites. Biomaterial-assisted tissue regeneration has garnered recent attention as a potential solution to this predicament. In order to enhance cell adhesion and proliferation, as well as the transportation of essential nutrients, it is required to carefully design scaffolds that can mimic the implant-site properties. Amongst the various methodologies to fabricate an ideal scaffold, high internal phase emulsion (HIPE, dispersed phase volume >74%) templating has been a recent subject of interest due to its capability to fabricate highly porous structures. Additionally, use of nanoparticles as stabilizers can not only avoid the use of harmful surfactants, but also lead to the formation of polymer nanocomposites leading to enhanced mechanical properties. Utilizing this methodology, nanocomposite scaffolds of crosslinked poly (ε-caprolactone) (PCL) were fabricated which involved single-step polymerization and crosslinking of ε-caprolactone emulsions that were stabilized using hydrophobically modified silica *nanoparticles. The properties of the scaffold were manipulated by altering the concentration of mSiNP and the dispersed phase. The presence of mSiNP led to an increase in pore surface roughness. Additionally, the increased concentration of mSiNP resulted in improved cyclic compressional stability, allowing for more than 5 cycles of compression. This cyclic compressional stability of scaffolds is highly desirable for bone tissue engineering as it ensures scaffold's dimensional stability under the natural compressional stresses that a bone subjected to during routine activities. The developed nanocomposite scaffolds demonstrated excellent in-vitro cytocompatibility against MG63 cells.*

4:15 PM SB05.02.08

A Multi-Functional Hybrid System Comprised of Polydopamine Nanobottles and Biological Effectors for Cartilage Repair *Min Hao and Younan Xia; Georgia Institute of Technology, United States*

Serving as the connective tissue between bones, articular cartilage plays an essential role in shock absorption and load-bearing. An injury to cartilage is expected to trigger degenerative changes, ultimately leading to osteoarthritis. Among the numerous methods for treating articular cartilage injuries, stem cell therapy stands out as a viable approach owing to the self-renewal and multi-directional differentiation capacities of stem cells. Despite recent progress, it remains a challenge to recruit stem cells to the injured site while ensuring subsequent cell survival and directing their differentiation into chondrocytes. Herein, we report a hybrid system consisting of polydopamine (PDA) nanobottles embedded in a hydrogel matrix to stepwise release biological effectors for the recruitment and protection of stem cells while promoting their chondrogenic differentiation. Specifically, we load a homing effector in the hydrogel matrix, together with the encapsulation of a cartilage effector in PDA nanobottles filled with a phase-change material. In action, the homing effector is quickly released from the hydrogel in the initial step to recruit stem cells from the surroundings. Owing to the antioxidation effect of PDA, the recruited cells are shielded from reactive oxygen species. The cartilage effector is then slowly released from the nanobottles to promote chondrogenic differentiation, facilitating cartilage repair. Altogether, this strategy encompassing recruitment, protection, and differentiation of stem cells offers a viable route to tissue repair or regeneration through stem cell therapy.

4:30 PM SB05.02.09

Ultrafast Selective Filter for the Bio-Medical Engineering *Milana O. Lisunova[1,2]; [1]Georgia Institute of Technology, United States; [2]University of Arkansas, United States*

The gradient distribution of the fabricated nanofibers can be used as robust, flexible, large-area, freely-suspended membranes with controlled transport properties. The main focus on the investigation of the transport properties across the membrane (diffusion coefficients and permeation mechanisms for different components) with different amounts of fibers in the membrane and nanoscale porosity. The utilization of the ultrathin porous electropsun polymer membranes will significantly reduce the thickness of the layered membrane that consequently will increase its selectivity and permeability that is the main requirements of the nanoscale filtration. Such membranes with different length-scale pore dimensions from sub-nanometers to micrometers could be used in numerous applications, such as water and wastewater treatment, chemical and pharmaceutical processing (blood oxygenation, drug delivery control devices), environmental monitoring and quality control, as well as food and beverage processing. Gradient electrospun polymer mebranes could be a key components in fuel cells and bio-separation systems.
The ultimate goal of the research is the understanding of how the fabricated membranes of nanofibers from the bio-compatible and bio-degradable polymers can be used as robust, flexible, large-area, freely-suspended membranes with controlled composition (thickness, pore size) and properties (mechanical and transport). One of the main focus is the investigation of the transport properties across the biofibers (diffusion coefficients and

permeation mechanisms for different components) with different amounts of bio-fibers in the membrane and nanoscale porosity. The utilization of the ultrathin porous electrospun bio-polymer membranes will significantly reduce the thickness of the membrane that consequently increase its selectivity and permeability at the same time maintain the mechanical stability.
The bio-polymer membranes (based on polysaccharide, protein) are found important in regenerative medicine for the construction of the scaffold for bone tissue engineering, and development bioactive nanomaterials for neural tissue engineering. These membranes possess separation properties to the mono-, di-, and multivalent cations and anions or neutral molecules able to control surface charge, hydrophilicity and permeability. The pore size of the polymer membrane could be easily changed from the several hundred nanometers to nanometer sizes with total thickness as low as 20 nm. The total thickness is the most crucial parameter that determines membrane resistance to flow and, as a result, will also significantly affect its permeability and selectivity. A modern membrane's market requires the further reduction of the thickness of the anisotropic membrane well below 50 nm which is difficult to achieve for known membranes. Thickness reduction down to below 20 nm might improve flux by 5-10 times with much improved selectivity.

SESSION SB05.03: Poster Session I: Biomaterials for Regenerative Engineering I
Session Chairs: Gulden Camci-Unal, Michelle Oyen, Natesh Parashurama and Janet Zoldan
Tuesday Afternoon, December 3, 2024
8:00PM - 10:00PM
Hynes, Level 1, Hall A

Conductive and Bioactive Supramolecular Scaffolds Enhance Neural Maturation *Anna Metlushko, Nick Sather, Nozomu Takata, Dina Simkin, Timmy Fyrner, Evangelos Kiskinis and Samuel I. Stupp; Northwestern University, United States*

Traumatic injury in the central nervous system (CNS) results in neuronal damage and death, with chronic symptoms such as damaged cognition and paralysis. While chemically engineered scaffolds can be delivered to provide a substrate to stimulate axon regrowth, many grafts lack efficacy due to inefficient electrical coupling between the material and the conductive in vivo environment. We have incorporated a conductive component, functionalized poly[3,4-(ethelynedioxythiophene)] (PEDOT), into a supramolecular biomaterial scaffold which facilitates neuronal differentiation and maturation. Peptide amphiphiles (PAs) can self-assemble into high-aspect ratio nanostructures that mimic native extracellular matrix and may be functionalized with bioactive epitopes such as (previously described) laminin mimetic (IKVAV). Interestingly, this synthesized PEDOT:PA enhanced neurite length and branching in murine primary cortical neurons. Furthermore, protein analysis clearly showed PEDOT:PA upregulated maturation and pre-/post-synaptic markers (Map2, PSD 95, Syn). Moreover, human induced pluripotent stem cell (iPSCs) derived spinal cord neuron models showed enhanced differentiation of iPSCs into human spinal cord progenitors through increased expression of TUJ-1. These results strongly suggest that PEDOT:PA promotes CNS maturation in mouse and human systems and shows its potential as a therapeutic in spinal cord injury.

SB05.03.02
Fibrillar Modulation of Densified Collagen Hydrogels for Tissue-Engineered Substitutes *Federico Cammarata, Alexander W. Justin and Athina E. Markaki; University of Cambridge, United Kingdom*

Fibrillar self-assembly of collagen type I is fundamental to its functionality. In physiological conditions, collagen fibrils exhibit a hierarchically organized architecture providing the necessary structural support to biological tissues. Understanding this assembly process is critical for unravelling the mechanisms underlying collagen's functional properties and exploring its often-overlooked possibilities in tissue engineering. Furthermore, cell repopulation is critical for functional tissue substitutes in vivo. Despite collagen's biocompatible properties, collagen hydrogels' inherent composition results in insufficient mechanical strength, making them unsuitable materials for building implantable tissue constructs. Therefore, approaches that can modify the physiological collagen fibrillar microarchitecture to strike a balance between sufficient mechanical properties and cellular repopulation are essential.

In this study, we explore the modulation of densified collagen at fibrillar level for the creation of strong biomimetic tissue alternatives. We present a novel fabrication method for highly densified collagen sheets (HDCS) based on interstitial fluid evacuation. By incorporating chemical and biological molecules with known mechanisms of action – ranging from electrostatic interactions to macromolecular crowding – we induce fibrillar modulation while keeping critical factors like collagen concentration, gelation temperature and pH stable. Through scanning electron microscopy and subsequent quantitative analysis, we demonstrate that modulation in HDCS affects fibril bundling and pore area, with a significant increase in average pore area as well as fibril diameters. Tensile testing shows that modulation increases strength up to 50%. Finally, we will present results from in vitro and in vivo studies comparing biological response and cellular infiltration between modulated and unmodulated HDCS. The present study holds promise for optimised collagen hydrogels with excellent biological activity and sufficient mechanical strength.

SB05.03.03

Laser Patterning of 3D Printed Near-Beta Ti Alloy for Modulated Response of Human Bone Marrow Stromal Cells *Annett Gebert[1], Avinash Hariharan[1], Phil Goldberg[1], Frederic Schell[2], Ute Hempel[3], Mariana Calin[1] and Andres-Fabian Lasagni[3]; [1]Leibniz Institute for Solid State and Materials Research Dresden, Germany; [2]Fraunhofer Institute for Material and Beam Technology, Germany; [3]Technische Universität Dresden, Germany*

Additive Manufacturing (AM) of low modulus beta-Ti alloys paves the way for patient-specific implants which reduce stress shielding and, laser surface functionalization has a high potential to improve bone healing processes. The presented project aims to design a laser-based processing chain for a beta-type Ti alloy with (i) AM of 3D parts with defined microstructures and (ii) surface texturing with direct laser interference patterning (DLIP). In vitro studies with human bone marrow stromal cells clarify how those tailored textures guide the cell response. Ti-13Nb-13Zr parts are fabricated by laser powder bed fusion (LPBF) and microstructure - mechanical performance relations are studied. DLIP with nanosecond (ns) and picosecond (ps) pulses generates single- and multi-scale surface topographies in micro- and nano-meter ranges, respectively. These surface textures are analysed with confocal laser scanning microscopy, electron microscopy and Auger electron spectroscopy and their impact on wettability and corrosion behavior in phosphate buffered saline is studied. Their influence on the behavior of human bone marrow stromal cells is assessed with fluorescence microscopy, electron microscopy and MTS assays. The enzyme activity of tissue non-specific alkaline phosphatase activity serves as early osteoblast differentiation marker.

The ns-DLIP textured surfaces exhibit high beta-phase fractions and thick passive films which enhance the corrosion stability compared to ps-DLIP ones. Compared to untextured specimens, both types of DLIP textures cause higher metabolic activity and cell proliferation. The single-scale ns-DLIP textures encourage cell extensions anchored in grooves, while multi-scale ps-DLIP textures promote cell extensions attaching to nanostructures on walls. The groove width and nanotopographies in groove areas facilitate cell spreading. Combined effects of *surface topography, roughness and chemistry influence cell adhesion, proliferation, and differentiation. Surface-functionalized 3D printed beta-Ti alloys hold potential for a novel generation of biocompatible implants. Funded by EFRE, Parliament of Saxony (100382988/-89), EC (H2020-BIOREMIA, GA 861046).*

SB05.03.04

Borate-Modified β-Glucan-Based Robust Nanotubes and Their Applications *Ivan Kelnar and Ludmila Kaprálková; The Czech Academy of Sciences, Czechia*

*Extensive research of various **β-**1,3-glucan polysaccharides with comb-like structures and triple helix conformation indicate their potential to form nanotube-like arrays. This structure of water-soluble **β-**1,3-glucans isolated from different cereals, bacteria, fungi, etc. was mostly formed in water whereas dissolution in organic solvents, like DMSO, leads to coils formation only. At the same time, relatively irregular tubular structures with thick wall and small inner space are reported. Here, application of glucans for in-situ encapsulation of some drugs and nanoparticles is more successful. In the case of yeast **β-**1,3-glucan, a more regular nanotubular structure can be self-assembled using a suitable annealing regime in concentrated formic acid solutions. In spite of more suitable geometry, marked disadvantage is formylation of glucans and difficult isolation of nanotubes with questionable dimensional stability. As a result, successful preparation and application of single polysaccharide nanotubes, similar to e.g. carbon nanotubes, is not reported. It was also demonstrated that triple-helix β-1,3-glucans can be chemically crosslinked to form hydrogels with nanochannels. We have successfully used interactions of comb-like β-1,3-glucan (with two β-1,6-glucan residues for every three main chain glucose units), extracted from Auricularia auricula-judae mushroom, with borate in dilute water solution to synergically influence self- assembling process. This consists in support/modification of triple-helix conformation and simultaneous strengthening of nanotube walls by borate-based physical and covalent bonds formation. In this way, robust straight glucan nanotubes (GNT) with outer diameter of ~50 nm and wall thickness of several nm were obtained. This was indicated by TEM images of water-dispersed GNT together with similar structure found by SEM evaluation of lyophilized mat and nanocomposite prepared by single mixing of water suspension of GNT and solution of carboxymethylcellulose or methylcellulose. In addition to comprehensive characterization using FTIR, XRD and electron microscopy, we present successful application of GNT in hydrogels, high voltage-assisted 3D printing-prepared materials, nanocomposites and related electro-spun fibres/scaffolds. Results indicate that borate-modified glucan nanotubes (GNT) represent polysaccharide-based equivalent of carbon and inorganic nanotubes with substantially higher potential for medical applications. As a result, application of GNT may lead to, e.g., high performance scaffolds for tissue engineering combining high specific surface (for drug loading) with unique medical activity of triple helix **β**-1,3-glucans.This work was supported by Ministry of Education Youth and Sports of the Czech Republic (Grant LUAUS 23004)*

SB05.03.05

Nitric Oxide Inhaler with Precise Delivery Control for Pulmonary Arterial Hypertension Treatment *Yoogyeong Oh and Jinkee Hong; Yonsei University, Korea (the Republic of)*

Nitric oxide (NO) has been acclaimed as a “miracle molecule”, winning the Nobel Prize in Medicine in 1998 for its role as a signaling messenger. Today, NO is still widely used in various biomedical applications, including wound healing, respiratory, cardiovascular, anticancer, and antibacterial.

Pulmonary arterial hypertension (PAH) is an incurable disease characterized by elevated pressure in the pulmonary arteries due to progressive narrowing and remodeling of blood vessels. This condition leads to increased pulmonary vascular resistance and places a significant strain on the right ventricle of the heart. NO is a powerful regulator of hemodynamics in the cardiovascular system, activating the expression of cyclic guanosine monophosphate (cGMP) in smooth muscle cells (SMCs). Thus, inhaled NO (iNO) act as a potential therapeutic *agent for PAH treatment.*

However, there are two limitations to the pulmonary delivery of NO via inhalation. First, NO has a concentration-dependent therapeutic effect. Low concentrations of NO (< 400 nm) promote cell proliferation and survival, whereas high concentrations of NO (> 1 μm) induce apoptosis and cell cycle arrest. Therefore, precise control of release behavior is essential to deliver the extremely low concentrations of NO, ranging from picomolar to nanomolar, required for vasodilation. The second limitation is the low bioavailability of NO. The therapeutic effect of NO is impeded due to its short half-life and limited diffusion distance. As a result, the targeted delivery system is required to ensure the action of NO in the PAH lesion.

To achieve this goal, we developed NO inhalers that deliver NO mimicking a healthy endothelial environment into deep lungs by using a nebulizer.

The porous structures were controlled to deliver NO into deep lungs to treat PAH. We prepared two kinds of NO inhalers with different porous structures: the open porous NO inhaler (OPNI) and the closed porous NO inhaler (CPNI). Despite having a large geometric diameter of 20 micrometers, OPNI had a small aerodynamic diameter of about 3.5 micrometers due to its highly porous structure. Furthermore, we confirmed that the stabilization effects by electrostatic interaction between unreacted amines and NONOates retarded NO release. As a result, OPNIs continuously released 0.277 nanomoles of NO, within a range of concentrations produced by endothelial cells, increasing the expression of cGMP in SMCs.

To summarize the presentation, we developed a nebulizer-based NO delivery system that can be an alternative to conventional pulmonary therapies. We anticipate that this translational study will contribute to expanding the potential of NO in various biomedical applications.

SB05.03.06

Macrophage-Targeted Therapeutic Immunomodulation via Poly-Glucose Nanoparticles *Biplab Sarkar and Christopher B. Rodell; Drexel University, United States*

Macrophages contribute 50% to the total mass of immune cells in the human body. They are the main professional phagocytes that recycle cellular debris during routine cellular turnover. Furthermore, these cells also orchestrate immune homeostasis and tissue function, playing a vital role in tissue repair and regeneration. Overactive macrophages may adversely affect tissue remodeling during chronic inflammation. Furthermore, in the tumor microenvironment, immunosuppressive macrophages promote tumor survival and growth. The wide distribution and phenotypic plasticity of macrophages, which underlie the diversity of their function, render it a suitable cell type for programming tissue response in pathological scenarios. Macrophages have a strong propensity to internalize poly-glucose nanoparticles. Utilizing this feature, we developed macrins (CD-Mac) and cyclodextrin-based nanoparticle (CDNP) platforms that include binding pockets for immunomodulatory drugs. We investigated the effect of particle size on nanoparticle uptake by macrophages and examined the receptor-mediated interactions driving macrophage-targeted delivery. Increasing particle size correlated with greater uptake by macrophages, and we identified receptors such as MSR1 and MRC1 as mediators of engulfment. These nanoparticles can either promote or inhibit inflammatory polarization of macrophages, depending on the drug payload. We used this versatility to design nanoparticle–drug combinations to promote pro-inflammatory or anti-inflammatory phenotype in macrophages, depending on pathological scenarios. In the context of cancer, we demonstrated that nanoparticles carrying agonists for toll-like receptors (TLRs) activate NF-κB in tumor-associated macrophages and induce them to produce the anti-tumor cytokine IL-12, overcoming their inherent immuno-suppressive properties. Furthermore, the myeloid-targeted therapy improved the efficacy of immune checkpoint therapy in murine models of cancer. In the context of inflammatory tissue remodeling, such as during left-ventricular remodeling after cardiac ischemia–reperfusion injury, we delivered anti-inflammatory drugs (such as celastrol) to inhibit chronic inflammatory programming in macrophages, preserving left-ventricular geometry and function. These results indicate the broad therapeutic potential of in vivo macrophage reprogramming via *poly-glucose nanoparticles.*

SB05.03.07

Surface Engineered Thromboresistant Vascular Graft as an Arterial Conduit *Nitisha Mehrotra[1,2], Suran Somawardana[2], Aparna Adumbumkulath[1], Paul Kim[1], Kirti Mhatre[3], Aladdein Mattar[4], Abdelmotagaly Elgalad[4], Ramyar Gilani[1], Crystal S. Shin[1], Pulickel Ajayan[2] and Ghanashyam Acharya[1,2]; [1]Baylor College of Medicine, United States; [2]Rice University, United States; [3]University of Houston, United States; [4]Texas Heart Institute at Baylor St. Luke's Medical, United States*

There is an unmet clinical need for long-term thromboresistant vascular grafts in cardiovascular surgery as conduits for coronary bypass and peripheral vascular substitutes. Currently available small diameter synthetic vascular grafts fail because of rapid blood clotting (thrombosis) at the blood-material interface and occlusion of the graft lumen. We hypothesized that the surface physicochemical properties of the graft (surface charge, surface energy, and porosity) affect the blood clotting process. In this study, we present the fabrication of a synthetic vascular graft (henceforth referred to as zetagraft) with programmable physicochemical and mechanical properties and its in vitro capacity to prevent the blood component adsorption on the graft surface. We demonstrate the ex vivo hemocompatibility and resistance to blood clotting (thromboresistance) by whole blood perfusion studies. We further demonstrate the in vivo thromboresistance of the zetagraft in pig carotid artery replacement model.

Methods: *We fabricated small diameter zetagrafts (of 2- and 4-mm diameter) with polyvinyl alcohol dissolved in dimethyl sulfoxide by the solvent extraction driven self-assembly strategy using a tubular assembly device. Zetagrafts were characterized for the physicochemical and mechanical properties by FTIR spectroscopy, Micro CT, scanning electron microscopy, confocal fluorescence microscopy, surface pH, and surface energy by water contact angle measurements. Mechanical testing was performed to determine the stretchability and elastic modulus. In-vitro studies for biocompatibility and cell viability were performed on the zetagraft using fibroblast, HUVEC and HASMC cell lines. Ex vivo hemocompatibility and blood component adsorption studies were performed by circulating fresh porcine blood using a peristaltic pump. The zetagrafts were implanted in pig carotid artery replacement model to evaluate its thromboresistance.*

Results: *The zetagraft was soft, uniform, highly stretchable. Laser confocal microscopy and scanning electron microscopy of a cross section of the zetagraft revealed circularly aligned fiber assembly along the graft's lumen. The polymer fibers (of ~25 µm diameter) were tightly arranged forming a smooth luminal surface with no large spaces or pores. Morphometric analysis by micro-CT confirmed a uniform and smooth luminal surface with a wall thickness of ~1 mm. In this study, we fabricated zetagrafts of different surface charges (–4.2, –2.5, and –1.9 mV) and surface free energies (72.1, 72.9, and 73.5 mJ/m^2). Ex vivo blood perfusion with pig whole blood followed by FT-IR analysis revealed no blood protein adsorption on the zetagraft luminal surface while the commercial grafts (Propaten, and Dacron) exhibited significant adsorption of blood proteins as broad peaks at 3500-3000 cm^{-1} indicative of –OH and $–NH_2$ groups and two peaks at 1640 cm^{-1} and 1580 cm^{-1} corresponding to amide I and amide II stretching bands confirming the presence of amide groups. These studies confirmed that the thromboresistance of the zetagraft is attributed to its high surface free energy (73.35 mJ/m^2) that facilitates the formation of tightly bound hydrogen bonded water molecular layer on the zetagraft luminal surface. In comparison, PTFE, PEVA, and PET have low surface energies in the range of 19 to 42 mJ/m^2 exhibited significant adsorption of the blood components due to the absence of a hydrogen bonded water layer.*

Conclusions: *In this study we demonstrated the development of a thromboresistant zetagraft. Currently we are evaluating its long-term thromboresistance in pig carotid artery replacement model. Our results are very promising* *and zetagraft will provide a novel small diameter vascular graft and thus fulfil an important unmet clinical need.*

SB05.03.08

Fabrication of Elastic 3D Macroporous Scaffolds with Tunable Mechanical Properties for Bone Tissue Regeneration

Yogendra P. Singh, Raj Kumar, Lydia Mathew, Shobhna Kapoor and Kamendra P. Sharma; Indian Institute of Technology Bombay, India

Abstract:

Repairing bone defects or injuries, especially with irregular shapes or at soft tissue insertion sites, presents a significant challenge. Scaffolds that can adapt to such bone defects, present stiffness gradient, and induce osteogenesis are essential for effective bone regeneration. Ceria nanoparticles (CeNPs), polyethyleneimine (PEI), and polyethyleneglycol diglycidyl ether (PEGDE)-based composite macroporous scaffolds with tailored architectures and optimized mechanical attributes and potential for bone regeneration have been demonstrated. We elucidate the physicochemical, mechanical and osteogenic properties of elastic and structurally robust yet deformable 3D macroporous scaffolds developed by freeze-templating PEI-coated ceria nanoparticles. All the designed scaffolds showed interconnected pores with sizes varying between 80-150 µm, overall porosity of ~ 90 %, and interestingly, could undergo compressive strains while exhibiting a zero Poisson's ratio behaviour. To address the stiffness gradient of the native bone environment, we either varied the composition of CeNPs, PEI, and PEGDE in the scaffolds or crosslinked the free amine-functional groups in the scaffold with glutaraldehyde to increase compressive modulus. E.g. scaffolds comprising 0.02 % and ~ 0.06 % w/v ceria showed an average compressive strength of ~ 1 MPa and ~ 5 MPa, mimicking the cartilage/spongy bone mechanical environment. The scaffolds exhibit excellent elasticity and fast recovery (in ~ 2-3 seconds) from 80 % compressive deformation with intact porous architecture in the wet state. Scaffolded MC3T3-E1 pre-osteoblast bone cells demonstrated enhanced cell proliferation, optimal adhesion and high cell viability, indicating a non-toxic and conducive environment rendered by the designed scaffolds. This was further strengthened by in vivo studies in animal models showing high biocompatibility, low toxicity and non-immunogenicity of the scaffolds. Compared to pristine scaffolds, higher cellular activities with ceria-containing scaffolds indicate that nanoceria promotes efficient osteoblast adhesion and proliferation. This work presents the design and development of mechanically tuneable, elastic and deformable 3D macroporous scaffolds that can be included in bone defects with irregular shapes or at different implant sites with high potential for clinical translation.

Keywords: *Biomaterials, 3D macroporous scaffold, mechanical properties, osteogenic properties, tissue engineering.*

SB05.03.09

Comparison of Blood Components in Enhancing Calcium Phosphate Craniofacial Bone Regeneration

Sze Wai Lau, Yassine Ouhaddi, Mirko Gilardino, Mitchell Bernstein, Edward Harvey, Nicholas Makhoul and Jake Barralet; McGill University, Canada

Background:

Repairing large cranial defects is almost entirely performed using autografts however they are not without issues such as resorption and limited graft supply. Monetite, a calcium phosphate biomaterial shows promise in bone regeneration as it is rapidly resorbed and osteoconductive. Blood is readily available during surgery, and we sought to compare how either whole blood cells or damage-associated molecular patterns (DAMPS) such as extracellular DNA, hemoglobin, and cell wall material created by rupturing cells by freeze thawing affected bone repair. Whole blood, and platelet-rich plasma(PRP) and their freeze-thawed counterparts were added to monetite and used to repair critical sized rat calvarial defects compared with material-only controls. In this study, we used monetite *granules to regenerate bone, providing an osteoconductive environment to support bone formation and mineralization, assessing in vivo regeneration with four groups: granules mixed with PRP(GP), frozen PRP(GF), frozen whole blood (GB) and a control group (GC). A group using fresh whole blood will be added later.*

Methods:
Monetite granules were prepared by fragmentating a scaffold involving monocalcium phosphate monohydrate and beta-tricalcium phosphate. The study involved 24 male Wistar rats, divided into four groups. For the GP group, granules were mixed with PRP obtained after centrifugating blood collected from the same rats one day before surgery. As for the GF group, the granules were mixed with PRP that had previously frozen and thawed. For the GB group, the granules were mixed with hemolyzed blood, handled similarly to the GF group but without centrifugation. The GC group only used monetite granules to fill the bone defects. A surgical drilling system with trephine is used to create 8mm diameter defects between the Lambda and Bregma cranial sutures of the rat. Defects were filled with monetite granules, and they were supported by suturing the overlying periosteum. The rats were monitored for 5 weeks. Samples will be examined using microCT, and histological techniques.

Results:
By comparing the μ-CT images, it is obvious that the GP and GB group has a nearly mature bone structure that occupied nearly half of the defect, and the newly regenerated bone has a comparable density with the surrounding bone. The GF group has some bone formation around the edge, but the extent is significantly less than the GP group. In the GC group, no distinct mineralized structure was observed. Quantitative evaluation of the μ-CT images revealed that the BV/TV ratio in the GP group (18.40% ± 1.94%) and GB group (20.56% ± 3.08%) was statistically higher than those in the GF group (4.53% ± 0.89%) and GC group (3.21% ± 0.64%). The granules volume (μm^3) of GP group ($8.80E^{+09} \pm 1.01E^{+09}$) and GB group ($9.67E^{+09} \pm 1.34E^{+09}$) reduced significantly after implantation when compared to GF ($1.40E^{+10} \pm 2.58E^{+09}$) and GC group ($1.42E^{+10} \pm 2.80E^{+09}$). H&E staining of the defect zone produced results consistent with the μ-CT imaging. In the GP and GB group, abundant osteocytes and new bone were distributed from the edge of the defect, and bone marrow cavity structure is observed. In the GF group, there is a thin layer of bone tissue formed around the granules that close to the edge, but the amount is notably less than the GP group. New bone staining in the GC group don't show much new bone formation.

Conclusion:
This study emphasizes the crucial role of monetite in skull bone regeneration. It mimics natural bone composition, promoting osteoconduction, and encouraging stem cell differentiation. The research highlights the incorporation of PRP and growth factors enhances the osteoblasts differentiation, leading to significant bone formation. The addition hemolyzed blood may enhance the immune response, potentially facilitate bone formation. Immunohistochemistry will be conducted to study the inflammatory reactions and understand the leukocytes responses with the monetite granules.

SB05.03.10
Novel 3D-Printing Process for Improved Mechanical Properties of Tissue Engineering Scaffolds *Mrinal Ganash; University of New Hampshire, United States*

Introduction:
The field of tissue engineering is rapidly adopting the principles of additive manufacturing, which provides a means to generate complex functional tissue constructs in a programmable manner with micron-scale precision. However, the low mechanical stiffness and strength of 3D printed constructs significantly limits the application of 3D bioprinting in tissue engineering. Here, we propose a novel bioprinting process using a bioink consisting of gelatin, methacrylated gelatin (GelMA) and alginate. Once printed, this bioink is crosslinked by (i)

photopolymerization of GelMA by UV radiation, (ii) enzymatic crosslinking of gelatin by microbial transglutaminase (mTG) and (iii) ionic crosslinking of alginate by calcium ions, to form an interconnected polymer network (IPN), which exhibits much improved mechanical properties with excellent biocompatibility in vitro.

Materials and Methods:

Characterization of bioink and crosslinked constructs: The bioink was made from 5% (w/v) gelatin, 5% GelMA and 2% alginate dissolved in DMEM. Viscosity of the bioink and stiffness of crosslinked hydrogels were measured by rheometer. Mechanical strength of the crosslinked constructs was measured by mechanical tester under the compressive mode. 3D bioprinting: For 3D bioprinting, human dermal fibroblasts (hDFs) were dispersed in the bioink at a final concentration of cells/ml. BioAssemblyBot 400 was used to print a grid-structure with a specified dimensions of 2.4 cm (L) x 3.0 cm (W) x 0.1 cm (H) with each square having dimensions of 2 mm x 2 mm. The grid was printed via a layer-by-layer extrusion method with each layer having a specified width of 0.25 mm. The printed constructs were crosslinked via UV irradiation and submerging them in the cell culture media with 5% microbial transglutaminase (mTG) or mTG supplemented with calcium chloride (24 mM). Biocompatibility: LDH assay was performed to assess cytotoxicity of the printing and crosslinking processes on day 1, 3 and 7 post-printing. Live/dead assay in conjunction with confocal microscopy was performed on day 1 and day 7 to visualize cell viability and cellular morphologies.

Results:

*The bioink showed a shear-thinning property, which makes it proper for extrusion-based 3D bioprinting. Stiffness of the IPN constructs significantly increased as more crosslinking mechanisms were incorporated: the hydrogel that was crosslinked by UV, mTG and Ca^{2+} (**UV+mTG+Ca**) had much higher G' (18.9 kPa) than the hydrogel crosslinked by UV only (**UV only**, G' = 2.34 kPa) or the hydrogel crosslinked by UV followed by mTG (**UV+mTG**, G' = 4.00 kPa) (**Figure 1A**). The ultimate strength of the constructs also followed a similar trend (**Figure 1B**). The bioprinted structures remained stable throughout the study in all groups. Cytotoxicity measured by LDH from the encapsulated hDFs gradually decreased over 7 days for all groups (**Figure 1C**). Confocal imaging showed high cell viability in all groups. However, different cell morphologies were observed depending on the stiffness of the hydrogel. **UV-only** displayed the highest spreading by day 7, followed by **UV+mTG**, while **UV+mTG+Ca** showed minimal cell spreading (**Figure 1D**). However, when mTG and calcium crosslinking were implemented at later time points (mTG and calcium on day 2, **UV+mTG2+Ca2** or mTG on day 2 and calcium on day 4, **UV+mTG2+Ca4**), cell spreading was on par with UV-only construct while achieving stiff and strong strcutures.*

Conclusions:

We have demonstrated the use of multiple crosslinking mechanisms to bioprint mechanically stiff and strong cell-hydrogel constructs with minimal cytotoxicity. As expected, stiff constructs resulted in less cell spreading. However, delayed applications of mTG and calcium crosslinking successfully addressed this issue. We believe that this project will eventually pave way for the construction of even more complex structures armed with improved mechanical properties.

SB05.03.11

Polymeric Antibacterial and Oxygen-Generating Films to Enhance Wound Healing *Ayden Watt[1], Dario Job[2], Justin Matta[1], Cat-Thy Dang[2], Yara Raphael[2], Nicholas Makhoul[1], Mirko Gilardino[1,1], Geraldine Merle[2] and Jake Barralet[1,1]; [1]McGill University, Canada; [2]Polytechnique Montréal, Canada*

Problem/Purpose: *Effective wound healing requires a multi-faceted approach that addresses infection control, oxygenation, and promotion of tissue regeneration. Traditional wound dressings often fail to provide these combined benefits, leading to prolonged healing times and increased risk of complications. Biomaterials that can generate oxygen and exhibit antimicrobial properties without relying on traditional antibiotics are particularly promising, as they avoid the increasing global risks associated with antimicrobial resistance (AMR). Borate has a long history of use as an antiseptic and has been claimed to have pro-regenerative effects in wounds. In this study,* *we compared the mammalian cytotoxicity and the antibacterial capacity of sodium perborate and sodium percarbonate with sodium borate and sodium carbonate.*

Methodology: *Polycaprolactone (PCL) films were prepared by incorporating SPB and SPC at three different concentrations (20 mg, 200 mg, and 2000 mg) in combination with iron oxide (Fe_3O_4) and sodium bicarbonate ($NaHCO_3$) to reduce toxicity and calcium dihydrogen monohydrate ($Ca(H_2PO_4)$) as a buffering agent. The films underwent comprehensive physicochemical characterization, including measurements of swelling index, Young's modulus, oxygen release profiles, pH variations, and hydrogen peroxide release. Antimicrobial efficacy in vitro was assessed through bacterial assays against S. aureus (Gram-positive) and P. aeruginosa (Gram-negative), and biofilm formation assays. Additionally, a human dermal fibroblast cytotoxicity assay evaluated biocompatibility.*

Results: *Physicochemical characterization of the films revealed that they maintained stability over time, with the SPB2000 sample exhibiting the highest mechanical strength. Oxygen release was dose-dependent; levels at the 2000mg dose were substantially higher than at 200mg (~40 $\mu M\ mol^{-1}$ vs ~10 $\mu M\ mol^{-1}$. pH measurements indicated a gradual increase correlating with the concentration of the peroxides, with the 2000mg doses peaking at a pH of ~9-10. In antibacterial assays, all doped SPB and SPC polymers exhibited significant reductions in bacterial counts for both S. aureus and P. aeruginosa. The SPB2000 sample reduced S. aureus and P. aeruginosa counts by over 99% within 24 hours and was the sole condition to significantly reduce biofilm mass; both bacterial strains experience a reduction of approximately 70%. The SPC 2000mg sample also completely eradicated both S. aureus and P. aeruginosa by the 48-hour timepoint, although had little effect on biofilm mass. Cytotoxicity assays indicated that fibroblast viability decreased with higher doses, with SPC2000 maintaining approximately 30% viability and SPB2000 maintaining below 10% viability over 72 hours. This highlights the need for careful dose optimization to balance antimicrobial efficacy with biocompatibility.*

Conclusion/Significance: *The integration of sodium perborate and sodium percarbonate within polycaprolactone films offered significant antibacterial activity and sustained oxygen release, creating an environment conducive to wound healing. The dual functionality of these films, combining over 99% reduction in bacterial counts and substantial biofilm inhibition alongside sustained oxygen release, addresses critical challenges in wound care, particularly in managing infections and promoting tissue regeneration. Future in vivo studies are warranted to optimize the therapeutic window, enhance biocompatibility, and validate the clinical efficacy of these films. Furthermore, we will investigate improving the base PCL structure by creating a fully degradable formulation.*

SB05.03.12

Improving the Hemocompatibility of Decellularized Vascular Grafts via Structural Modification of Collagen Fibers

Atsushi Mahara[1], Hue T. Le[1], Raghav Soni[1] and Tetsuji Yamaoka[2]; [1]National Cerebral and Cardiovascular Center, Japan; [2]Komatsu University, Japan

[Introduction] *Decellularized tissues are attractive materials for tissue-engineered cardiovascular devices. Decellularized tissues match well with native tissues because they have similar mechanical and structural properties. However, the main component of decellularized tissue is the extracellular matrix containing collagen and elastin, which easily causes blood clotting when in contact with blood flow. Our research group has successfully developed a small-diameter artificial vascular graft from the ostrich carotid artery. To be compatible with blood, the luminal surface of the graft was modified with antithrombotic peptides that induce rapid endothelialization [1]. On the other hand, if we can induce antithrombogenicity and tissue regeneration in decellularized tissue without peptide modification, it would be possible to design ideal and practical cardiovascular devices. In this study, we developed a decellularized material that does not cause blood clotting by modifying the collagen structure of the decellularized tissue [2].*

[Methods] *Blood vessels were isolated from the ostrich carotid artery. According to a previously reported procedure, decellularized blood vessels were prepared via ultra-high-pressure treatment (DC-Graft)[1]. The* *material was freeze-dried by alcohol replacement (FD-Graft). Next, the FD-Graft was immersed in various aqueous ethanol solutions for 20 min and then dried under reduced pressure. After drying, the material was rehydrated and evaluated. Collagen structure was evaluated using Optical Coherence Tomography (OCT) and tissue staining. In addition, the reaction of the sample to the material was examined using a blood-contact test. Finally, the material was transplanted into the carotid artery of a miniature pig, and tissue regeneration was evaluated over 1 year.*

***[Results and Discussion]** SEM observations revealed that the macroscopic structures of the FD-grafts and the alcohol-treated grafts were similar to DC-Grafts. The tensile tests showed no change in the characteristic slope of the stress-strain curve in the early and late phases. These results indicate that alcohol treatment did not significantly change the macroscopic features of the DC-Graft. OTC images revealed that the fiber density on the surface of the alcohol-treated grafts increased by approximately three-fold. However, the orientation of the collagen fiber in the graft tissues was not changed. The triple-helix structure of collagen was partially deformed by ethanol treatment, and its degree depended on the ethanol concentration. The amount of platelet adsorption was reduced to 10% or less by treating the decellularized tissue with 75% or more ethanol solution. Furthermore, blood perfusion tests showed that the grafts completely suppressed platelet adsorption. These results demonstrate that treatment with ethanol in decellularized tissue can strongly control platelet adsorption by inducing structural changes in collagen.*

Tailored Forest Microneedles Using Cross Over Lines Laser Writing for Simultaneous Delivery of Multiple Drugs

Hasika Suresh, Danilo M. dos Santos, Atul Sharma, Darian Myers, Sanjana Vissapragada and Sameer Sonkusale; Tufts University, United States

Microneedles (MNs) are gaining traction as a promising method for transdermal delivery of therapeutics via painless and user-friendly patches. Notably, direct write fabrication using CO2 laser-based cross-over-lines (COL) laser writing offers a cost-effective and scalable approach for MN production.

The COL method utilizes a three-step cleanroom-free method to make microneedles [1]. The microneedle master mold was engraved on clear cast acrylic sheet using a 60W CO2 laser cutter. The laser beam ablates a 2D pattern of crossing lines on the acrylic, creating conical microneedle molds. Two PDMS molds were fabricated: a positive replica at a 5:1 pre-polymer to curing agent weight ratio and a final negative mold at a 10:1 ratio. We fabricated microneedles of different geometries and heights on one single patch by exploring different laser cutting parameters, like power, speed and focus. The resulting microneedles vary in in height, widths, and spacing, resembling a forest. This design, coupled with the specific formulation within each microneedle, allows for a controlled and unique drug release profile. To showcase the range of possibilities, a microneedle patch was formed into the letters "NANOLAB" with different heights and base diameters.

To demonstrate multiple drug loading capacity, we co-delivered two drugs: simvastatin (anti-inflammatory) and tetracycline hydrochloride (antibacterial) for treating burn wounds [2] from a single patch. Specific areas of the acrylic master mold were rastered to create individual wells for loading different drugs without any mixing. These patterns were then replicated onto the negative PDMS mold ensuring precise alignment. To the best of our knowledge, this is the first platform to have delivered multiple drugs using a single microneedle patch fabricated with any laser-based approach.

To make the dual drug loaded microneedle patch, 10 mg of each drug powder was separately added to 10mg/mL *of zein solution (made in 80% ethanol) and loaded onto the PDMS negative microneedle molds. A flexible backing layer consisting of Elastic 50A resin was added for better conformability. The microneedle patch contained needles of different heights (1100±30 μm for simvastatin (tall) and 670±45 μm for TH (short)) while all other microneedle properties remained constant.*

The mechanical properties of the microneedles were tested and they proved to have enough strength to penetrate the skin (> 0.5 N/needle). The delivery profile of both the drugs were conducted invitro with phosphate buffer saline (PBS). For the same drug concentration, simvastatin and TH had different delivery profiles owing to the different heights of the microneedles and distinct interaction with zein. Zein's balanced hydrophilic and lipophilic nature makes it ideal for sustained drug/protein release [2]. Simvastatin, a lipophilic drug, enhanced the curvature of zein, leading to the formation of smaller, spherical particles with an increased surface area. In addition, the larger surface area from the tall microneedles promoted a faster initial release: 50% of simvastatin delivered within the first 24 hours, followed by a sustained release of the remaining drug over 3 days. In contrast, TH accumulated on the surface of zein due to its hydrophilic nature creating films with zein rather than spheres. Due to the hydrogen bonding of the TH with zein, a sustainable release profile is seen with only 30% within 24 hours, while 60% is released over 4 days. Identifying suitable polymer and drug combinations can further help with tailoring the release profiles for targeted applications.

In conclusion, we aim to fabricate of forest microneedles with tunable geometries using COL laser writing to deliver multiple drug cargos, with distinct release profiles at different depths, for the treatment of burn wounds, or other medical ailments.

Control of Elongation Properties of Biocompatible Poly(2-Methoxyethyl Acrylate) Network Containing Silica Particles Similar to Biological Soft Tissue

Moe Sakamoto[1], Mitsuo Hara[1,2], Xiaobin Liang[3], Ken Nakajima[3], Kenji Urayama[4], Taiki Hoshino[5], Masaru Tanaka[6] and Yukikazu Takeoka[1]; [1]Nagoya University, Japan; [2]Kagawa University, Japan; [3]Tokyo Institute of Technology, Japan; [4]Kyoto University, Japan; [5]Tohoku University, Japan; [6]Kyushu University, Japan

In recent years, there have been active attempts to enhance resistance and provide new functions by incorporating nano-sized materials, known as fillers, into plastics and resins. In the medical field, biocompatible polymers are actively studied, with poly(2-methoxyethyl acrylate) (PMEA)gaining attention as an antithrombotic coating agent for medical devices. In our laboratory, we have succeeded in fabricating a soft yet tough PMEA-Silica composite elastomer by integrating silica nanoparticles into PMEA, a viscous liquid. Furthermore, this system can be 3D printed to create three-dimensional models. Given PMEA's inherent blood compatibility in composite materials, this composite is expected to be a promising candidate for new medical applications, such as small-diameter artificial blood vessels with inner diameters of 4 mm or less, whose development is currently lagging.

The stress-strain relationship of this composite elastomer under uniaxial elongation exhibits non-linearity (J-type) with a significant increase in stress at high strain, similar to the characteristics of biological soft tissues. Focusing on the strain position at stress rise, the PMEA-Silica composite elastomer achieves about 350%, whereas biological soft tissues are on the lower strain side at about 100-200%. For biological soft tissues, this stress rise is crucial to prevent sudden failure during deformation.

In this study, we aimed to establish a method to control the position of stress rise while maintaining J-shaped

properties to develop materials more akin to biological soft tissues. Previous studies have shown that there is no chemical bonding at the PMEA-Silica interface in this composite elastomer. Therefore, we employed a silane coupling agent, 3(Acryloyloxy)propyltrimethoxysilane (APTMS), which has the same polymerization group as the monomer. APTMS was modified on the silica particle surface before compositing to form a bond point between the polymer chain and the silica nanoparticles.
The results of uniaxial tensile tests of the elastomers with bonding points introduced at the polymer chain-silica interface revealed that this elastomer exhibits a new property of stress increase at lower strains than conventional materials, while maintaining flexibility at initial elongation. Furthermore, this property was successfully controlled by adjusting the coverage of APTMS, the amount of silica particles, and the amount of cross-linking agent.
In the presentation, we will detail the mechanism behind the development of the new physical properties. The results of this research will ultimately lead to the provision of a material preparation method useful for practical artificial blood vessels.

Silk Fibroin/Starch-Based Microporous Hemostatic Sponge for Structural Retentivity and Contact Activation During Coagulation *Seo Hyung Moon[1], Jaeyun Lee[2], Ha Neui Choi[1], Hyung Joon Cha[2] and Yun Jung Yang[1]; [1]Inha University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)*

Hemostatic agents of various types and materials are essential for controlling excessive bleeding during surgery and improving visibility. Proper application of these agents significantly reduces the risk of dehydration, oxygen deficiency, and even death. Polysaccharide-based hemostatic agents have been scientifically validated for human use and are widely employed in clinical settings. Among polysaccharides, starch exhibits exceptional swelling capacity, though its use has been limited to powdered formulations for controlling non-compressible bleeding.
In this study, a combination of starch and silk protein was crosslinked with glycerol to enhance structural strength. The silk/starch solution was then lyophilized, creating a sponge with interconnected pores. This process confirmed that clot formation was promoted due to increased swelling capacity and improved water retention for plasma absorption. Additionally, direct contact between the sponge and blood components activated coagulation through the intrinsic pathway and platelet response, without causing hemolytic or cytotoxic effects. Bleeding tests using animal models demonstrated the clinical efficacy of the silk/starch sponge as a local hemostatic agent.

SB05.03.16
Dual-Responsive Antibody Production and Releasing Platform for Anti-Cancer Immunotherapy *Mihyeon Park and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)*

Immune Checkpoint Blockade (ICB) therapies have emerged as a groundbreaking strategy in cancer immunotherapy. Despite their potential, their effectiveness in treating solid tumors is significantly challenged by several factors, including the insufficient accumulation of therapeutic agents and the prevalence of "cold" tumors with limited T-cell infiltration and strong immunosuppressive environments. These factors collectively limit the response rate to ICB therapies. To address these limitations, our study explores the integration of ICB with treatments inducing Immunogenic Cell Death (ICD). ICD plays a crucial role in transforming the tumor microenvironment by releasing damage-associated molecular patterns (DAMPs), which recruit and activate dendritic cells. This process not only aids in presenting tumor antigens to T cells but also boosts the overall anti-tumor immune response, making immunologically "cold" tumors more "hot" and responsive to ICB therapy.

We aimed to use ICD not just to release DAMPs, but as a key to regulate antibody release. We combined photodynamic therapy (PDT), a laser-sensitized method of inducing cell death, with gene delivery techniques to produce antibodies, facilitating the laser-sensitized release of these antibodies. This strategy ensures that the *laser-sensitized release of antibodies occurs directly within the tumor microenvironment. Such spatial and temporal precision in antibody release maximizes the therapeutic potential of the antibodies, enhancing their ability to target and neutralize tumor cells effectively. Furthermore, this method minimizes off-target effects and reduces the risk of systemic toxicity, a common concern with conventional immunotherapy approaches. In this study, we successfully demonstrate a novel approach to overcoming the limitations of ICB therapies by developing a laser-activated nanoparticle platform that enhances antibody delivery and immune response through the targeted production and release of anti-PD-L1 antibodies and induction of ICD.*

Composite Hydrogels with Calcium-Curcumin Complexes *Keyu Chen, Yan Luo and Kyle Vining; University of Pennsylvania, United States*

Introduction: *Managing periodontal diseases, which are characterized by inflammation and bacterial infection of gingival tissues surrounding teeth, remains a significant challenge in oral health. There is a pressing need for localized strategies to control tissue inflammation within the oral environment. This study aims to develop a hydrogel composite material incorporating calcium-curcumin complexes for targeted delivery to gingival tissues. Curcumin, derived from turmeric, is known for its antibacterial and anti-inflammatory properties but suffers from poor bioavailability due to limited solubility. Investigating the formation and characterization of calcium-curcumin complexes aims to develop new biomaterials for controlling tissue inflammation and infection, thereby enhancing the bioavailability of curcumin.*
Methods: *The calcium-curcumin complex is synthesized by combining calcium chloride and curcumin in a solvent mixture of N,N-Dimethylformamide (DMF) and anhydrous ethanol, followed by heating at 120°C for 48 hours. This complex is then encapsulated within an alginate matrix. Under acidic conditions, it is proposed that the complexes will degrade and release calcium ions and curcumin, forming a calcium ion ionically crosslinked hydrogel with curcumin releasing from the alginate matrix. Characterization techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), and Fourier-transform infrared spectroscopy (FTIR) confirm the successful synthesis and structure of the complex. Rheological tests are performed to evaluate the hydrogel's formation and mechanical properties, driven by the release of calcium ions under acidic conditions. Ultraviolet-visible (UV-Vis) spectroscopy is employed to quantify the release profile of curcumin.*
Results: *The synthesis and characterization processes validated the formation of the calcium-curcumin complex with the desired structural attributes. Rheological tests demonstrated the effective formation of an ionically crosslinked hydrogel upon the release of calcium ions in acidic environments. UV-Vis spectrometry indicated a controlled and sustained release of curcumin from the hydrogel matrix.*
Conclusions: *This study presents the development of novel composite materials combining calcium-curcumin complexes with alginate hydrogels for potential biomedical applications. The versatile materials platform described can be adapted to incorporate other divalent cations and organic ligands to form similar complexes, thereby broadening its impact within the biomaterials field.*

SB05.03.18

Solvent Vapor Annealing-Induced Hierarchically Structured Polymer Fibers *Bingbing Li, Adam J. Bauer and Reem Ghubayra; Central Michigan University, United States*

Hierarchically structured polymer fibers have drawn widespread attention from researchers in the fields of biomedical materials, energetic materials, and materials for environmental remediation. Secondary nanostructures inscribed onto hierarchically structured polymer fibers allow modifying the functions of materials by offering significantly higher porosity and larger surface area, in comparison to polymer fibers with smooth surfaces. Our pioneering work has shown that solvent vapor annealing (SVA) can be utilized to induce the *secondary nanostructures on electrospun neat poly(caprolactone) (PCL) fibers. Free amorphous PCL chains can be delocalized during acetone vapor treatment and then crystalized onto the pre-existing lamella upon solvent evaporation, giving rise to hierarchically nanostructured PCL fibers. The SVA method adopted in this early study paves a way to fabricate uniform hierarchically structured fiber materials. Neat PCL fibers prepared using various solvents and PCL/poly(ethylene oxide)(PEO) fibers with various blend ratios were thoroughly studied in our previous work. For neat PCL fibers, the quality of the SVA-induced hierarchical structures is largely defined by PCL's crystallization behavior during electrospinning. While for PCL/PEO blend fibers, the regularity of secondary nanostructures depends on both the phase separation morphology and the crystallinity of the PCL phase.*

For PCL-based polymer blends, their phase behavior is controlled by multiple factors including but not limited to molecular weight, types of phase separation (spinodal decomposition vs nucleation and growth), solvent, temperature, processing methods, etc. This presentation will focus on (1) the effect of PCL and PEO molecular weights on the evolution of SVA-induced secondary nanostructures and (2) the regularity of secondary nanostructures modulated by adding PCL-b-PEO into the PCL/PEO blends. SVA-induced nanostructures prepared using PEO(300K)/PCL(75K), PEO(600K)/PCL(75K), PEO(600K)/PCL(45K), and PCL/PEO blends containing PCL-b-PEO copolymers are reported in this presentation. The discuss focuses primarily on the spinodal phase separation during electrospinning process, as well as its impact on phase separation morphology and the SVA-induced hierarchical structures. For instance, SVA-induced hierarchical structures of high regularity were observed for both 50:50 and 40:60 by mass PEO/PCL(45K) samples. In contrast, for PEO/PCL(75K) samples, spinodal decomposition starts from 50:50 by mass samples, which give rise to hierarchical structures with less fullness in the surface contour. This observation is correlated to the shift of phase diagram for different molecular weight PCL. Furthermore, for 60:40 and 70:30 by mass PEO/PCL samples, free amorphous PCL chains are not sufficient to grow into uniform secondary nanostructures that can cover all fiber surfaces. In this case, loading up 30wt% of PCL-b-PEO could not only provide more PCL segments but also better define the phase boundary between PCL and PEO, leading to more obvious secondary nanostructures after SVA treatment.

Adhesive Hydrogel with Suppression of the Fibrotic Encapsulation by Implant Tissue Interface

Jingjing Wu, Hyunwoo Yuk and Xuanhe Zhao; Massachusetts Institute of Technology, United States

The implanted biomaterials and devices face compromised functionality and efficacy in the long-term by foreign body responses and the subsequent formation of the fibrous capsule at the implant-tissue interface. Here, we demonstrate that an adhesive implant-tissue interface can avoid fibrous capsule formation by minimizing infiltration of inflammatory cells at the implant-tissue interface. Histological analysis shows that the adhesive implant can preserve the implant-tissue interface without fibrous capsule formation in diverse organs including abdominal wall, colon, stomach, lung, and heart over 12 weeks in rat models in vivo. Immunofluorescence analysis, RNA sequencing, and quantitative PCR are further performed to validate the hypothesis. This finding may offer a promising strategy for long-term implant-tissue interfacing.

SB05.03.20

Enhancing Osteogenic Differentiation of Dental Pulp Stem Cells Via Iron Oxide-Infused PLA in a Static Magnetic Field

Dvita Bhattacharya[1], Rohan Hablani[2], Alice He[3], Matthias Kim[4], Yiwei Fang[5], Adam Hansen[5], Shi Fu[5], Jessica Hofflich[5], Huiting Luo[5], Yu-Chung Lin[5], Marcia Simon[5] and Miriam Rafailovich[5]; [1]Kent Place School, United States; [2]Arnold O. Beckman High School, United States; [3]Phillips Academy, United States; [4]Interlake High School, United States; [5]Stony Brook University, The State University of New York, United States

Dental pulp stem cells (DPSCs) have promising potential for stem cell-based regenerative dental therapy due to *their high capacity for proliferation and differentiation. Polylactic acid (PLA) is a degradable biocompatible polymer often used for bone regenerative scaffolds [1]. Exposure to a static magnetic field (SMF) can enhance biomineralization [2]. Here, we present the results of a study where DPSCs were plated on PLA scaffolds with and without iron oxide particles and cultured for 28 days in an external SMF of $B=0.0375T$, generated by neodymium magnets. Previous studies have used iron oxide nanoparticles to enhance the magnetic field, but these particles were observed to have entered the cells, resulting in potential toxicity. We therefore compounded the particles within the PLA scaffolds, where the particles were not available for cellular uptake. Furthermore, the cells were initially cultured in 3-D microspheres, which have been postulated to enhance differentiation [3], and then collected for plating on the PLA scaffolds.*

To form spheroid-derived DPSCs (sd-DPSCs), DPSCs of strain 13, passage 7 were cultured in round bottom 96-well plates for 7 days without dexamethasone, an osteogenic inducer, and then resuspended. Sigma Aldrich Iron-Oxide Nanopowder and Nature Works PLA were combined in a twin screw extruder Brabender to produce 10% iron-oxide-infused PLA (IO-PLA). The scaffolds were produced via molding into 1.38 and 0.63 cm discs, which were then submerged in 70% ethanol, sterilized by UV exposure, and placed into 6-well plates. To ensure cell adhesion, a thin coating of 10 µg/mL collagen was applied prior to cell plating. Three different substrates were probed: Tissue Culture Plastic, PLA, and IO-PLA. Half of these plates were placed in the static magnetic field while the other half were not, as a control.

The elastic moduli of mesenchymal stem cells correlate to their differentiation potential and lineage – cells in the osteoblast lineage tend to have a higher elastic modulus pre-differentiation. Although there was no difference between the elastic moduli of sd-DPSCs and 2D-DPSCs on day 1, more than a two-fold difference was observed in the elastic moduli of sd-DPSCs compared to 2D-DPSCs on day 4, suggesting that sd-DPSCs are likely to exhibit more robust osteogenic differentiation than 2D-DPSCs.

The substrates were imaged on day 28 with SEM and EDX. The data clearly showed the deposition of collagen fibers, distinct triple helix spacing, and templated CaP mineralization on the substrates exposed to the magnetic fields, with the samples containing iron oxide particles exhibiting greater deposition of both minerals and ordered collagen fibers. Despite collagen deposition, minimal fiber structures were observed in the absence of the magnetic field. Even though some mineral deposition was observed, it was of a particulate nature, without specific templating. RT-PCR and Raman scattering results will be reported, which will identify whether differentiation occurred along osteogenic or odontogenic lineages.

We gratefully acknowledge the Louis Morin Charitable Trust for their support of this work.

SB05.03.21

Effects of Titanium Dioxide Nanoparticles on UV-Exposed Human Dermal Fibroblasts *Xinyu You[1], Hunter Maguire[2], Aryan Agahtehrani[3], Vincent Lo[4], Isabelle Chan[5], David Sun[6], Dylan Wang[7], Calvin Yu[8], Nikita Karnik[9], Adam Hansen[10] and Miriam Rafailovich[10]; [1]Western Reserve Academy, United States; [2]Garden City High School,* *United States; [3]DuPont Manual High School, United States; [4]Evergreen Valley High School, United States; [5]Michael E. DeBakey High School for Health Professions, United States; [6]Joseph A. Gregori High School, United States; [7]Trinity Preparatory School, United States; [8]Weston High School, United States; [9]Carnegie Mellon University, United States; [10]Stony Brook University, The State University of New York, United States*

Titanium dioxide (TiO_2) nanoparticles (NPs) are commonly found as an active ingredient in mineral sunscreens due to their strong absorbance of UV-B irradiation. Although the absorption spectrum underpinning therapeutic applications of TiO_2 is well characterized, recent studies suggesting potential genotoxicity of TiO_2 NPs in vitro[1] have called into question the efficacy and safety of titanium nanoparticle' cosmetic use.

Human dermal fibroblasts (HDFs), the cell type analyzed in this study, are integral to synthesizing collagen and thus, maintaining extracellular matrix (ECM) structures throughout the skin. Age of HDFs is correlated with diminished collagen production and, by extension, weakened ECM quality and integrity. Likewise, deleterious outcomes such as reduced actin filament integrity and morphological changes resulting in reduced collagen synthesis or destruction via apoptosis[2] have been observed in HDFs as a result of ultraviolet (UV) radiation exposure. This research aims to clarify the effectiveness of TiO_2 NPs in reducing UV-induced damage to HDFs by assessing the impact of varying rutile TiO_2 NP (50 nm) concentrations on the morphology and survival of fibroblast cells exposed to UV dosages of intensity 7 J/cm^3.

HDFs collected from patients aged 19, 29, 62, and 71 with passage numbers ranging from 7 to 8 were cultured, treated with TiO_2 NPs or left undisturbed, and subjected to none, single, or double exposure to UV light. In single-exposure trials, HDFs were treated at 0.4 mg/ml TiO_2 concentration, and in double-exposure trials, HDFs were treated at 0.2 and 0.4 mg/ml TiO_2 concentrations. Cell counts were conducted to quantify cell viability post-UV exposure for all exposed samples, elucidating the effect of TiO_2 NPs with respect to UV-induced cellular damage. Decreased cell viability was observed after TiO_2 addition alone in all trials. Younger HDFs exhibited greater survival after TiO_2/1x UV treatment versus UV exposure alone; survival of older UV-exposed HDFs decreased under the same criterion. Intensified cell death was observed after 2x UV exposure. Variable change in survival was observed in 0.2 mg/ml TiO_2/2x UV groups compared with 2x UV alone (decline in ages 19, 62, increase in ages 29, 71); survival consistently declined in 0.4 mg/ml TiO2/2x UV groups. Exemplifying such trends were HDFs aged 19, in which control, 0.2 mg/ml TiO2, and 0.4 mg/ml TiO_2 groups showed death rates of 32.9%, 36.6%, and 43.7%, respectively, and HDFs aged 62, in which otherwise identical groups experienced death rates of 30.5%, 50.0%, and 62.6%, respectively.

Upon immunofluorescence staining and imaging, UV-exposed fibroblasts exhibited modified, less elongated morphology, potentially signifying damage at the cellular level. For HDFs aged 29 and 71, aspect ratio decreased by 30.4% and 58.2% after 1x UV treatment and 47.9% and 61.0% after 2x UV treatment, respectively. Absorption of TiO2 NPs in significant quantities occurred uniformly. Though altered shape was again observed with increasing NP concentration, TiO_2 was shown to strongly modulate such structural changes, with decreases in aspect ratio after 2x UV as low as 15.6% and 6.1% for 0.2 mg/ml TiO_2/2x UV groups in HDFs 29 and 71, respectively.

The study examined differential fibroblast response to TiO2 and/or UV exposure in evaluating the potential of TiO_2 NPs to modulate cellular response to UV irradiation. Findings corroborate TiO_2 NPs' ability to induce damage in HDFs, highlighting a need for greater investigation of health risks inherent to titanium dioxide's cosmetic applications. Though physical sunscreens maintain health and environmental advantages over chemical alternatives, potential adverse effects must be understood to provide transparency and guarantee buyer safety.

Up-to-date as of November 14, 2024

Characterizing Mechanical and Cell Proliferation Properties of Poly(vinyl Alcohol) and Resorcinol Diphenyl Phosphate Clay Blend Towards Brain Aneurysm Modeling *Risa Rogers[1], Joseph Yung[2], Leora Stochel[3], Grace Wong[4], Kevin Wu[5], Robert Wong[6], Aaron Sloutski[6], Chander Sadasivan[6] and Miriam Rafailovich[6]; [1]Schechter School of Long Island, United States; [2]Georgetown Preparatory School, United States; [3]University of Massachusetts Amherst, United States; [4]University of Oxford, United Kingdom; [5]State University of New York at Geneseo, United States; [6]Stony Brook University, The State University of New York, United States*

It has been shown that physicians have found it very beneficial in simulating complex surgeries on 3-D printed model analogues before performing the actual procedure [1]. 3-D modeling provides far more detail and allows for dynamic modeling of fluid flow through venous structures. Brain aneurysms are an excellent example where this approach has been advantageous due to its complex 3-D branching and anomalous cerebral spinal fluid circulation. Synthesizing these structures directly from micro-CT scans and integrating them into a realistic flow system can offer significant advantages. Furthermore, if trials of medication or materials for obduration are being developed, in vivo experiments are required. Replicating human-like aneurysms in animal models presents significant challenges, making the incorporation of printed aneurysm models into animal analogues a more desirable approach. The success of these models depends on its ability to stimulate the nature of surrounding blood vessels, with Poly(vinyl alcohol) (PVA) hydrogels emerging as a potential material.

In this study, we present PVA and PVA-methacrylate (MA) hydrogels formulations that simulate the mechanical properties found in native vasculature and where the mechanical properties could be controlled via different cross linking mechanisms. We showed that PVA's lack of cell adhesiveness could be addressed with the addition of Resorcinol Diphenyl Phosphate (RDP) coated clays, and we experimented with different strategies to enable formation of complex vessel geometries.

Cell adhesion and proliferation of Sodium Hydroxide (NaOH) and Sodium Trimetaphosphate (STMP) crosslinked PVA hydrogels were tested, where 0%, 1% and 5% RDP clay were blended into a 10% PVA hydrogel, plated with HUVEC-EGFP at a density of 8000 cells/cm2 and conducted Alamar blue assays on days, 1, 3, and 5. Results indicate a lack of cell adhesion in pure 10% PVA hydrogels; but increased cell adhesion and proliferation was observed with increasing concentration of RDP clay.

To assess its mechanical properties, PVA hydrogel sheets were formed, cut into strips and disks, placed and measured on an Instron Universal Mechanical Tester and Kinexus Pro + Rheometer (Netzsch). For the 0%, 1%, and 5% RDP concentrations no statistically significant difference for both Young's Modulus (~19kPa) and Shear Modulus (~55kPa) was observed.

In order to synthesize the vascular grafts, two processes were developed. In the first process, 20% PVA-MA was radically crosslinked with Ammonium Persulfate (APS) and Tetramethylethylenediamine (TEMED), inserted into the vessel mold from the bottom up.

The second process involved dip-coating and spinning dry 10% NaOH/STMP crosslinked PVA on a single axis spinner. A systematic study of spin rate for the dip coating of the PVA was conducted between 49.5 rpm and 68 rpm, where 60 rpm proved optimal in uniformity and human-like mechanics. A model was proposed where the heightened drying speed of the PVA solution surrounding the wax rod decreased fluid motion thereby increasing uniformity.

The vessels were imaged under a Keyence VHX-7000 microscope, where we obtained mean diameters for composites with 10% PVA and RDP close to the desired value of 2000 μm. The burst pressures though were *dependent on RDP content, decreasing below physiological values at a loading of 5% RDP clay. Vascular grafts created with 20% PVA-MA were more uniform and had a shorter production time, but 10% PVA vascular grafts exhibit stronger mechanical properties. Currently, we are examining the implementation of dual-crosslinking, integrating both methodologies to maximize mechanical properties and production efficiency.*

The cell adhesion and proliferation properties of the PVA/RDP clay blends along with our novel synthesization methods demonstrate great promise towards eventually modeling complex brain aneurysms.

Bioprinting Human Vasculature Within a Collagen Gel

Ananya Anand[1], Jenny Dinh Nhu Zhang[2], Shreyaa Sanjay[3], Jenny Jia[4], Viraj Pahuja[5], Jerry Gu[6], Theodora Siu[7], Brooklyn Ratel[8], Divleen Singh[8], Eugene Jiang[8], Shi Fu[8], Huiting Luo[8], Gurtej Singh[8] and Miriam Rafailovich[8]; [1]Johns Creek High School, United States; [2]Renaissance International School Saigon, Viet Nam; [3]West Windsor-Plainsboro High School North, United States; [4]The Experimental High School Attached to Beijing Normal University, China; [5]The Wheatley School, United States; [6]Princeton International School of Mathematics and Science, United States; [7]Ward Melville High School, United States; [8]Stony Brook University, The State University of New York, United States

Angiogenesis, the formation of new blood vessels from pre-existing vasculature, facilitates wound healing, repair, and tissue regeneration. The use of cell-delivery approaches—such as cell-loaded scaffolds or scaffold-free systems—to induce angiogenesis is thereby a potent area of study in wound healing research. However, an intense angiogenic response in the wound site corresponds with a lag of recession of blood vessels during the remodeling phase of wound healing thereby being associated with a higher risk of scar formation and in more severe cases, keloid formation. Our objective is to investigate a bioprinted blood vessel model that enables precise and controlled regulation of the angiogenic process during wound healing.

This study explores the potential and application of bioprinting human blood vessels within collagen. We used free-form printing to create vascular structures with human umbilical vein endothelial cells (HUVEC) stained with green fluorescent protein (GFP). These cells were suspended in a 3% gelatin gel and extruded into a viscous collagen solution to give the researcher control over printing the blood vessels. Gelatin was incorporated into the gel to act as a sacrificial material by dispersing once the collagen gels, allowing the cells to attach to the nearest binding site of the collagen. Through repeated parameter testing of the pump, rheology of the gel, a proof-of-concept model using fibroblasts within the bioink, and cell vitality assay, coupled with the ultimate use of HUVEC cells, a synthetic model of human vasculature was printed within a collagen solution and then initiate the gelation process.

The experimental setup of which the HUVEC-gelatin structure in the collagen gel was achieved consisted of a extrusion syringe containing 2mL of the un-gelled HUVEC-gelatin suspension. The suspension was pre-chilled at 4°C for uniformed gelling and then extruded into a 6-well plate, which was also at 4 °C to ensure the collagen-media solution inside the wells stayed as a liquid upon extrusion of the HUVEC-gelatin gel. A singular line of the suspension was extruded onto each of the 3 wells. The well plate was subsequently incubated at 37°C and 5% CO2 to allow the gelation of collagen, meanwhile the release of HUVEC from gelatin gel. EVOS M7000 imaging microscope to assess whether the GFP-stained endothelial cells branched from the gelatin structure after one day. The finding that could demonstrate the gel/cell suspension's ability to form structure akin to human *vasculature. Additionally, the cell vitality assay—conducted by comparing HUVEC cells before extrusion, in the syringe, and after extrusion—provided data that further supports the possibility of synthesizing human vasculatures from HUVEC-gelatin structures within a collagen gel.*

The current data and results gathered from the aforementioned experiments thus support this prospective method of synthesizing human vasculature from HUVEC-gelatin gel. This consequently provides promising results for the future plan to integrate these synthetic vasculatures into bioengineered skin grafts.

SB05.03.24

New Coating for Stent with a Charged Silane Coupling Agent to Confer Antithrombotic and Cell-Adhesion Properties *Yuji Teramura[1], Naoki Inuzuka[2], Yasuhiro Shobayashi[2] and Satoshi Tateshima[3]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]N.B. Medical Inc, Japan; [3]University of California, Los Angeles, United States*

The evolution of endovascular therapies, particularly in the field of intracranial aneurysm treatment, has been truly remarkable and is characterised by the development of various stents. However, ischaemic complications related to thrombosis or downstream emboli pose a challenge to the wider clinical use of such stents. Despite advances in surface modification technologies, an ideal coating that fulfils all the desired requirements, including anti-thrombogenicity and rapid endothelialisation, has not been available. To address these issues, we investigated a new coating based on 3-aminopropyltriethoxysilane (APTES) with both anti-thrombogenic and cell-adhesive properties. We assessed the anti-thrombogenic property of the coating using an in vitro blood loop model by evaluating platelet count and thrombin-antithrombin (TAT) complex levels, and by examining thrombus formation on the surface using scanning electron microscopy (SEM). We then assessed the adhesion of endothelial cells to the metal surfaces. In vitro blood tests showed that the coating significantly inhibited platelet aggregation and thrombus formation compared to a bare stent; more human serum albumin spontaneously adhered to the coated surface to block thrombogenic activation in the blood. Cell adhesion assays also showed a significant increase in the number of cells adhering to the APTES-coated surfaces compared to either the bare stent or the stent coated with an antifouling phospholipid polymer. Finally, we performed an in vivo safety test by implanting the coated stents into the internal thoracic and ascending pharyngeal arteries of minipigs and then assessing the health and patency of the arteries by angiography over the course of one week. We found that there were no adverse effects on the pigs and that the lumens of their vessels were well preserved in the APTES-coated stent group.Therefore, our new coating has both high anti-thrombogenicity and cell adhesion properties, which meet the requirements of an implantable stent.

SB05.03.25

Enhancing Bone Tissue Regeneration—A Mechanistic and Comparative Study *Precious O. Etinosa[1], Ali Salifu[2], Sarah Osafo[3], John Obayemi[1] and Winston W. Soboyejo[4]; [1]Worcester Polytechnic Institute, United States; [2]Boston College, United States; [3]University of Ghana, Ghana; [4]State University of New York Polytechnic Institute, United States*

This study explores the combined effects of RGD functionalization and host immune response on bone tissue regeneration. Hydroxyapatite (HAp) biomaterials, synthesized from sustainable resources, were combined with polycaprolactone (PCL) to design implantable scaffolds. hFOB cell-laden PCL/HAp scaffolds, functionalized with RGD-C (arginine-glycine-aspartate-cysteine) peptides and BMP-2 (bone morphogenetic protein-2), were subcutaneously implanted into immunocompromised (nude) and immunocompetent (C57) mice for 12 weeks. The quality of the regenerated bone in both mouse models was evaluated via histological studies (including H & E, alizarin red S, and trichrome staining), along with medical CT and micro-CT scans, and mechanical *characterization. The ability of the regenerated bone tissue to support dental implants was also investigated by measuring the interfacial mechanical strengths of inserted dental screws. Histological and medical CT analyses show evidence of accelerated mineralization with RGD functionalization as early as the second week post-implantation. However, the synergistic effects of RGD-functionalization and host immune system enhance the mechanical properties over the 12-week period. Notably, higher toughness and elastic modulus in the C57 mice suggest more effective mineralization and a denser collagen network, supported by micro-CT measurements and histological results. The progressive increase in mechanical properties and improved visco-elastic properties are indicative of a successful, active remodeling process. The mechanical characterization emphasizes the structural and functional viability of RGD-functionalized PCL/HAp scaffolds, validating the scaffold design and role of the host's immune response in tissue engineering. These findings have implications for the regeneration of high-quality bone suitable for dental implants in patients with significant alveolar bone loss.*

SB05.03.26

Backbone Cationized Highly Branched Poly(β-Amino Ester) as Gene Delivery Vectors in Lung Cystic Fibrosis Gene Therapy *Yinghao Li, Bei Qiu, Jing Lyu and Wenxin Wang; University College Dublin, Ireland*

Gene therapy holds great potential for treating Lung Cystic Fibrosis (CF) which is a fatal hereditary condition arising from mutations in the CF transmembrane conductance regulator (CFTR) gene, resulting in dysfunctional CFTR protein. However, the advancement and clinical application of CF gene therapy systems have been hindered due to the absence of a highly efficient delivery vector. In this work, we introduce a new generation of highly branched poly(β-amino ester) (HPAE) gene delivery vectors for CF treatment. Building upon the classical chemical composition of HPAE, a novel backbone cationization strategy was developed to incorporate additional functional amine groups into HPAE without altering their branching degree. By carefully adjusting the type, proportion, and backbone distribution of the added cationic groups, a series of highly effective HPAE gene delivery vectors were successfully constructed for CF disease gene therapy. In vitro assessment results showed that the backbone cationized HPAEs with randomly distributed 10% proportion of E7 amine groups exhibited superior transfection performance than their counterparts. Furthermore, the top-performed backbone cationized HPAEs, when loaded with therapeutic plasmids, successfully reinstated CFTR protein expression in the CFBE41o- disease model, achieving levels 20-23 times higher than that of normal human bronchial epithelial (HBE) cells. Their therapeutic effectiveness significantly surpassed that of the currently advanced commercial vectors, Xfect and Lipofectamine 3000.

SB05.03.27

Using Hydrogels to Achieve an Antibacterial, Injectable and Retrievable Drug Delivery Vehicle for Dental Regeneration *Brenna Ren[1], Aadi Bordia[2], Candy Deng[3], Eli Krasnoff[4], Linda Liang[5], Mira Setia[6], Zoe Katevatis[7], Abdel Mahmoud[7], Aaron Sloutski[7], Robert Wong[7], Huiting Luo[7], Shi Fu[7], Kuan-Che Feng[7], Stephen Walker[7], Thomas Manders[7], Jerome Cymerman[7] and Miriam Rafailovich[7]; [1]The Harker School, United States; [2]Archimedean Upper Conservatory, United States; [3]YK Pao School, China; [4]The Loomis Chaffee School, United States; [5]Experimental High School Attached to Beijing Normal University, China; [6]New Providence High School, United States; [7]Stony Brook University, The State University of New York, United States*

Endodontic treatment failures, commonly caused by Enterococcus faecalis, pose a significant challenge in dental treatment. While calcium hydroxide remains the predominant medicament, it lacks sufficient antimicrobial efficiency against E. faecalis, is caustic, and has poor injection properties. This study demonstrates the potential of a mixture of calcium hydroxide and salicylic acid (CASA) encapsulated in thermoreversible hydrogels (F127-DMA) as an injectable and retrievable intracanal medicament with strong antibacterial efficacy and controlled drug release.

We tested different ratios of calcium hydroxide to salicylic acid [1], and a 1:6 ratio proved to have optimal water solubility. This mixture was then added to F127-DMA and UV-crosslinked using Lithium phenyl (2,4,6-trimethylbenzoyl) phosphinate (LAP). The FT-IR and RAMAN spectroscopy of CASA indicated that calcium salicylate had been formed. The optimal formulation exhibited a pH of ~7, superior crosslinking efficiency (80.9%), and a swelling ratio after a 14-day immersion in DI water of <16%. The addition of CASA decreased the contact angle of F127-DMA, from 81° to ~62°, leading to better absorption of the inflammatory exudate into the root canal. Encapsulation of the CASA (1:6) in F127-DMA, decreased the viscosity of the original paste by nearly three orders of magnitude, enabling facile injection into root canal models, which demonstrated that it was also easily retrievable. Liquid suspension tests indicated that F127-DMA loaded with only 5% CASA was effective against planktonic E. faecalis resulting in at least a six-log reduction in bacterial count. E. faecalis is one of the most difficult organisms to eliminate due to its protective biofilm. We therefore infected bovine anterior tooth slices with E. faecalis suspension and allowed a biofilm to mature for three weeks. The slices were examined with scanning electron microscopy (SEM), demonstrating penetration of the bacteria deep into the dentin tubules. CFU analysis was performed on suspensions obtained from the tooth slices to determine the bacterial activity following treatment with 10% F127-DMA/CASA, calcium hydroxide, and the empty hydrogel vehicle. The results indicated a log reduction of 3 logs relative to the controls and no significant difference relative to the endodontic gold standard of CaOH.
In order to probe the regenerative potential of F127-DMA/CASA, human dental pulp stem cells were cultured on the filled crosslinked hydrogel for 28 days. Proliferation and adhesion were observed within the first four days and were not found to be significantly different from the control on TCP. Rt-PCR demonstrated upregulation of OCN and DSPP, while RAMAN and SEM indicated Hydroxyapatite biomineralization, consistent with odontogenic differentiation. This aspect is in sharp contrast to calcium hydroxide, whose high pH is known to cause severe tissue damage, preventing regeneration of surrounding tissue. Hence the superior rheological properties of F127-DMA/CASA, which permit injectability and retrieval from the confined space of the root canal, together with superior antibacterial properties, and regenerative potential make it a promising new alternative to standard intracanal treatments.

SESSION SB05.04: Biomaterials for Regeneration of Tissues
Session Chairs: Gulden Camci-Unal and Janet Zoldan
Wednesday Morning, December 4, 2024
Hynes, Level 3, Room 312

8:00 AM SB05.04.01
Advancing Vascularization Through Microenvironment Engineering *Janet Zoldan; The University of Texas at Austin, United States*

DepartmentIn the realm of regenerative medicine, human induced pluripotent stem cells (hiPSCs) are taking center stage, especially within the rapidly expanding field of tissue engineering. Realizing the full therapeutic potential of these cells demands innovative strategies that guide their growth and differentiation in situ towards *specific and valuable subtypes. In this talk, I will describe our ongoing efforts to orchestrate the assembly of hiPSC-derived cells into functional cardiovascular tissue within three-dimensional microenvironments mimicking the extracellular matrix (ECM). To begin, I will delve into our exploration of the intricate interactions between these hiPSC-derived cells and their ECM. By manipulating variables like structural protein density, the presence of angiogenic growth factors, and relative proteolytic activity in controlled in vitro microenvironments, we have uncovered how these factors influence the functionality of these progenitors. Building upon this foundational work, I will then discuss the practical applications of these engineered systems in disease modeling and in vivo interventions aimed at salvaging ischemic tissue. Throughout this talk, I will journey through the juncture of stem cell manipulation and engineering microenvironments, highlighting the vast potential of these systems to redefine the landscape of regenerative medicine and pave the way for innovative personalized therapeutic interventions.*

Biofabrication Using Spider Silk Proteins *Thomas Scheibel; Universität Bayreuth, Germany*

Proteins reflect one fascinating class of natural polymers with huge potential for technical as well as biomedical applications. One well-known example is spider silk, a protein fiber with excellent mechanical properties such as strength and toughness. We have developed biotechnological methods using bacteria as production hosts which produce structural proteins mimicking the natural ones. Besides the recombinant protein fabrication, we analyzed the natural assembly processes and we have developed spinning techniques to produce protein threads closely resembling natural silk fibers. In addition to fibers, we employ silk proteins in other application forms such as hydrogels, particles or films with tailored properties, which can be employed especially for biomaterials applications. We could e.g. design spider silk-based sheets and scaffolds that prevent adherence of microbes. However, the spider silk sheets and scaffolds do not kill any cells. Unlike current treatments they prevent infestation to begin with. The designed spider silk scaffolds are even bio selective, meaning that this designer silk repels microbes while allowing human cell attachment and proliferation. Spider silk hydrogels can be even employed as bioinks for biofabrication (3D bioprinting together with cells), but also non-aqueous solvents can be used to 3D-fabricate spider silk scaffolds. Their elastic behavior dominates over the viscous behavior over the whole angular frequency range with a low viscosity flow behavior and good form stability. No structural changes occur during the printing process, and the hydrogels solidify immediately after dispense plotting. Due to the form stability it was possible to directly print multiple layers on top of each other without structural collapse. Cell-loaded spider silk constructs can be easily printed without the need of additional cross-linkers or thickeners for mechanical stabilization. Encapsulated cells show good viability in such spider silk hydrogels.

8:30 AM SB05.04.03
Engineering Liquid-Liquid Phase Separation to Control Microstructure and Cell Behavior in Polysaccharide Hydrogels *Linqing Li; University of New Hampshire, United States*

The compositional heterogeneity and structural diversity of native extracellular matrix are essential in regulating cell behavior and promoting tissue regeneration. Thermoresponsive polysaccharide-based materials with tunable transition temperatures and phase-separated microstructure offer substantial opportunities in tissue engineering, drug delivery, and wound healing applications. To develop novel synthetic thermoresponsive polysaccharides, we employed versatile chemical routes to attach intrinsically hydrophobic adducts to the backbone of hydrophilic dextran and developed protocols to form hydrogels with defined microstructures. Systematically conjugating methacrylate moieties to the dextran backbone yielded a continuous increase in macromolecular hydrophobicity that induced a reversible phase transition whose lower critical solution temperature can be systematically modulated via variations in polysaccharides concentration, molecular weight, degree of methacrylation, ionic strengths, and Hofmeister salts. Photo-initiated radical polymerization permits facile chemical crosslinking and *kinetic capture of phase separation, enabling the formation of hydrogels with defined microdomains. The resulting heterogeneous hydrogels feature tunable microstructures and exhibited both microspheres and continuous phases that promoted enhanced cell adhesion in 2D and interfacial-driven cell migration in 3D. Engineering macromolecular hydrophobicity with temperature-triggered phase separation of conventional hydrophilic, non-phase separating polysaccharides to generate heterogeneous hydrogels with controlled microstructures will find potential applications in chronic wound healing.*

8:45 AM *SB05.04.04

Immunomodulatory Polymeric Elastomers for Biofabrication of Organotypic Structures *Milica Radisic; University of Toronto, Canada*

Function of engineered tissues and organs-on-a-chip such as permeability and contractility critically depends on the properties of their scaffolds. Scaffolds for soft tissue engineering and organs-on-a-chip require precise control of: a) structure to the mm-scale, b) elasticity from 1kPa to 500 kPa, c) mechanical anisotropy and d) biocompatibility. Complex structures can be 3D printed from hydrogels but a lack of mechanical support (1-10kPa) often results in the collapse of the prefabricated structure as cells exert tractional forces during tissue formation. Polymers can solve this problem, but common polyesters, such as PLGA are too rigid (1-200MPa) for soft tissues. Polymers are also inherently non-permeable to proteins and cells. These limitations are critical in vascularization approaches that require embedding enclosed branching conduits within a suitable lattice that holds cells in place, while controlling mechanical properties, or in engineering entire functional organs such as the heart left ventricle. In this presentation, I will discuss extrusion 3D printing of thermoplastic elastomer composites that enabled us to increase the fabrication efficiency of Biowire heart-on-a-chip device by over 60,000%. I will also discuss a high throughput 3D printing approach via coaxial extrusion to fabricate perfusable elastomeric microtubes of unprecedently small inner diameter (350 to 550 mm) and wall thickness (40-60 mm). This approach afforded the fabrication of multiple biomimetic shapes resembling cochlea and kidney glomerulus and afforded facile, high-throughput generation of perfusable structures that can be seeded with endothelial cells for biomedical applications. Relying on capillary microfluidics followed by UV crosslinking, monodisperse elastomeric polymer particles have been generated. These particles effectively reinforced hydrogel structures in 3D printing and enabled fabrication of a new class of self-healing and 3D printable granular materials with superior permeability.

The Effect of Electrical Stimulation on the Cellular Response of Human Mesenchymal Stem Cells on SiC-coated CNW Scaffolds *Koki Ono[1], Ayako Tanaka[1], Kenji Ishikawa[1], Wakana Takeuchi[2], Kenichi Uehara[3], Shigeo Yasuhara[3], Masaru Hori[1] and Hiromasa Tanaka[1]; [1]Nagoya University, Japan; [2]Aichi Institute of Technology, Japan; [3]Japan Advanced Chemicals Ltd., Japan*

Introduction

In recent years, regenerative medicine has been actively researching ways to heal damaged tissues in the body by applying electrical stimulation (ES) to cells on implanted scaffolds, which controls cell differentiation and growth. Scaffold materials are important factor in this process. Currently, polymer materials are primarily used as scaffold materials for electrically stimulated scaffolds in vivo. However, polymer materials have issues with mechanical properties and electrical conductivity, so they are not ideal.

Carbon nanowalls (CNWs) have excellent conductivity and mechanical properties, and graphene sheets oriented perpendicularly to the substrate, giving them a unique surface morphology. This material has been reported to promote osteoblast differentiation due to its unique surface structure and to enhance cell proliferation when combined with ES in vitro. However, using CNWs as scaffold electrodes in vivo has safety concerns due to the reported genotoxicity of graphene, which consists of CNWs. To improve this issue, I thought that coating CNWs *with biocompatible silicon carbide (SiC) could solve the problems related to using CNWs as scaffold electrodes in the body. SiC is chemically stable and has excellent mechanical properties, so it is used as a coating for stents and implants. Additionally, its excellent mechanical properties have been reported to induce bone formation in osteoblasts, which suggests that SiC is an attractive material for cell culture scaffolds. This suggests that SiC is suitable as a coating material for CNWs.*

However, the typical chemical vapor deposition (CVD) method for depositing SiC has a high deposition temperature of over 1200°C, which can cause CNWs to etch due to residual oxygen, making coating difficult. Our previous research successfully deposited SiC at a growth temperature of 700°C using thermal CVD with vinylsilane, a using novel precursor. We believe that using this precursor can achieve SiC coating on CNWs. Additionally, there are no reports of applying ES to cells on SiC-coated CNWs, so the effects of SiC on cells under ES remain unclear. Thus, it is necessary to investigate the effects of ES on cells with SiC-coated scaffolds.

In this study, we aim to investigate the cellular response to ES on mesenchymal stem cells on SiC-coated CNW scaffolds, with the goal of applying carbon materials as scaffold electrodes in vivo.

Method

We deposited SiC on CNWs using thermal CVD method with 5 sccm of vinylsilane, 500 sccm of Ar dilution gas, a growth pressure of 1 Torr, a surface temperature of 700°C, and a growth time of 5 to 30 minutes. Human mesenchymal stem cells (hMSCs) were used for cell culture. We used CNWs only, SiC-coated CNWs with varying deposition times, and a 48-well plate as a control for these samples as cell culture scaffolds. ES of 226 mVpp at a frequency of 10 Hz was applied one day after cell seeding for 3 days. The surface morphology of SiC-coated CNWs was evaluated using Scanning electron Microscope (SEM). Cell proliferation on each scaffold was assessed using the MTS assay.

Result and Discussion

SiC-coated CNWs retained their unique high-aspect-ratio structure, with the thickness of the CNWs walls increasing with longer growth times. Without ES, cell proliferation increased as the wall thickness of CNWs coated with SiC increased. In the samples with 15 minutes of SiC coating, the cell proliferation rate was lower than the control without ES, but it was comparable to the control when ES was applied. For samples with 30 minutes of SiC coating, there was no significant difference in cell proliferation rates with or without ES, and the rates were comparable to the control. This indicates a synergistic effect between SiC coating and ES, as the effect of ES was more pronounced on SiC-coated CNWs than on CNWs only.

Bioprinting Strategies to Control Biochemical Heterogeneity Within 3D Scaffolds *Murat Guvendiren; New Jersey Institute of Technology, United States*

In this presentation, novel strategies developed in our research laboratory is discussed to fabricate complex 3D cell-laden structures with user-defined and tunable spatial control of biochemical and mechanical properties for musculoskeletal tissue engineering. First, we present a 3D bioprinting technique designed to create dense cellular structures within photocurable hydrogels, offering precise spatial and temporal control of cell-instructive cues. Our method involves printing a photocurable viscous hydrogel support layer and depositing cell aggregates within it as needed. By adjusting the viscosity of the hydrogel ink, we enable needle movement and material extrusion within the printed layer, eliminating the necessity for shear thinning and recovery behavior, thus broadening the range of suitable hydrogel inks for the support medium. This technique allows the use of cell-instructive hydrogels as a stable support medium during long-term culture to influence cell behavior, or as a removable medium to leave behind pure cell constructs. Our approach facilitates the use of multiple hydrogel inks to create localized matrix heterogeneity and the bioprinting of diverse cell-only inks to form multicellular structures. We demonstrate *the effectiveness of this method by fabricating dense cellular structures within methacrylated hyaluronic acid (MeHA) hydrogels, showcasing the impact of controlled cell-instructive matrix heterogeneity on patterned stem cell osteogenesis. Then, we report fabrication of 3D printed polycaprolactone (PCL) scaffolds with airbrushed gelatin methacrylate (GelMA) hydrogel membranes. We demonstrate the use of GelMA membranes to control seeded stem cell heterogeneity including spatial control of osteogenesis within 3D scaffolds. Overall, our versatile techniques mark a significant advancement in the creation of complex heterogeneous microtissues and tissue interfaces, such as the osteochondral interface.*

10:30 AM *SB05.04.07
Development of Regenerative Technologies for Muscle Repair—Sheets, Gels, Powders and Sponges *George Christ; University of Virginia, United States*

Warfighters with battlefield injuries and civilians with analogous injuries from vehicular or other accidents can suffer extensive head, neck and extremity damage that results in permanent cosmetic and functional deficits to skeletal muscle. There are also numerous other congenital (e.g., cleft lip) and acquired (e.g., inflammation, infection and tumor resection) conditions that can result in permanent absence or loss of skeletal muscle form and function. Regardless of cause, extensive and irreparable loss of skeletal muscle, referred to as volumetric muscle loss (VML), leaves affected patients with debilitating and prolonged impairments. Despite increasing research activity, recent advances have still not identified solutions for satisfactory, no less full, functional recovery from VML injuries. Thus, there is still room for significant therapeutic improvement(s) to address this major unmet medical need. Moreover, it is important to keep in mind that the functional deficits associated with VML injuries, even those that occur in the same muscle or same muscle compartment, may not be equivalent. As such, VML can be thought of as a virtual continuum of magnitudes and complexities that will likely need to be treated by a corresponding spectrum of regenerative technologies. Furthermore, despite the prevalence of craniofacial VML injuries, much of the preclinical research to date is focused on limb and trunk muscles, with only a handful of reports on VML injuries in craniofacial muscles. Consideration of the unique features among craniofacial muscles, as well as relative to limb and trunk muscles, may shed important mechanistic insight for improved therapeutic development of customized biomaterial and cell-based treatment options that address muscle-specific features of VML injuries. In this setting, this presentation will review how use of several well-established VML models to the extremities (tibialis anterior, gastrocnemius, rotator cuff), trunk muscles (latissimus dorsi) and craniofacial muscles (masseter muscle) will permit muscle-specific evaluation of VML injury as well as evaluation of the regenerative efficacy of multiple technologies with distinct biomaterials. Specifically, the presentation will be focused on discussion of the following technologies for repair of VML injury: 1) a sheet-based decellularized extracellular matrix used as a muscle progenitor cell delivery vehicle(i.e., a biomanufactured tissue engineered muscle repair (TEMR) technology platform), 2) two distinct form factors of a bioinspired, tunable hyaluronic acid-based therapeutic (MuscleMatrix™), both a hydrogel and cryogel (MuscleMatrix™), and finally, 3) the potential of a powder form of a keratin-based hydrogel (KeraStat powder). When combined with rigorous, multiscale metrics of functional recovery, this approach will allow a more direct comparison of the regenerative efficacy of multiple biomaterial approaches across a diverse array of VML injuries. This represents an important first step toward development of improved muscle injury-specific, impairment-based, regenerative therapeutics (i.e., precision medicine) for more complete functional recovery from neuromuscular extremity trauma.

11:00 AM SB05.04.08
3D Printed Eggshell Microparticle Reinforced Thermoplastic Scaffolds for Engineering Bone *Mert Gezek and Gulden Camci-Unal; University of Massachusetts Lowell, United States*

Critical-size bone defects represent a major challenge in the regenerative engineering field. These defects can be caused by congenital anomalies, trauma, and various diseases. While autologous and allogenic grafts can be used in reconstructive surgeries, there are limitations with potential complications and limited availability of donor tissues. Moreover, recurring surgeries might involve prolonged and expensive recovery processes affecting the quality of life of patients. There is an unmet need for practical solutions for development of bone grafting materials with appropriate properties.

Three-dimensional (3D) printing, which is an additive manufacturing method, can be utilized to generate intricate 3D structures with high precision and represents a promising approach for personalized medicine. Despite its advantages, challenges exist with the use of cost-effective and accessible materials for developing biofunctional inks to print the desired structures with the required physiochemical and biological properties. In this study, eggshell microparticles (ESPs) were used as a reinforcement in thermoplastic poly(ε-caprolactone) (PCL) scaffolds through extrusion-based 3D printing. The overall goal is to establish a sustainable and affordable approach for developing customizable and personalized implants. Different concentrations of eggshells, from 0 to 50% (w/w) within PCL, were used to produce the 3D scaffolds. Scanning electron microscopy, Fourier-transform infrared spectroscopy, thermogravimetric analysis, differential scanning calorimetry, and X-ray diffraction methods were used to assess the physiochemical properties. Compression tests and degradation tests are used to investigate the mechanical properties and degradation kinetics respectively. MC3T3-E1 preosteoblast cells were used in the in vitro biological characterization studies. We performed alamar blue assays, confocal imaging, and real-time quantitative polymerase chain reaction to study the cell viability, proliferation, attachment, and differentiation behaviors. Our results revealed that our 3D printed biocomposite scaffolds utilizing novel biofunctional ink are promising materials for bone regenerative engineering.

Rational Design and Fabrication of Mineral-Graded Scaffolds for Use in Tendon-to-Bone Insertion Repair

Yidan Chen, Min Hao and Younan Xia; Georgia Institute of Technology, United States

The enthesis is a specialized fibrocartilaginous tissue responsible for transmitting mechanical loads between the connective tissue and bone during joint motion. Due to the complex nature of the soft-to-hard tissue interface, it has been a challenge to regenerate the transitional tissue and thereby restore its function. Critical features, including a spatially graded composition, hierarchical structure of the extracellular matrix, and a unique population of cells with a phenotypic gradient, are not recreated during the healing process. To address this problem, we are developing biomimetic scaffolds with a controllable mineral gradient to facilitate surgical repairs of the enthesis through the regeneration of tendon-to-bone insertion. The gradient in mineral content can be created by sequentially spin-coating with hydroxyapatite/poly(e-caprolactone) suspensions containing hydroxyapatite nanoparticles in decreasing concentrations. To produce an interdigitation geometry mimicking that of the natural enthesis for stress alleviation and facilitate cell infiltration, the mineral-graded film is then patterned with an array of funnel-shaped microchannels by laser machining. The unique design provided both mechanical (i.e., substrate stiffness) and biochemical (e.g., hydroxyapatite content) cues to spatially control the graded differentiation of mesenchymal stem cells (MSCs). Immunocytochemical analysis of human-derived MSC-seeded scaffolds demonstrates the creation of a gradient in cell phenotype from osteoblasts to mineralized chondrocytes depending on the level of mineralization in the scaffold. We can also incorporate a gradient of developmentally-inspired biofactors in the scaffold to further promote the phenotypic transition from mineralized chondrocytes to tendon fibroblasts. By recreating compositional and cellular features of the native tendon enthesis, the biomimetic scaffolds offer a promising avenue for improved tendon-to-bone insertion repair. This strategy potentially has broad applications in many clinically relevant scenarios, including rotator cuff repair, anterior cruciate ligament *reconstruction, and meniscal repair.*

11:30 AM SB05.04.10

Simulations-Driven Materials Design of Mechanically and Biologically Tuned Tissue Engineering Scaffolds for Bone Regeneration

Dinesh R. Katti[1], Krishna C. Kundu[1], Hanmant Gaikwad[1], Sharad V. Jaswandkar[1], Preetham Ravi[1], Parth Vyas[2] and Kalpana Katti[1]; [1]North Dakota State University, United States; [2]Sanford Hospital, United States

A computational approach to design novel scaffolds for bone tissue regeneration and cancer bone metastasis testbeds has been used to tune the mechanical properties and biological response of polymer clay nanocomposite-based biomaterials. Molecular dynamics simulations and altered phase theory are used to screen unnatural amino acid modifiers for designing tissue engineering scaffolds with tailored mechanical properties. Three amino acids were identified. The scaffold material is a nanocomposite of polymer (polycapralactone), amino acid-modified nanoclays, and hydroxyapatite mineral. We modify montmorillonite clay (MMT) with three unnatural amino acids: 5-aminovaleric acid, (±)-2-aminopimelic acid, and 4-(4-Aminophenyl) butyric acid. Molecular dynamics simulations and experimental studies reveal that the interaction energies in the amino acid intercalated nanoclays influence the mechanical properties of the scaffolds. The amino acid significantly affects the mechanical properties despite being less than 0.14% of the scaffold composition. The 4-(4-Aminophenyl) butyric acid had the highest attractive interactions with the clay, followed by (±)-2-aminopimelic acid and 5-aminovaleric acid. The mechanical response and the elastic modulus values followed the same pattern. All three composites show good biocompatibility with the human mesenchymal stem cells (hMSCs). The amino acids within the nanoclays also impact mineralization on scaffolds seeded with hMSCs. We observe enhanced mineralization in the presence of human breast cancer cells (MCF-7). The scaffolds containing 5-aminovaleric acid exhibited the highest bone mineralization, followed by (±)-2-aminopimelic acid and 4-(4-Aminophenyl) butyric acid. Thus, the selection of unnatural amino acids, guided by simulations, enables the design of biomechanically tunable 3D scaffolds for bone regeneration and bone metastasis cancer testbeds.

11:45 AM SB05.04.11

In Silico and In Vitro Insights of Clay-Integrin Interactions—Evaluating Na-Montmorillonite's Role in Biomineralization and Osteogenic Differentiation of Mesenchymal Stem Cells in Nanoclay Scaffolds

Hanmant Gaikwad, Preetham Ravi, Kalpana Katti and Dinesh R. Katti; North Dakota State University, United States

Montmorillonite (MMT) clay, a prevalent natural mineral, significantly influences biomineralization processes within biopolymer scaffolds, a crucial mechanism for bone tissue regeneration through osteogenesis. Various extracellular and intracellular signaling pathways facilitate the osteogenic differentiation of human mesenchymal stem cells (hMSCs) into mature osteoblasts. Extracellular minerals, including MMT clay, can alter the conformation of membrane proteins such as integrins, initiating intracellular signal transduction. However, the precise molecular mechanisms governing these signaling events during biomineralization within nanoclay-based polymer scaffolds remain largely unexplored. To address this challenge, the clay-integrin interface was analyzed to explore the interaction and activation of integrin (αVβ3), which subsequently triggers intracellular events leading to osteogenesis. Our molecular modeling study revealed that the non-bonded interactions between Na-MMT clay and integrin induce a hinge opening between the βA and hybrid domains of integrin, confirming conformational changes necessary for its activation. Moreover, we elucidated the cell adhesion mechanism facilitated by clay-integrin binding, which promotes the formation of a stable adhesion complex between cells and clay minerals through non-bonded interactions. The impact of clay mineral proximity on the mechanical behavior of integrin was further examined using steered molecular dynamics simulations, demonstrating that such proximity influences the mechanical stimuli applied to integrins, which regulates biological responses. Additionally, experimental studies

were conducted to examine the activation of integrin (αVβ3) expression in relation to biomarkers associated with various stages of osteogenic differentiation in the presence of nanoclay scaffolds. The inclusion of Na-MMT clay in biopolymer scaffolds enhanced the expression of αVβ3 integrin and osteoblast marker genes, as well as run-related transcription factor 2, indicating improved osteogenic differentiation of hMSCs. Our combined computational and experimental approach provides new insights into clay-integrin interactions that promote biomineralization and influence cell adhesion mechanisms, paving the way for more effective biomaterial designs.

SESSION SB05.05: Cellular Approaches for Regenerative Engineering
Session Chairs: Gulden Camci-Unal and Janet Zoldan

Engineering Organ Substitutes for Transplantation *Basak Uygun[1,2]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States*

Organ decellularization and recellularization is a promising approach in tissue engineering that results in organ specific scaffolds that can be repopulated with healthy cells to recapture the functions of the native organ. Organ decellularization has numerous advantages over bottoms-up approaches scaffold preparation because decellularized organ scaffold the organ specific microarchitecture and is composed of native extracellular matrix (ECM) composition. Our group has done the pioneering work in whole liver engineering with first demonstration in the rats. We developed a patent pending gentle decellularization protocol that leaves the ECM intact by efficiently removing the cellular component, a methodology for effective recellularization scaffolds with parenchymal and non-parenchymal cells with long term functions in vitro and short-term viability in vivo. We successfully identified ECM components in decellularized scaffolds using proteomics analysis and found that decellularized liver matrix (DLM) contains unique ECM proteins not present in other commonly used ECM derived substrates and established a DLM platform to efficiently differentiate human induced pluripotent cells into hepatocytes. Our current work focuses on generation of human liver grafts with parenchymal and non-parenchymal cells in addition to identifying donor age specific factors in the DLM that affect cell behavior. It is likely that several years still separate transplant patients from the availability of engineered livers and other organs, but that gap is closing perhaps even faster than the demand for organs grows.

Ulcer-Targeting Prodrug Particles to Promote Regenerative Healing in Inflammatory Bowel Disease *Erika E. Salzman, Elaine Tong and Phillip B. Messersmith; University of California, Berkeley, United States*

The current standard of treatment for inflammatory bowel disease (IBD), including ulcerative colitis and Crohn's disease, is to reduce idiopathic intestinal inflammation with anti-inflammatory, immunosuppressant, and biologic drugs. However, there is a critical need for therapeutics that specifically address ulcer healing. Intestinal ulcers cause pain and intestinal dysfunction during disease flare ups, and chronic recurrence of mucosal and submucosal intestinal tissue damage can lead to fibrotic stenosis, stricture, and blockages. Ultimately, pathological ulcer healing leads 50-80% of Crohn's and 10-30% of ulcerative colitis patients to require invasive *bowel resection surgery within their lifetimes.*

To address this need, we present a therapeutic prodrug particle containing the small molecule PHD inhibitor 1,4-dihydrophenanthrolin-4-one-3-carboxylic acid (DPCA), which has been shown to induce epimorphic-like regeneration in various mammalian tissues in vivo. This regeneration is the result of stabilization of transcription factor hypoxia-inducible factor 1α (HIF-1α), which mediates many downstream cellular processes critical to inflammation management and wound healing. DPCA was modified to assemble into ulcer-targeting prodrug particles, which show good biocompatibility and HIF-1α stabilization in vitro. Furthermore, oral administration of the particles in vivo showed protective effects on mouse weight and tissue architecture in a dextran sodium sulfate (DSS)-induced model of murine colitis. Mice treated with the particles also showed improved gut barrier function and regulation of immune response in colonic tissue. This prodrug particle represents a promising new platform to address the outstanding goals of preventing fibrosis and inducing histological healing in IBD.

3:45 PM SB05.05.03

Xenogeneic-Free Culture of Human Intestinal Stem Cells on the Vapor-Phase Synthesized Polymers for Regeneration of Intestinal Diseases *Seonghyeon Park[1], Ohman Kwon[2], Hana Lee[2], Mi-Young Son[2] and Sung Gap Im[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Bioscience and Biotechnology, Korea (the Republic of)*

Intestinal stem cells (ISCs) which reside at crypt base in the intestinal epithelium, served as a promising cell source for regenerative medicine in the context of gastrointestinal diseases. Recently, human Intestinal organoid (hIO) culture was a prominent technology for investigating the molecular and cellular nature of ISCs in vitro. However, it was challenging to efficiently and rapidly expand ISCs in vitro because it constituted a small portion of the cells within the large population of cells in the hIOs. Previously, we developed a novel 2D culture method of ISC$^{3D\text{-}hIO}$ which supported fast expansion, long-term maintenance, and cryopreservation of ISC$^{3D\text{-}hIO}$ by enriched culture of ISCs population and improved luminal side accessibility through in vitro differentiation into 2.5 dimensional (2.5D) intestinal epithelium.
However, due to the undefined nature of basement membrane extract (BME), such as Matrigel, the use of BME for ISC culture posed a significant barrier that had to be overcome for the development of clinical-grade cell therapies. To address limitations posed by traditional culture system, we developed Xenogeneic-Free Dish for ISC (XF-DISC) using initiated chemical vapor deposition (iCVD) process on cell culture substrates. The XF-DISC not only facilitated the rapid expansion with a 24-fold propagation in 30 days, but also enabled long-term expansion of 30 sequential passages. Additionally, XF-DISC supported stable stock banking system of ISCs$^{3D\text{-}hIO}$ stored for over 3 years and enabled efficient differentiation into intestinal epithelium, with no discernible distinctions compared to Matrigel-coated surfaces. Furthermore, ISCs$^{3D\text{-}hIO}$ cultured on XF-DISC were capable of engrafting and regenerating of intestinal epithelium of the EDTA-induced injury and DSS-induced colitis models by direct transplantation into colon of mouse. This innovative culture method for ISCs$^{3D\text{-}hIO}$ presented here underscored its potential for developing intestinal stem cell therapies applicable to regenerative medicine in human intestinal diseases.

4:00 PM SB05.05.04

The Research of Bioactive Glass Functionalized Poly (L-Glutamic Acid) Hydrogels Loaded with VEGF in Bone Defect Repair *Chao Huang and Zongke Zhou; West China Hospital of Sichuan University, China*

Objectives*: Critical-size bone defects have been a challenge for clinical treatment, and many studies have been devoted to solving this problem. This study developed an inorganic-organic multi-functional composite hydrogel (PLG-g-TA/VEGF/Sr-BGNPs) for synergistic therapy of bone defects.*
Methodology*: Monodisperse Sr-BGNPs were prepared by sol-gel method, PLG-g-TA polymer was synthesized*

from L-glutamic acid γ-benzyl ester and then grafted with tyramine, and PLG-g-TA hydrogel was prepared by in situ cross-linking under the action of HRP and H_2O_2. PLG-g-TA/VEGF/Sr-BGNPs composite hydrogels were finally prepared by loading Sr-BGNPs and VEGF. The composite hydrogel was conducted with rBMSCs and HUVECs to explore the osteogenic and angiogenic abilities in vitro. A 5 mm diameter cranial bone defect model was surgically constructed in rats, and the composite hydrogel was implanted in situ to investigate its bone repair performance in vivo.

Results: *The composite hydrogel could be mineralized to form hydroxyapatite, slow the release of functional ions (Si, Ca, B, and Sr) and VEGF, and maintain the alkaline surrounding environment. In vitro experiments showed that the composite hydrogel could promote the proliferation and osteogenic differentiation of rBMSCs, express the most osteogenesis-related genes and proteins, significantly enhance the tube-forming ability of HUVECs, and effectively inhibit the process of osteoblastic differentiation of RANKL-induced Raw 264.7 and the bone resorption ability of osteoclasts. In vivo, results showed that after the implantation of composite hydrogel, osteogenic and angiogenic biomarkers were upregulated compared with no treatment, and the composite hydrogel could effectively promote the repair of bone defects. Meanwhile, the composite hydrogel showed no apparent adverse effects in vitro and in vivo.*

Conclusion*: The multi-functional composite hydrogel significantly accelerates the bone growth in the hydrogel and bone repair in critical bone defects, thus providing an advanced adjuvant therapy candidate for large-segment bone defects. It is a promising artificial renewable bone grafting biomaterial.*

4:15 PM SB05.05.05

The Hydrophilic Amorphous Layer Around Bone Apatite Promotes Osteogenesis

Stanislas Von Euw[1], Kian Eichholz[2], Olwyn Mahon[2] and Daniel Kelly[2]; [1]University of Galway, Ireland; [2]Trinity College Dublin, The University of Dublin, Ireland

Bone tissue can be regarded as a nanocomposite material primarily built from an organic collagenous matrix reinforced with inorganic apatite nanoparticles[1]. The function of bone apatite nanoparticles does not, however, simply boil down to mechanical reinforcement. There is growing appreciation that they are pivotal factors in the mechanisms underlying bone remodelling[2] and bone metastasis[3], while they are also affected by certain metabolic bone diseases[4]. In this regard, biomaterial-based therapies aimed at regenerating damaged or diseased bones have long been using different forms of synthetic calcium phosphate particles to improve their overall performance[5]. However, from pre-clinical testing at the laboratory scale to clinical solutions, the aforementioned therapies are based on synthetic analogues that are often not biologically relevant as they tend to disregard the intricate complexity of biogenic calcium phosphates[6–9], especially the fact that the composition, structure and other physicochemical characteristics of calcium phosphate particles in bone are heterogeneous in space and time[10]. Using a series of synthetic organic–inorganic nanocomposite materials containing well-defined proxies for biogenic calcium phosphate particles at the different stages of bone biomineralization, we show that human mesenchymal stem/stromal cells (hMSCs) osteogenesis is substantially enhanced when a hydrophilic amorphous layer is present at the surface of the calcium phosphate particles. This hydrophilic amorphous surface layer is naturally occurring around bone apatite nanoparticles[6] and, hence, may contribute to the so far unrivalled performance of autologous bone grafting procedures. These results offer a previously unexplored perspective around intrinsic osteoinductive properties and emphasize the critical importance of truly biomimetic designs for developing competitive biomaterials for bone healing. They also open new avenues to uncover the extent to which this hydrophilic amorphous surface layer may also regulate the behaviour of other types of cells and, in turn, influences a number of key bone physiological and pathological processes.

Antibacterial Electrospun Wound Dressing with Flame-Made Ag/SiO$_2$ Nanoparticles *Reshma V. Ramachandran[1], Thomas Thersleff[1], Maria Samara[1], Matthew Fielden[2] and Georgios Sotiriou[1]; [1]Karolinska Institutet, Sweden; [2]KTH Royal Institute of Technology, Sweden*

Wound healing is a multifaceted biological phenomenon that encompasses tissue repair and the restoration of functionality. The healing process can be significantly impeded by wound infections, which occur when microbes infiltrate the wound. These infections can cause severe health issues, including prolonged healing, septicemia, and deep tissue and bone infections, leading to reduced mobility, financial burden, and potential limb amputation [1]. To mitigate this, antibacterial dressings have been developed to decrease bacterial colonization in wounds. Many of these dressings contain antibiotics, but with the increasing prevalence of antibiotic resistance, there is a growing need for antibiotic-free alternatives [2].

One potential solution is the use of antimicrobial nanomaterials, such as nanosilver, in wound dressings [3]. However, commercially available silver-based dressings often fail to demonstrate clear clinical effectiveness due to the uncontrolled release of silver ions (Ag^+) at sub-lethal concentrations, which could unintentionally foster resistance. To ensure the successful integration of nanoparticles, it is crucial to employ a scalable and reproducible method that allows for precise control over the size and shape of the nanoparticles while minimizing product development costs. In response to this challenge, we propose a solution that combines two industrial manufacturing processes: flame spray pyrolysis [4] and electrospinning.

In our research, we present antibacterial wound dressings composed of electrospun nanofibrous membranes made from polyvinyl alcohol (PVA) and chitosan, which are infused with Ag/SiO$_2$ nanoparticles produced via flame spray pyrolysis. Four different membranes were used with varying ratios of PVA and chitosan – 100:0, 95:5, 90:10 and 80:20, to examine the influence of the membrane composition on their antibacterial activity. Notably, the dressings with PVA: chitosan ratios of 90:10 and 80:20 demonstrated robust antibacterial activity against gram-positive Methicillin-resistant Staphylococcus aureus (MRSA) and gram-negative Pseudomonas aeruginosa, both of which are common pathogens responsible for wound infections.

To further validate their effectiveness, these dressings were tested using an ex-vivo model with porcine skin. Additionally, biocompatibility tests were conducted on fresh human skin obtained from surgical procedures.

Moreover, we carried out comprehensive mechanistic investigations, which revealed that the composition of the fibers and the manufacturing process significantly influence the sustained release of Ag^+ ions from a minimal amount of Ag/SiO_2 nanoparticles. This results in potent antibacterial properties while reducing the risk of Ag^+ ion resistance and nanosilver toxicity, thereby representing a promising strategy for the development of effective, antibiotic-free wound dressings.

4:45 PM SB05.05.07

Stretch Activated Multifunctionalization of Disulphide Linked Hydrogels *Jamie J. Kruzic[1], Yuwan Huang[1], Alaa Ajam[1], Zihao Li[1], P. Bhakthi Jayathilaka[1], Md. Shariful Islam[1], Chavinya Ranaweera[1], Meredith N. Silberstein[2] and Kristopher Kilian[1]; [1]University of New South Wales Sydney, Australia; [2]Cornell University, United States*

Inspired by how forces in biological tissues guide their functions in-vivo using mechanochemical reactions, we have developed bioinspired hydrogels where an applied tensile stretching force facilitates molecule immobilization from the surrounding environment to provide multiple avenues for functionalization. Specifically, we have developed disulfide linked polyethylene glycol hydrogels that are reinforced with a second ionically bonded sodium alginate network to simultaneously achieve stretchability and mechanochemical functionalization. To demonstrate and quantify the mechanochemical functionalization behavior, thiols produced by disulfide bond rupture were sensed during stretching using a reaction activated fluorophore dissolved in the hydrating solution. By monitoring the increase in fluorescence intensity upon stretching, it was determined that force activated molecule immobilization becomes more prominent in hydrogels with high stretchability under low stress. Such results provided guidance to design double network hydrogels that balance favorable mechanical properties and mechanochemical responsiveness. Finally, for the most mechanochemically active hydrogel, we demonstrated how the stretch-activated immobilization of a maleimide containing peptide can functionalize the gels to promote the growth of human fibroblasts. Results of this work are anticipated to encourage further research into the development of stretchable and multifunctionalizable hydrogels for biotechnology and biomedical applications.

Gradient Hydrogel for the Reconstruction of Full-Thickness Skin Loss *Mina Kwon, Min Seok Kang, Hye Eun Choi, Su Bin Lee and Ki Su Kim; Pusan National University, Korea (the Republic of)*

The skin is composed of three main layers: the epidermis, dermis, and hypodermis where the physical cues are not

uniform but distributed in a gradient manner. The gradient structure of skin tissue allows for the distribution of different cell types, extracellular matrix (ECM) components, and other factors in a spatially organized manner. This organization is crucial for the proper functioning and regeneration of the skin. Mimicking the ECM structure of the skin is a focus of tissue engineering approaches for regeneration of skin wounds. Conventional hydrogels have a homogeneous environment with an isotropic distribution limiting complete mimicking of the natural gradient of ECM. Gradient hydrogels, on the other hand, represent an innovative approach in wound care, offering a promising solution for improving the outcomes of wound healing, particularly in complex and chronic wounds. They provide a customizable and multifaceted approach to address various aspects of the wound healing process, from moisture control to cell proliferation and scar minimization. In this work, we report hydrogel with gradient mechanical properties using hyaluronic acid (HA) for the reconstruction of full-thickness skin loss. We used HA as the hydrogel backbone, which is a natural polymer and an excellent candidate for use in tissue engineering due to its excellent biocompatibility and biofunction. HA was conjugated with methacrylate (MA) to induce photocrosslinking properties. We successfully prepared the gradient hydrogel with syringe pumps for gradient generation and a fluidic mixer for homogenous mixing of HA-MA with two different degrees of MA substitution. The gradient hydrogel was characterized in vitro and evaluated for potential wound healing applications. The successful formation of the gradient in crosslinking density is confirmed by NMR spectrum and the viscoelastic properties of the hydrogels were tested on a rheometric fluid spectrometer. The SEM confirmed that the different cross-sectional morphology and the pore size in our hydrogel system. The interior morphology of hydrogel changed significantly along the vertical direction, and the bottom section of hydrogel shows the biggest pore size. In vitro tests, the hyaluronic acid gradient hydrogel exhibits excellent cell compatibility with L929 fibroblasts. Rhodamine B loaded hydrogel was examined for its drug release profile. The hyaluronic acid gradient hydrogel showed continuous drug release for 12 h and more than 50% of the drug was released after 12 h. Finally, in vivo wound treatment experiment was conducted using rats to verify the wound healing effect of the gradient hydrogel. The prepared gradient hydrogel shows noticeable wound healing effect and minimal scar formation. Taken together, this gradient hydrogel, which reproduces the physical gradients of skin, is biocompatible and can be used as a potential candidate for excellent regeneration of full thickness skin loss.

SB05.06.03

Ultrasound-Activated Piezoelectric Antibacterial Silk Composite Scaffolds Guiding Differentiation of Mesenchymal Stem Cells

Namrata Tiwari and Neetu Singh; Indian Institute of Technology Delhi, India

Smart materials for tissue engineering have been in extensive use for few decades now. This work delves into the exploration of ultrasound-activated piezoelectric and antibacterial silk-based composite scaffolds as a pioneering strategy to guide the differentiation of human mesenchymal stem cells into osteogenic lineage without the application of any exogenous growth factors by utilizing the charges generated by these films. The study evaluates the biocompatibility and antibacterial attributes of these scaffolds, which incorporates Barium Titanate Nanoparticles (BTNPs) and calcium doped Barium Titanate (BCTs) nanoparticles along with Zinc Oxide nanoparticles for obtaining high piezo modulated electrical stimuli and antibacterial properties. The choice of using calcium as a doping material allows to increase its piezoelectric potential and retain its biocompatibility. The results reveal that, under the influence of ultrasound stimulation, these composite scaffolds respond to mechanical cues like low frequency ultrasound stimulations to facilitate lineage-specific differentiation of the seeded human mesenchymal stem cells. Ultrasound stimulations being wireless avoid complicated wired electric circuits and are also known to activate calcium channels in the cells which aids osteogenesis, and this property is further enhanced by calcium doped BCT nanoparticles in the scaffolds. Significantly, our findings exhibit the profound potential of these scaffolds to exploit the piezoelectric properties of BTNPs, effectively enhancing the differentiation trajectories of stem cells. Furthermore, their demonstrated antibacterial capacities underscore their pivotal role in infection prevention, an imperative facet in the domains of tissue engineering and medical *implantation. This study strongly suggests the utility of ultrasound-activated silk-based composite scaffolds in advancing the frontiers of regenerative medicine and tissue engineering.*

SB05.06.05

Orally Administrated Inflamed Colon-Targeted Nanotherapeutics for Inflammatory Bowel Disease Treatment by Oxidative Stress Level Modulation in Colitis

Dongkwang Min and Jaeyun Kim; Sungkyunkwan University, Korea (the Republic of)

Inflammatory bowel disease (IBD) is an autoimmune disease that is characterized by excessive gastrointestinal tract inflammation. Although the exact cause of IBD remains unclear due to its multifactorial nature, it is believed to result from the inappropriate and continuous inflammatory immune responses that lead to prolonged gut microenvironment inflammation. Therefore, current clinical therapies for IBD primarily focus on blocking specific molecules involved in inflammation. However, the efficacy of these treatments varies significantly among individuals, and they often cause inflammation reoccurrence. Thus, there is a high demand for safe and targeted therapy that can be orally administered for effective IBD treatment. Characteristics of colonic inflammation include high expression of the positively charged protein on gut epithelial cells, indicating that negatively surface-charged formulation could target to inflamed lesions through oral administration. Hence, we aimed to design the use of inflamed colon-targeted antioxidant nanotherapeutics (ICANs) with high durability in gastrointestinal tract for in situ oxidative stress level modulation in colitis. ICANs consist of mesoporous silica nanoparticle (MSN) with surface-attached ROS-scavenging ceria nanoparticles (CeNPs), which are further coated with poly-acrylic acid (PAA) to facilitate preferential adherence to inflamed colon tissues through electrostatic interaction. We achieved a high ROS-scavenging property and negative surface charge that remained effective even after artificial gastrointestinal fluid incubation by optimization of the molecular weight and PAA-coating pH. Orally administrated ICANs demonstrated enhanced adherence to inflamed colon tissues in an acute inflammation mouse model of IBD induced by dextran sulfate sodium. Furthermore, administration of ICANs led to recovery of body weight, decreased levels of pro-inflammatory cytokines and CD11b^{+} cell infiltration, and restoration epithelial barriers against colitis. These data suggest that targeted delivery of ROS-scavenging nanotherapeutics led to modulation of pro-inflammatory gut microenvironment by regulating redox balance and reducing inflammatory cell infiltration, thereby suppressing the colitis-associated immune response. These findings highlight the potential of non-invasive ICANs as a promising candidate for treating inflammatory intestinal diseases by oxidative stress level modulation in colitis.

SB05.06.06

Aortic Smooth Muscle Cells Influence the Growth of Neural Progenitor Cells in GelMA-Encapsulated 3D Cultures

Selina Banerjee, Abigail Koppes, Guohao Dai and Ryan Koppes; Northeastern University, United States

In recent years, organ-on-chip technology has advanced greatly and shown immense potential for drug screening and advancement of tissue engineering methods. Organ chips allow control over spatial orientation of cells and materials compared to traditional cell culture platforms and animal models, providing increased relevance to the human physiology. However, maintenance of viable co-cultures on organ chips remains a challenge. For example, nerves and arteries are closely associated physiologically, but they are seldom co-cultured in vitro. In this study, we aimed to develop and characterize the co-culture of neural and vascular cells using a novel organ chip developed in our lab. In preliminary studies, human aortic smooth muscle cells showed extensions and network formation when encapsulated and cultured in gelatin methacryloyl (gelMA) hydrogel, while iPSC-derived neural progenitor cells showed some extensions in gelMA-encapsulated cultures. Therefore, we hypothesized that a co-culture of aortic smooth muscle cells with iPSC-derived neural progenitor cells, both gelMA-encapsulated in adjacent chambers on the organ chip, will improve neural cell outgrowth.

On Day 6 of neuronal differentiation, gelMA-encapsulated iPSC-derived neural progenitor cells were seeded in the outer hydrogel chambers of the organ chip. GelMA-encapsulated aortic smooth muscle cells were seeded in the middle chamber, forming a physiologically relevant nerve-artery model. The two gel chambers formed a contiguous 3D culture system through GelPins, a technology established by our lab that allows contact and interaction of cells in adjacent 3D culture chambers. Cells were cultured in 1:1 neuronal differentiation: vascular media. 3D cultures were immunostained for neural and vascular markers at various timepoints until Day 55 of neuronal differentiation, to confirm differentiation and visualize the extent of neurite outgrowth into neighboring gel compartments. To our knowledge, this is the first report of a human vascular smooth muscle cell – human autonomic neural co-culture in 3D.

Interestingly, though neural cells showed some outgrowth into their own chamber, neural progenitor cells unexpectedly migrated into the smooth muscle chamber of the organ chip. Arterial smooth muscle cells are known to secrete growth factors that guide autonomic innervation of arteries during development. Therefore, these findings may be reflective of the physiological interactions between immature cell types. These results also support our hypothesis that co-culture with vascular smooth muscle cells will influence neurite outgrowth. However, this study reveals that the maturity and influence of cell types must be considered when designing a co-culture, even when cells are encapsulated in a hydrogel, as cellular migration may occur. Next steps will include differentiating neural progenitor cells farther towards mature phenotypes before seeding on the organ chip to reduce their propensity for migration.

SB05.06.07

Material Mediated Tissue Induction—Geometrical, Surgical and Material Parameters *Sabah Oghazian, Edward Harvey, Nicholas Makhoul, Mitchell Bernstein, Jake Barralet and Sze Wai Lau; McGill University, Canada*

INTRODUCTION*: Marrow transplantation or even extramedullary marrow formation is known to often result in new bone formation. Extramedullary marrow may form as a result of haematological diseases, however, it has also been reported to occur as a result of injury such as surgery or other trauma. The implantation of biomaterials results in a sterile inflammation and marrow is occasionally reported as an incidental finding. The simplest system reported to pre-clinically induce extramedullary marrow and ectopic bone was simply an open-ended glass tube. This study recreates this early report for the first time and determines if the tissue induced by this bioinert material had any regenerative potential.*
METHODS: *We conducted this pre-clinical study using male Wistar rat models after approval from McGill University Animal Care Committee (AUP 7660). Glass and silicone open-ended tubes were introduced subcutaneously and subperiosteally in the skull region. To insert the tubes beneath the skin, a horizontal incision on the nuchal skin provided access, and the tube was positioned over the cranium. A vertical incision over the midline of the animal's head was made to place the tube directly over the bone. We maintained periosteum either over or under the implants in all experimental groups except one. In this particular group, the periosteal flap was removed to allow direct contact between the tube, skin and bone. Moreover, to assess the effect of decortication, several monocortical holes were created in the calvarial bone in one of the groups. Tubes were either 3 mm or 6 mm in height and 9 mm in diameter. Five weeks post operatively, all animals were sacrificed, and further analyses including gross examination, micro-CT analysis, and histological evaluation were conducted.*
RESULTS*: Macroscopic examination of the specimens revealed a central cord connecting the skin to the basal connective tissue over the skull. This cord appeared thinner in the silicone tube group compared to the shorter and thicker cords observed in the other groups. Micro-CT evaluation indicated osseous features were present in all glass tubes but not in silicone tubes placed under skin. The highest amount of bone formation was found in shorter glass tubes which were placed under periosteum, followed by subperiosteal 6 mm-height glass implants.*

Surprisingly removal of periosteum and decortication was not correlated with a significant difference in the amount of bone formed within the tubes. Histological examination confirmed vascularization in all samples' central tissue cords. In subcutaneous silicone group, basal tissues comprised adipose tissue and a distribution of fibroblasts and inflammatory cells, with no evidence of bone formation. Subcutaneous glass tubes shared the same pattern with additional islands of intramembranous bone formation. Ectopic lamellae of bone were found encircling the central cord in short glass tubes, whereas the cord showed no peripheral bone in other groups. The newly formed bone connected to the skull showed evidence of hematopoietic tissue.
CONCLUSIONS: *Our study suggests that physical stimuli alone, not related to the physicochemical properties of the biomaterial could induce bone formation. This is highly important since it suggests that some tissue regeneration observed in biomaterials can be attributed in part to the foreign body reaction. Deliberate manipulation of this phenomenon would appear a new and underappreciated route to materials mediated tissue regeneration.*

SB05.06.09
Mechanics of Carbon Monoxide Binding to Hemoglobin in Oxygen-Rich Environment Revealed by Molecular Dynamics Simulation with Advanced Force Field *Mingrui Jiang and Zhao Qin; Syracuse University, United States*

Carbon monoxide (CO) is a byproduct of the incomplete combustion of carbon-based fuels like wood, coal, gasoline, or natural gas. As incomplete combustion in a fire accident or in an engine, massively produced CO leads to a serious life threat because CO competes with oxygen (O_2) binding to hemoglobin and makes people suffer from hypoxia. Although there is hyperbaric O_2 therapy for patients with CO poisoning, the nanoscale mechanism of CO dissociation in the O_2-rich environment is not completely understood. We construct the classical force field parameters compatible with CHARMM for simulating the coordination interactions between hemoglobin, CO and O_2, and use the advanced force field to reveal the impact of an O_2-rich environment on the binding strength between hemoglobin and CO. We use density functional theory calculations and Car-Parrinello molecular dynamics simulations to obtain the bond energy and equilibrium geometry, considering essential spin states. Machine learning enabled via a feedforward neural network model is then used to obtain the classical force field parameters for our molecular dynamics simulations. Steered molecular dynamics simulations with our advanced force field are applied to characterize the mechanical strength of the hemoglobin-CO bond before rupture under different simulated O_2-rich environments, represented by bias potentials confining an O_2 molecule at different radiuses from Fe^{2+} of heme. The results show that as O_2 approaches the Fe^{2+} at a distance smaller than ~2.8 Å, the coordination bond between CO and Fe^{2+} is reduced to 50% bond strength in terms of peak force observed in the rupture process. The free energy landscape measured by our metadynamics simulation also shows this weakening effect. Our work suggests that the O_2-rich environment around the hemoglobin-CO bond effectively weakens the bonding, so designing an O_2 delivery vector to the site helps alleviate CO binding, which may shed light on de novo drug design for CO poisoning.

SB05.06.10
Bioactivity of Calcium Phosphate Nanoparticles in Scaffolds for Bone Tissue Engineering *Reshma V. Ramachandran[1], Yael Suárez[2], Varvara Platania[3], Alexandra Teleki[2], Maria Chatzinikolaidou[3] and Georgios Sotiriou[1]; [1]Karolinska Institutet, Sweden; [2]Uppsala University, Sweden; [3]University of Crete, Greece*

Bone fractures and defects pose a significant health challenge, stemming from various sources such as osteoporosis, physical injuries, bone malformations, skeletal disorders, and tumor excisions. These conditions lead to considerable morbidity and a decline in life quality, thereby presenting a substantial public health concern [1]. Bone grafts, despite their widespread use, are plagued by limitations such as scarce availability, potential for infection, and a high rejection rate when integrated with host tissues [2]. An emerging solution is the use of *scaffolds that replicate the natural bone structure, which comprises hydroxyapatite nanocrystals of calcium phosphate embedded within collagen nanofibers [3].*

In this regard, we suggest a unique scaffold composed of electrospun Poly(lactic-co-glycolic acid) (PLGA) fibers infused with calcium phosphate (CaP) nanoparticles. These nanoparticles are produced using flame spray pyrolysis [4], which provides precise control over the particles' size, composition, and crystallinity. This novel approach enables us to explore the chemical, mechanical, and topographical cues offered by the nanostructures of calcium phosphates. Specifically, we can examine their influence on cellular adhesion, proliferation, and osteogenic differentiation, which are vital processes in bone regeneration and healing.

CaP is known to exist in polymorphic crystal phases (for instance, monocalcium phosphate monohydrate and anhydrous, dicalcium phosphate dihydrate, α- and β-tricalcium phosphate (TCP), amorphous CaP, and hydroxyapatite) and various structures (such as particles, spheres, rods, needles, wires, disks, platelets) [5]. In this study, we employ flame spray pyrolysis to fabricate four different CaP nanoparticles of varying crystallinity, ranging from amorphous to hydroxyapatite. These particles are then incorporated into electrospun PLGA fibers. Viability studies on these scaffolds with pre-osteoblastic cells have demonstrated that cell proliferation increases with the crystallinity of the particles, while significant cellular adhesion was observed regardless of the crystallinity. Furthermore, osteogenic differentiation was studied using the markers alkaline phosphatase and collagen, where the differentiation was observed to be highest for the hydroxyapatite form of calcium phosphate. Interestingly, the manufacturing process also allows the particles to have various ratios of carbonate and phosphate. However, there was no significant influence of the carbonate content on osteogenesis or cell proliferation.

In conclusion, we have conducted a thorough analysis to understand the influence of CaP nanoparticles embedded within scaffolds on osteogenesis. This research could potentially lead to advancements in the field of bone tissue engineering, resulting in more effective treatments for bone fractures and defects.

Amyloid-β and Mucin Debris Removal Using Magnetite-Ceria Nanoparticle Assemblies for Alzheimer's Disease and Pseudomyxoma Peritonei

Hyek Jin Kwon[1], Mohammad Haroon Choudry[1] and Taeghwan Hyeon[2];
[1]University of Pittsburgh, United States; [2]Seoul National University, Korea (the Republic of)

The presence of Aβ protein in the brain significantly contributes to Alzheimer's disease progression, while mucin accumulation in Pseudomyxoma Peritonei (PMP) cancer obstructs drug delivery, emphasizing the need for its removal to enhance treatment effectiveness. We introduce an Aβ cleansing system utilizing multifunctional magnetite/ceria nanoparticle assemblies for targeted removal of Aβ peptides from circulating blood through specific capture and magnetic separation. The magnetite nanoparticles in the core of these assemblies enable the magnetic isolation of captured Aβ peptides, exerting a strong attractive force under an external magnetic field. Concurrently, ceria nanoparticles in the shell alleviate oxidative stress by scavenging reactive oxygen species generated during immune responses. Application of this blood Aβ cleansing system in 5XFAD transgenic mice not only reduces Aβ levels in both blood and brain but also prevents spatial working memory deficits, indicating its *potential for Alzheimer's disease prevention and therapy. This technology is also applied to reduce mucin debris in an ascites PMP mouse model.*

SB05.06.13

Development of a ZnO Nanomaterial with Silver and Copper Supported on Hydrogel *Mariana I. Garay, Dania O. Govea Alonso and Edgar G. Villabona Leal; Universidad Autónoma de Guadalajara, Mexico*

Exposed wounds are tissue injuries with slow healing that can remain open for more than a month. These wounds have been characterized as a silent epidemic and global health problem due to their impact on patients quality of life and can be cause by diseases such as diabetes mellitus.

Diabetes mellitus is a metabolic disease primarily characterized by hyperglycemia, resulting from defects in insulin secretion, insulin action, or both. One of the complications of diabetes mellitus is known as diabetic foot, which includes exposed wounds, infections, ulcerations, and destruction of deep tissues. Diabetic foot occurs due to the combination of peripheral neuropathy and peripheral artery disease. According to literature, proper management is critical to prevent severe outcomes such as amputation.

It is estimated that approximately 40 million cases of chronic wounds occur worldwide each year. These wounds appear more frequently in the adult population at a rate of 1.3%, and reach 3.6% in people over 65 years old, increasing to more than 5% in those over 80 years old.

Currently, the treatment of exposed wounds involves oral antibiotics, local cleaning, and sterile dressings that only function as a physical barrier. However, antibiotic treatments have become more difficult due to the rise of antimicrobial resistance, leading to wound infections. Therefore, it is important to propose materials that combine biocompatibility, inmunomodulatory properties, and antimicrobial activity using biotechnology, materials science, and nanotechnology.

Nanomaterials exhibit new properties, due to their small size, enhancing their potential for nanomaterials applications. Nanomaterials are those that possess tiny particles no larger than 100 nanometers. At these dimensions, materials exhibit new properties, such as a higher surface-to-volume ratio, increased energy, and specific surface area. Due to their small size, nanomaterials can diffuse in extracelullar environments, promoting specific cellular contact.

It has been demonstrated in the literature that metal nanoparticles, including silver, gold, iron, copper, titanium, and zinc oxide, possess antimicrobial properties that help destroy drug-resistant organisms and promote wound healing and re-ephitelialization.

In this project, zinc oxide nanoparticles will serve as a support for silver and copper nanoparticles; this material will be integrated into a hydrated polymeric matrix or hydrogel, with high biocompatibility. These nanocomposites will be optimized to exhibit the highest physicochemical stability, excellent antimicrobial properties, and low synthesis costs.

SB05.06.14

Transfection of Cancer Cells on 3D Engineered Extracellular Matrix Using Surface Capped Protein Nanoparticle Toward Effective Autologous Cell Therapy *Seongjun Moon, Fjorela Xhyliu and Joerg Lahann; University of Michigan–Ann Arbor, United States*

Autologous cell therapy holds promising potential for personalized cancer treatment, contingent on rapid proliferation and efficient genetic transfection of patient-derived cancer cells. Our prior research capitalized on a three-dimensional engineered extracellular matrix (3D eECM) to foster cell growth. However, traditional electroporation for gene delivery presents significant drawbacks, notably the reduction of cell viability and increased risk of gene mutation, resulting in a decreased number of desired modified therapeutic cells. Furthermore, the requirement for cell detachment from the 3D eECM during electroporation exacerbates cell loss

and genetic instability.
Addressing these challenges, we propose an advanced transfection approach utilizing surface-capped protein nanoparticles that are prepared through an electrohydrodynamic jetting process and capped with a polymeric material. This method transcends the constraints of electroporation by enabling direct gene delivery to cells on the 3D eECM, ensuring cell viability and optimizing transfection efficacy, resulting in a high number of desired modified therapeutic cells. By obviating the need for cell detachment, we maintain the integrity of the proliferative milieu provided by the eECM and minimize the risk of gene alterations. Our innovative strategy holds the potential to enhance the viability and genetic stability of therapeutic cells, representing a significant advancement in the application of autologous cell therapy for cancer treatment.

SB05.06.15

Development of an Adhesive Hydrogel-based Platform Using Disulfide Bonds for Endogenously Improving Nitric Oxide Concentration for Diabetic Wounds *Kyungtae Park[1,2,3]; [1]Yonsei University, Korea (the Republic of); [2]Brigham and Women\'s Hospital, United States; [3]Harvard University, United States*

The prevalence of diabetes is rapidly increasing. However, comprehensive management, including diagnosis and treatment for diabetes, is not being properly conducted. Diabetes is becoming more prevalent due to insulin resistance, which worsens with age-related decreases in muscle mass and physical activity, as well as the use of multiple medications for chronic diseases. Diabetic patients can suffer from various complications in the cardiovascular system, kidneys, peripheral nerves, etc., due to chronic vascular damage. The risk of complications is very high due to disruptions in the immune system. Patients with diabetes and cardiovascular diseases experience increased blood viscosity and narrowed blood vessels, leading to impaired blood circulation in peripheral vessels and various related diseases. Therefore, it is crucial to repair vascular damage and effectively form new blood vessels.
Nitric oxide, an endogenous gaseous signaling molecule, is involved in various physiological processes such as cardiovascular homeostasis regulation, cell proliferation, and cancer cell apoptosis. Specifically, nitric oxide can induce vascular dilation by increasing the expression of cGMP in smooth muscle cells. Current clinical treatments using nitric oxide involve inhaling high-pressure nitric oxide gas, which delivers nitric oxide to the lungs. However, due to the short half-life of nitric oxide, it is challenging to use this method for effective delivery. Although hydrogels for transdermal and local delivery of nitric oxide are being developed in the research field, they have not been applied in clinical treatments. The biggest issue is that to deliver nitric oxide externally to the reduced levels within the blood vessels, it is necessary to continuously inject a carrier that releases nitric oxide into the affected area or apply hydrogels transdermally. Additionally, as these methods do not effectively increase the nitric oxide concentration within the blood vessels, they are limited in treating diseases caused by permanently reduced nitric oxide levels due to vascular damage or aging.
Herein, we developed a platform that can normalize abnormal nitric oxide concentrations in the vascular system by utilizing the breakdown and bonding characteristics of disulfide bonds to intrinsically regulate the release of nitric oxide within the human body, thereby upregulating nitric oxide levels. We controlled the nitric oxide release by adjusting the properties of surrounding functional groups of the disulfide bonds. Based on this, we verified the changes in the chain mobility of the disulfide bonds and consequently controlled the breakdown of GSNO, an intrinsic nitric oxide-releasing substance in the human body. For validation of promoting wound healing efficiency for chronic wounds caused by diabetes, this system helps normalize vascular dilation functions and promotes vascular formation in peripheral vessels, thereby inducing wound healing. The platform being developed in this study for endogenously improving nitric oxide concentration is unique in that it intrinsically increases nitric oxide levels, unlike existing nitric oxide-based treatments. Additionally, it is expected to contribute to treating chronic diseases such as open wounds and chronic vascular diseases, thereby improving the overall health level of the population and enhancing the quality of life for ordinary citizens suffering from diabetes complications and

vascular diseases.

SB05.06.16

Optimizing PNVCL Hydrogels for Drug Delivery—A Molecular Weight Odyssey *Arthur M. Gabriel[1,2], Maria Luiza L. Silva[3,1], Robert d. Paiva[1], Sandra A. Cruz[1] and Emerson R. Camargo[1,2]; [1]Universidade Federal de São Carlos, Brazil; [2]Centro de Desenvolvimento de Materiais Funcionais, Brazil; [3]Embrapa Instrumentation, Brazil*

The consumption of traditional drugs, usually by oral intake, injections or topical has some limitations that has driven the development of modern drug delivery systems. Among those limitations, the lack of targeted delivery systems leads to active ingredients distributed throughout the body, which can result in adverse effects. Another limiting factor is the difficulty of controlling the drug release profile. Medications need to be delivered at a specific and controlled rate at the target site to achieve best efficacy and safety, however traditional methodologies often struggle to achieve precise release profiles, leading to suboptimal treatment outcomes. Furthermore, some medications are sensitive to environmental factors such as pH, temperature, or enzymatic activity. Without proper protection or targeting, these drugs may degrade prematurely or become inactive before reaching their intended site of action. To overcome these limitations, stimuli-responsive drug delivery systems (DDS) have emerged as a promising solution. These materials are designed to respond to specific stimuli, triggering drug release only at the proper time and location. This approach enhances drug efficacy, minimizes systemic exposure and reduces the risk of adverse effects. In light of that, this study aims to use poly(N-vinylcaprolactam) (PNVCL) hydrogels as controlled drug delivery systems. PNVCL with different molecular weights (MW) were synthesized in order to understand how the MW affect the absorption and release profile of a range of antibiotic drugs. The polymer was synthesized by radical polymerization of NVCL using 2,2'-azobis(2-methylpropionitrile) (AIBN) as initiator at 70 °C for 4 h in DMSO. 18nm SiO_2 nanoparticles were used to catalyze the reaction and obtain polymers of different molar weights. Measurements of DLS and viscosimetry showed that the polymers with molecular weights ranging from 66 to 195 kDa were obtained. Kinetic studies revealed that increasing SiO_2 resulted in a lower conversion rate and higher molecular weights. The solubility temperature was determined by dynamic light scattering, where aqueous solutions of the polymers were analyzed between 25 and 38 °C. The LCST was attributed to the temperature at which a substantial change in the hydrodynamic diameter was observed. This temperature is the point or range below which the polymer is soluble in water and above which it becomes insoluble. Results shown a consistent pattern where the LCST increases with decreasing molecular weight, while the glass transition temperature shows a directly proportional increase. These materials were used as a vehicle for controlled release of target molecules, given that above the LCST they exist in a hydrogel form. Those materials were encapsulated with methylene blue dye in neutral (pH = 7.4) and acidic (pH = 4.0) environments to determine kinetic parameters and release mechanism, as well as with antibiotics (ciprofloxacin and metronidazole) and doxorubicin. Significant differences were observed in the release profiles at different pHs, determining that in a neutral environment, the drug release occurs through matrix diffusion, whereas in an acidic environment, it happens through anomalous transport, involving both diffusion and dissolution. For the other drugs, controlled and prolonged release for 7 days was observed, with release rates varying depending on the type of drug and molecular weight of the matrix. The results suggest that the differences between the materials come from the nature of the target molecules and their own, as well as the way in which they interact with the polymer chains. These assays demonstrate that the material is a strong candidate for use as a vehicle of controlled drug release, especially due to its ability to control molecular weight and thus tune release parameters.

Utilizing Digital Image Speckle Correlation (DISC) for Non-Invasive Wound Healing Assessment *Yoonsoo Song[1], Shreyaa Sanjay[2], Jenny Jia[3], Corey Zhang[4], Jerry Gu[5], Viraj Pahuja[6], Jenny Dinh Nhu Zhang[7], Ananya Anand[8], Theodora Siu[9], Eugene Jiang[10], Brooklyn Ratel[10], Divleen Singh[10], Shi Fu[10], Huiting Luo[10], Gurtej Singh[10] and Miriam Rafailovich[10]; [1]Maclay School, United States; [2]West Windsor-Plainsboro High School North, United States; [3]The Experimental High School Attached to Beijing Normal University, China; [4]Eastlake High School, United States; [5]Princeton International School of Mathematics and Science, United States; [6]The Wheatley School, United States; [7]Renaissance International School Saigon, Viet Nam; [8]Johns Creek High School, United States; [9]Ward Melville High School, United States; [10]Stony Brook University, The State University of New York, United States*

Traditional wound healing assessments (like visual inspection and histology analysis), face limitations because of their low accuracy and invasive nature. In severe wounds, skin grafts from the patient or biomaterials engineered constructs, are inserted into the wound site. Healing of the wound can not be determined simply by visual inspection, since it can be subjective and influenced by a variety of other factors, which can lead to inconsistent evaluations. Especially in the case of the engineered materials constructs, the integration with the underlying tissue depends on initiation of vasculature and anastomosis with underlying tissue, which is not easily apparent upon visual surface inspection . Histology analysis, while accurate, is invasive, costly, and time-consuming and can not be taken too frequently. Here we propose an alternative solution, which is non-invasive, convenient, cost effective, accurate, and hence can be applied as frequently as necessary. This method involves a modified version of elastometry, where we designed an apparatus to inflect a segment of the skin, while consecutive video images are obtained. The images are then analyzed using digital image correlation (DISC) which tracks the displacement of speckles, i.e. skin pores of hair follicles, formed on the surface of the skin under mechanical stimulation, allowing for the calculation of strain and elasticity changes. Skin elasticity and force propagation differ significantly between healthy, healing, and fully recovered tissue, making DISC an ideal tool for evaluating the healing and skin integration progress. Furthermore, DISC images can be obtained at the bedside, by the patient, and hence lends itself to remote consultation via telemedicine platforms.

The system was initially tested in a mouse study where the integration of an engineered scaffold was probed. DISC images taken before the incision, immediately after the incision, and at day 7 clearly showed the location of the wound which was mechanically distinct from its surroundings. This distinction decreased, but was still present at day 7, where visually complete wound closure had occurred. Histological images of the biopsy indicate that despite supervisual closure the vascular network had just begun to be established, with corresponding anastomosis. Alonger study is currently being conducted on a pig model, where a 28-day burn study on pigs is in progress. From the initial data, we can clearly see the demarcation of the wound boundary, and areas lacking integration with the underlying wound bed, even in regions where visual analysis indicated complete coverage. A full analysis of the healing process over the entire 28 day span, and a comparative evaluation of the scaffold integration process--including anastomosis and vascularization will be presented. In sum, our study thus far indicates that DISC is a promising non-invasive tool for monitoring wound healing, offering an accurate, real-time alternative to traditional methods. By quantifying skin mechanics, DISC can enhance wound care, reducing the need for invasive procedures and enabling more personalized patient management. Future work will focus on expanding the application of DISC to various wound types and conducting larger clinical trials to further validate its efficacy in diverse clinical settings.

Determining the Correlation Between Aging and Cellular Mechanics *Jenny Dinh Nhu Zhang[1], Ananya Anand[2], Jenny Jia[3], Shreyaa Sanjay[4], Jerry Gu[5], Viraj Pahuja[6], Corey Zhang[7], Yoonsoo Song[8], Brooklyn Ratel[9], Divleen Singh[9], Eugene Jiang[9], Shi Fu[9], Huiting Luo[9], Gurtej Singh[9] and Miriam Rafailovich[9]; [1]Renaissance International School*

Saigon, Viet Nam; [2]Johns Creek High School, United States; [3]The Experimental High School Attached to Beijing Normal University, China; [4]West Windsor-Plainsboro High School North, United States; [5]Princeton International School of Mathematics and Science, United States; [6]The Wheatley School, United States; [7]Eastlake High School, United States; [8]Maclay School, United States; [9]Stony Brook University, The State University of New York, United States

The mechanical behavior of a cell is both a consequence and regulatory factor of biological function and cellular architecture. Researchers globally are investigating the forces that cells generate and sustain within their environment to provide a cellular-level perspective on pathologies among other pressing research questions. Cellular Traction Forces (CTFs) are critical to the physiology of cells, through their structural support, and facilitation of migration within tissues. These aforementioned features have been associated with aging due to gradual physiological cellular decay and warrant further investigation to expand etiological understanding.

This study investigates this correlation on both a cellular and macroscopic(tissue) level. At the cellular level, testing for cell morphology, cell proliferation, and cell modulus through Atomic Force Microscopy (AFM) were conducted. Macroscopically, fibroblasts from three distinct age groups–neonatal, 29-years, and 71-years–were placed within collagen gel individually to resemble the dermis layer of skin. The collagen gel was then rimmed to perform consequent gel contraction. Microscopically, analysis using Digital Image Speckled Correlation (DISC) was also conducted to quantify the cell mechanical force exerted on the surrounding extracellular matrix. Morphological analysis was conducted displaying a physical difference within the distinct cell types such that the neonatal and 71 y.o. cells have a more slender and elongated structure compared to the 29 y.o. cells' more condensed and compact shape. After a three-day cell proliferation assay was conducted, it was determined that the 29 y.o. cells displayed the greatest and fastest cell proliferation. Cell modulus, the biophysical property that describes the cell elasticity and measures their resistance to strain4. The neonatal, 29 y.o, and 71 y.o. cells had moduli of 1, 1.264, and 2.022 respectively. It was found that the 71 y.o. cells had the greatest modulus and resistance to deformation. Over a period of 9 hours, and with final imaging at the 24 hour mark, imaging was conducted to observe the cellular gel contraction as a reflection of the CTFs. The collagen gel area contraction results demonstrated that the 29 y.o. and 71 y.o. cells produced a similar trend in gel area rate, whereas the neonatal cells demonstrated a smaller rate of decrease of the gel area. Fibroblasts incorporated with red fluorescent beads were plated atop mtG-crosslinked-gelatin and the CTFs are visualized through the observation of bead displacement during EVOS imaging, and heat maps were generated using DISC algorithm where the 29 y.o. cells displayed the greatest force.

Ongoing experimentation and future steps include conducting further examination on cell displacement using DISC, as well as conducting Polymerase Chain Reaction to identify how the 3 different aged cells promote angiogenesis to provide critical insight into wound healing given that younger, more elastic skin has been found to allow for a smoother and faster wound healing process when compared to older, more rigid skin.

SB05.06.19

Modular Molecular-Level Design of Poly(Pro-Estrogen) Scaffolds Enables Controlled Astrocyte Response

Jayant Saksena, Edmund Palermo and Ryan Gilbert; Rensselaer Polytechnic Institute, United States

Despite extensive efforts aimed at finding a cure, spinal cord injuries (SCI) remain notoriously incurable, resulting in a five-fold mortality risk, and disproportionately impacting vulnerable populations such as veterans and the elderly. Thus, there exists an urgent need for treatments that can offer potential for functional recovery. 17β-estradiol (estrogen, E2) has demonstrated robust neuroprotective properties in countering oxidative stress-induced neurotoxicity in SCI lesions, as well as strong neurotrophic properties to promote axonal growth in *numerous studies. However, oral or injected E2 is a suboptimal drug, as systemic administration fails to achieve a therapeutic dose at the injury site, in addition to being contraindicated in male patients. Polymerized pro-drug scaffolds can mitigate these issues; hence, we sought to develop poly(pro-E2) scaffolds with tunable material properties that are capable of providing sustained, targeted delivery of E2 at the site of injury. Further, astrocytes are the most abundant cell type in the central nervous system and play vital roles in regulating axonal growth and remyelination, as well as modulating immune responses and supporting the blood-cerebrospinal fluid barrier – which are key functions essential for promoting spinal cord regeneration after injury. Hence, herein we also sought to study the effect of novel poly(pro-E2) scaffolds on astrocyte behavior, as well as to gauge the biomaterial properties that would lead to optimal astrocyte functionality.*

We synthesized pro-E2 as carbonate and ester derivatives and copolymerized monomers with hydrophilic oligoethylene glycol dithiol (EG) and hydrophobic hexylene dithiol (Hex) linkers of equal length to generate poly(pro-E2) polyesters (PE) and polycarbonates (PC) of high M_w *(40-60kDa). Faster hydrolysis of polyesters and differential water affinities of linkers resulted in a library of poly(pro-E2) scaffolds with tunable hydrophobicity, ranging from least (PE-EG) to most (PC-Hex) hydrophobic. We quantified thermal characteristics and observed* T_g *in the physiological range in polymers with Hex-linkers. We analyzed mass-loss and soluble drug elution from scaffolds incubated in PBS at 37C over 6-weeks to verify that polyesters degraded more readily than polycarbonates. Turbidity and profilometry measurements of films indicated bulk erosion. We also observed that incorporation of Hex-linkers led to markedly stiffer and harder scaffolds compared to EG-linkers, demonstrating the ability of linkers to tune mechanical properties.*

Next, we performed cell viability studies of mixed primary cortical cells (consisting of neurons and astroglia) cultured on poly(pro-E2) scaffolds for 7-days. None of the polymers displayed significant cytotoxicity compared to control. We studied adhesion of primary cortical astrocytes on scaffolds since robust astrocyte adhesion is vital for their long-term viability and functionality for promoting spinal regeneration. We observed that only scaffolds with Hex-linkers supported sustained astrocyte adhesion. To explain this behavior, we investigated further. SEM data for scaffolds submerged for 7 days showed marked surface roughness with micro- and nano-scale topography for scaffolds with Hex-linkers due to separation of hydrophilic and hydrophobic phases, whereas those with EG-linkers appeared smooth – indicating that astrocytes preferentially adhere to rougher surfaces. Finally, while all polymers exhibited hysteresis during mechanical testing, scaffolds with Hex-linkers demonstrated greater dissipation suggesting increased viscoelastic creep – indicating that astrocytes preferentially adhere to viscoelastic surfaces.

In conclusion, we developed novel poly(pro-E2) scaffolds with tunable material characteristics that can offer sustained, targeted delivery of E2 to spinal lesions and demonstrated that increasing surface roughness and material viscoelasticity can make them conducive to robust astrocyte functionality.

SB05.06.20

Physico Mechanical Evaluation of Electrospun Nanofibrous Mats of Poly(3-hydroxybutyrate)/Poly(butylene Succinate) Blends with Enhanced Swelling Dynamics and Hydrolytic Degradation Kinetics Stability for Pliable Scaffold Substrates

Harshal Peshne; *Indian Institute of Technology Delhi, India*

Biodegradable blends of PHB/Bio-PBS were successfully electrospun with solvent system 2,2,2-trifluoroethanol as the solvent to obtain electrospun mats (EMs) of fiber diameters ranging from ~ 534 to ~ 181 nm. The addition of $CaCl_2$ *led to defect/bead free morphology of PHB and PHB/Bio-PBS blends with the exception for Bio-PBS at ~ 20 wt% concentration. Bio-PBS based electrospun mats with* $CaCl_2$ *led to the lowest fiber diameter (due to high conductivity and low viscosity of solution). Mechanical properties were affected by immiscibility, resulting in lower* *tensile strength from ~ 4.0 to ~ 2.0 MPa and tensile modulus from ~ 186 to ~ 64 MPa, while strain-at-break increased from ~ 1.5 to ~ 46.5% with Bio-PBS content in PHB matrix. Electrospun mats with up to 50% Bio-PBS loading demonstrated optimal ductility and strength and also exhibited a tensile modulus comparable to that of cancellous bone. Additionally, the blend with ~ 50 wt% of Bio-PBS showed increased hydrophobicity (116°) and decreased swelling characteristics (84%) compared to neat PHB (95° and 124%). Hydrolytic degradation studies showed improved structural robustness and consistent morphology in Bio-PBS based electrospun mats even after 30 days in phosphate buffer solution compared to PHB based mats. Thus, up to 50 wt% Bio-PBS incorporation into Polyhydroxyalkanoates matrices, i.e. in the blends with 50:50 composition ratio the mats obtained showed enhanced pliability in combination with the desired extent of physico-mechanical properties and stiffness for soft bone tissue engineering.*

A Chitosan-Based Micromesh Platform for Enhanced Myoblast Alignment and Three-Dimensional Tissue Formation in Cultured Meat *Jiacheng Xu[1], Takeshi Hori[1], Buntaro Tsurumi[2], Yuji Nashimoto[1], Shotaro Yoshida[2] and Hirokazu Kaji[1]; [1]Institute of Science Tokyo, Japan; [2]Chuo University, Japan*

As global demand for meat continues to rise, cultured meat technology is emerging as a sustainable solution to solve future meat shortages. While various three-dimensional cell culture methods have been developed, those without scaffolds produce tissues that are difficult to handle and lack the layered structure of natural tissues, making them unsuitable for cultured meat production. Conversely, scaffold-based methods are easier to manage but result in significant scaffold material inclusion in the final product. Additionally, creating tissue-like layered structures has been labor-intensive.

In this study, we developed a cultured meat platform utilizing edible micromesh sheets composed of chitosan. These micromesh sheets form a high-porosity, diamond-shaped micromesh sheet. Our cultivation method involves first adhering cells to the microscale mesh sheet, followed by the formation of a cell sheet as proliferating cells fill the mesh openings. In this approach, cells within the mesh openings primarily rely on cell-cell adhesion for survival, mimicking the environment of cell growth in vivo and differing from cells attached to conventional plastic substrates. Cells dependent on intercellular adhesion can easily form three-dimensional structures, enabling the facile production of thick cell sheets through this mesh culture method.

Using this carrier, we successfully cultivated thick cell sheets of C2C12 cell line, a mouse myoblast cell line. We demonstrated that the cells align uniaxially along the long axis of the diamond-shaped openings, exhibiting characteristic alignment properties. Simulating this alignment pattern is crucial for achieving physiologically relevant cell sheets for potential applications in cultured meat production or regenerative medicine.

SB05.06.22

Biomaterial-Based Patterning-Driven Pseudo-3D Topological Alignments Regulate Mechanotransduction and Maturation in Muscle Tissue Engineering *Yeji Lee and Jihyeon Song; Pohang University of Science and Technology, Korea (the Republic of)*

Biomaterials used in muscle tissue engineering must account for the sensitivity of muscle tissue to mechanical stimuli, making it crucial to understand mechanotransduction pathways and their impact on muscle cell fate. Yes-associated protein 1 (YAP) translocates to the nucleus in response to mechanical cues, functioning as a pivotal regulator of phenotypic alterations in human smooth muscle cells (SMCs). However, the influence of biomaterial-driven topographical cues on YAP activity and the maturation processes of SMCs is not fully understood, leading to inconsistent findings across studies. This research investigates how different topographical patterns engineered *into biomaterial substrates influence SMC mechanotransduction and maturation. Utilizing laser engraving techniques, we developed biomaterial scaffolds with line, cross, and curve patterns (300 μm width and 150 μm depth), replicating natural muscle tissue's structural characteristics, along with flat control regions. Results indicated that cross-patterned biomaterial substrates, coupled with cell-cell interactions, enhanced YAP-mediated mechanotransduction and promoted SMC maturation, particularly through calponin-related pathways. In contrast, at lower SMC densities, mechanotransduction associated with Lamin A was enhanced, though maturation was limited due to insufficient cell-cell communication. Inhibition assays revealed that YAP-mediated mechanotransduction, rather than focal adhesion signaling pathways, played a predominant role, particularly in calponin-linked maturation over α-SMA-linked contractile phenotype shifts, both in vitro and in vivo. These findings were consistent across dynamic environments, highlighting the role of topographical cues in guiding mechanotransduction and SMC maturation. The study underscores the importance of biomaterial-based patterning in scaffold design for muscle tissue engineering, offering insights into tailoring material properties to direct specific cellular responses.*

SB05.06.24

Piezoelectric Nanostructured Scaffold Based on Natural Protein for Synergistic Tissue Regeneration Via Electrical Stimuli and Upregulated-Mineralization

Ji Yeon Lee[1], Chan Hee Park[2] and Cheol Sang Kim[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

With an increase of the aging population, the advances of nanotechnology have attracted significant attention as a method to address the fracture of elders via complementing their poor bone quality associated with the loss and deformation of cellular matrix proteins. Despite showing excellent performance in bioapplications through mimicking the structural microenvironment of the native extracellular matrix, nanostructured scaffolds were limited by immune response from artificial polymers and disconnected electric signal pathways for cell-to-cell physiological interactions. Here, we designed a hierarchical core-shell structured nanofiber scaffold based on beta-sheet transformed natural protein to produce appropriate electrophysiological signals and suppress immune responses. The natural protein nanofibers with enhanced beta-sheet contain provided electrical potentials for activating cell-to-tissue regeneration via piezoelectricity under bioactive cell motility. The hierarchical structure of the scaffold releases hydroxyapatite and simvastatin in sequential via gradual biodegradation of the protein to accelerate homogenous growth of ion concentration for mineralization. The designed nanostructured scaffold proposes a novel tissue regeneration platform using the synergistic effect of electrical stimuli and mineralization by their phase functionality. Overall, the proposed strategy is a promising candidate to meet the challenging requirements of inducing rapid tissue function reconstruction.

Engineering a Photocurable mCMC/CNC Nanocomposite Hydrogel for Extrusion-Based 3D Bioprinting

Jessica Fonseca, Rafael Azoubel and Marcos Akira d'Avila; Universidade Estadual de Campinas, United States

This study develops a photocrosslinkable hydrogel for extrusion-based 3D bioprinting, combining methacrylated carboxymethyl cellulose (mCMC) with cellulose nanocrystals (CNC). Two mCMC degrees of methacrylation (1mCMC and 2mCMC) were combined with CNC concentrations (5% and 10% w/v), and rheological behavior and mechanical properties were studied. Also, we studied the influence of crosslinking methods on hydrogel compositions. Adding CNC promoted gelation and the formation of a percolated network on CMC solutions, leading to significant increases in viscosity, shear-thinning, and viscoelastic behavior. UV photocrosslinking enhanced mechanical properties compared to the two other crosslinking methods. Printability tests showed suitable printing parameters to print each hydrogel composition. Higher shape-fidelity was achieved with mCMC at *a higher degree of methacrylation (2mCMC) and CNC at 10% w/v.*

Elastin Peptide-Based Fusion Proteins to Promote Skin Wound Repair *Francois Berthiaume, Hwan J. Kang, Agnes Yeboah, Melissa Olekson, Suneel Kumar, Rick Cohen and Martin Yarmush; Rutgers, The State University of New Jersey, United States*

With an aging population and an increased prevalence of diabetes, there is a concomitant increase in incidence of chronic nonhealing wounds of skin. Common types of chronic wounds are diabetic foot ulcers, pressure ulcers, and venous ulcers, which require a series of expensive and complex treatment modalities. Chronic wounds typically exhibit lowered levels of chemokines and growth factors that are normally responsible for promoting cell migration and proliferation, the basic processes that are involved in tissue repair. Peptide growth factors have generally not been successful as therapeutics, with the exception of topical platelet-derived growth factor (PDGF), due to impaired responsiveness of wound cells to growth factor signals, and increased levels of proteases in the wound environment that degrade exogenously applied growth factors.

We have developed, using fusion protein technology, recombinant proteins comprising bioactive peptides relevant to woind healing and elastin like peptides (ELPs). ELPs are derivatives of tropoelastin and confer the ability of the protein to reversibly self-assemble into nanoparticles. In addition, the nanoparticles can be easily purified by centrifugation during manufacture of the product, thus obviating the need for expensive chromatographic methods. We have used this approach for the development of a stabilized form of stromal-derived factor-1 (SDF-1), a pro-angiogenic chemokine in wound healing, and a stabilized form of the v-domain of the receptor for advanced glycation endproducts (vRAGE). The ELP-SDF-1 and ELP-vRAGE fusion proteins exhibit bioactivities similar to that of their counterparts SDF-1 and sRAGE, respectively, in in vitro cell culture assays. However, they exhibit greater efficacy when used topically on mouse wounds. We hypothesize that the greater efficacy in vivo is due to greater stability in the wound fluid environment. Our next step is to develop other fusion proteins that can be combined together that target different cell types and processes in the wound healing cascade.

Wound Healing Effect of Detachable Microneedle *SuHyang Lee and KangJu Lee; Chonnam National University, Korea (the Republic of)*

Severe wounds often entail prolonged treatment times and a heightened risk of infection, potentially leading to chronic wounds and tissue necrosis. Current clinical treatments involve systemic drug delivery, antibiotics, dressings, and surgical debridement of necrotic tissue. However, the frequent pain associated with dressing changes and surgical procedures significantly diminishes patients' quality of life. Moreover, compromised blood circulation in severe wounds reduces the efficacy of medication delivery to the affected area, necessitating frequent administration to achieve therapeutic levels. This can result in unnecessary systemic side effects and increased healthcare costs, along with low patient compliance. In recent years, microneedles (MNs) have *emerged as a promising technology for localized and sustained drug delivery. MNs are typically a few hundred micrometers in length, offering minimal invasiveness and reduced pain during application. However, conventional patch-type MNs have inherent limitations. These MN patches require adherence to the target tissue throughout the drug delivery period, potentially causing discomfort and reducing patient compliance. To overcome these limitations, we developed a novel detachable MN patch. This innovative design consists of a detachable drug-tip consisting of poly(lactic-co-glycolic) acid (PLGA) and a substrate made SU-8. The substrate supports the drug-tip to penetrate to an optimal depth within the tissue without exposing any part of the drug-tip after implantation. Once patched, the drug-tip of MN releases the drug over a certain period. The detachable drug-tips were pre-molded using PLGA solution into the MN mold. The volume of drug-tip could be controlled after evaporation of solvent by using different concentration of PLGA solution. SU-8 was then molded onto the MN molds containing the pre-molded drug-tips and cross-linked by UV curing. Detachability of the drug-tip of MN patches was demonstrated by ex vivo tests using porcine skin tissue. In addition, mechanical test was conducted for investigating MN penetration. In vitro studies revealed a drug release profile over 14 days, demonstrating sustained drug delivery of drug-tips from a single administration without the need for frequent dosing. In vivo experiments in rat muscle-exposed wounds showed a significant 50% reduction in wound area over 14 days with the drug-tipped detachable MN patches. These findings underscore the potential of drug-tipped detachable MN patches for localized and sustained drug delivery directly to wound sites. By minimizing systemic side effects and enhancing patient compliance, this technology represents a significant advancement in wound care management.*

Synthetic Barrier Material for the Prevention of Surgical Adhesions *Crystal S. Shin[1], Aparna Adumbumkulath[1], Kirti Mhatre[1], Bradford Scott[1], Pulickel Ajayan[2] and Ghanashyam Acharya[1]; [1]Baylor College of Medicine, United States; [2]Rice University, United States*

Background

Adhesions, abnormal tissue bridges that form between adjacent organs or tissues following surgery, can lead to significant morbidity and complications for patients. To prevent surgical adhesions (SAs), barrier membranes have been developed to prevent the occurrence of SAs and improve patient outcomes. Conventional adhesion barrier membranes are made of biopolymers and biological materials that rapidly degrade within a few days while the synthetic membranes are nonbiodegradable and cause adverse effects, that necessitate surgical removal and pose risks of long-term complications. In this study, we developed an anti-adhesion membrane (Anti-Mater) using phosphate crosslinked polyvinyl alcohol (PVA) and showed the impact of physicochemical properties of Anti-Mater on SAs prevention. Based on our previous findings that the negative surface charge of biopolymer could modulate inflammatory responses in tissues, we studied the effect of Anti-Mater and its properties on preventing adhesions.

Methods

To fabricate Anti-Mater, we first prepared PVA solutions of different concentrations (5-15% w/v) in water and we then added sodium trimetaphosphate to the solutions. The PVA solutions were either dried overnight as a thin film on a flat, smooth surface or used as a bioink for 3D-printing. We characterized their physicochemical and mechanical properties by FT-IR, tensile testing, water contact angle, surface energy measurements, and surface pH. We also evaluated swelling capacity and degradation of Anti-Mater. We confirmed the hemocompatibility, biocompatibility, and immune modulation of Anti-Mater using fresh porcine blood, mouse bone marrow-derived macrophages, and human peripheral blood mononuclear cells. We evaluated in vivo anti-adhesion effects of Anti-Mater and Seprafilm, a commercially available membrane, by surgically implanting Anti-Mater in mice for 1-4 weeks. After the study, we harvested tissues and studied immune responses, adhesion and scar formation.

Results

This study confirmed that the crosslinking not only increased the mechanical stability of Anti-Mater but also *yielded a negatively charged surface. The 3D printing method allowed us to fabricate membranes with more uniform thickness and modify their elasticity and mechanical strength by adjusting the number of layers printed. We demonstrated that the degradation of Anti-Mater could be tuned from 4 to 8 weeks, by varying the crosslinking density, i.e., low crosslinking density accelerated degradation compared to high crosslinking density in vitro. In cell lines, we showed that Anti-Mater is biocompatible and hemocompatible with more than 85% cell viability and no hemolysis. We observed that LPS-induced cells showed lower proinflammatory cytokine levels after incubation with Anti-Mater. After 1-4 weeks of implantation, we observed Anti-Mater did not cause inflammation or scar formation in the surrounding tissues in mice.*

Conclusions

This study demonstrated the feasibility of synthetic adhesion barrier membranes and their effect on preventing SAs by manipulating physicochemical and mechanical properties. In addition, the phosphate crosslinking enhanced Anti-Mater's mechanical properties and functionalized the surface that modulates inflammatory responses, thus preventing adhesion formation. Therefore, Anti-Mater is a promising barrier membrane with tunable properties that can effectively prevent SAs.

9:30 AM *SB05.07.04

Engineered Fibrotic Tissue Models for Disease Modeling and Drug Testing *Ruogang Zhao; University at Buffalo, The State University of New York, United States*

Fibrotic diseases constitute a significant portion of mortality in developed nations, yet effective treatments remain elusive due to limited understanding of disease mechanisms and predictive capabilities of pre-clinical models. Recent advancements in microphysiological 3D tissue models offer new opportunities to replicate key pathophysiological features of fibrotic tissues, thereby enhancing disease modeling and therapy screening. This presentation will highlight our latest innovations in biofabrication technologies for creating biomimetic tissue fibrosis models, focusing specifically on pulmonary fibrosis and tumor immune-stroma interactions. The discussion will focus on two main areas: 1) Development of fibrosis-on-chip systems with tissue morphogenesis and force sensing capabilities. We utilize microfabricated arrays of flexible micropillars to generate lung alveolar-like microtissues, facilitating drug screening for anti-fibrosis treatments and investigation of immune-stroma interactions in pulmonary fibrosis. 2) Patho-mimetic tumor microenvironment models to explore T cell-stroma interactions in cancer immunotherapy. These advanced tissue models demonstrate promising clinical relevance, highlighting their potential for translational research.

Engineering Nanostructured Materials for Infection Nanomedicine *Georgios Sotiriou; Karolinska Institutet, Sweden*

Even though there is concentrated effort from nanotechnology research laboratories worldwide against cancer, there is only limited nano-related research against infections. This might be counter-intuitive due to the more deaths globally attributed to infections than cancer. Furthermore, because of the continuous use and abuse of antibiotics to fight infections, antimicrobial resistance in some bacterial strains (the so-called "superbugs") has emerged. That constitutes the most serious public health threat today termed as "slow- motion catastrophe". Therefore, there is an urgent societal need to provide innovative antimicrobial solutions as also highlighted by the WHO. Nanoscale materials offer advantages and solutions to this public health threat because they may exert antimicrobial action by multiple mechanisms rendering the emergence of antimicrobial resistance rather unlikely.

In this talk, I will highlight a few examples utilizing responsive nanomaterials against infections. This is explored using a nanomanufacturing process with proven scalability and reproducibility, flame aerosol technology [1-2], to assist rapid technology transfer to industry. We employ flame direct nanoparticle deposition on substrates and combine nanoparticle production and functional layer deposition in a single-step with close attention to product nanoparticle properties and assembly of devices [3,4]. For example, utilizing this technology, it is possible to develop nanomaterials as biosensors for physiological parameters (e.g. pH, H_2O2) [5-7] relevant to bacterial infections or for food safety, as nano-enabled coatings on medical devices to eradicate bacterial biofilms [8,9,10], or even as drug nanocarriers for biologics (e.g. peptides, proteins) for localized treatments [11].

Enhanced Degradability of Thiol-ene Based Composite Networks Through the Inclusion of Isosorbide-based Polycarbonates *Jorge San Jacinto Garcia, Natalia Sanz del Olmo, Daniel J. Hutchinson and Michael Malkoch; KTH Royal Institute of Technology, Sweden*

Open reduction internal fixation (ORIF) metal plates and screws represent the standard-of-care for complex fracture fixation; however, they have drawbacks such as soft-tissue adhesions, lack of degradation and poor customization, which may necessitate a second removal surgery.
One of our strategies for overcoming these issues is to replace metal plates with a triazine trione (TATO) based composite patch fixated to the bone either with metal screws or through chemical adhesion by priming the bone surface. The composite contains allyl- and thiol-containing monomers with a high percentage of hydroxyapatite, and is rapidly cured on demand via high-energy visible-light-induced thiol–ene coupling chemistry.[1,2] In vivo studies showed that this bone-like composite patch did not induce soft-tissue adhesions. The customization, bone-like nature and soft-tissue repelling properties of the composite fixation patch are highly compelling features that traditional metal implants lack. Moreover, in contrast to some commercial bone glues, the composite is applied topologically over the bone fracture as opposed to being inserted in the cross-section of the bone, which allows for bone healing without interference from the composite.[1]
Thus far, the composites that we have developed have not shown degradability over time. However, it is our hypothesis that degradation can be achieved by adding degradable polymers to the composite formulation. These

degradable polymers introduce hydrolysable linkages into the system while reacting covalently with the rest of monomers thanks to the presence of allyl functionalities. Aliphatic polycarbonates and polyesters are good examples of such degradable polymers that provide controlled degradation rates and are therefore widely used in the medical field as degradable agents.[3,4] *In this work, we present the development of novel composite systems that include polycaprolactone and polycarbonates. The impact of these polymers with respect to degradation and mechanical properties of the final composites will be described thoroughly. Finally, the best candidates will be used as demonstrators for comminuted fracture fixators in wet and dry conditions, using synthetic bones as a substrate.*

Design, Fabrication and Characterization of Piezoelectric and Dielectric Materials for Tubular Electrospun Grafts

Mario Milazzo[1], Damiano Rossi[1], Claudio Ricci[1], Lorenzo Zavagna[2], Massimiliano Labardi[3] and Serena Danti[1,3]; [1]University of Pisa, Italy; [2]Università degli Studi di Siena, Italy; [3]Consiglio Nazionale delle Ricerche, Italy

The development of tubular grafts is a hot topic in research, especially in the biomedical field due to the high request of tissue replacements for recovering from specific diseases. The ideal graft, in addition to providing a mechanical stability and stiffness, should be able to be hosted by native tissues, and to promote cell growth. This latter property has been found particularly enhanced by piezoelectric materials.

In this study, we developed millimetric tubular grafts made of dielectric or piezoelectric materials, namely Polycaprolactone (PCL) and Polyacrylonitrile (PAN) .

We fabricated millimetric tubular grafts using an electrospinning setup after preparing the solutions as follows. The PCL solution was prepared with a concentration of 15% w/v in a Tetrahydrofuran/ Dimethylformammide mixture (1:1 w/w), while the PAN solution was prepared with a concentration of 15% w/v in Dimethylformammide, by magnetic stirring at 300 rpm overnight at room temperature. Solutions were kept under gentle stirring at room temperature prior to usage.

The morphological characterization was performed optically using a stereomicroscope for measuring the macro-features, and a scanning electronic microscope to assess the micrometric features of the grafts. Wettability of the surfaces was assessed through the measurement of the water contact angle (WCA) after depositing a drop of distilled water on planar samples. The mechanical properties of the tubular grafts under radial expansion were obtained through a dedicated system that was designed to measure the deformation of the fibrous mesh structure as a function of the internal pressure. In contrast, the measurements of the d_{31} *piezoelectric coefficient of the* *produced meshes were conducted using a setup specifically developed in-house. This setup involves clamping a stripe of the nanofiber mesh between a rigid support and a flexible steel cantilever, which serves as a sensitive force gauge. An electric field is thus applied orthogonally to the mesh thickness by electrically biasing two parallel metal plates. Pooled poly(vinylidene fluoride) (PVDF) film was used as a standard control, whereas electrospun fibers of PVDF/$BaTiO_3$ and poly(ethylene oxide terephthalate)-poly(butylene terephthalate) (PEOT-PBT) as a positive and negative control, respectively.*

PCL and PAN tubular grafts were produced with an average diameter of 8 mm. Fiber size was different depending on the constitutive material: image analysis revealed that PAN electrospun fibers had a mean diameter of 0.30 ± 0.04 μm; instead, PCL showed a broader diameter distribution with a mean value of 0.67 ± 0.39 μm. Pore equivalent diameters of PAN and PCL meshes were 0.32 ± 0.18 μm and 0.51 ± 0.37 μm and their average porosities 50% and 42%, respectively. Both PAN and PCL meshes displayed an appreciable porosity, i.e., 50% and 42%, and pore size of 0.8 and 2.0 μm^2, respectively. From the mechanical standpoint, the PAN scaffold resulted less deformable than the PCL one, and therefore more resistant, for pressures above 20 kPa. Upon an inner expansion leading to a 18% circumferential deformation, the PAN tubular scaffolds were able to hold 42% higher pressure (i.e., 39 kPa) than PCL ones (i.e., 27 kPa). The two polymers gave rise to fibrous meshes with different wettability, measured WCA, being PCL highly hydrophobic (WCA = 129° ± 21°) and PAN hydrophilic (WCA = 20° ± 6°). Measurements of the piezoelectric coefficients of the produced fiber meshes showed that PAN scaffolds showed a higher piezoelectric coefficient d_{31} = 20.0 ± 16.0 pm/V than PCL scaffolds (d_{31} = 1.12 ± 0.25 pm/V).

This work shows a new approach to develop electrospun tubular grafts made of either dielectric or piezoelectric materials, with interesting morphological and mechanical properties that may be exploited in several biomedical applications, including the replacement of vascular and intestine tracts.

11:30 AM SB05.07.08

One-Step Alignment of Cell-Embedded Collagen Promotes Spontaneous Osteogenesis of Mesenchymal Stem Cells for Bone Regeneration

Minjung Chae[1,2], Cheol Ho Heo[3], Ki Baek Yeo[4], Seon Young Bak[1], Nakwon Choi[1], Seung-Kyun Kang[2], Sang Ho Jun[4], Myoung-Ryul Ok[1] and So Yeon Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Kookmin University, Korea (the Republic of); [4]Korea University, Korea (the Republic of)

Recent advancements in biomaterials for tissue engineering have focused on developing biomimetic materials engineered to induce precise cellular responses and facilitate tissue regeneration through biomolecular recognition. These biomimetic materials replicate numerous functions of the extracellular matrix (ECM) such as delivering biological signals for cell-matrix interactions to enhance tissue regeneration.

One such application within tissue engineering is bone regeneration, where strategies have increasingly emphasized the use of stem cells embedded in hydrogels. Hydrogels are regarded as excellent candidates for addressing bone defects due to their similarity to natural ECM and their capacity for functionalization, enabling them to mimic the physiological environment and regulate cell fates and tissue regeneration.

In this study, we developed the three-dimensional (3D) aligned collagen embedding human mesenchymal stem cells (hMSCs) for bone regeneration, aiming to elucidate the impact of collagen alignment on the osteogenic differentiation of hMSCs. Our research focused on mimicking the structure of the natural bone matrix by applying one-step mechanical strain to hMSCs-embedded collagen. Notably, hMSCs in aligned 3D collagen spontaneously differentiated into osteoblasts without the need for any inducing agents. We demonstrated that the BMP2-Smad1/5 signaling pathway, which strongly promotes osteogenic differentiation of hMSCs, is activated by aligned 3D collagen, as evidenced by analyzing the distribution and orientation of focal adhesions (FAs), measured by integrin α2 (ITGA2) and collagen immunofluorescence.

We confirmed the efficacy of this approach in promoting new bone formation through in vivo studies using a critical-sized rat calvarial defect model. The bone volume percentage within the defect was significantly higher in *the 3D aligned hMSCs embedded collagen group compared to the randomly oriented hMSCs embedded collagen and the bare collagen group in 8 weeks post-surgery. Histological and morphometric analyses revealed substantial bone remodeling and enhanced structural integrity. Our comprehensive findings from both in vitro and in vivo studies suggest that these engineered 3D collagen scaffolds embedding stem cells have considerable promise for clinical application for rapid and effective bone regeneration.*

11:45 AM SB05.07.09

Development of Rod Shaped Microgels for Multiphasic Anisotropic Systems *Ninon Moehl[1,2], Susan Babu[1], Camille Bonhomme[1], Daphne Bouwens[2], Matthias Mork[1], Ramin Nasehi[1], Tamás Haraszti[1], Gilles Wittmann[3], Baohu Wu[4], Rostislav Vinokur[1], Kyoohyun Kim[5], Jochen Guck[5], Rafael Kramann[2] and Laura De Laporte[1,2,6]; [1]DWI–Leibniz Institute for Interactive Materials, Germany; [2]Universitätsklinikum Aachen, Germany; [3]Technische Universität München, Germany; [4]Forschungszentrum Jülich GmbH, Germany; [5]Max Planck Institute for the Science of Light, Germany; [6]Institut für Technische und Makromolekulare Chemie (ITMC), Germany*

The production of anisometric rod-shaped microgels has become important over the past few years as they provide extraordinary properties as building blocks in tissue engineering. Properties such as injectability, high porosity, macroscopic anisometry and biochemical functionality are crucial to guide cells and enhance cell-cell interactions. This work aims to elucidate the possibilities with rod-shaped microgels produced via microfluidics, their production method and how their different properties can be applied to answer various questions in the field of tissue engineering. Such building blocks can - among other applications - be used to linearly guide cells in 3D multiphasic hydrogels or function as cellular templates. Both applications require very different microgel properties. In order to guide cells in 3D hydrogel systems, the microgels need to be < 5 µm in thickness to orient nerve cells efficiently [1]. Hence, a technique to continuously produce thin, elongated microgels, while offering a control over their stiffness, size, and aspect ratio is required. So far, microgels with diameters limited to ~8 µm have been produced by our group using a newly developed technique, called compartmentalized jet polymerization [2]. Meanwhile, thinner and softer high aspect ratio microgels can reduce the amount of synthetic material used in regenerative constructs. This works demonstrates a modified production method to further break the limits of microfluidics and explore the boundaries of compartmentalized jet polymerization by producing ultra-thin rod-shaped microgels in a continuous manner. The rod-shaped microgels are further functionalized with magnetic nanoparticles to induce cellular unidirectional guidance in 3D.

On the other hand, to function as cellular templates, rod-shaped microgels have to provide cellular adhesion sites, as well as a controlled degradability. This is crucial as depending on the biomechanical requirements and cellular behavior, the degradation rate of the rod-shaped microgels would need to be adjusted. This can be achieved through on-demand enzymatic degradation, where tuning of the polymer network and enzyme concentration offers a wide range of degradation times (minutes – days). Such rod-shaped microgels can be used as templates for tubular structures that are for example present in the kidney. When covering these rod-shaped microgels with kidney epithelial cells, these constructs resemble kidney tubuli after microgel degradation. Together with kidney endothelial and supporting cells inside a 3D hydrogel matrix, this results in an in vitro 3D human kidney model. The advantage of using rod-shaped microgels over other templates (e.g. bioprinting) is the dimension of the microgels (50 – 100 µm diameter), which is much more physiologically relevant in current kidney models and could potentially provide more reliable data on e.g. kidney diseases.

Microgel-Embedded DLP Bioink for Printing Complex Tissue Structures *Ryan Davis, Yuang Zhang and Akhilesh K. Gaharwar; Texas A&M University, United States*

Purpose: *Digital light processing (DLP) is a vat polymerization printing method that forms complex structures through a layer-by-layer process. The high resolution, fast printing time, and cell-friendly nature of the printing process has resulted in numerous biomedical applications for DLP. Monolithic polymer solutions are generally used to form DLP inks, leading to the formation of bulk hydrogel structures with limited tunability. By leveraging the heterogeneity of composite systems, DLP can be used to print structures that more accurately represent the behavior of natural tissues. In this study, we propose the use of embedded spherical microgels within a DLP photoink to form complex cell-laden tissue grafts. To achieve this, a DLP photoink will first be fabricated using gelatin-methacrylate (GelMA). Microfluidics will then be used to generate monodisperse GelMA microparticles with two different polymer concentrations. These particles will then be incorporated with the ink at varying volume ratios to assess effects on printability and mechanical properties of the resulting structures.*

Methods: *The DLP photoink was formed by mixing GelMA (12.5%), LAP photoinitiator, and tartrazine photoabsorber. Microgels were formed with a concentration of 8% or 12.5% GelMA and added to the ink at varying volume fractions from 5% to 75%. Rheological measurements were used to assess the pre-print viscosity and gelation time of different groups. Compression testing and nanoindentation were performed to further investigate how both the bulk and surface stiffness were affected by microgel inclusions. Using ANSYS, a computational simulation of compression was performed to assess the force distribution within printed constructs. To assess the feasibility of use as a complex tissue graft, multi-cell laden constructs will be formed using DLP. By encapsulating hMSCs within microgels and adding HUVECs to the ink precursor, anatomical structures with a heterogenous cell population will be formed. Alamar blue assays and staining cultured constructs for angiogenic markers will indicate the ability of the microgel-embedded system to promote blood vessel formation in vitro. The chick chorioallantoic membrane assay (CAM assay) will assess in ovo angiogenesis by quantifying the enhancement of blood vessel formation.*

Results: *Fluorescence imaging indicated control over microgel size using microfluidics, showing a uniform size of 120±15μm. Rheological tests showed that above 50%, microgel-embedded inks are too viscous for proper use as a DLP ink. The addition of microgels also reduces crosslinking density of the overall system, reducing the gelation time and overall stiffness of the structures. This trend was consistent through measurement of the storage modulus, bulk compressive modulus, and local Young's modulus at the surface. Computational simulations showed that the embedded structures produced more representative non-uniform stresses in response to applied strain as compared to uniform stress in the bulk structure. Additionally, lower stresses were produced by microgels which speaks to their ability to preserve encapsulated cells via stress shielding. Cell encapsulation in* *addition to in vitro and in ovo assays on printed structures will highlight the ability of the composite system to integrate with host systems and promote angiogenesis.*

2:00 PM SB05.08.02

Cost-Effective Method of Fabricating Hollow Microneedle Using Superimposed Arc Imprint Laser Writing for Tailored Drug Delivery *Hasika Suresh, Darian Myers, Atul Sharma, Danilo M. dos Santos and Sameer Sonkusale; Tufts University, United States*

Microneedles (MN) have been widely studied for efficient and painless drug delivery. Among them, hollow MNs are used to deliver large quantities of drug cargoes either passively or actively. However, fabricating hollow MNs is considered challenging due to the precision required for a hollow center and a sharp tip to penetrate skin without clogging.

Our proposed method for hollow MN fabrication, named Superimposed Arc Imprint Laser (SAIL) writing, was adapted from our previous work [1]. To the best of our knowledge, laser writing has only been used to produce solid MNs; it has yet to be used to fabricate hollow MNs. SAIL utilizes a layered arc design to achieve hollow microneedle molds. The hollow microneedle master mold was engraved on clear cast acrylic sheet using a 60W CO2 laser cutter. The laser beam ablates the 2D arcs on an acrylic sheet to create sharp tips and tapered bases. By tuning the laser power, speed, and focus, we can precisely control the height, sharpness, inner diameter, outer diameter, and overall geometry of the hollow microneedles. Two PDMS molds were fabricated: a positive replica at a 5:1 pre-polymer to curing agent weight ratio and a final negative mold at a 10:1 ratio.

In this study, we have fabricated hollow MNs using a biocompatible UV-curable resin, named BioMed Clear. The biomed clear resin was poured over the negative mold using a syringe and allowed to cure in a UV chamber. On peeling the hollow microneedles, there was clear evidence of a hollow channel that went from the needle through the back of the patch. The microneedles' height was 1mm, with a bore size was 0.7mm, and pitch of 1.5mm.

To demonstrate drug delivery with SAIL hollow MNs, we simultaneously delivered two drugs on one patch: Naltrexone Hydrochloride (NH) and Clonidine (Clo). Naltrexone is a classical opioid antagonist prescribed for alcohol and opioid use disorders [2], while Clo is primarily used for its antihypertensive properties, but it has been shown to mitigate some of the side effects associated with naltrexone therapy [3]. Specific areas of the acrylic master mold were rastered to create individual wells for loading different drugs without any mixing. These patterns were then replicated onto the negative PDMS mold ensuring precise alignment. Solutions of the naltrexone (20mg/mL) and Clonidine (0.5mg/mL) were prepared in PBS and injected into separate acrylic reservoirs glued to the back of the negative PDMS mold. A PDMS sheath was added on top of the reservoir to prevent the drug solution from leaking. This also enables the refilling of drug solutions as needed.

We performed compression tests on the hollow MN and they proved to have sufficient strength to penetrate the skin (Force/needle > 0.5 N). Additionally, we performed an in vivo penetration test on mice skin and there were visible punctures showing successful penetration. The two drugs with vastly different dosing needs (NH: 20 mg/day, Clo: 0.5 mg/day) were co-delivered invitro using an agarose hydrogel. The drugs passively diffused into the hydrogel and were measured at periodic intervals using UV-Vis spectroscopy. Notably, all the loaded drug was released within 24 hours indicating therapeutics can be delivered in highly customizable amounts.

In conclusion, SAIL combines the creation of microneedles and the microfluidic channel into one step. This innovation offers the potential for both passive/active drug delivery and can be integrated with wireless pumps, reservoirs, and actuators. SAIL's compatibility with various polymers broadens the possibilities for microneedle design and applications. Our goal is to be able to combine drug delivery with sensing/diagnostics using the hollow microneedle platform for closed loop theranostic applications for truly personalized medicine.

Oxygen-Rich Dressings for Enhanced Healing of Ischemic Tissue *Ayden Watt, Benjamin Dallison, Nitin Chandra Teja Dadi, Nicholas Makhoul, Mirko Gilardino and Jake Barralet; McGill University, Canada*

Problem/Purpose: *Tissue can become transiently fully or partially ischaemic following surgical repair and replantation and while the vasculature remodels this tissue is at risk of necrosis and infection. Necrosis can spread beyond the region of tissue repair and results in permanent tissue loss. Effective healing requires a sufficient oxygen supply to prevent cell death, maintain activity of oxygen dependent enzymes, allow oxidative phosphorylation and normal development of the inflammatory process. There is some evidence for the use of hyperbaric treatments to raise tissue oxygen concentrations with specific indications, but this process is expensive, cumbersome, and oxygen levels drop to atmospheric concentrations rapidly after the patient leaves the hyperbaric chamber. In this study, a degradable biomaterial-based oxygen releasing dressing was evaluated for efficacy in improving tissue regeneration, mitigating necrosis, and enhancing wound healing in a preclinical ischemic wound model.*

Methodology: *The biomaterial composite was prepared from a suspension of CaO_2 and Fe_3O_4 in 10% (w/v) PCL solution in chloroform which was subsequently cast, dried, and embedded in sterile 3% (w/v) sodium alginate and crosslinked with sterilized $CaCl_2$ (1M). Oxygen and hydrogen peroxide release was measured over 3 days in vitro. In vivo studies were performed using an ischemic rabbit ear full thickness wound mode. Bacterial counts (colony forming units, CFU) were evaluated in vivo in an ischemic dorsal rat full thickness wound model. Ethical approval for this study was obtained from the Research Institute of the McGill University Health Center (MUHC-8075). Wound vascular supply was observed via fluorescein injection and tissue samples were histologically evaluated. Wound size, healing rate, tissue regeneration quality (epithelialization, granulation), and necrosis incidence for the peroxide treated group were compared to an alginate-based non-oxygen eluting control and conventional wound dressings.*

Results: *In vitro findings showed that the peroxide-polymer composite sustained oxygen release for up to 72 hours. In vivo experiments showed that wound closure at day 17 was 54±29% for the group treated with the peroxide-polymer composite versus 31±23% N=15, $P<0.05$ for the group receiving alginate only. Fluorescein injections for wound vascularization showed no fluorescence beyond the edges of the wound at any time point in the control group, while the experimental group expressed significantly higher levels ($P<0.01$) as early as day 7 inside the wound perimeter. Wound cultures demonstrated sustained decreases in bacterial load in treated wounds compared to control at postoperative day 4 ($4x\ 10^3$ CFU in control vs 24 CFU in experimental, N=24, $P<0.05$) and day 8 (4×10^3 CFU in control compared to $1x\ 10^2$ CFU in experimental, N=24, $P<0.05$). Notably, there was decrease in full thickness necrosis from 87% in the control group to 40% in the experimental group. Treated wounds exhibited enhanced cell proliferation, and higher levels of re-epithelialization ($0.9±0.0mm^2$ vs $0.5±0.0mm^2$ for control) and granulation tissue (43.7±25.5% vs 27.3±13.9% for control). These results demonstrate that the oxygen-eluting biomaterial dressing supported the healing process, decreased bacterial colonisation and improved outcomes across a variety of parameters after 17 days compared to control.*

Conclusion/Significance: *Oxygen releasing calcium peroxide composite successfully maintained tissue viability and reduced infection without disrupting the healing process in an ischemic full thickness wound model. Its ability to deliver sustained oxygen directly to the wound site has shown to significantly improve the healing process and enhance tissue regeneration, without the drawbacks inherent in solutions like hyperbaric oxygen therapy. This technology has promising applications in improving diabetic wound care, where peripheral vasculopathy often* *leads to chronic, ischemic ulcers.*

Biohybrid 3D Printing of Magnetically Actuated Extracellular Matrices for Muscle Tissue Engineering *Seyedeh Ferdows Afghah, Tara Sheehan, Jane Bai, Vera McCoy, Farrah Ye and Ava Ladd; Massachusetts Institute of Technology, United States*

Introduction: *Skeletal muscles make up about 45% of total human body mass and are important for skeletal support and movement. Skeletal muscle can regenerate itself after minor injuries in normal circumstances but this does not apply to situations where more than 20% of the volume is lost. Various means like casting have been traditionally used in skeletal muscle tissue engineering, though they failed to fully mimic the complex architecture and cellular organization required for muscle function. This necessitates the development of innovative approaches in skeletal muscle tissue engineering to restore muscle function.*
Traditional methods like injection molding have been used to engineer skeletal muscle tissue, but they struggle to replicate the complex structure and cellular organization needed for effective muscle function. To address this, 3D bioprinting has emerged as a promising solution. This technique allows for precise control over the placement of cells and materials, creating constructs that closely resemble natural muscle tissue. Recently, advancements by our group in magnetically actuated matrices (MagMA) have shown that dynamic mechanical stimulation can improve muscle fiber alignment, maturation, and contractile function in 2D cultures. In preliminary experiments, MagMA was performed by manually embedding magnetic microparticles in fibrin hydrogels and controlling matrix actuation with an external magnet. By combining MagMA with the extrusion bioprinting of 3D cell-laden hydrogels, we can achieve more precise control over magnetic microparticle placement in 3D, enhancing the spatial resolution of mechanical stimulation and ensuring reproducibility. This method also enables us to thoroughly explore how different MagMA deposition patterns and hydrogel types affect muscle cell formation and differentiation, paving the way for more effective muscle tissue engineering.
Methods: *This work presents a novel method for creating 3D magnetically actuated muscle constructs using hybrid bioprinting. By employing embedded 3D printing within a support bath, we accurately deposit C2C12 cell-laden GelMA/fibrinogen hydrogel alongside spatially patterned magnetic microparticles embedded in PDMS. The pre-cured PDMS allows for precise printing and deposition within the hydrogel. We optimized the curing time and temperature of the PDMS, as well as various concentrations and crosslinking agents for the GelMA using LAP and Irgacure. The resulting thick muscle structure is biofabricated and cultured in differentiation media supplemented with insulin-like growth factor (IGF-1) and electrically stimulated to further enhance tissue maturation. Magnetically-controlled non-invasive mechanical stimulation is then applied, and the muscle constructs are evaluated for fiber alignment, maturation, and force generation capabilities.*
Results & Discussion: *We have demonstrated that pre-curing PDMS with embedded magnetic particles facilitates the bioprinting of MagMA in various configurations within a cell-laden hydrogel. By optimizing the curing time and temperature, we achieved successful spatial deposition of magnetic microparticles in 3D hydrogels commonly used as extracellular matrices in tissue engineering. This technique allows for non-invasive mechanical stimulation of developing muscle tissue through external magnetic fields, mimicking essential mechanical cues for muscle maturation and functional alignment. This study explores the impact of combining hybrid biofabrication with magnetic actuation. Ultimately, our research aims to advance the development of mechanically programmed 3D muscle grafts to promote functional regeneration following traumatic injuries. Future studies by ourselves and others could extend the impact of 3D bioprinted MagMA to other cell types known to be impacted by mechanical stimulation.*

Development of a Novel Chitosan/Sodium Hyaluronate/Iridium Hydrogel Nanocomposite to Enhance

Keratinocyte Cell Migration for Wound Healing Applications *Wai-Hong Cheang[1], Li-Jie Chen[1], Tsung-Chun Yu[1], Bo-Han Huang[1], Kuang-Chih Tso[2], Yen-Fang Song[3], Gung-Chian Yin[3], Jai-Sing Yang[4] and Pu Wei Wu[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Nara Institute of Science and Technology, Japan; [3]National Synchrotron Radiation Research Center, Taiwan; [4]China Medical University, Taiwan*

Chitosan is a chemical substance extracted from the shells of crustaceans, known for its impressive biocompatibility and antibacterial properties. Due to its low cost and easy availability, chitosan and its derivatives have been explored for biomedical applications, such as wound dressings, bio-scaffolds, drug delivery, and disease diagnosis. Our laboratory has developed a novel chitosan/sodium hyaluronate/iridium (CHI/SH/Ir) hydrogel nanocomposite through electrophoresis, featuring a unique microstructure with vertically aligned pores. The formation of ordered vertical pores in the CHI/SH/Ir hydrogel nanocomposite is due to the restriction of hydrogen bubbles generated by water electrolysis during the electrophoresis process, which limits their lateral movement and coalescence. The diameter of the vertical pores is 600-700 µm and the thickness is 500 µm in the wet state. The porosity of the CHI/SH/Ir hydrogel nanocomposite is 76.7%, and the water absorption rate is 350%. Compared to similar products without added iridium, its tensile strength is nearly doubled, reaching 8.7 MPa. In the CHI/SH/Ir hydrogel nanocomposite, iridium nanoparticles are uniformly distributed, with an average size of 3 nm. The CHI/SH/Ir electrophoretic suspension exhibits negligible cytotoxicity. In cell migration tests using human keratinocyte HaCaT cells, the relative migration rate of the CHI/SH/Ir hydrogel nanocomposite was 122.15 ± 9.02 % ($p < 0.001$) compared to the blank sample. Furthermore, reactive oxygen species (ROS) inhibition and next-generation sequencing experiments are applied to study the enhancement of migration properties. The vertically aligned pores observed with SH and iridium nanoparticles suggest broad prospects for applications in wound healing.

Promising Antibacterial Coverings for Catheters Made from Electrospun Polyhydroxyalkanoate Fibers that Incorporate Components from the Extra Virgin Olive Oil Production Cycle *Claudio Ricci[1,2], Doretta Cuffaro[1], Lorenzo Zavagna[3], Maria Grazia Cascone[1], Maria Digiacomo[1], Giovanna Batoni[1], Marco Macchia[1] and Serena Danti[1,2]; [1]University of Pisa, United States; [2]OTOLab Cisanello Hospital, Italy; [3]Università degli Studi di Siena, Italy*

Patients undergoing catheterization have a high risk of microbial infection (prosthetic infections PI) because of the possibility of the devices acting as a conduit for the transmission of bacteria to other organs. It is difficult to make nontoxic antimicrobial coatings with chemicals derived from renewable resources. Antibiotic drugs or, in the worst situations, a second surgery are now the mainstays of PI therapy, which has a significant impact on both patient recovery and health care costs. To combat this disease, it may be possible to produce an antimicrobial surface that contains extracts, derived from natural waste materials, and is able to reduce microbial colonization while avoiding the typical drug-resistance mechanism.
We recently designed new coatings based on extra virgin olive oil extract (EVOO) and embedded them in biobased polymeric scaffolds consisting of fibers known as polyhydroxyalkanoates (PHAs). High-performance liquid chromatography (HPLC) was used to assess the polyphenolic content of the EVOO extracts. Subsequently, the extracts were integrated into PHA fibers, particularly in poly(hydroxybutyrate-co-hydroxyvalerate) fibers, by the use of the electrospinning technique. PHBHV is a naturally occurring polyester with excellent biocompatibility and biodegradability qualities that is made by a wide range of microorganisms. Using Scanning Electron Microscopy (SEM) examination, the morphological characteristics of the novel EVOO/PHBHV were determined. Using representative PI bacteria (Gram + (Staphylococcus epiedrmidis) and Gram – (Pseudomonas aeruginosa), the extracts and the newly constructed nanofibers were assessed for their antimicrobial activity using the Agar Gel

Immunodiffusion assay (Halo test). By using HPLC analysis, the diffusion of the primary phenolic compounds in PBS buffer was assessed at predetermined time intervals in order to examine the release of phenols from the polymer. Additionally, the Almar Blue assay was run to assess the novel biofibers' cytocompatibility. The analysis of the polyphenolic content of the EVOO extracts showed a significant concentration of significant polyphenols with antioxidant and antibacterial qualities, including pinoresinol, hydroxytyrosol, and tyrosol—all of which are found naturally in antimicrobial solutions. In actuality, the growth of bacteria was effectively inhibited by EVOO extracts. The resulting composite nanofibers EVOO/PHBHV had a repeatable shape and a uniform size of roughly 1-2 µm in diameter. When compared to EVOO extracts alone, the EVOO/PHVBH fibers demonstrated enhanced cytocompatibility and a progressive and comprehensive release of polyphenols over the course of 48 hours, all while maintaining the antibacterial activity. Due to their polyphenolic content, EVOO extracts showed encouraging antibacterial qualities and were added to particular PHVBH nanofibers in order to create new coating. These novel biodevices, namely the contrast PI, may find usage as antimicrobial coatings in biomedical applications. Funding for this study was provided by PON Research and Innovation - DM 1062/2021, 2014-2020.

3:45 PM SB05.08.07

Advancing Cancer Treatment with Mechano-Electrically Active Tissue Engineering *Clarisse Ribeiro, Sylvie Ribeiro and Senentxu Lanceros-Mendez; Universidade do Minho, Portugal*

Cancer is one of the most malignant diseases and a leading cause of death worldwide. Among the various types of cancer, sarcomas, which develop from connective tissues such as muscles, fat, and bones, can lead to aggressive solid tumors. Additionally, breast cancer, which primarily originates from the epithelial cells of the mammary ducts or lobes, is another prevalent form. The incidence of sarcomas is higher during childhood and adolescence, while breast cancer predominantly affects adults. Current therapeutic strategies include conventional chemotherapy, radiation therapy, and surgical resection. However, ongoing research aims to discover less aggressive and more effective approaches, as preventive measures are more acceptable and outweigh potential risks. In this context, a promising strategy is the development of therapies based on tissue engineering (TE) concepts, as these methods allow for the modulation of cell behavior through the implementation of scaffold structures and the application of biochemical or biophysical stimuli.

In this work, we introduce electroactive scaffolds, specifically piezoelectric ones, commonly used for bone and skeletal muscle regeneration, as a novel approach to address and mitigate both sarcoma-related cancers and breast cancer. It is successfully demonstrated that electrically active dynamic microenvironments can be suitable to develop new effective cancer therapy strategies. These strategies not only target cancer cells but also support the regeneration of damaged tissues. The integration of electroactive scaffolds into therapeutic protocols shows potential in enhancing the effectiveness of treatment while minimizing the adverse effects associated with conventional therapies. The results indicate that piezoelectric scaffolds can modulate cellular activities, promote tissue regeneration, and create an inhospitable environment for cancer cell proliferation, thereby offering a multifaceted approach to cancer therapy.

4:00 PM SB05.08.08

Tailoring Cell Response on Electroactive Piezoelectric Materials Though Surface Protein Deposition and Morphology *Paula Rodriguez[1], Sara Martin[1], Sylvie Ribeiro[2], Clarisse Ribeiro[2], Viktor Petrenko[1], Unai Silvan[1] and Senentxu Lanceros-Mendez[1,2]; [1]BCMaterials, Spain; [2]Universidade do Minho, Portugal*

The physical-chemical properties of scaffolds used for tissue regeneration strategies have a direct impact on cell shape, adhesion, proliferation, phenotypic and differentiation. Thus, biophysical and biochemical cues have been widely used to design and develop biomaterial systems for specific tissue engineering strategies.

Further, the protein-material interface is driven by the physical-chemical interactions that occur when proteins *come into contact with the surface. These interactions are facilitated by the properties of the biomaterial, including wettability, stiffness, topography and chemical composition, and determine the biological effect of the biomaterial on the cells adhering to it. However, a significant limitation for the design and modification of materials to improve their biological activity lies in the insufficient understanding of the mechanisms that govern the formation of the protein interface.*

This is particularly relevant in the case of electroactive materials, increasingly used for the development of active microenvironments for tissue regeneration. Poly(vinylidene fluoride) (PVDF) is a piezoelectric polymer known for its high biocompatibility and non-biodegradability [1]. PVDF has been consequently used for static cultures and in dynamic setups in which a variation of the surface charge provides cells with a cyclic electrical stimulus, showing its potential for bone, muscle, and neural tissues regeneration [1].

In this context, we have explored the interaction of collagen type-I, the most abundant mammalian extracellular protein, with polyvinylidene fluoride (PVDF), revealing significant differences in collagen affinity, conformation, and interaction strength depending on the electric charge of the PVDF surface, which subsequently affects the behaviour of mesenchymal stem cells seeded on them. These findings highlight the importance of surface charge in the establishment of the material-protein interface and ultimately in the biological response to the material.

Moreover, the specific surface morphology of those piezoelectric polymers allows to further guide cell response, by taking into consideration both final functional cell shape and electroactivity. It is shown how patterned anisotropic electroactive scaffolds allow to promote muscle differentiation, whereas isotropic ones are more suitable for osteoblast differentiation. Those effects are reinforced by biochemical stimuli. However, when the physical stimulus is not adequate to the tissue, e.g. isotropic microstructure, the biochemical stimulus has the opposite effect, the differentiation process is hindered. Therefore, the proper morphological design of the electroactive scaffold combined with dynamic electroactive and biochemical stimulus allows to enhance cell differentiation and allows the development of advanced strategies for effective tissue engineering of electroactive tissues.

Venous Angiogenesis of Decellularized Dermis—Towards Transplantable Dermal Substitutes *Sze Wai Lau, Sabah Oghazian, Arturo Vela Lasagabaster, Mirko Gilardino, Mitchell Bernstein, Edward Harvey, Nicholas Makhoul and Jake Barralet; McGill University, Canada*

Background:
When skin wounds are so extensive that conventional wound healing proves inadequate, pedicled and free flaps become pivotal. These flaps either preserve existing vasculature or are transferred and re-anastomosed. However, in severe wounding the available tissue for grafting is limited. Creating transplantable vascularized dermal equivalents is demanding. This study aims to explore the potential of decellularized dermis to be revascularized through venous angiogenesis. Decellularized dermis was implanted around a femoral vein (DV), and a control group (DC) was implanted subcutaneously. This investigation compared the vascularization patterns of these two

groups and their potential to support cell viability.

Methods:
The decellularized dermis was prepared under chemical and enzymatic approaches involving sodium chloride and DNAse (I) solution. This study was approved by the McGill University Ethics Committee (AUP 7662). The surgeries were performed on N=10 Wister rats (350-500 grams, 4-6 months old) that were divided into two groups based on the placement of the decellularized dermis. In the DC group, incisions were made along the inguinal fold, allowing for the subcutaneous implantation of the decellularized dermis, which was then sutured under the skin. As for the DV group, dissection proceeded laterally and deepened to access the femoral vessels. Careful dissection and cauterization were performed on the femoral vein to remove any branches. Subsequently, the dissected femoral vein was enveloped with a decellularized dermis and secured in place using two sutures. The rats were monitored for 8 weeks, at which point they were sacrificed, and blood supply was visualized using Microfil contrast agent by microCT. Hematoxylin and Eosin staining of paraffin sections and CD31 immunohistochemistry were conducted to further quantify the vessel density within the samples.

Results:
Histological evaluation revealed a statistically significant difference in the mean number of vessels per mm^2*. The DV group exhibited a higher mean number (20.4 ± 5.1) compared to the DC group (4.3 ± 1.7). The vascularization in the DV group was 4.7 times greater than in the DC group. The results from CD31 IHC were consistent with measurements from H&E stained sections. There was a significant increase in the number of CD31-positive vessels in the DV group (21.3 ± 4.8) compared to the DC group (4.0 ± 1.5), which is a 5.3-fold increase in CD31-positive vessel density in the DV group relative to the DC group. Vessels in the DV group primarily originated from the inner femoral vein, extending outward, consistent with microCT imaging. In contrast, vessels in the DC group mainly grew around the DV's edge, penetrating and developing within the dermis alongside surrounding fibrous tissue. In order to assess transplantability, DV vascularized by a central vein was excised and anastomosed with the femoral artery, and the dermal matrix was observed to bleed upon light injury with a scalpel indicating a functional vascular supply. These findings highlight the efficacy of the DV group's approach and its potential application in advancing vascularized tissue engineering strategies.*

Conclusion:
In summary, this study confirms the effectiveness of decellularized dermis in promoting robust vascularization. Particularly in the DV group, the results substantiate the feasibility of an alternative approach to arteriovenous loops. The quantifiable difference in vessel density between DV and DC groups supports the exploration of innovative strategies for skin defect treatment. The enhanced transplantability of DV implants indicates promising clinical potential.

4:30 PM SB05.08.10
Ionic Control to Enhance Chronic Wound Healing Dynamics *Parsa Azizi-Mehr, Sze Wai Lau, Yu Ling Zhang, Yassine Ouhaddi, Kevin Watters, Gregory Berry, Edward Harvey, Nicholas Makhoul, Mirko Gilardino and Jake Barralet; McGill University, Canada*

INTRODUCTION: *Post-surgical complications leading to chronic wounds remain problematic for the health care system. In the United States alone, chronic wounds impact approximately 5-8 million patients, costing between $20-30 billion dollars annually. Ischemia, as a result of the reduction in blood and oxygen supply, results in major disruptions to tissue homeostasis. The local environment of wounds has a substantial impact on wound recovery. Many inorganic ions have been used throughout history to treat wounds. Carbonates have been identified as likely being the cause of anecdotal evidence surrounding some natural spas allegedly being beneficial for poorly healing*

wounds. Subsequently carbonates have been shown to variously affect capillary formation, vasodilation, and moisture content in wounds. In this study, we sought to determine whether a commercial carbonate powder sold for wound healing was equivalent to regular laboratory grade calcium carbonate and magnesium carbonate to establish whether the anion or the cation or their combination were significant. ***METHODS:*** *Wistar rats were randomized into 7 groups. 2 full thickness lateral incisions were made to create a bipedical flap intended to have compromised blood supply. Lateral incisions were then cleaned with saline and sutured using Ethicon polypropylene sutures. 5 wounds were created using an 8mm biopsy punch. 4 of 5 of these wounds were placed within the bipedical flap, and 1 wound was placed outside the flap, to serve as a positive control (n=16). The negative control group (n=16) received no treatment within the ischemic wounds. 5 experimental groups (n=16) received inorganic compounds either treated to adjust initial pH and buffering capacity or left untreated. The wounds were photographed on days 0, 4, 7, 10, 14, and 17 after surgery. Wounds were cleaned by removing debris and washed with saline prior to taking photographs. ImageJ software was used to analyze the percentage of the wound size remaining on each day. Morphological analysis (scanning electron microscopy) and phase characteristic (X-ray diffraction analysis) studies were completed to ensure the maintained integrity of pH adjusted compounds. Histochemical (H&E, Masson's Trichrome) and immunohistochemical (CD-31, smooth muscle actin) analysis was completed to examine tissue for scarring and blood vessel density.* ***RESULTS****: Following a one-way ANOVA assessment and post hoc Tukey analysis confirmed that medical grade calcium carbonate significantly reduced wound size on day 7 ($p<0.05$) and day 10 ($p<0.05$). Similarly, laboratory grade magnesium carbonate significantly improved wound healing on day 10 ($p<0.005$), however only when adjusted to physiological pH with citrate. Magnesium phosphate initially worsened wound healing, however when initial pH were adjusted, magnesium phosphate improved ischemic wound healing on day 7 ($p<0.05$). Histological and immunohistological data depicted reduced scaring, greater appendage density, and fewer blood vessels in the positive control, medical grade calcium carbonate, and magnesium carbonate adjusted with citrate.*
CONCLUSION: *In this study, we created a model predictive of wound healing by adjusting the initial pH of carbonate compounds. These results suggest that improved healing was due to physio-chemical effects, rather than effect of a particular cation or anion. These discoveries will impact the future design of biomaterials, particularly in the development of predictive assays to evaluate and anticipate the biological effects of biomaterials.*

Effects of Degraded Dimethylpolysiloxane (PDMS) on Polyethylene Glycol Diacrylate (PEGDA) Copolymer Scaffolds for Bone Tissue Engineering *Andre A. Fatehi[1], Sam Lloyd-Harry[1], Ozgul Yasar-Inceoglu[1] and Ozlem Yasar[2]; [1]California State University, Chico, United States; [2]The City University of New York, United States*

Tissue Engineering is a rapidly advancing field concerned with fabricating scaffolds that can assist in cell regeneration and proliferation, requiring a controllable degradation rate. While polyethylene glycol diacrylate (PEGDA) hydrogels have been proven to be biocompatible and to have highly tunable material properties, chemical alterations are required to further control degradation as tissue cells grow and replace the scaffold for bone tissue applications. This study expands upon our previous work investigating 24 hour degradation effects on the mechanical properties of PEGDA and dimethylpolysiloxane (PDMS) copolymer scaffolds by extending the investigation to include 48 and 72 hour degradation effects. Samples were submerged in phosphate buffered saline (PBS), a medium that closely mimics the conditions within the human body, and a natural body temperature of approximately 37°C was maintained. Characterization techniques of the copolymer scaffolds were conducted using Scanning Electron Microscopy (SEM), Fourier Transmission Infrared Spectroscopy (FTIR), Raman Spectroscopy, and X-Ray Diffraction (XRD). Compression tests were conducted using a QT 50 universal testing machine at a rate of 0.75 mm/min. These tests were executed on 85:15 (V:V) PEGDA to PDMS copolymer and 100:0 pure PEGDA degraded samples over 24, 48, and 72 hour time intervals, as well as non-degraded samples.

Up-to-date as of November 14, 2024

This work provides a further understanding of the effects of PDMS on PEGDA scaffolds for bone tissue engineering applications.

Industrial Production of High Quality 2D Materials *Francesco Bonaccorso[1,2]; [1]BeDimensional, Italy; [2]Istituto Italiano di Tecnologia, Italy*

We will present our latest progresses on the industrial scaling up of the production of 2D materials.[1-3] Defining scalable, reliable, and inexpensive production processes is a must for the extensive use of 2D materials in various applications,[1-8] involving a balance between final product quality and ease of fabrication. We will show the efficiency of the manufacturing of high-quality 2D materials by wet-jet milling[3] and the path towards industrial production.
Afterward, we will provide an overview on a few key applications of the as-produced 2D materials. We will show how the production of 2D materials in liquid phase by wet-jet milling[3] represents a powerful pathway towards the development of 2D materials-based devices, offering massive integration flexibility compared to other production methods.[4-10]

Xenes and Their Surface Chemistry for Nanomedicine *Zdenek Sofer; University of Chemistry and Technology, Prague, Czechia*

Two-dimensional materials composed of a single element, known as Xenes, have garnered significant attention in recent years. Following the pioneering isolation of graphene, numerous monoelemental 2D materials from Group 14 (tetrels) and Group 15 (pnictogens) of the periodic table have been extensively studied. Over the past decade, various Xenes, including derivatives of phosphorene, silicene, and germanene, have been described alongside graphene and its derivatives. The chemistry of graphene-based materials is well-established, with numerous derivatives such as fluorographene and graphane (fully hydrogenated graphene) being documented. Silicene and germanene, the heavier analogues of graphene, are typically synthesized through the chemical exfoliation of their layered precursor compounds. Several derivatives of these materials have been developed, and some have shown promise in drug delivery applications. Conversely, the surface chemistry of pnictogen-based 2D materials remains relatively underexplored, with only a few derivatives reported to date. The ability to control the surface chemistry of two-dimensional materials is vital for their application in nanomedicine, particularly for targeted drug delivery and the controlled release of therapeutic agents. This presentation will discuss various methods of surface functionalization and their implications for controlled drug delivery.

Tuning the Properties of 2D Materials via Chemical Functionalizations—From Hairy Nanosheets to Their Hetero-Networks *Paolo Samori; Université de Strasbourg, France*

The already exceptional properties of 2D materials can be further modulated, enriched and enhanced by interfacing them with ad hoc molecules via chemical functionalization. Molecules can be designed and synthesized to integrate both one or more anchoring moieties to guarantee immobilization on the basal plane or edges of 2D nanosheets, and one or more functional groups to tune the properties of the 2D material or impart them additional ones. The engineering of such hybrid structures represents a viable strategy to confer novel dynamic chemical and physical properties to 2D materials. [1]

In my lecture I will present our recent endeavour on the covalent functionalization of 2D materials by using different chemical reactions including the healing of point vacancies such as missing S, Seand Te atoms in the lattice of transition metal dichalcogenides nanosheets, including 2D MoS_2, WSe_2 and $MoTe_2$ by exploiting sulfur exposing molecules (equipped with thiols or disulfides end groups).[2] Moreover, liquid phase exfoliated 2D nanosheets of MoS_2 have been functionalized with dithiolated molecules has thereby generating networks with enhanced inter-sheet electronic cross talk.[3] Depending on the chemical structure of the molecular bridge linking adjacent nanosheets, enhancement in the charge transport through the film [4] or higher selectivity in the recognition process of specific analytes can be attained.[5] Furthermore, enhanced compositional complexity could be achieved by sequential deposition of a series of multiple 2D nanosheets and molecular bridge making use of a microfluidic strategy thereby generating hetero-networks and hetero-structures.

Alongside the tunable opto-electronic properties, these hybrids can display also programmable mechanical properties which can be exploited for the realization of unprecedented physical sensors for medical diagnosis and health monitoring, with sensitivities in the low-pressure or medium-pressure range. Example of flexible piezoresistive pressure sensors compatible with wearable technologies for digital healthcare, human-machine *interfaces and robotics will be provided. [6]*

The presented modular strategies provide a glimpse on the chemist's toolbox to generate multifunctional 2D materials -based hybrids with ad-hoc properties to address key global challenges in electronics, sensing and energy applications.

Biocompatible 2D Material Inks Enabled by Supramolecular Chemistry *Cinzia Casiraghi; The University of Manchester, United Kingdom*

The emergence of two-dimensional (2D) materials, such as graphene, transition metal dichalcogenides, and hexagonal boron nitride has sparked significant interest in various biomedical applications due to their unique physicochemical, optical, electrical, and mechanical properties. However, the interaction of the material with the biological environment is strongly dependent on the surface chemistry and morphology of the crystals, [1] hence it is crucial to develop methods able to finely tune the surface charge and types of functional groups. In this talk I will show that supramolecular chemistry allows to achieve in one-pot approach both liquid-phase exfoliation in water and non-covalent functionalization of the material, hence enabling to produce a wide range of biocompatible 2D materials with specific surface chemistry. [2-5] I will provide seminal biomedical studies based on 2D material produced with the supramolecular approach, ranging from Lysosomal Storage Disorders therapeutics to trained immunity in macrophages and to immune-compatible nanoplatforms for single-cell mass cytometry by time-of-flight.[6-8]

Redox-Based Cation Intercalation for a Large-Scale Production for Metallic Transition Metal Dichalcogenides *Juhwan Lim, Ebin Sebastian, Jiho Han, Christoph Schnedermann and Akshay Rao; University of Cambridge, United Kingdom*

Chemical cation intercalation is a promising method for scaling up 2D materials via liquid exfoliation. For group-6

TMDs, this process induces a phase transition from natural trigonal prismatic (2H) to octahedral (1T), transforming their electronic properties from semiconducting to metallic. Solutions of 1T-TMDs have demonstrated excellent capabilities for creating electrochemical devices, such as batteries and catalytic systems. The most widely-used method involves the organolithiation agent n-butyllithium (n-BuLi), first demonstrated 50 years ago. While highly successful in various lab-scale applications, the slow reaction time and pyrophoric nature of n-BuLi have hindered the rational scale-up of liquid exfoliation. Here, we investigate this reaction on the nano- to mesoscale using in-situ optical microscopy, ex-situ optical techniques, X-ray photoemission spectroscopy (XPS), and electrochemical lithiation/sodiation, elucidating the roles of photons and redox potential. We demonstrate that polyaromatic hydrocarbons with appropriate redox potentials and alkali metals can replace pyrophoric n-BuLi in this chemical process. Additionally, we expand our strategy to sodium intercalation. Finally, by combining low-cost visible light with our newly synthesized redox metalization agents, we achieve a rapid cation intercalation reaction, presenting a feasible route for large-scale production of exfoliated TMDs in the solution phase.

Optimization of Bismuth Telluride Nanoparticles Synthesized via Spark Ablation *Eliane Bsaibess, Joumana El-Rifai, Stavros Christopoulos, Amna N. Yusuf, Hamed S. Alawa, Ahmed Slimani and Valerie Laux-Le Guyon; Sorbonne University Abu Dhabi, United Arab Emirates*

Nanoparticles are pivotal in advanced applications such as thermoelectric devices, sensors, solar cells and energy storage, owing to their increased surface area, enhanced phonon scattering, and reduced thermal conductivity. They are typically synthesized using high-temperature or wet chemical methods for larger sizes (~100 nm), while smaller nanostructures (20 nm - 40 nm) are often achieved through solvothermal techniques, involving high temperatures and complex processes.

Our study focuses on applying a one-step spark ablation method to synthesize Bi_2Te_3 *nanoparticles, aiming to optimize the diffusion parameters to produce high-purity nanoparticles with controllable sizes. Spark ablation is a simple, clean and versatile approach, ideal for producing thermoelectric materials. It requires only a base material and a carrier gas, resulting in a low-waste, rapid process that operates at room temperature without the need for complex equipment.*

The spark ablation process involves ablation of two opposing metallic or semiconductor rods using repetitive high-voltage electrical sparks, which generate a supersaturated metal vapor in a carrier gas. This vapor rapidly condenses into nanoparticles, forming an aerosol of particles ranging from 2 nm to 20 nm in size. By producing several hundred sparks per second, a continuous nanoparticle flow is created and transported by an accelerated gas flow toward a target substrate for deposition.

Key parameters such as applied current, voltage, flow rate and ablation time are systematically varied to investigate their effects on the diffusion processes that govern nanoparticle growth and agglomeration. Through this methodical variation, the study aims to fine-tune the production process, ensuring optimal nanoparticle size and homogeneous distribution.

Through a series of experiments and comprehensive characterization techniques, including Scanning Electron Microscopy (SEM) combined with Energy Dispersive Spectroscopy (EDS), UV-Vis-IR Spectrophotometry, Raman spectroscopy and X-Ray Diffraction (XRD), we analyze the morphological, optical and structural properties of the produced nanoparticles. Our results reveal a strong correlation between the applied voltage and current and the produced nanoparticle size, while the carrier gas flow rate significantly impacts the homogeneity of both the nanoparticle dispersion and their agglomerates.

In conclusion, fine-tuning the spark ablation parameters effectively controls diffusion kinetics, leading to a tailored nanoparticle size range suitable for varied applications. Additionally, the spark ablation process enables direct deposition of nanoparticles onto any temperature sensitive substrate or prefabricated electronics.

5:00 PM SB06.01.07

Giant Circularly Polarized Emission in $NiPS_3/WSe_2$ 2D Heterostructures *Adi Harchol[1], Shahar Zuri[1], Rajesh Kumar Yadav[2], Kusha Sharma[1], Ellenor Geraffy[1], Thomas Brumme[3], Doron Naveh[2] and Efrat Lifshitz[1]; [1]Technion-Israel Institute of Technology, Israel; [2]Bar-Ilan University, Israel; [3]Technische Universität, Germany*

The recent interest in magnetic two-dimensional (2D) van der Waals (vdW) materials changed paradigms in science and technology, unveiling novel physical phenomena such as valleytronics, spin selectivity, and quantum effects. These 2D materials possess nearly atomically thin layers with strong intralayer bonding but weak vdW interlayer coupling, while metals within the plane are organized in a honeycomb lattice. The weak vdW forces enable the separation of a single or a few layers by micromechanical or chemical exfoliation. Furthermore, the formation of vdW heterostructures (HSs) through stacking dissimilar layers offers unprecedented functionalities beyond those of individual components.

This study investigates the electronic and optical characteristics of HSs composed of $NiPS_3$ and Wse_2. $NiPS_3$, an antiferromagnetic material, and WSe_2, known for its spin-valley features, exhibit a quasi-type II band alignment when coupled. Magneto photoluminescent (PL) measurements reveal substantial alterations in polarization behavior under external magnetic fields, achieving up to 80% circular polarization at -8 Tesla and 45% at 0 Tesla, indicative of a Rashba effect induced by spin-orbit coupling. Circularly polarized PL measurements further unveil energy band splitting arising from spin and valley interactions, highlighting potential applications in quantum and photo-spintronic devices. These findings underscore the mutual interaction between magnetic and optical properties in HSs, offering new insights for future research in material science and device applications.

SESSION SB06.02: Theranostic Applications

2D Material Inks for Printed Self-Powered Wearable Sensors *Cecilia Mattevi; Imperial College London, United Kingdom*

Healthcare systems are increasingly reliant on wearable devices which can enable continuous monitoring of key indicators which can trigger interventions. Wireless and continuous monitoring can be achieved by self-powered sensor platforms which rely on energy storage devices such as batteries. Commercially available batteries are normally large, rigid and difficult to customize. In this talk, I will present our work on 3D printed miniaturized supercapacitors and rechargeable aqueous batteries to power wearable sensors. The use of continuous-extrusion-3D printing enables the manufacturing of complex architectures which can meet specific integration requirements, including small footprint areas, small features sizes and mechanical flexibility. We use 2D materials as the materials of choice for the electrodes, and water-based gel electrolytes, to manufacture energy storage devices on flexible substrates. I will discuss the materials challenges in formulating functional inks of 2D materials and different architectural designs to optimize the electrochemical performance of the energy storage devices. Finally, I will then show how these devices can power wearable sensors, from commercial sensors as well as organic electrochemical transistors (OECT).

2D Nanostructures for Theranostics *Zhuang Liu; Soochow University, China*

2D nanomaterials with unique nanosheet structures, large surface areas, and extraordinary physicochemical properties have attracted tremendous interest. In the area of nanomedicine, research on graphene and its derivatives for diverse biomedical applications began as early as 2008. Since then, many other types of 2D nanomaterials, including transition metal dichalcogenides, transition metal carbides, nitrides and carbonitrides, black phosphorus nanosheets, layered double hydroxides, and metal–organic framework nanosheets, have been explored in the area of nanomedicine over the past decade. In particular, a large surface area makes 2D nanomaterials highly efficient drug delivery nanoplatforms. The unique optical and/or X-ray attenuation properties of 2D nanomaterials can be harnessed for phototherapy or radiotherapy of cancer. Furthermore, by integrating 2D nanomaterials with other functional nanoparticles or utilizing their inherent physical properties, 2D nanomaterials may also be engineered as nanoprobes for multimodal imaging of tumors. 2D nanomaterials have shown substantial potential for cancer theranostics. In this talk, our efforts in the development of 2D nanomaterials for cancer theranostic applications will be introduced. Current challenges and future perspectives of 2D nanomaterials applied in nanomedicine will also be discussed.

Tailoring Boron Nitride Nanomaterials for Cancer Therapy *Xia Li[1], Nobutaka Hanagata[1] and Dmitri Golberg[2,3,4]; [1]National Institute for Materials Science, Japan; [2]Queensland University of Technology, Australia; [3]Queensland University of Technology (QUT), Australia; [4]National Institute for Materials Science (NIMS), Japan*

Boron nitride (BN) nanomaterials are representative layered nanomaterials with alternatively linked boron and nitrogen atoms, including zero-dimensional (0D) nanoparticles, one-dimensional (1D) nanotubes, two-dimensional (2D) nanosheets and so on. Over the past years, our research has focused on tailoring BN nanomaterials for cancer therapy, such as chemotherapy and cancer immunotherapy, due to their good biocompatibility, high drug loading efficiency, unique chemical composition, and biological activity.

1) BN nanomaterials as carriers for chemotherapy drugs

BN nanomaterials have great potential as carriers for chemotherapy drugs based on their low toxicity and high drug loading capacity. However, pristine BN nanomaterials suffer from high hydrophobicity, easy aggregation, and weak targeting ability, which limits their application as delivery systems. We have explored several approaches to solve these problems. i) Pristine BN nanotubes were oxidized, shortened, and modified with mesoporous silica to create core@shell structures to greatly improve their suspension ability and hydrophilic properties in an aqueous solution. ii) The perfectly water-soluble and porous BN nanomaterials, featuring unprecedentedly high hydroxylation degrees, were synthesized via an original and simple thermal substitution method. These hydroxylated BN nanomaterials can effectively load anticancer drugs (e.g., doxorubicin, DOX) up to contents three times exceeding their own weight. iii) In addition, BN nanotubes were functionalized with europium-doped sodium gadolinium fluoride to enable magnetically targeted chemotherapy. Under an external magnetic field, the cellular uptake of modified BN nanotubes by cancer cells was increased approximately 2-fold, and the modified BN nanotubes loaded with DOX exhibited significantly high chemotherapeutic efficacy, compared with those in the absence of magnetic field.

2) BN nanomaterials as boron reservoir for chemotherapy of prostate cancer

Boron compounds have attracted attention as preventative and therapeutic agents for prostate cancer and other cancers. However, systemic administration of soluble boron compounds is associated with the drawbacks of short half-life period, low bioavailability, and limited effectiveness. We fabricated hollow BN nanospheres with controlled crystallinity and boron release. The optimized BN nanospheres effectively induced apoptosis and *necrosis in both androgen-sensitive LNCap and androgen-independent DU-145 prostate cancer cells in vitro. In vivo experiments in subcutaneous tumor mouse models and orthotopic tumor growth models confirmed the antitumor efficacy of BN nanospheres. The work demonstrates that hollow BN spheres may function as a new agent for prostate cancer treatment.*

3) BN nanomaterials as adjuvants for cancer immunotherapy
Cancer immunotherapy seeks to harness the exquisite power of the immune system to fight against cancer. Inspired by the positive effects of boron supplementation on the immune system by promoting the production of Th1 cytokines, we investigated BN nanospheres as novel adjuvants for cancer vaccines to enhance the antitumor immunity. Cancer vaccines prepared with BN nanospheres exhibited much higher antitumor efficacy in vivo than those prepared with free boric acid, their carbon counterparts and commercially used alum adjuvants. Mechanistic studies showed that the addition of BN nanospheres significantly enhanced the antitumor immune responses by stimulating the secretion of Th1 cytokines, such as IL-2, IFN-γ and TNF-α, and increasing the cytotoxic $CD8^+$ T cell population in lymphocytes. Histological section studies suggested that the addition of BN nanospheres can inhibit metastasis.

9:30 AM SB06.02.04

Actively Targeting Redox-Responsive Multi-Functional Micelles for Synergistic Chemotherapy of Cancer

Haile F. Darge[1,2]; [1]University of Waterloo, Canada; [2]National Taiwan University of Science and Technology, Taiwan

Stimuli-responsive polymeric micelles decorated with cancer biomarkers represent an optimal choice for drug delivery applications due to their ability to enhance therapeutic efficacy while mitigating adverse side effects. Accordingly, we synthesized a digoxin-modified novel multifunctional redox-responsive disulfide-linked poly (ethylene glycol-b-poly (lactic-co-glycolic acid) copolymer (Bi(Dig-PEG-PLGA)-S_2) for targeted and controlled release of doxorubicin (DOX) in cancer cells. Within the micellar aggregate, the disulfide bond confers redox-responsiveness, while the presence of digoxin moiety acts as a targeting agent and chemosensitizer for DOX. Upon self-assembly in aqueous solution, Bi(Dig-PEG-PLGA)-S_2 formed uniformly distributed spherical micelles with hydrodynamic diameter (D_h) of 58.36 ± 0.78 nm and zeta potential of -24.71 ± 1.01 mV. The micelles exhibited desirable serum and colloidal stability with substantial drug loading capacity (DLC) of 6.26 % and encapsulation efficiency (EE) of 83.23 %. In addition, the release of DOX demonstrated the redox-responsive behavior of the micelles that approximately 89.41 ± 6.09 % and 79.64 ± 6.68 % of DOX was diffusing from DOX@Bi(Dig-PEG-PLGA)-S_2 in the presence of 10 mM GSH and 0.1 mM H_2O_2, respectively, over 96 hrs. Therefore, in HeLa cell lines, DOX@Bi(Dig-PEG-PLGA)-S_2 showed enhanced intracellular accumulation and subsequent apoptotic effect, attributed to the targeting ability and chemosensitization potential of digoxin. Hence, these findings underscore the promising characteristics of Bi(Dig-PEG-PLGA)-S_2 as a multifunctional drug delivery vehicle for cancer treatment.

9:45 AM SB06.02.05

Carbon Quantum Dots as Theranostic Agents for Photothermal Therapy and Simultaneous Fluorescent Imaging

María Fernanda Amézaga González[1], Daniel Martínez Osuna[1], Oscar Alberto Álvarez Quezada[1], Jorge Alberto Pérez León[1], Claudia Alejandra Rodríguez González[1], Florinda Jiménez Vega[1], Mauricio Salcedo Vargas[2] and Imelda Olivas Armendáriz[1]; [1]Universidad Autónoma de Ciudad Juárez, Mexico; [2]Instituto Mexicano del Seguro Social, Mexico

Theranostic agents are biomaterials that are characterized by having dual functionality to diagnose, monitor and treat diseases simultaneously. One of these applications is diagnosis to obtain fluorescent images both in vitro and in vivo and the other application is the treatment against different diseases, one of them, cancer. Recent *research is focusing on improving the efficiencies of these agents with just one application through chemical modifications and bioconjugation selectively and specifically at the tumor site, eliminating and/or reducing the side effects of conventional treatments. That is why CQDs were synthesized by microwaves and characterized using DLS, XRD, IR, UV-Vis and photoluminescence methods. It is desired to continue research by functionalizing this material with the PSG1 antibody, to explore its diagnostic capabilities by producing fluorescent bioimages and its therapeutic property by converting NIR light into thermal energy to generate localized heat (phototherapy). All this to assess the specificity and effectiveness of the bioconjugate as a theranostic agent in cells with expression of the carcinoembryonic antigen in vitro and photoirradiate it at a specific length to induce a phototherapeutic.*

10:00 AM BREAK

10:30 AM *SB06.02.06

Low Energy X-Ray Irradiated 2D Functional Nanosystems for Deep Solid Tumor Therapy, Agnostic of Cancer Type *Giancarlo Salviati[1], Filippo Fabbri[1], Bengt Fadeel[2], Avi Schroeder[3], Francesco Bonaccorso[4], Evie L. Papadopoulou[4], Jeny Shklover[3], David Beke[5], Árpád Jakab[5], Carmen Rodriguez[6], Franca Bigi[7,1], Francesca Rossi[1], Claudio Ferrari[1], Melissa Santi[1], Nicola Rivi[7], Marco Villani[1], Valentina Sinisi[1], Marco Bormetti[7], Elena Ferrari[1], Laura Lazzarini[1] and Noelia Gonzales Ballesteros[6]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Karolinska Institutet, Sweden; [3]Technion–Israel Institute of Technology, Israel; [4]BeDimensional, Italy; [5]Wigner Research Centre, Hungary; [6]Universidade de Vigo, Spain; [7]Università di Parma, Italy*

In conventional cancer treatments, chemotherapy, radiation therapy and more recently targeted therapy, and immunotherapy are considered successful approaches. However, limitations such as cytotoxicity, multi-drug resistance and lack of specificity are challenges for beneficial cancer treatments. Light-based treatments (e.g. phototherapy, photodynamic therapy) are less invasive and have been shown to be promising even if deep-seated tumors pose a challenge due to limited tissue penetration. The use of X-Rays to excite oncotherapy, enhanced by nanomaterials able to transfer cytotoxic species to the tumor mass, can overcome this drawback. In this respect 2D nanomaterials, like graphene, transition metal dichalcogenides, layered double hydroxides, etc. have shown intriguing performance both in-vitro and in-vivo.

We present here an oncotherapic approach based on properly engineered (patent-pending) 2D organic/inorganic nanomaterials under low energy X-ray irradiation conditions. The approach does not deliver specific drugs for a particular type of tumor (like e.g. chemotherapy), rather it excites material-mediated physico-chemical processes. Therefore, the therapy is agnostic to the type of cancer and to gender incidence because it doesn't affect the body biochemistry.

Computer simulation procedures to define the most efficient X-Ray absorbing materials and best irradiation conditions will be discussed. Then, the synthesis and characterization of the new hybrid nanosystems will be presented and a few emblematic examples of their radiosensitizing efficacy under low energy X-Ray irradiation on cancer cells will be shown.

11:00 AM *SB06.02.07

2D Nanosilicates for Sustained and Prolong Therapeutic Delivery *Akhilesh K. Gaharwar; Texas A&M University, United States*

Therapeutic delivery remains a significant clinical challenge due to the lack of biomaterials capable of sequestering and delivering biomolecules in a sustained manner over prolonged durations. Here, we present two-dimensional (2D) nanosilicates as a versatile platform for the sustained delivery of various growth factors, promoting stem cell differentiation and angiogenesis. The high surface area and charged properties of nanosilicates enable the prolonged release (>30 days) of therapeutic molecules while maintaining protein conformation and bioavailability. We demonstrate the efficacy of nanosilicates in delivering a range of growth factors, including vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and bone morphogenetic protein 2 (BMP2). Incorporating pro-angiogenic therapeutics-loaded nanosilicates into polymeric hydrogels stimulates endothelial cell invasion in 3D in vitro angiogenesis models, with invasion controlled by the specific growth factors conjugated to the nanosilicates. Moreover, BMP2 released from nanosilicates maintains high efficacy, enhancing osteogenic differentiation in human mesenchymal stem cells (hMSCs) at lower concentrations compared to exogenous controls. Overall, this work underscores the potential of nanosilicates as a platform technology for non-covalent conjugation and sustained delivery of therapeutic growth factors, offering a promising solution for directing cell functions in regenerative medicine.

11:30 AM SB06.02.08

Significant UV Emission Absorption by Silicon in Upconversion Nanoparticles *Vladimir Sivakov[1] and Vaidas Klimkevicius[2]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Vilnius University, Lithuania*

Nanocontainers based on silicon nanostructures (SiNSs) have a number of undeniable advantages over other inorganic nanostructures used for drug delivery. The main advantage is their proven high biocompatibility as well as biodegradability. Due to the ease of modification of SiNSs, specific delivery of various hydrophobic and hydrophilic drugs to cells within the required time frame can be achieved. Due to the presence of red PL, SiNSs can also be used as contrast agents for multimodal bioimaging. Our group has reported in previous studies multimodal bioimaging using Raman spectroscopy of SiNSs nanocontainers without and with doxorubicin loading [1-3]. The main scientific goal of this work is to combine silicon-based nanostructures and upconversion nanoparticles (UCNPs) and improve the possible energy transfer between SiNSs and NaYF4 upconversion nanoparticles doped with thulium (Tm^{3+}) with strong UV-blue emission as a possible drug delivery or targeting system for theranostics applications in nanomedicine. To realize the effective interaction between both nanostructures, a novel in situ synthesis strategy was developed and investigated (TEM, UV-vis, emission), in which silicon nanoparticles were added as a nucleation center in the solution to grow UCNPs. Our results clearly show that more than 97% of the UV-blue emission of UCNPs is absorbed by SiNSs, which is a direct evidence of direct interaction and energy transfer between SiNSs and UCNPs. We found that the SiNSs-UCNPs composite can be efficiently excited by at least two different light sources (UV and/or NIR lasers). The main discovery is related to the efficient absorption of UV radiation by SiNSs emitted by UCNPs, which in total can significantly reduce UV damage to cells and protect the biological object from photodegradation. Silicon-UCNPs system exhibit emission bands in the red-orange (650-800 nm) spectral range, which makes them in demand for the initiation of reactive oxygen species (ROS) photogeneration and as carriers of photodrugs that can be effectively used in theranostic applications.

High-Dimensional Approaches for Immune Profiling of 2D Materials *Lucia G. Delogu[1,2]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]Unviersity of Padua, Italy*

We recently depicted the "Nano-immunity-by-design" where the characterization of 2D materials is not solely based on their physical-chemical parameters but also on their immuneprofiling. [1] The immune-profiling can reveal its complexity in unique, informative ways: high-dimensional approaches. [2,3] We exploited high-dimensional approaches, such as single-cell mass cytometry and imaging mass cytometry on graphene and other novel two-dimensional materials, such as transition metal carbides/carbonitrides (MXenes). [4-6] We revealed that the amino-functionalization of graphene oxide increased its immunocompatibility. [4] Moreover, we combined graphene with AgInS2 nanocrystals, enabling its detection by single-cell mass cytometry on a large variety of primary immune cells. [5] Recently, we reported the immune modulation of specific MXenes and their label-free detection by single-cell mass cytometry and other high-dimensional approaches. [6-7] Together with our published works, I will present unpublished results on a wider variety of novel 2D materials, Mxenes, MoS2, WS2, and bismuthene. Our results conceptualize that chemical and immunological designs of 2D materials offer new strategies for their safe exploitation in biomedicine.

2:30 PM *SB06.03.02

Exploring the Impact of Graphene and Other 2D Materials on the Immune System *Bengt Fadeel; Karolinska Institutet, Sweden*

The discovery of graphene twenty years ago sparked a revolution in materials science and beyond. Due to their versatile properties, graphene and its derivatives as well as other two-dimensional (2D) materials are currently being explored for a wide range of applications including drug delivery, imaging, tissue engineering, and biosensing. To this end, close attention to the biocompatibility of these materials is required. In particular, understanding how 2D materials interact with and/or modulate the human immune system is of fundamental importance as the immune system represents the first line of cellular defense against pathogens and other foreign agents. Here we will discuss studies conducted in the EU-funded Graphene Flagship project on the biocompatibility of 2D materials (Fadeel et al., 2018; Lin et al., 2024). In particular, we will highlight recent studies on the interactions between graphene oxide and phagocytic cells of the innate immune system. We will also discuss results obtained using other 2D materials including transition metal dichalcogenides (MoS_2 and WS_2) and transition metal carbides and nitrides (Ti_3C_2 MXenes) with emphasis on the innate immune responses to these materials. Biocompatibility assessment of novel heterofunctional 2D materials prepared in the EU-funded PERSEUS project to enable X-ray-triggered cancer therapy will also be discussed. Taken together, these examples will shed light on the biocompatibility (and degradability) of several different 2D materials.

SESSION SB06.04: Nanomaterial Uptake and Bio-Distribution Dynamics
Session Chairs: Avi Schroeder and Jeny Shklover
Thursday Afternoon, December 5, 2024
Hynes, Level 1, Room 111

_3:30 PM *SB06.04.01_
Defect Engineering of Transition Metal Dichalcogenides Nanomaterials and General Nanomaterials Induced Endothelial Leakiness *David T. Leong; National University of Singapore, Singapore*

Transition metals dichalcogenides (TMD) nanomaterials present many opportunities for bioapplications. Here we demonstrate a bottom-up strategy utilizing TM oxides or chlorides and chalcogen precursors to synthesize a small library of TMD nanomaterials (MoS_2*, *WS_2*, *RuS_2*, *$MoTe_2$*, *$MoSe_2$*, *WSe_2* and *$RuSe_2$*). The synthesis reactions were ultrafast under mild aqueous and room temperature conditions. Tunable defect engineering can be achieved within the same reactions by deviating the precursors' reaction stoichiometries from their fixed molecular stoichiometries. Defect engineered *MoS_2* nanomaterials for proof-of-concept biomedical applications show that increasing sulfur defects enhanced oxidative stress generation, through the photodynamic effect, in cancer cells. As many of these therapeutic and bioimaging bionanomaterials are delivered via the bloodstream, Nanomaterials induced Endothelial Leakiness (NanoEL) can greatly enhanced the accessibility of these materials to the target site from the blood side. Fundamental findings and recent applications of NanoEL for nanomedicine delivery will be discussed.*

_4:00 PM *SB06.04.02_
Internalisation and Distribution of Polystyrene Nanoparticles in Human Cells *Christoffer Åberg; University of Groningen, Netherlands*

Both for nanoparticle-based drug delivery as well as potential risks to human health posed by nanoparticles, it is pertinent to understand how nano-sized objects interact with human cells. Within this realm it is key to understand how many nanoparticles are internalised by cells, where they go once inside, and how quickly they arrive there, as the local dose will determine the majority of effects, whether they be beneficial or hazardous. Here we will discuss quantitative measurements of the internalisation efficiency and intracellular distribution of polystyrene nanoparticles in simple cell lines as a model system. We observe adsorption of these nanoparticles to the cell membrane, but most nanoparticles rapidly desorb again. Nevertheless, some nanoparticles are internalised by the cell, most of them surprisingly rapidly (~seconds), an observation we interpret to stem from non-specific internalisation. The subsequent distribution of the nanoparticles inside cells is dominated by endolysosomal processing, with the lysosomes being the predominant final location. Nanoparticles that arrive to the lysosomes *do not appear to exit the cell, but there are indications that a small fraction of internalised particles are rapidly routed back to the outside of the cell again, presumably without lysosomal accumulation. There is a large cell-to-cell variability, even for cells within the same population, in both nanoparticle accumulation and subsequent distribution. The role played by the cell-division-cycle, cell size distribution, and genetics in the nanoparticle accumulation variability can be measured, but nevertheless part of the variability remains unaccounted for.*

Nanotoxicology, Long-term Biodistribution/Excretion and Current Status of Scaled-Up Synthesis/Characterization of a Potentially Translatable Tantalum Oxide Agent *Peter J. Bonitatibus[1], Jacob Aubrey[1], John Leman[1], James Gibson[1] and Marina Dobrovolskaia[2]; [1]Rensselaer Polytechnic Institute, United States; [2]Nanotechnology Characterization Laboratory, United States*

The Nanotechnology Characterization Laboratory (NCL) under NIH's National Cancer Institute accepts the most promising cancer nanomedicine candidates into its Assay Cascade characterization and testing program. This talk will discuss very favorable hematological compatibility and in vitro immunotoxicity profile of a tantalum oxide-based material featuring a zwitterionic siloxane polymer top coating as a clinically translatable general-purpose CT contrast agent. This candidate agent exhibits (1) substantially improved imaging efficacy compared to clinical small molecule iodinated contrast agents in rats, rabbit, and swine encased in phantoms emulating larger adult abdomens including superior vascular contrast enhancement of thoracic arteries and veins, (2) promising biological safety profiles showing near-complete renal clearance and low tissue retention at 3x anticipated clinical dose (ACD), and (3) clinically acceptable physiochemical parameters as concentrated bulk solutions (250-300 mg Ta/mL). Here, we review requirements for general-purpose intravenous CT contrast agents in terms of patient safety, X-ray attenuating properties and contrast-producing capabilities, and physicochemical and pharmacokinetic properties. We report the current status of an agent, including chemical process technology developments and results of newly defined scaled-up processes for synthesis and purification yielding reproducible formulations with appropriate size and concentration specifications. We discuss recent results of recent pre-clinical in vitro immunology, non-GLP high dose tolerability in rats (10x ACD), non-GLP long term biodistribution in rats at 3x ACD, and GLP repeat dose in rats and dogs at ACD. We also include a discussion of characterization, in particular size-stability testing results under accelerated conditions (37C) and insights into purity, surface structure, and bonding of the zwitterionic siloxane polymer coating by multinuclear (^{1}H, ^{13}C, ^{29}Si) and multidimensional (2D) solution NMR spectroscopy.

SESSION SB06.05: Poster Session: 2D Materials for Theranostics
Session Chairs: Filippo Fabbri, Evie L. Papadopoulou and Jeny Shklover

SB06.05.01

Selenium Containing Dendritic Prodrugs with Anticancer Activity *Natalia Sanz del Olmo[1], Jorge San Jacinto Garcia[1], Yikai Yin[2,3], Ying Zhao[2,3], Moustapha Hassan[2,3] and Michael Malkoch[1]; [1]KTH Royal Institute of Technology, Sweden; [2]Karolinska Institutet, Sweden; [3]Karolinska University Hospital, Sweden*

Reactive oxygen species (ROS) are free radicals containing oxygen that react with other cell molecules. Under *normal physiological conditions cells control the generation of ROS through the presence of natural scavenging systems. However, elevated rates of reactive oxygen species (ROS) have been detected in almost all cancers where they promote many aspects of tumor development and progression. Among all redox modulating compounds, selenium derivatives have gained substantial attention due to their promising chemotherapeutic potential and redox modulating capacity.[1] These properties provide selenium compounds with increased selectivity for cancer cells overcoming one of main drawbacks of the current chemotherapeutic treatments. In the development of new treatments to reduce chemotherapy induced side effects, dendrimers with nanometric size arise as the ultimate unimolecular precision polymers in the biomedical field with the capability of accumulating in the tumor environment due to the enhanced permeability and retention (EPR) effect. Previously our group reported the synthesis of polyester dendrimers with internal disulfide functionalities that collapse inside human lung carcinoma cells and alter the redox balance by upregulating oxidative stress.[2] In this work, funded by the Marie Sklodowska-Curie Actions programme, selenium-containing polyester dendrimers up to third generation have been synthesized and characterized. These dendrimers contain a skeleton based on 2,2 bis-(hydroxymethyl)propionic acid (bis-MPA) with imbedded selenium functionalities. The presence of peripheral functionalities allows for the post-functionalization with interesting molecules from a biological point of view such as polyethylene glycol (PEG) or cationic groups that could potentiate the water solubility, half-life or even the anticancer potential. Due to the presence of selenium, the synthesized dendritic polymers show faster degradation profile intracellularly than extracellularly where the concentration of glutathione is considerably less. Additionally, the presence of ester bonds makes those systems responsive to pH, where at higher pHs the dendritic structures undergo degradation through a depolymerization mechanism from the exterior to the most inner layers as previously observed for traditional bis-MPA dendrimers.[3] In vitro preliminary studies indicate a promising anticancer potential towards breast cancer cells for the synthesized selenium-based dendrimers. Additionally, the presence of selenium promotes the in vitro selectivity for breast cancer cells compared to non-cancer cells, in contrast to what has been observed for analogue dendrimers without selenium used as controls.*

Photothermally Enhanced Magneto-Nano Drug Delivery for Treating Hearing Loss *Neshwanth Kumar Tene[1], Daniel Sun[1] and Donglu Shi[1,2]; [1]University of Cincinnati, United States; [2]College of Engineering and Applied Science,University of Cincinnati, United States*

Sensorineural hearing loss (SNHL) was a pervasive global health challenge, affecting millions worldwide. Despite advances, efficient drug delivery to the inner ear remained elusive, hindering therapeutic progress. This study aimed to characterize the transport dynamics of superparamagnetic iron oxide nanoparticles (SPIONs) and Brain-Derived Neurotrophic Factor (BDNF) across the round window membrane (RWM) of guinea pigs, a crucial barrier for drug delivery to the cochlea. SPION transport was investigated in relation to core size and magnetic field strength. Size-dependent transport rates were explored using custom-synthesized SPIONs under varying magnetic field strengths and exposure times. Methodology included seed-mediated growth synthesis, and rigorous physicochemical characterization. The effect of SPION surface charge on transport across the RWM was assessed. Positively and negatively charged SPIONs were tested for transport efficiency. Data analysis elucidated the impact of surface charge on SPION-RWM interactions. The photothermally-enhanced SPION transport was also investigated. Laser-induced photothermal activation was aimed at augmenting nanoparticle transport *through the RWM. Photothermal experiments and transport studies were conducted under laser irradiation. The optimal SPION properties were identified for enhanced BDNF delivery across the RWM, elucidating the roles of surface charge and photothermal activation on nanoparticle transport, and assessing transport dynamics in guinea pig and human RWM models. These findings advanced our understanding of nanoparticle-mediated drug delivery mechanisms, offering insights for targeted SNHL therapies.*

SB06.05.03

Impact of Mg Doping on Structural, Morphological and Thermoelectric Properties of SnO_2 Nanoparticles Synthesised by Hydrothermal Technique *Muhammad Isram[1,2]; [1]Università degli Studi di Modena e Reggio Emilia, Italy; [2]Government College University Faisalabad, Pakistan*

Thermoelectricity is considered a promising sustainable energy source that has ability to address the current energy scarcity. This clean and environmentally friendly technology has promise as a viable solution. The compound SnO_2 exhibits considerable potential as a versatile metal oxide, with its thermoelectric conversion capabilities being extensively utilised within the domain of waste heat recuperation. In this study, we examine the effects of pristine and doped Mg substitution on the thermoelectric characteristics of SnO_2. We synthesis pristine and Mg doped SnO_2 nanoparticles (0.05%, 0.10%, and 0.15%) was conducted using a straightforward hydrothermal technique. The investigation of the pristine and doped materials revealed that SnO_2 possesses a tetragonal rutile type structure, as determined through structural and morphological examination. The crystalline size of all samples decreases as the Mg doping concentration was increased. The analysis of the SEM images revealed that the nanostructure of the condensed nanoparticles exhibits a relatively smooth, crystal-like surface. The utilisation of Hall measurement and Seebeck coefficient has been employed for the purpose of ascertaining thermoelectric characteristics. As Mg content increased, both Seebeck coefficient and electrical conductivity value increased from -20 μV/K to -91 μV/K and 29.8 S/cm to 112.6 S/cm, confirming semi conductivity behaviour. The Mg doped 0.15, demonstrate the highest power factor when evaluated at a temperature of 150K, yielding a value of 9.4×10^{-5} Wm^{-1} K^{-2}.

SB06.05.04

Bioinspired Synthesis of Virus-Like Silica Nanocapsules with Controllable Size Using Engineered Capsid Proteins for Drug Delivery *Chang Sup Kim and Ae Sol Lee; Dongguk University, Korea (the Republic of)*

Virus-like silica nanoparticles offer significant advantages as carriers in biomedical applications, including a large surface area, excellent biocompatibility, and high loading capacity. These nanoparticles have shown superior performance in terms of prolonged blood circulation time and high binding efficiency to cancer cells compared to flat nanoparticles. In this study, we developed hierarchical silica nanoparticles by combining the controlled silica mineralization of diatom and the hierarchical structure of human papillomavirus (HPV) 16. A novel fusion protein HPV 16 L1-R5 was prepared by genetically inserting silica-forming R5 peptide from a diatom into the F-G loop of HPV 16 capsid protein L1. HPV16 L1-R5 proteins self-assembled into virus-like particles (VLPs) identical to native HPV 16. Hierarchical HPV16 L1-R5 VLP@SiNPs were synthesized with a size of ca. 60–80 nm under an optimized condition of diatom-inspired silicification. HPV16 L1-R5 VLP@SiNPs exhibited high cellular uptake efficiency compared to flat mesoporous SiNPs. We anticipate that our virus-like silica nanoparticles will serve as highly effective carriers for biomedical applications.

SB06.05.05

Optimal Biomarker Combinations for Early Diagnosis of Colorectal Cancer—AI-Driven Analysis of EV-Derived Markers Isolated by the ZAHVIS System *Bonhan Koo and Yong Shin; Yonsei University, Korea (the Republic of)*

Colorectal cancer (CRC) remains a significant contributor to cancer-related mortality globally, highlighting the critical importance of early detection for improving survival rates. While extracellular vesicles (EVs) show promise as biomarkers for CRC diagnosis, their clinical utility has been limited by complex and time-consuming isolation processes, low sensitivity, and unvalidated biomarkers.

In this study, we introduce a novel system that combines a zeolite-amine and homobifunctional hydrazide-based extracellular vesicle isolation (ZAHVIS) platform with artificial intelligence (AI) analysis. This innovative platform streamlines EV isolation with EV enrichment, enabling rapid and cost-effective extraction of EV-derived proteins and nucleic acids in a single step. The ZAHVIS platform demonstrates remarkable efficiency, completing EV isolation in just 15 minutes. Additionally, the extraction of EV-derived proteins is achieved within 30 minutes, and the extraction of EV-derived nucleic acids is completed in 35 minutes, making it a highly rapid and effective platform.

The ZAHVIS platform utilizes zeolite-amine (ZA) for its high surface area, uniform pore size, positive surface charge, and biocompatibility to efficiently capture negatively charged EVs. Malonic acid dihydrazide (MDH) enhances binding efficiency through both electrostatic and covalent interactions. MDH contains hydrazide reactive groups (C=ONHNH2) at both ends, providing dual functionality. The positively charged hydrazine groups (NH-NH2) facilitate electrostatic interactions with negatively charged EVs, while the carbonyl components (C=O) of MDH form stable imine bonds (C=N) with the amines of ZA, ensuring the successful and secure binding of EVs to the ZA surface.

Through the analysis of cell line models and blood plasma samples from 80 CRC patients across different stages and 20 healthy individuals, we identified four EV-derived miRNA biomarkers (miR-23a-3p, miR-92a-3p, miR-125a-3p, and miR-150-5p). These biomarkers were statistically validated using relative quantification (RQ) values obtained from real-time PCR and integrated with carcinoembryonic antigen (CEA) levels into an AI-driven diagnostic model. By evaluating 31 different combinations, the system identified optimal biomarker sets for overall CRC, early and late-stage, and individual stage CRC, thereby improving diagnostic accuracy across the disease spectrum.

The combination of miR-125a-3p, miR-150-5p, and CEA yielded the best diagnostic performance for overall CRC detection, achieving an area under the curve (AUC) of 0.9583, outperforming individual markers such as miR-150-5p (AUC: 0.87 without AI and 0.875 with AI) and CEA (AUC: 0.69 without AI and 0.7222 with AI). The system demonstrated perfect diagnostic performance for stages 0-1 and 2, with an AUC of 1.0, and high efficacy in detecting early-stage CRC (stages 0-2, AUC: 0.9861). This integrated approach represents a significant advancement in CRC diagnostics, offering a reliable and clinically relevant tool for early detection and monitoring.

Magnetic Elements Doped WTe_2 *Dimitre Dimitrov[1,2] and Vera M. Gospodinova[1]; [1]Institute of Optical Materials and Technologies, Bulgaria; [2]ISSP-BAS, Bulgaria*

Doping WTe_2 (tungsten ditelluride) with magnetic ions presents a promising avenue for inducing magnetic ordering within this crystal structure, potentially opening new doors for various practical applications. Our research investigates the effects of doping WTe_2 single crystals with different magnetic ions—specifically iron (Fe), vanadium (V), and chromium (Cr). We compare the magnetic and structural properties of these doped crystals, examining both annealed and unannealed states, to understand the influence of the doping process and subsequent heat treatments.

Key findings from our study indicate significant alterations in the physical properties of WTe_2 upon doping, suggesting the successful incorporation of magnetic ions into the crystal lattice. The comparative analysis between doped and undoped WTe_2 provides insight into how each type of dopant and thermal treatment affects the overall magnetic behavior and stability of the crystals. These observations could pave the way for tailoring the magnetic properties of WTe_2 for specific technological applications, such as in spintronic devices or magnetic sensors, where controlled magnetic ordering is crucial.

SB06.05.07

Functionalization of Metal Nanoparticles/2D Nanocrystals with Photosensitizers Giving Water Dispersed Nanosystems for Cancer Treatment Under Dow Dose X-Ray Irradiation

Franca Bigi[1,2], Nicola Rivi[1], Marco Bormetti[1], Giorgia Gullo[1], Evie L. Papadopoulou[3], Marco Villani[2], Francesca Rossi[2], Elena Ferrari[2] and Gloria Cenci[1]; [1]Università degli Studi di Parma, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]BeDimensional, Italy

The functionalization of nanomaterials for cancer treatments can improve their sensitivity and therapeutic efficiency, enabling to increase the stability in the body and achieve a remarkable theranostic ability.

Among cancer treatments, PhotoDynamic Therapy (PDT) is a well-known oncotherapy based on the light activation of a photosensitizer (PS) that produces reactive oxygen species (ROS), in particular singlet oxygen (1O2), highly cytotoxic, under light irradiation. The main two drawbacks of classical PDT are the very low penetration of visible or near infrared light into biological tissues and the hydrophobicity of most PSs in aqueous solution. Indeed, they form aggregates in aqueous environment thus lowering their efficiency since only the monomeric form is photoactive. In addition, they do not target only the diseased tissue when applying PDT.

To overcome the first limitation, the use of X-rays to reach deep-seated tumors is increasingly proposed in the literature. In this respect, here we present the functionalization of a novel patent-pending nanosystem (NS) made of multifunctional 2D nanocrystals able to convert low energy X-rays into reactive oxygen species and radiosensitizing agents to treat deep-seated cancers. The functionalization is performed with an ad-hoc modified photosensitizer derivative belonging to the class of porphyrins, that are the most useful class of PS employed in clinical PDT. The chemical route to obtain the novel multifunctional nanosystems is discussed and the successful organic-inorganic conjugation is confirmed by a comprehensive panel of characterization techniques, including morphological, structural and spectroscopic characterizations (UV-Vis, fluorescence, Raman, HRTEM/STEM, XPS). The potential of the nanosystems for biological applications for cancer treatment under low energy X-Ray irradiationare discussed.

SB06.05.08

Functionalized Nanomaterials Based on 2D Flakes and Metal Nanoparticles Activated by Radiation for Antitumoral Therapy

Gloria Cenci[1,2], Silvana Pinelli[2], Melissa Santi[1], Nicola Rivi[2], Marco Villani[1], Marco Bormetti[2], Elena Ferrari[1], Claudio Ferrari[1], Valentina Sinisi[1], Evie L. Papadopoulou[3], Francesco Bonaccorso[3], Filippo Fabbri[1], Franca Bigi[2,1], Giancarlo Salviati[1] and Francesca Rossi[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Parma, Italy; [3]BeDimensional, Italy

Cancer remains one of the leading causes of mortality worldwide, affecting millions of individuals and accounting for approximately 10 million deaths annually.[1] Traditional clinical approaches, such as Photodynamic Therapy and Radiotherapy, often have limitations related to low efficacy and significant side effects, highlighting the need for *more effective cancer treatments.*

Photodynamic Therapy (PDT) traditionally relies on UV – near infrared light activation of a photosensitizer to generate Reactive Oxygen Species (ROS) that destroy cancer cells. Recently, the use of X-rays as an external excitation source in PDT has proven effective due to their superior penetration capacity, extending the potential of conventional PDT to deeper tissues and overcoming the limitations of visible light penetration. Radiotherapy, on the other hand, kills cancer cells by the direct action of X-rays on biological tissues, leading to numerous side effects on non-tumoral cells.[2]

This study presents a novel patent-pending nanomaterial, based on functionalized 2D flakes and metal nanoparticles, designed as radiosensitizer and PDT mediating agent, that can be activated by an external energy source (light, X-Ray radiation), enabling to locally arrest the proliferation of cancer cells.

In vitro experiments were conducted on HT29 human colorectal adenocarcinoma cells to evaluate the cytotoxicity and efficacy of the novel nanomaterial. Cell viability and oxidative stress were assessed at different times before and after the treatment with increasing concentrations of nanomaterial and irradiation doses. The optimal conditions to enable the highest efficacy were identified, as a range of treatment parameters that result in minimal cytotoxicity of the nano-system itself and maximum enhancement of irradiation-induced effects, able to induce a significant cell viability reduction.

Acknowledgment: *This work has been funded by the Horizon Europe Project "PERSEUS" [grant number 101099423].*

Electronic Structure Modulation on SnO_2 and Hexagonal Boron Nitride with Sulfur Atom for Effective Electrochemical Sensing of Bendiocarb

Sung Mi Jung; *Korea Institute of Toxicology, Korea (the Republic of)*

Here we demonstrated the sulfur atoms induced an electronic structure modulation of SnO_2 *and its synergism with hexagonal boron nitride (hBN) by simple one-step vulcanization process. Thus, S-*SnO_2*/S-hBN exhibits extraordinary catalyst material for the electrochemical detection of a toxic insecticide bendiocarb (BDC). The introduction of sulfur atoms to* SnO_2 *and hBN results an in situ dynamic electronic structure transition, further facilitate the interactions of target with the catalyst structure. Detailed investigation of S-*SnO_2*/S-hBN indicates the role of sulfur atoms as an electron acceptor to facilitate electron transfer to* SnO_2*/hBN for the electrochemical process. The remarkable interfacial active site in S-*SnO_2*/S-hBN provides the lowest limit of detection of 0.285 μM and the best sensitivity of 0.023* $\mu A\ \mu M^{-1}\ cm^{-2}$ *under the wide range addition of BDC i.e. 0.02–150.02 μM. Meanwhile, it has proven the top-notch selectivity of BDC even at a higher concentration level of interfering molecules present. This work also satisfies the requirements of commercializing by an appreciable recovery in* *real-time analysis of food samples with accurate reproducibility and considerable stability shown for electrochemical detection of BDC.*

SB06.05.10

Thermal Conductivity Measurement of $Ti_3C_2T_x$ MXene Thin Film Using Frequency-Domain Thermoreflectance

Yuki Akura[1], Yuki Matsunaga[2], Hiroya Morotomi[1], Masaki Shimofuri[1], Amit Banerjee[1], Toshiyuki Tsuchiya[1] and Jun Hirotani[1]; [1]Kyoto University, Japan; [2]Nagoya University, Japan

Two-dimensional materials have attracted much attention due to their unique physical and chemical properties. MXene is one of the most promising 2D materials, whose chemical formula is $M_{n+1}X_nT_x$ (n=1-3, M for early transition metal, X for carbon or nitrogen, T_x for surface functional groups), and has an alternating structure of atomic layers composed of M and those of X. This 2D material has high electrical and ionic conductivity, excellent mechanical properties and physical and chemical stability, a huge specific surface area, and the ability to add functionality and control properties by chemical modification and intercalation. These outstanding properties are expected to lead to a wide range of applications, including next-generation electronic devices, transparent electrodes, photonic devices, physical sensors, biosensors, batteries, etc. For such applications, it is essential to evaluate the various physical properties of the material. Much research has been conducted to evaluate the physical properties such as electrical and optical properties. On the other hand, there are few reports on the thermal properties of MXene due to the difficulty of measurements.

The thermal conductivity of MXene was reported by R. Liu and W. Li [1] and L. Chen et al. [2], where the thermal conductivity of $Ti_3C_2T_x$ MXene film was reported. However, R. Liu and W. Li reported the thermal conductivity of thin films made from un-delaminated multilayered MXene [1], whose properties differ from those of thin films made from delaminated nano-flake MXene, which are currently widely studied. In the report by L. Chen et al., the thermal conductivity of thin films made from delaminated nano-flake MXene is measured by the T-type method [2], but measured thermal conductivity is only in the in-plane direction. MXene is a 2D material and the physical properties of thin films made from MXene are considered to be anisotropic in the in-plane and out-of-plane directions. Therefore, the evaluation of thermal conductivity in the in-plane direction alone is insufficient to discuss the thermophysical properties of MXene thin films.

In this study, a thermal conductivity measurement system using the frequency-domain thermoreflectance, which has a high sensitivity to the thermophysical properties of thin film samples, was constructed, and the thermal conductivity of MXene thin film was measured. Frequency-domain thermoreflectance is a method to measure the thermophysical properties of a sample by periodically heating the sample surface and measuring the resulting surface temperature change. In this study, delaminated nano-flake $Ti_3C_2T_x$ MXene films, produced by vacuum-assisted filtration and transferred onto a single-crystal silicon substrate, were used as the measurement sample. The thickness of the film was 108 nm. A gold thin film with a thickness of 68 nm was deposited on its surface, which acted as a heater and thermometer in the measurement, and the thermal conductivity was measured by irradiating the gold film surface with two lasers, one for heating and one for temperature measurement. The obtained temperature response was fitted to a theoretical model, and a value of 0.41±0.17 W/(m K) was obtained as the thermal conductivity of the MXene film. As the frequency-domain thermoreflectance is a particularly sensitive measurement system for the out-of-plane thermal conductivity of thin film samples, the thermal conductivity obtained in this measurement is regarded as the out-of-plane thermal conductivity of the MXene thin film. This value is determined by the thermal conductivity inside MXene and the thermal resistance between the MXene flakes. This is the first report on the out-of-plane thermal conductivity in MXene films measured by frequency-domain thermoreflectance, and the values obtained here will be fundamental parameters for future device applications of MXene.

Advanced Irreversible Electroporation Ablation with Highly Biocompatible and Conductive Catalytic Materials *Seongchan Kim[1,2]; [1]Gyeongsang National University, Korea (the Republic of); [2]Northwestern University, United States*

Irreversible electroporation (IRE) ablation has become one of the new ablation techniques for treating solid tumors. The success of IRE relies on the coverage of the whole tumor volume with a high electrical field while minimizing damage to healthy tissue. However, the irregular distribution of the high-voltage pulsed electric field is inevitably presented from the heterogeneous electrical properties of tumor tissue and surrounding structures. The inconsistency of IRE over tumor tissues induces cancer cell survival in the IRE ablation zone, increasing the risk of tumor recurrence and distant metastasis by incomplete tumor ablation. The applied high voltages frequently generate the patient's muscle cramps, further limiting the potential impact of IRE in the ablation therapies.
Novel nanoparticles with self-height conductivity during IRE ablation therapy can catalyze to enhance the effective electric field application around the tumor to expand the ablation boundary and reduce the electric threshold of tumor cell perforation, minimizing muscle contraction toward input voltages. Nanoparticle catalysis during IRE ablation of solid tumors is expected to overcome the current challenges of IRE ablation therapy. We aimed to develop highly biocompatible and conductive nanoparticles catalyzed advanced IRE ablation therapy that demonstrates enhanced cancer cell killing, minimized cancer cell survival, and CT contrast effect of IRE ablation

SB06.05.12

Development of Immune-Modulating Magnetic Nanoparticles for Dendritic Cell Maturation and Inhibition of Breast Cancer Growth *Jaesung Lim[1,1], Hee Seung Seo[1,1], Se-Na Kim[2,3], Wooram Park[1] and Chun Gwon Park[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]MediArk Inc., Korea (the Republic of); [3]Chungbuk National University, Korea (the Republic of)*

The immunosuppressive tumor microenvironment (TME) facilitates tumor growth and metastasis. Reversing this TME is crucial for effective cancer treatment. CpG oligonucleotides (ODN), well-known agonists of toll-like receptor (TLR) 9, promote dendritic cell (DC) maturation and stimulate both innate and adaptive immunity. However, achieving efficient and stable delivery of therapeutic ODN presents significant challenges. Recent advancements highlight the potential of magnetic nanoparticles (MNPs) combined with surface modifications. Cationic polymers like polyethyleneimine (PEI) can complex with ODN through strong electrostatic forces, offering enhanced delivery efficacy. The high surface area of MNPs chemically coated with PEI allows for the loading of CpG ODN, resulting in more efficient DC maturation compared to free CpG delivery. This study explores the potential of PEI-coated functionalized magnetic nanoparticles (FMNPs) to enhance the delivery efficacy of CpG ODN, aiming to minimize cytotoxicity and achieve efficient DC activation.
The fabrication of FMNPs involved changes to their physicochemical properties at each step. The final product, CpG-FMNPs, exhibited a size of approximately 150 nm, an 8% (w/w) ODN binding affinity, and high cell viability. Additionally, there was a 1.5 to 2-fold increase in the expression of surface markers CD80, CD86, CD40, and MHC class II on DCs compared to the same dose of free CpG. To confirm the reversing effects on the immunosuppressive nature of TME, CpG-FMNPs were administered to a 4T1-Luc2 breast cancer model. Intratumorally inoculated CpG-FMNPs led to observed tumor size regression for up to 25 days. These results suggest that CpG-FMNPs activate DCs in close proximity to the tumor site, thereby enhancing the immune response against the tumor.
In this study, we successfully developed FMNPs for the efficient delivery of CpG ODN to immature DCs, eliciting tumor suppression effects. The heat-up synthesis method was used to synthesize the MNPs, which were

subsequently coated with caffeic acid, polydopamine, and PEI. Comprehensive in vitro and in vivo experiments were conducted to evaluate the biocompatibility, delivery efficiency, and immune-modulating capabilities. This approach demonstrated significantly improved delivery efficacy of CpG ODN and presents a promising immunotherapeutic method. While CpG-FMNPs might lead to DC maturation in tumor tissue, further studies are necessary to explore systemic immunity in the spleen and lymph nodes by confirming changes in T cell populations.

SB06.05.13

Increasing the Efficiency of the In-Plane Seebeck Effect in the Homostructure Through O2 Plasma Treatment on the PtSe2 Surface *Gangmin Park, Sang-Kwon Lee, Gil-Sung Kim, No-Won Park, Won Yong Lee, Min-Sung Kang, Jae Won Choi, Yun-Ho Kim, Jung-Min Cho and Hyeok-Jun Kwon; Chung-Ang University, Korea (the Republic of)*

Transition metal dichalcogenide (TMDC) films have garnered significant attention in the semiconductor field due to their exceptional thermoelectric properties. When TMDCs are stacked in multiple layers and bonded by van der Waals forces to form a homo- or heterostructure, these materials exhibit unusual thermoelectric characteristics. In our research, we employed PtSe2 as a 2D TMDC material and created a PtSe2/PtSe2 (3 nm/3 nm) homostructure. Prior to stacking the PtSe2 layers, the surfaces were subjected to O2 plasma treatment, inducing vacancies at the junctions between the PtSe2 layers. We investigated the effect of these vacancies by preparing several samples with varying O2 plasma treatment durations and measuring the in-plane Seebeck effect in each sample. The presence of vacancies facilitates the exchange of momentum by charge carriers, driven by the temperature gradient in the vertical direction. As a result, the electrical conductivity remains unaffected even as the stacked structure thickens, while the Seebeck coefficient is enhanced.

SB06.05.14

Temperature-Dependent Thermal Transport of Vertically Stacked Two-Dimensional $PtSe_2$/$PtSe_2$ Homo-Structure *Jung-Min Cho, Gil-Sung Kim, No-Won Park, Min-Sung Kang, Jae Won Choi, Yun-Ho Kim, Gangmin Park and Sang-Kwon Lee; Chung-Ang University, Korea (the Republic of)*

Two-dimensional (2D) transition metal dichalcogenide (TMDC) thin films are attracting significant attention as next-generation materials due to their tunable energy band gaps. In particular, 2D $PtSe_2$ thin films are excellent materials that can adjust their energy band gaps based on thickness. Additionally, a non-ideal thermoelectric effect has been discovered in stacked structures of 2D TMDC thin films. Typically, the Seebeck effect according to thickness is expressed as a parallel conductor model. However, in the case of vertically stacked 2D $PtSe_2$ thin films, a non-ideal Seebeck effect has been observed. Our research reports that vertically stacked $PtSe_2$ thin films exhibit an improved Seebeck coefficient compared to 1-stacked $PtSe_2$ films due to interfacial effects. This enhancement is attributed to the interaction of hot carriers with the interface, which results in properties independent of the general Seebeck coefficient. Measurements using self-manufactured thermoelectric performance equipment (CAU-system, CAU-SYS) show that the Seebeck coefficient increased by approximately 261% in 4-stacked $PtSe_2$ samples compared to 1-stacked $PtSe_2$ samples. Additionally, the power factor increased dramatically by about 570% in 5-stacked $PtSe_2$ samples. Furthermore, temperature-dependent measurements using Quantum Design's physical properties measurement system (PPMS) demonstrate that this phenomenon remains stable even at low temperatures. The decrease in Seebeck coefficient, electrical conductivity, and power factor with decreasing temperature can be explained by the temperature-dependent electronic behavior of p-type $PtSe_2$ semiconductors. To calculate the figure of merit (ZT), thermal conductivity measurements are being conducted using the heat diffusion imaging method. This research highlights the dramatic improvement in thermoelectric performance due to the interface-induced Seebeck effect in vertically stacked structures. Therefore, it is anticipated that semiconductor and thermoelectric research using stacked structure technology *will be actively pursued in the future.*

SB06.05.15

Spectroscopic Signatures of Layer Rotation and Grain Boundaries in WSe_2 *Sourav Paul, Abhijith M B, Chandra Sekhar Tiwary and Vidya Kochat; Indian Institute of Technology Kharagpur, India*

Two-dimensional transition metal dichalcogenides, a novel class of 2D layered materials, exhibit interesting optical and electronic properties that are markedly different from bulk characteristics. Artificially stacked bilayers and defects in monolayer transition metal dichalcogenides allow us to explore unique quantum effects in these 2D semiconductors. Here we report spectroscopic signatures of twisted bilayer WSe_2 and different types of grain boundaries in monolayer WSe_2. 2D bilayers obtained by stacking atomically thin monolayers with specific twist angle form Moiré superlattices which offers an excellent platform to achieve artificial quantum materials with emergent optical and electronic properties. The twist angle modifies the band structure, interlayer coupling in transition metal dichalcogenides and offers new excitonic properties such as characteristic of Moiré excitons, exciton-phonon coupling etc. We fabricated the twisted bilayer WSe_2 samples with twist angles ranging from 0 to 60^0. The Raman spectroscopy suggest how interlayer coupling changes with twist angle. The generic quantum effects on electron and exciton transport across the grain boundary on monolayer WSe_2 is still unclear. Here using photoluminescence mapping we have investigated the different types of grain boundaries in monolayer WSe_2 such as mirror and tilt grain boundaries. Along with identification of grain boundary angle, these maps also provide useful insights into defect-induced quenching and doping-induced enhancement of photoluminescence for various grain boundary configurations.

SB06.05.16

Hybrid Nanosystems to Treat Deep-seated Tumors Under X-Ray Irradiation *Marco Bormetti[1], Gloria Cenci[1,2], Nicola Rivi[1], Paolo Minessi[1], Elena Ferrari[2], Francesca Rossi[2] and Franca Bigi[1,2]; [1]Università di Parma, Italy; [2]Consiglio Nazionale delle Ricerche, Italy*

Photodynamic therapy (PDT) is a clinical approach to treat cancer by activating a photosensitizer (PS) through light exposure ranging from UV to near-infrared. This activation induces the production of reactive oxygen species (ROS), particularly singlet oxygen ($^1O_2$), well known for its cytotoxic impact on cancer cells. Studies reported in the literature highlighted the possibility to enhance $^1O_2$ production by combining photosensitizers with metal nanoparticles under laser irradiation. The main drawback of conventional PDT lies in the limited penetration of visible light in biological tissues, impeding effective photosensitizer excitation in deeper tissues. Consequently, substantial efforts have been directed towards overcoming this limitation through X-ray irradiation. Metal nanoparticles with elevated Z values exhibit efficient X-ray absorption, facilitating energy delivery to surrounding tissues[1]. It has been reported that the presence of photosensitizers onto metal nanoparticles (NPs) could enhance their $^1O_2$ and ROS generation. In particular, Gold nanoparticles (AuNPs) have gained prominence due to their biocompatibility, making them widely used as contrast agents.

This study presents the synthesis of new hybrid nanosystems realized by conjugating rose bengal (RB) derivatives, prepared by reacting a proper linker with the RB carboxylic moiety, to AuNPs. An effective binding was obtained and the ability of the nanosystems to produce $^1O_2$ and ROS under irradiation was demonstrated. Preliminary biological tests were performed, demonstrating the efficacy of a nanosystem-mediated X-Ray triggered treatment.

Fabrication of Oxidized Transition Metal Dichalcogenides Monolayers for van der Waals Heterostructure

Junwon Jang, Jae-Ung Lee and Seungjae Lim; Ajou University, Korea (the Republic of)

This study explores oxidized monolayer transition metal dichalcogenides (TMDs) as a new functional layer in van der Waals (vdW) heterostructures. We investigated the influence of mild O_2 *plasma treatment on the optical properties of TMDs. Single-layer and multilayer samples of TMDs were prepared using metal-organic chemical vapor deposition (MOCVD) and mechanical exfoliation. Thickness was determined by optical contrast, photoluminescence (PL), and Raman spectroscopy. We systematically investigated the effect of* O_2 *plasma treatment on the optical properties of TMDs. Raman spectroscopy exhibited notable peak shifts in the* E_{2g} *and* A_{1g} *modes of TMDs with* O_2 *plasma treatment, indicating the formation of TMD oxides on the surface layer. PL spectroscopy showed changes in emission intensity and peak positions, further corroborating the selective oxidation of the surface layers. Interestingly, the oxidized monolayers of TMDs exhibited enhanced optical transparency, which is attributed to the reduced excitonic effect due to oxidation. This makes oxidized TMDs promising as a functional layer in vdW heterostructures based optoelectronic devices, where high transparency is essential. Furthermore, oxidized surface layers act as effective protective layers. These layers prevent the degradation of the underlying material, thereby enhancing the lifetime and reliability of the devices.*

We fabricated vdW heterostructures using oxidized monolayer TMDs as a constituent layer. The oxidized monolayers are easily integrated into the fabrication process of vdW heterostructures. A simple dry stamping method is used to create functional vdW heterostructures. Oxidized monolayers are used to control the interlayer interaction, which allows us to design the optical properties of the fabricated vdW heterostructures. Mild O_2 *plasma treatment of TMDs offers a straightforward and effective method for enhancing their optical properties and functionality. The selective oxidation process enables the creation of heterostructures with tunable properties, improved stability, and enhanced performance. These findings highlight the potential of oxidized TMDs as transparent functional layers and protective coatings in van der Waals heterostructure-based optoelectronic devices.*

Degradation of Cephalexin in the Presence of Pure and Doped ZnS Nanostructures

Kerianys N. Torres, Angelie M. Núñez Colón and Sonia Bailon Ruiz; University of Puerto Rico in Ponce, United States

The rapid discharge of antibiotic pollutants into natural water sources by pharmaceutical industries poses a significant threat to human health and the environment. This issue has become a global concern due to its adverse effects on ecosystems and potential risks to human well-being. Organic pollution is challenging to address because conventional water treatment methods often fail to remove these contaminants effectively and because they can develop resistance. Consequently, there is a pressing need for environmentally friendly approaches to degrade these pollutants. In recent years, semiconductor materials such as zinc sulfide have attracted attention for their potential to degrade organic contaminants, thanks to their unique optical and electronic properties. This study aimed to generate iron-doped zinc sulfide nanoparticles using a microwave-assisted technique in an aqueous solution. The primary objectives were twofold: first, to synthesize pure and doped zinc sulfide nanoparticles while evaluating the photocatalytic efficiency in the degradation of Cephalexin antibiotic. The results of the photoluminescence spectroscopy revealed strong emission peaks with varying intensities attributed to changes in reaction times and temperature. Results in photocatalytic efficiency are evidenced by the QTOF-LC-MS, which shows that pure and doped ZnS could degrade the antibiotic pollutant of Cephalexin. The photocatalytic

pathway of Cephalexin included hydroxylation, demethylation, decarboxylation, and dealkylation.

A Nano Analysis Method for Early Diagnosis of Prostate Cancer with PCA3 Biomarker Through Surface Enhanced Raman Spectroscopy

Xinying Yao[1], Arthur McClelland[2] and Tingying (Helen) Zeng[3]; [1]Choate Rosemary Hall School, United States; [2]Harvard University, United States; [3]InnoBridge Institute, United States

Prostate Cancer (PC) is one of the most common cancers among male patients. The diagnosis process is challenging when distinguishing between indolent and aggressive PC. Current diagnosis includes PSA test, which requires other tests such as MRI or tissue biopsy to further distinguish the type and phase of prostate cancer. A clinically significant Prostate Cancer (csPC) requires a PSA level higher than 20 ng/mL. Previous research on determining whether a patient qualifies for csPC focused mainly on different calculation systems using multiple biomarkers found in patients' urine samples. Exosomal Vesicles (EV) are lipid bilayer organelles containing various proteins and RNAs, including Prostate Cancer Antigen 3 (PCA3), a messenger RNA that is overexpressed in PC patients. In this research, we demonstrate the effect nano analysis of trace concentration of biomarker PCA3 through Surface Enhanced Raman Spectroscopy (SERS) with silver nanoparticles. After established the SERS enhancement versus the concentration of PCA3 calibration curve, artificial urine samples are used for the study. This SERS nano analysis shows a highly sensitive method to diagnose trace concentration changes in artificial urine samples, indicating its great potential for the early diagnosis of Prostate cancer for patients near future. This would allow doctors to find effective treatments for the patients as early as possible, so as to save their lives.

Fabrication of Resistance-Changing Silicon Dioxide Nanofilms and Their Potential for Secure Communication

Kosei Ando[1], Takeru Suzuki[1], Takahisa Ichinohe[2], Ritsuko Eguchi[1] and Seiichi Sato[1]; [1]University of Hyogo, Japan; [2]National Institute of Technology, Tokyo College, Japan

Internet of Things (IoT) devices are particularly vulnerable to cyberattacks, necessitating advanced security measures, especially for medical and healthcare wearable devices transmitting sensitive personal and life-critical data. However, these devices face limitations due to their materials, computational power, and size. Chaos cryptography, using simple chaotic circuits, offers a promising solution to these constraints. By modulating chaotic waves generated by these circuits with data signals, highly secure transmission can be achieved. Incorporating resistance-changing materials like memristors into these circuits further enhances security.

In this study, we experimentally demonstrate that SiO_2 nanofilms exhibit memristive-like resistance changes. Unlike traditional oxide memristors, our nanofilms do not require doping. By adjusting the thickness of the SiO_2 nanofilms to approximately 5–10 nm, the nanofilms mostly retain capacitive properties while enabling current injection. In addition to these properties, the formation of Schottky barriers at the electrode/SiO_2 nanofilm interfaces induces memristive-like resistance changes. We then simulated encryption/decryption capabilities of chaotic circuits incorporating SiO_2 nanofilms to evaluate their potential as security devices.

SiO_2 nanofilms up to ~10 nm were grown on Si substrates through thermal oxidation, with the substrates serving as bottom electrodes. Au films were sputter-deposited on the nanofilm surfaces as top electrodes. Applying sine wave voltages (100–1000 Hz) across electrodes injected carriers into the nanofilms, and current–voltage characteristics were systematically examined. SiO_2 nanofilms demonstrated memristive-like resistance changes, maintaining high resistance (R_H) during voltage increases and low resistance (R_L) during decreases. For instance, when a 5 V sine wave voltage was applied to an SiO_2 film (~6 nm thick), R_H/R_L ratios at 3 V were 4.4 at 100 Hz and 1.6 at 1 kHz. As an equivalent circuit for these electrical characteristics, we considered a circuit composed of a resistor and capacitor representing the SiO_2 nanofilm, and two diodes representing the Schottky barriers at the electrode/SiO_2 interfaces. The LTspice simulations of this equivalent circuit closely matched the experimental

results. The capacitance values chosen to match the experimental results were reasonable, assuming a typical dielectric constant of SiO_2 (3.9); however, the resistance values were significantly lower than expected. Possible reasons for this discrepancy include leakage current passing through defects in the SiO_2 nanofilms, Fowler–Nordheim tunneling, and/or bandgap narrowing due to many-body effects arising from electron-hole interactions between the electrodes and SiO_2.

We conducted simulations of chaos-based encrypted communications using Chua's circuit with SiO_2 nanofilms. The rate of voltage change in the chaotic wave was modulated by data signals in the chaotic circuit of the transmitter. To simulate thermal noise during actual communication, white noise was added to the modulated chaotic wave before it was transmitted to the receiver. At the receiver end, the signal was decrypted by comparing the received chaotic wave with that generated by the chaotic circuit of the receiver. MATLAB/Simulink simulations showed that even with a signal-to-noise ratio of 10 dB, the communication accuracy remained at 95%, demonstrating robust noise-resistant communication.

SiO_2 nanofilms are suitable for applications owing to their easy integration into existing microfabrication processes and their simplified manufacturing, which does not require doping procedures. In addition, because they are constructible using SiO_2, Si and Au, security devices can be easily incorporated into medical and healthcare IoT devices.

SB06.05.23

Two-Dimensional Anisotropic Semiconductor for Highly Polarized Quantum Photonic Devices *Avijit Dhara; Indian Institute of Technology Kharagpur, India*

Two-dimensional (2D) layered materials such as graphene and group VI transition metal dichalcogenides (TMDs) have gained considerable interest due to their fascinating optical and electronic properties, with promising applications in photonics and optoelectronics. In contrast, group VII Re-based chalcogenides like rhenium disulfide (ReS2) have been less extensively studied. These materials exhibit strong anisotropic optical and electronic properties, attributed to their reduced crystal symmetry. Notably, excitonic resonances in ReS2 remain strongly bound even in multilayer configurations due to the decoupling of layers. The structural anisotropy complicates the understanding of ReS2 electronic band structure. This work significantly advances the comprehension of complex band structure of ReS2 and its anisotropic optical resonances, highlighting their potential applications in developing polarized exciton-polaritons and a thresholdless polariton-Raman laser.

SB06.05.24

Rapid Crystal Growth and Its Control of C60 by Mist-Vapor Deposition Method *Shigetaka Katori and Risako Taguchi; Tsuyama College, Japan*

Mist-Vapor Deposition (MVD) method, a new film deposition technology using ultrasonic spraying, is attracting attention as a next-generation semiconductor process. We are studying the process of mass production and large area of various flexible devices. Practical application of flexible devices requires deposition technology to fabricate highly controlled thin films and crystals in a short time. In general, vacuum evaporation and spin coating are the most widely used processes for organic semiconductor materials, but neither is suitable for mass production. This is because it is difficult to deposit films on large-area substrates and flexible substrates. The advantages of the MVD method are that films can be deposited under atmospheric pressure and that it can be easily applied to large-area substrates. Furthermore, the properties of the thin film can be highly controlled by controlling simple parameters.

Fullerenes are typical organic semiconductor materials that exhibit n-type properties. Its crystals are known to form face-centered cubic lattice (fcc) and hexagonal crystals (hcp). However, it is difficult to form and separate these crystals in a short time. In this study, we investigated the control of crystallinity in the preparation of fullerene *crystals by using two different solvents with different boiling points. A solvent with a boiling point of about 170°C was used as the main solvent to dissolve the fullerene, and a solvent with a boiling point of about 250°C was used as the additive solvent. The crystallization of fullerenes was controlled by changing the mixing ratio of the additive solvents to control the evaporation rate of the solvents. The deposition temperature was varied from 65°C to 150°C in 5 degree increments. The flow rate of the carrier gas transporting the mist and the deposition time (10 min) were kept constant. The surface of the deposited thin film was observed using a scanning electron microscope (SEM). The crystal structure was analyzed by XRD.*

There was a significant difference in the formation of crystals between the films deposited using only the main solvent and those deposited using mixed solvents. Rod and cubic crystals were formed in both the main solvent only and the mixed solvent, but the crystal formation temperatures and crystal shapes were different. XRD analysis revealed that fcc and hcp were formed in a mixture. However, the hcp peak became smaller when mixed solvents were used. This result suggests that not only the crystal shape but also the crystal structure can be controlled by controlling the solvent mixing ratio and deposition temperature. It was also found that crystals formed in only 10 minutes, even at temperatures as low as 100°C.

SB06.05.25

Effects of Graphene Oxide and Partially Reduced Graphene Oxide on Escherichia Coli and Staphylococcus Aureus

Sichen Liu[1,2], Anastasiia Bezugla[3,2], Ariel Khavulya[4,2], Tavan Bhatia[5,2], Shi Fu[2], Stephen Walker[6], Rebecca Isseroff[2] and Miriam Rafailovich[2]; [1]Shanghai Foreign Language School, China; [2]Stony Brook University, The State University of New York, United States; [3]American International School - Salzburg, Austria; [4]Rambam Mesivta High School, United States; [5]Cornell University, United States; [6]Stony Brook School of Dental Medicine, United States

Escherichia coli (E.Coli) and Staphylococcus aureus (S.A.) are common bacterial species and leading causes of infectious diseases, especially dangerous among the elderly. Previous literature has shown that graphene oxide (GO), composed of strongly oxidized carbon nanosheets; and partially reduced graphene oxide (pRGO), made by partially reducing GO - display antibacterial properties. The effectiveness of GO and pRGO to combat these two bacteria was examined in this study.

E.Coli and S.A. were diluted in a 1:10 ratio with water (control group) or GO or pRGO (experimental groups) and the mixtures incubated while shaken for three days and then examined for cell viability; experimental results demonstrated that neither GO nor pRGO possessed antibacterial properties against these two strains. When GO or pRGO solutions were added into E. Coli and S.A. solutions in a 1:1 ratio and incubated, no obvious increase in the number of dead cells was observed in a live/dead stain using an EVOS Microscope. However, it was noted that in the mixture of E. Coli with either GO, pRGO, or both GO and pRGO together, large clumps of E. Coli were observed under transmitted light microscopy.

Thus, it was speculated that GO and pRGO may promote the formation of biofilms in these bacteria. To measure the extent of biofilm production, a crystal violet assay was conducted. The violet absorbance intensity of four identical samples of each of the two bacteria incubated with GO and pRGO was measured, with a higher absorbance indicating greater formation of biofilm. In the E. Coli assays, the optical density (OD) of the control was 0.22 at 592 nm, while the absorbance of E. Coli incubated with GO was 0.47; incubation with pRGO had an OD of 0.54, and E. Coli incubated in a mixture of GO and pRGO had an OD of 0.43, indicating that all three test mixtures more than doubled the biofilm production as compared to the control. In contrast, GO seems to inhibit biofilm formation in S. aureus by 40%; pRGO does not exhibit a significant effect on biofilm formation, having an optical density similar to that of the control, 0.30; and a mixture of GO and pRGO decreased the OD by 20%. These findings suggest there may be a difference in the response to GO and pRGO between gram negative bacteria such as E. Coli and gram positive bacteria such as S.A., with both GO and pRGO stimulating biofilm production in the gram negative but not the gram positive bacteria. Other gram negative and gram positive bacteria will be tested in the future to see if this is the trend.

To determine whether GO and pRGO are actually pro-bacterial by inducing the formation of biofilms to protect the bacteria from external threats, E. coli was cultured in a 6-well tissue culture plate for two days: two samples in phosphate-buffered saline (PBS), two in a 1:1 mixture of GO and pRGO, one in GO, and one in pRGO. Each sample was divided and treated with either PBS or ampicillin to discern whether the biofilm provides resistance to ampicillin. Results will be discussed.

SESSION SB06.06: Advances in Bio-Sensing

Multiplex Pathogenic Bacteria Detection in Milk with the Nanoparticle-Assisted Porous Silicon-Based SERS Microarray Biosensor *Divagar Muthukumar[1], Omer Tamari[2] and Giorgi Shtenberg[1]; [1]ARO Volcani Center, Israel; [2]The Hebrew University of Jerusalem, Israel*

The ongoing threat of milk-related pathogens poses a substantial risk to human health, necessitating the development of efficient detection methods. This study explores the creation of a SERS based multiplex biosensor to meet the demand for simultaneous detection of multiple pathogens, thereby reducing measurement time and enhancing food safety. The biosensor utilizes an indirect immunoassay, leveraging gold nanoparticles as selective Raman reporters and a silver nanoparticle-modified porous silicon microarray (Ag-pSi) as the SERS substrate. In the initial phase, experiments focused on optimizing physical parameters and conditions, leading to the successful construction of an assay capable of detecting bacterial cells, specifically E. coli, S. aureus, and B. cereus, within the concentration range of log1 to log5 CFU/mL, with detection limits of 6 CFU/mL, respectively. The assay's selectivity was validated through experiments involving common interfering pathogens. Subsequently, the developed assay was applied to detect specified bacterial cells spiked in various milk qualities and presented recovery values ranging from 80% to 105%. Notably, the overall assay timing was maintained under 90 minutes. These findings underscore the efficacy of the multiplex detection approach for bacterial pathogens in diverse samples, representing a significant advancement toward the realization of a portable SERS biosensor.

Immune State Monitoring by Resilient 3DFG Electrochemical Aptamer-Based Sensor *Liyang Wang[1], Reem Khan[1], Daniel Ranke[1], Xudong Ji[2], Jonathan Rivnay[2] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]Northwestern University, United States*

Immunotherapies such as cytokine therapy regulate cell communication in the tumor environment and activate the innate immune system to fight against malignancies. Hyperactivation of immune system induces cytokine release syndrome which secretes excessive cytokines and leads to severe illness during immunotherapy. Monitoring patients' cytokine concentration to measure immune state will provide valuable information for immunotherapy dosage guidance. Electrochemical aptamer-based (E-AB) sensors allow real-time, label-free, selective, and accurate detection of cytokines with low limit of detection. However, state-of-art gold electrode E-ABs suffer from voltage-driven desorption and competitive displacement of gold-sulfur thiol bond by thiolated molecules in biofluids. Here, we report an E-AB biosensor based on 3-dimensional fuzzy graphene (3DFG) electrodes, modified with aptamers using robust binding chemistries to enhance the sensitivity and stability of the *sensor. Wafer scale plasma enhanced chemical vapor deposition synthesis of 3DFG is optimized to allow a highly controlled graphene flake density. Flake density facilitates fast electron transfer of redox reporter signal upon target binding, thereby improving sensitivity. Covalent bonds to the graphene flakes are used to decrease aptamer desorption. Preliminary data indicates 3DFG E-AB sensors stability post 48-hour continuous square wave voltammetry scans. With improved stability in cytokine detection, resilient 3DFG E-AB sensors have the potential for translational immune state monitoring for long-term in vivo and clinical measurement. Integrating with cytokine therapies, 3DFG E-AB sensors can achieve feedback regulated immunotherapies which prevent side effects and improve efficacy of treatment outcomes.*

Corona Phase Molecular Recognition of Fluorescent Carbon Nanotube for Theragnostic *Wonjun Yim, Xiaojia Jin, Maeve E. McGinnis, Xun Gong, Gabriel Sánchez-Velázquez, Zitang Wei and Michael S. Strano; Massachusetts Institute of Technology, United States*

Understanding molecular recognition is of fundamental significance in theragnostic. The key to biorecognition lies in unique three-dimensional structures that create binding sites, or interfaces, capable of recognizing a specific molecule such as antibodies or aptamers. We have introduced various synthetic heteropolymers, designed to adsorb onto a single-walled carbon nanotube, forming a specific corona phase that exhibits a highly selective optical response to target analytes. This technique is called Corona-Phase Molecular Recognition (CoPhMoRe). Leveraging the CoPhMoRe technique, we have developed more than 20 nanosensors for hormones, vitamins, neurotransmitters serum proteins, and reactive oxygen species. In this session, we plan to discuss carbon nanotube fluorescent sensors and their potential in cancer diagnostics. We have created a novel polymer library to engineer the corona phase of carbon nanotubes. An array of selected nanosensors exhibits the ability to distinguish cancer biomarkers. Lastly, we will introduce a novel two-dimensional (2D) polymeric material that is chemically stable and highly processable. These 2D polymeric materials exhibit strong fluorescence that may have significant value in future sensing and imaging applications

11:00 AM SB06.06.04
Systematic Closed-Loop Identification Method for Volatile Organic Compound-Selective Peptide Recognition Element on Carbon Nanotubes *Daniel Sim[1,2] and Steve Kim[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States*

Ubiquitous, autonomous, and real-time biomarker sensing is imperative to human health and performance monitoring. Volatile organic compounds (VOCs) found in exhaled breath are essential biomarkers for assessing human physical and physiological status. Biorecognition elements (BREs), biological materials with high affinity to the target molecules, can be used to detect VOCs. Among BREs, short peptides are promising for realizing sensors as they offer chemical stability and design flexibility. Although high-throughput methods are available to identify potential peptide libraries using computation and biological assays, realizing the tangible device requires follow-up experimental characterization in an operationally relevant environment to optimize peptide-based sensors. However, this in-operando characterization is challenging and time-consuming because the interface between peptide and tangible devices is an additional factor that can compromise functionality. Here, we present a novel closed-loop pipeline to optimize peptide-functionalized sensors in-operando based on data-driven feedback. As a proof of principle, a carbon nanotube (CNT) chemiresistor platform serves as a tangible device. CNTs have been widely used as chemical sensors due to their advantageous characteristics, such as being nano-sized, mechanical/electrical stability, and compatibility with functional materials. The suggested method comprises *library identification, solution preparation, fabrication, output acquisition, and analysis, and then data-driven feedback suggests new peptide combinations for the specific targets to iterate the following pipeline to reach improved performance. First, the pipeline randomly selects two peptides from the library. Then, each step is performed and evaluated regarding the solubility of the peptide in the CNT solution and device fabrication yield. The fabricated devices generate outputs that are CNT resistance changes in response to the VOC. The output data are used to perform cluster analysis to evaluate the performance in differentiating target VOCs. The analysis results and peptide properties provide an idea to suggest a new combination of peptides, and then the subsequent pipeline starts testing the suggested peptides. These feedback-based systems improved the clustering performance of the peptides after three iterations, demonstrating efficient and rapid optimization compared to random repetition. This methodology paves the way for the high-throughput design of tangible devices functionalized by the peptide sequence specific to target VOCs and developing susceptible CNT-based VOC sensors.*

Solution-Gated One-Piece ITO-Based 2D Transistor for Biosensing Applications *Toshiya Sakata, Ritsu Katayama and Akiko Saito; The University of Tokyo, Japan*

Solution-gated field-effect transistors (FETs) have attracted attention owing to their applicability to biological sensing. Various semiconductive materials have been widely utilized as the channel of FETs for biosensing devices, such as one-dimensional (1D) and two-dimensional (2D) materials. When the channel thickness of 2D materials is smaller than the maximum depletion width, which is more than the extrinsic Debye length, that is, the screening length of Coulomb scattering, the electrical communication between the source and drain (S/D) electrodes is induced by a very small density of free electrons in the depletion region, resulting in a clear on/off state of FETs. Thus, 2D-material FETs, the channel thickness of which is controlled to be approximately less than the depletion width, are expected to be highly sensitive in detecting of biomolecules that attach to the channel in a solution. That is, a solution-gated 2D-channel FET biosensor, the channel of which is directly in contact with an electrolyte solution, is expected to have a steep subthreshold slope (SS), resulting in an ultrahighly sensitive biosensing owing to a relatively large capacitance of the electric double layer at the electrolyte solution/channel interface.

Among such semiconductive materials, we focus on a thin-film indium tin oxide (ITO) with a thickness less than 30 nm, which is useful as the channel of a solution-gated 2D-channel FET biosensor [1–3]. In particular, the solution-gated ITO-based FET sensor with the ultrathin channel was fabricated by a one-step procedure, which contributed to the all-by-ITO technology [1]. This was simply realized by using the metal shadow mask with thin sheets at both ends because the bottom of the metal shadow mask corresponding to the channel became slightly raised from the substrate owing to the thin sheets and then some particles crept into the gap during sputtering. The 20-nm-thick ITO channel resulted in the bandgap increase and free-carrier depletion in the same way as in 2D materials. The threshold thickness of the depleted ITO channel was determined to be approximately 30 nm from the significant change in the on and off current ratio. The remarkably steep SS (ca. 60–80 mV/decade) was derived from the interfacial trap-free structure based on the one-step fabrication, which was due to the absence of the interfaces among source/channel/drain ITO electrodes "One-Piece ITO-based 2D Transistor", as well as the relatively large capacitance of C_{dl} based on the direct contact of electrolyte solutions with the ITO channel, and caused the exponential pH sensitivity in the subthreshold regime. This one-piece ITO-based 2D transistor could be fabricated by an etching method of 100 nm-thick conductive ITO to 20 nm-thick semiconductive ITO channel [2]. Moreover, in this talk, we would like to show the ultrasensitive DNA detection as a model of biomolecular recognition in the subthreshold regime of the one-piece ITO-based 2D transistor [3] and then mention its perspective.

Enzyme Engineering to Produce SWCNT Nanosensors as a Generalizable Platform for Biochemical Sensing

Shoichi Nishitani and Markita Landry; University of California, Berkeley, United States

Single-walled carbon nanotubes (SWCNT) stand out as attractive candidates for near-infrared (nIR) fluorescent imaging and chemical sensing. However, to render SWCNT chemically-selective, rational design of the surface corona is required to achieve sufficient sensitivity and selectivity to the target analyte. Recently, we reported on a facile sonication-based generation of glucose oxidase (GOx)-SWCNT conjugate for glucose detection [1]. Notably, we found that the analyte response mechanism does not involve catalytic oxidation of glucose, which motivated us to develop nanosensors using catalytically inactive GOx for enhanced reversibility and biocompatibility. In this study, we study the generalizability of our approach in producing SWCNT-based nanosensors based on 1- facile direct probe tip sonication, and 2- with engineered enzymes, showing the potential applicability of the sonication-based approach as a generalizable strategy for generating rationally designed nanosensors capable of detecting and imaging various analytically-relevant biomolecules.

In this work, to test the generalizability of generating enzyme-SWCNT nanosensors, we generated conjugates by facile direct sonication of SWCNT with following enzymes: GOx, choline oxidase (ChOx), horseradish peroxidase (HRP), acetylcholineesterase, tyrosinase, cholesterol oxidase (CholOx), lactate oxidase, alcohol oxidase, xanthine oxidase, and galactose oxidase. Remarkably, six out of nine enzymes yielded stable suspensions of enzyme-SWCNT conjugates following probe-tip sonication, all of which successfully worked as nanosensors to detect their corresponding analytes. These nanosensors, in particular HRP-SWCNT and CholOx-SWCNT, exhibited excellent responses to their targets, with a maximum ΔF/F0 of up to 300% and 100%, respectively. H_2O_2 is known to quench SWCNT fluorescence, and H_2O_2 nanosensors previously developed with SWCNT exhibited a negative fluorescence modulation as the sensor output with some challenges towards nanosensor selectivity. We highlight that our approach enables HRP-SWCNT nanosensor generation, which provides a strong $\Delta F/F_0$ = 300% and instantaneous turn-on response towards H_2O_2 within 2 s. Next, we sought to show that enzyme inactivation can produce SWCNT-based nanosensors that detect analytes without analyte consumption. To do so, we use ChOx as a model system to show that recombinant enzymes can be used as a generalizable approach to generating catalytically-inactive nanosensors. As expected, nanosensors prepared with mutant-ChOx exhibited responses comparable to those prepared with native ChOx, but without consuming the analyte or producing toxic byproducts such as H_2O_2. Thus, sonication-based physisorption of engineered enzymes to SWCNTs holds the potential to facilitate rapid nanosensor generation capable of detecting various biologically relevant molecules with reversibility and biocompatibility, thereby motivating their use in in vivo applications.

SESSION SB06.07: Advances in Biomedical Applications

Session Chairs: Filippo Fabbri, Evie L. Papadopoulou and Jeny Shklover
Friday Afternoon, December 6, 2024
Hynes, Level 1, Room 111

1:30 PM *SB06.07.01

Neuro-Nanotechnology—Graphene-Based Materials to Target Network Excitability *Mattia Bramini[1,2], Andrea Capasso[3], Ester Vazquez[4], Andrea Armirotti[2], Evie L. Papadopoulou[5] and Fabio Benfenati[2]; [1]Universidad de Granada, Spain; [2]Istituto Italiano di Tecnologia, Italy; [3]International Iberian Nanotechnology Laboratory, Portugal; [4]Universidad de Castilla - La Mancha, Spain; [5]BeDimensional, Italy*

The growing interest in utilizing graphene and graphene-based materials (GBMs) for applications such as drug and gene delivery, biomedical imaging, and diagnostic biosensors in the central nervous system has spurred neuroscientists to investigate the impact of GBMs on primary neural cells. Our focus has centered on characterizing the interactions of graphene nano-sheets within the central nervous system and exploring the potential of 2D graphene-based supports as biocompatible scaffolds for neurological applications. The goal is to leverage the conductive properties of graphene to regulate neural network activity closely associated with these structures. Our findings reveal that while exposure to graphene materials does not compromise neuronal and glial viability or blood-brain-barrier permeability, it does exert notable effects on neuronal and glial physiology. These effects encompass synaptic activity, intracellular Ca^{2+} dynamics, and astrocyte glutamate uptake. The results suggest that graphene oxide may play a protective role in neuro-pathologies characterized by hyperexcitability. Interestingly, our ongoing investigation is displaying a very high biocompatibility of graphene flakes with microglia cells, thus encouraging the future application of GBMs in neuroscience.

Additionally, we delved into the molecular and cellular mechanisms governing the interaction between 2D graphene-based supports and primary neurons and astrocytes. This exploration aims to evaluate the feasibility of employing these materials as flexible, transparent, and implantable devices for stimulating and triggering neuron excitability. We treated monolayer graphene, grown via chemical vapor deposition (CVD), with remote hydrogen plasma to demonstrate that hydrogenated graphene enhances cell-to-cell communication in primary cortical neurons compared to pristine graphene. This enhancement manifests through increased excitatory synaptic connections and a doubled frequency of miniature excitatory postsynaptic currents. Once again, there is no sign of glial reactivity when hydrogenated graphene is interfaced with primary astrocytes. Furthermore, we successfully modified P3HB, an amorphous biocompatible polymer, for neuronal interfacing by incorporating graphene oxide nano-platelets into the polymer structure. Finally, we are investigating laser-induced graphene 2D supports as their preparation is less time consuming and cheaper compared to CVD-graphene. These investigations indicate that wettability, more than electrical conductivity, is the crucial parameter to control when designing neural interfaces.

Multicomponent Nanoscintillators for Enhanced Radiotherapy Ad Alzheimer's Disease Treatment *Angelo Monguzzi; Università degli Studi di Milano-Bicocca, Italy*

Multicomponent nanomaterials consisting of dense scintillating particles functionalized by or embedding optically active conjugated photosensitizers (PSs) for cytotoxic reactive oxygen species (ROS) have been proposed in the last decade as coadjuvant agents for radiotherapy of cancer. [1] They have been designed to make scintillation-activated sensitizers for ROS production in an aqueous environment under exposure to ionizing radiations. However, a detailed understanding of the global energy partitioning process occurring during the scintillation is still missing, in particular regarding the role of the non-radiative energy transfer between the nanoscintillator and the conjugated moieties which is usually considered crucial for the activation of PSs and therefore pivotal to enhance the therapeutic effect. We investigate this mechanism in a series of PS-functionalized scintillating hydrated magnesium silicate nanotubes (NT) where the non-radiative energy transfer yield has been tuned by control of the intermolecular distance between the nanotube and the conjugated system. The obtained results indicate that non-radiative energy transfer has a negligible effect on the ROS sensitization efficiency, [2] thus opening the way to the

development of different architectures for breakthrough radiotherapy coadjutants to be tested in clinics.
The obtained results allow to design effective therapeutic agents for the radiothterapy of the Alzheimer disease. [3]
Soluble A�� oligomers are identified as neurotoxic species in AD and targeted in antibody-based drug development to mitigate cognitive decline. However, controversy exists concerning their efficacy and safety. In this study, an alternative strategy is proposed to inhibit the formation of A�� oligomers by selectively oxidizing specific amino acids in the A�� sequence, thereby preventing its aggregation. Targeted oxidation is achieved using biocompatible and blood-brain barrier-permeable multicomponent nanoscintillators that generate singlet oxygen upon X-ray interaction. Surface-modified scintillators interact selectively with Aβ and, upon X-ray irradiation, inhibit the formation of neurotoxic aggregates both in vitro and in vivo. Feeding transgenic Caenorhabditis elegans expressing human Aβ with the nanoscintillators and subsequent irradiation with soft X-ray reduces Aβ.
Surface-modified scintillators interact selectively with Aβ and, upon X-ray irradiation, inhibit the formation of neurotoxic aggregates both in vitro and in vivo. Feeding transgenic Caenorhabditis elegans expressing human Aβ with the nanoscintillators and subsequent irradiation with soft X-ray reduces Aβ oligomer levels, extends lifespan, and restores memory and behavioral deficits

Prebiotic-Combined ROS-Scavenging Nanotherapeutics for Gut Microenvironment Remodeling and Targeted Therapy of Inflammatory Bowel Disease *Dongkwang Min and Jaeyun Kim; Sungkyunkwan University, Korea (the Republic of)*

Inflammatory bowel disease (IBD) is a dysregulated gut-associated autoimmune disease resulting from inappropriate and continuous immune response, leading to excessive inflammatory molecules generation, including reactive oxygen species (ROS) and pro-inflammatory cytokines, collapsed gut epithelial tissues, and imbalanced immunity. Current IBD treatments have focused on directly blocking inflammatory cytokines. However, these treatments have not been able to restore balanced immunity against colonic inflammation. Therefore, strategies to restore gut immune homeostasis have come into the spotlight for IBD treatments. In this study, prebiotic-combined ROS-scavenging nanotherapeutic was proposed to restore gut immune homeostasis in IBD. The nanotherapeutic consisted of ROS-scavenging polydopamine nanoparticles (PNP) loaded with metformin (Met), an immunomodulatory drug, and subsequently coated with tannic acid (TA) as a potential phytochemical prebiotic (PNP-Met-TA). In in vitro sets, PNP-Met-TA could effectively scavenge intracellular ROS in LPS-treated macrophages, resulting in decreased production of inflammatory cytokines (TNF-α, IL-6). When PNP-Met-TA was orally delivered to dextran sulfate sodium (DSS)-induced IBD murine model, the nanotherapeutics exhibited extended resident time in inflamed lesions and enhanced accumulation in mesenteric lymph nodes with high cellular uptake by innate immune cells (macrophages, dendritic cells). Furthermore, when PNP-Met-TA was orally administered to the DSS-induced IBD model, the significant recovery of body weight, the suppression of the pro-inflammatory gut microenvironment, and the restoration of epithelial barriers were simultaneously observed. Most importantly, the elevated production of butyric acid, one of the gut metabolites with anti-inflammatory functions, was found. The downregulation of costimulatory molecules on dendritic cells in mesenteric lymph nodes and the increased ratio of Treg to Th17 suggest that the gut immune homeostasis was recovered. Taken together, our designed prebiotic-combined ROS-scavenging nanotherapeutics shed light on gut microenvironment remodeling for intestinal disease treatment.

Controlled Release of Molecular Intercalants from Textured Two-Dimensional Nanosheet Films for Antiviral Coatings *Muchun Liu[1,2] and Robert Hurt[2]; [1]Massachusetts Institute of Technology, United States; [2]Brown University, United States*

Two-dimensional (2D) materials possess outstanding flexibility, mechanical performance, and high specific surface area, making them promising delivery platforms for drug and antiviral payloads. Encapsulation and controlled release over long periods are essential for designing next-generation drug-eluting or antiviral coatings. Current progress in loading and releasing active ingredients focuses on physical absorption/desorption and chemical functionalization of 2D material surfaces. In our study, we explore the 2D nanochannels between sheet-like nanolayers as delivery vessels and develop them into antiviral-loaded, controlled-release coatings. Solution co-deposition of 2D nano-sheets with chemical solutes yields nanosheet−molecular heterostructures. A feature of these macroscopic layered hybrids is their ability to release the intercalated molecular agent to express chemical functionality on their surfaces or in their near surroundings. Systematic design methods are needed to control this molecular release to match the demand for rate and lifetime in specific applications. We hypothesize that release kinetics are controlled by transport processes within the layered solids, which primarily involve confined molecular diffusion through nanochannels formed by intersheet van der Waals gaps. Here a variety of graphene oxide (GO)/molecular hybrids are fabricated and subject to transient experiments to characterize release kinetics, locations, and mechanisms. The measured release rate profiles can be successfully described by a numerical model of internal transport processes, and the results used to extract effective Z-directional diffusion coefficients for various film types. The diffusion coefficients are found to be 8 orders of magnitude lower than those in free solution due to nanochannel confinement and serpentine path effects, and this retardation underlies the ability of 2D materials to control and extend release over useful time scales. In-plane texturing of the heterostructured films by compressive wrinkling or crumpling is shown to be a useful design tool to control the release rate for a given film type and molecular intercalant. The potential of this approach is demonstrated through case studies on the controlled release of chemical virucidal agents.

Integrating 2D Materials into Drug Delivery Systems Improves Cancer Treatment *Avi Schroeder[1], Orly Shyaderman[1], Ibrahim Knani[1], Mohammed Alyan[1], Jeny Shklover[1], Ravit Abel[1,2], Shanny Ackerman[1], Noga Sharf-Pauker[1,2] and Omer Kfir[1]; [1]Technion-Israel Institute of Technology, Israel; [2]Technion–Israel Institute of Technology, Israel*

Nanotechnology holds numerous potential benefits for treating and diagnosing disease, including the ability to transport complex therapeutic cargoes and target specific tissues. 2D-materials, embedded inside therapeutic nanoparticles, have the ability to enhance the therapeutic potency. Specifically, 2D materials loaded into liposomes sensitize the tumor to treatment, improving patient-specific therapeutic activity. The talk will also describe how the liposomal lipid composition affects its ability to internalize into triple-negative breast cancer cells, looking at the different molecular features, and how these can be leveraged to induce an anti-tumor immune response.

The evolution of drug delivery systems into synthetic cells, programmed nanoparticles with an autonomous syn-bio capacity to synthesize diagnostic and therapeutic proteins inside the body, and their promise for treating disease, will be discussed.

Integrating inorganic 2D materials into drug delivery systems enable new therapeutic capabilities.

Hydrogenated Amorphous Carbon Coatings for Calibration Targets of Fluorescence-Based Optical Instruments *Monalisa Ghosh[1], Kerstin Thorwarth[1], Götz Thorwarth[2] and Sebastian Siol[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]IMT Masken und Teilungen AG, Switzerland*

Hydrogenated amorphous carbon (a-C:H) coatings are developed for calibration targets in fluorescence-based optical instruments. Fluorescence microscopy, integral to biological imaging and DNA sequencing, necessitates precise calibration using stable and reproducible photoluminescent structures. Traditional calibration materials, such as fluorescein dyes and fluorescent glass, pose challenges in terms of stability, integration, and uniformity. This study introduces a-C:H as a promising alternative. By employing reactive High Power Impulse Magnetron Sputtering (HiPIMS) coupled with plasma-enhanced chemical vapor deposition using toluene as a precursor, a-C:H coatings with varying amounts of hydrogen are synthesized. The incorporation of hydrogen, confirmed through Rutherford backscattering and elastic recoil detection analysis (RBS-ERDA), significantly enhances photoluminescence. By adjusting the HiPIMS parameters and toluene flow, the film's hydrogen content can be optimized to achieve intense and stable photoluminescence under laser excitation. Additionally, the stability of the coatings under repeated laser irradiation is significantly improved compared to traditional materials, with further enhancement achieved through multilayer structures incorporating aluminum nitride for thermal management. Overall, the results demonstrate that a-C:H coatings offer a robust and reliable solution for calibration targets in advanced fluorescence microscopy, such as next-generation DNA sequencing.

4:15 PM SB06.07.07
Optical Tracing and Inhibition of Metastatic Tumor with Metal Quantum Clusters *Priyanka Sharma[1], Asifkhan Shanavas[1], Andrew K. Whittaker[2], Changkui Fu[2], Rodolphe Antoine[3] and Hao Yuan[3]; [1]Institute of Nano Science and Technology, India; [2]Australian Institute for Bioengineering & Nanotechnology, Australia; [3]Institut Lumière Matière, France*

Metal quantum clusters, characterized by their ultra-small size of fewer than 100 atoms, represent a promising class of nanomaterials with unique properties such as photoluminescence, high photostability, and water solubility, accompanied by a commendable quantum yield. Among these, gold quantum clusters (GQCs) have garnered significant attention, particularly in the realm of biomedical applications. Their size, below the physiological cut-off limit of 6-8nm, positions GQCs as ideal candidates for in-vivo applications due to their efficient renal clearance. Preliminary findings from our research underscore the potential of GQCs in the field of biomedicine. Notably, GQCs exhibit emission maxima at approximately 800 nm, extending up to 1000nm. This characteristic makes them particularly valuable for optical imaging, offering a wavelength range suitable for penetrating biological tissues. The versatility of GQCs extends beyond their role as imaging agents. Our investigations reveal that GQCs also display a remarkable capacity to inhibit secondary metastasis, specifically in the lungs. This inhibitory effect parallels the efficacy of Doxorubicin, a well-established chemotherapeutic drug used clinically. This dual capability of GQCs – optical imaging and metastasis inhibition positions them as multifunctional tools in the fight against cancerous cells. Moreover, the photostability of GQCs allows for *prolonged imaging periods without compromising the quality of signals. Additionally, the water solubility of these clusters enhances their compatibility with biological systems, facilitating their integration into various medical applications. In the context of optical imaging, GQCs offer a distinct advantage. Their unique combination of optical properties, biocompatibility, and therapeutic potential positions GQCs as promising candidates for the development of innovative cancer theranostics*

Regulating Bacteria Growth within 3D Hydrogels–Material-based Strategies For Biocontainment *Aránzazu Del Campo; INM–Leibniz Institute for New Materials, Germany*

Many applications of synthetic biology involve the delivery of engineered microbes to natural environments and require biocontainment strategies to control the proliferation of the engineered systems and avoid alteration or colonization of the natural milieu. Microbial biocontainment systems primarily target the inhibition of cellular proliferation by further engineering of the organism itself. An alternative strategy with additional benefits is the use of physical confinement to regulate microbial growth. 3D hydrogels can be engineered to encapsulate functional microbes, to shield them from external predators, and tightly regulate their proliferation and function. We will *present dynamic hydrogel compositions that can contain and control the proliferation and metabolic activity of encapsulated cell biofactories and can be processed into useful living devices with living therapeutic functions. We also present microarrays with engineered material microenvironments to study multifactorial microbial responses in parallelized experimental formats.*

11:00 AM *SB07.01.02
Revolutionizing Biomedical Fabrication—Two-Photon Polymerization for Multimaterial 3D Printing *Benjamin Richter, Marc Hippler, Andrea Bertoncini, Mareike Trappen, Matthias Blaicher, Daniel Götz, Alexander Quick, Fabian Niesler and Michael Thiel; Nanoscribe GmbH & Co. KG, Germany*

Multimaterial 3D printing, particularly via two-photon polymerization (2PP), revolutionizes the landscape of cell culturing, offering a bridge between traditional 2D methodologies and the need for dynamic 3D environments akin to in vivo conditions. While 2D cell culturing remains vital for high-throughput imaging, its limitations in mimicking physiological complexity underscore the necessity for 3D approaches. However, current 3D culturing techniques often struggle to replicate organic structures and are confined to simplistic shapes.

In this study, we harness the power of two-photon polymerization (2PP), employing techniques like Two-Photon Grayscale Lithography (2GL®) and Aligned 2-Photon Lithography (A2PL®) to create intricate in vitro microstructures tailored for advanced cell culturing. Our research showcases a novel workflow utilizing aligned 2PP microfabrication for 3D cell assays and perfusion within microfluidic devices. Additionally, we explore the application of 2GL® printing in generating AI-driven topographies, enhancing 2.5D cell culturing scalability and efficacy.

The versatility offered by both aligned and 2GL® printing methodologies hold immense promise across diverse fields such as biotechnology, tissue engineering, and microfluidics. By unlocking new avenues for innovation, these techniques present unprecedented opportunities for advancement within the biomedical and pharmaceutical sectors.

11:30 AM SB07.01.03
Predicting Printability of Bio-inks by Capillary Rheology *Farhad Sanaei[1], Pascal Bertsch[2], Juliette Lafosse[1], Sander Leeuwenburgh[1] and Mani Diba[1]; [1]Radboudumc, Netherlands; [2]University of Copenhagen, Denmark*

Background and purpose:
Extrusion-based 3D bioprinting offers a promising avenue for the fabrication of near-physiological tissue models. However, it remains a technical challenge to achieve reliable and reproducible printing since fundamental understanding of the causes of extrusion instabilities during bioprinting is still poor. Hydrogel printability is commonly assessed by rotational rheology (RR), which does not capture the flow profile of the extrusion process, resulting in poor reliability and predictability of the assessment, while visual assessment of filament morphological features is commonly performed after the bioprinting. Lack of reliable methodologies for faithful analysis of hydrogel extrusion affects material design, bio-ink development, cell viability, and 3D print quality, which further limits the translatability of results obtained from RR to real-life extrusion of these materials. These limitations impede the development and translation of such materials for biofabrication applications. We hypothesize that a faithful assessment of printability requires understanding the phenomena affecting bio-inks in the reservoir and the nozzle during the extrusion process. To this end, we employ principles of capillary rheology (CR), which characterizes material deformation and flow through capillaries, for quantitative assessment of bio-ink printability.
Methods:
We developed a CR system that enables real-time quantification of in situ bio-ink properties in a printing-like

setup. The bio-ink flows through a capillary with integrated pressure and temperature sensors to measure bio-ink rheological properties, which are simultaneously supplemented by visual data. For these experiments, we selected model bio-inks based on Pluronic F-127 and gelatin methacrylate (GelMA). In addition, GelMA-based granular materials with unknown flow behavior were selected to further highlight the applicability of the CR-based method.

Results and conclusions:

Our results show a considerable discrepancy in key printability-related properties such as viscosity and shear-thinning for CR compared to RR. Besides, CR pressure data reveal nuanced flow dynamics throughout the extrusion process, which reflect material-dependent changes in extrusion uniformity. The effects of material properties such as viscoelasticity, temperature sensitivity, and shear-thinning are reflected in these pressure data. For example, the amplitude of local pressure fluctuations suggests material-dependent impairment in extrusion uniformity. These discrepancies are further accentuated when assessing GelMA-based granular materials. The RR demonstrates non-significantly differing shear-thinning behavior for all compositions of granular materials, but the CR reveals significantly higher local pressure fluctuation and a higher pressure requirement to extrude fully granular material compared to other compositions. Moreover, the CR temperature sensors show a dramatic temperature gradient throughout the bio-ink, which significantly affects bio-ink behavior. These discrepancies suggest that RR, due to its differences in process mechanics, cannot faithfully predict the material flow behavior under capillary extrusion, which leads to inaccurate data and information when translating to the extrusion process. These results underscore the importance of temperature-viscosity relations and bio-ink capillary flow behavior in extrusion-based bioprinting. Overall, CR provides accurate and detailed information on the extrudability of hydrogels and pinpoints extrusion-dependent phenomena in each stage of the printing course which cannot be captured with RR.

Our ongoing work will correlate CR and visual data to establish quantitative printability assessment criteria. Overall, our approach offers new fundamental insight into the rheological properties of the bio-inks during the extrusion process, which can considerably improve the translation of bio-inks and the optimization of 3D printing processes.

11:45 AM SB07.01.04

Enzymatic Mineralization of 3D Printable Granular Hydrogels *Francesca Bono[1], Mariangela Miccoli[1], Lorenzo Lucherini[1], Anna Puiggalí-Jou[2], Marcy Zenobi-Wong[2] and Esther Amstad[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]ETH Zürich, Switzerland*

Many biological materials are structured as organic-inorganic composites. A paradigmatic example of this apparent dichotomy is bone, a biomineralized tissue with a polymeric matrix. Inspired by the natural design strategy, recent work has been done to encapsulate living components such as bacteria into a granular polymeric matrix to then trigger biomineralization [1]. Taking advantage of the intrinsic rheological properties of jammed microgels, organic/inorganic composites can be 3D printed. However, applications are limited if living organisms are involved.

In this work, we introduce a 3D printable ink that can be mineralized to yield load-bearing composites after the 3D printing process has been completed. This is achieved by formulating enzyme-loaded hydrogels that are exclusively made of naturally sourced soft polymers as microgels. The enzyme-loaded microgels are jammed to obtain the required rheological properties. These microgel-based inks are 3D printed at room temperature through direct ink writing before they are converted into load-bearing mineralized scaffolds. We demonstrate how the local composition, mineral content, and porosity can be adjusted with the formulation of the granular ink. The obtained scaffolds are biocompatible with low cytotoxicity when tested with osteoblast cells showing great potential for tissue engineering applications such as bone reparation.

Advancing the Field of Biofabrication Through Standardized Bioinks *Aysu Arslan and Jasper Van Hoorick; BIO INX BV, Belgium*

Bioprinting has emerged as a transformative technology for both in vitro and in vivo applications, offering unprecedented precision and versatility in creating complex biological structures. This technology is capable of operating across a spectrum of resolutions, from low to high, enabling the production of structures that range from macro-scale scaffolds to intricate micro-scale designs. A crucial aspect of bioprinting is the development and utilization of bioinks that are functional, reproducible, and standardized, ensuring consistency and reliability in the printed constructs. These advancements are instrumental in various fields, including the development of innovative approaches to tissue regeneration, and the creation of organ-on-chip systems. By leveraging the diverse capabilities of bioprinting and ensuring high-quality bioinks, significant progress is being made in biomedical research and regenerative medicine, ultimately leading to the development of functional tissue and organ replacements, advanced drug testing systems and a deeper understanding of complex biological processes. This lecture will explore the importance of reliable and standardized bioink development for the field of biofabrication, particularly those based on gelatin and poly-ε-caprolactone, with a focus on their applications in tissue regeneration, organ-on-chip systems, and cancer models.

2:30 PM SB07.02.02
Predicting Emergent Behavior in Cellular Automata and 3D-Printed Bioinspired Hierarchical Architected Metamaterials with Generative Pre-Trained Transformer Models *Jaime A. Berkovich, Markus J. Buehler and Noah David; Massachusetts Institute of Technology, United States*

Biological materials, such as bone, nacre, tendon, and wood, owe their exceptional mechanical properties to their complex hierarchical structures. Current structural metamaterial design often mimics these end structures without incorporating the dynamic processes of their formation, such as multicellular behavior. Real biological materials are not static; they continuously evolve through processes that span multiple orders of magnitude in scale, often involving the emergent effects of cellular cooperation. Some have argued that biological systems intrinsically favor information-based solutions to save energy, using collective cellular dynamics to process data from their environments. In this work, we demonstrate the potential of bioinspired and biomimetic strategies that manipulate information using cellular automata (CA) for hierarchical material design. We find that these strategies can create fractal-like structures, optimized for multiple purposes, such as strength, toughness, and lightweighting. Multicellular organisms can be thought to algorithmically utilize ‘biological CA’ to create complex (somewhat ordered and disordered) hierarchical biological materials. The emergence of these biostructures is remarkable, as their geometries and functionalities are not readily discernible through a formal analysis of the rules governing their cell-mediated self-assembly. Likewise, CA, as computational models, generate emergent, *complex behavior from a set of simple, local rules applied recursively through time on a multidimensional lattice of virtual cells. CA have been useful across disparate fields of study for phenomenologically modeling systems ranging from urban traffic flow to neuronal dynamics and chemical systems, making them widely applicable to the study of biological self-assembly and morphogenesis. We demonstrate the application of 2D CA and inverse tomography for architecting structural metamaterials, leveraging their ability to produce complex, branch-like forms through local recursive rules in a discrete, 3D configuration-space. We also 3D-print and mechanically test these architected structures to show that they overcome the strength/toughness tradeoff, like other hierarchically organized biological materials. Furthermore, we relate these mechanical properties to the informational entropy of the 2D initial conditions (seeds) from which each structure is generated, which suggests property tunability is feasible in these systems. Moreover, we show that generative pre-trained transformer models (GPTs) can learn the rules of CA systems via training off large synthetic datasets. We believe that this shows promise for the future of CA-architected hierarchical materials, as future GPTs may be able to learn the bidirectional relationships between rulesets, initial conditions, and mechanical properties. Finally, we outline the potential for GPTs to take in data from real-world, dynamic biological materials, to create CA models approximating the time-evolution of these systems, which may be applicable to tissue engineering, and for the inverse design of bioinspired materials.*

2:45 PM SB07.02.03
Highly Tunable and Extensible Physically Crosslinked Hydrogel for Use in 3D Bioprinting *Ye Eun Song and Eric A. Appel; Stanford University, United States*

Hydrogels have emerged as promising materials for bioprinting and many other biomedical applications due to their high degree of biocompatibility and ability to support and/or modulate cell viability and function. Yet, many hydrogel bioinks have suffered from low efficiency due to limitations on accessible printing speeds, often limiting cell viability and/or the constructs which can be generated. In this study, we report a highly extensible bioink system created by modulating the rheology of physically crosslinked hydrogels comprising hydrophobically modified cellulosic biopolymers and additives such as surfactants or cyclodextrins. We demonstrate that these hydrogel materials are highly shear-thinning with broadly tunable viscoelasticity and stress-relaxation behaviors through simple modulation of the composition of the additives. Rheological experiments demonstrate that increasing concentration of rheology-modifying additives yields hydrogel materials exhibiting extensional strain-to-break values up to 2000%. We demonstrate the potential of these hydrogels for use as bioinks by evaluating the relationship between extensibility and printability, demonstrating that greater hydrogel extensibility enables faster print speeds and smaller print features. Our findings suggest that optimizing hydrogel extensibility can enhance high-speed 3D bioprinting capabilities.

Thermo-/Photo-Responsive Bioink for Improved Printability in Extrusion-Based Bioprinting *Seo Hyung Moon and Yun Jung Yang; Inha University, Korea (the Republic of)*

Extrusion-based bioprinting has shown great promise for manufacturing constructs, especially for 3D cell culture. However, the number of bioink candidates suitable for extrusion-based bioprinting techniques is greatly limited, as they meet the opposing requirements for printability with certain rheological features and for biochemical functionality with a desirable microenvironment. In this study, a blend of silk fibroin (SF) and iota-carrageenan (CG) was chosen as a cell-favorable printable material. The SF/CG ink exhibited appropriate viscosity and shear-thinning behaviors, along with the rapid sol-gel transition characteristic of CG. By employing photo-crosslinking of SF, the printability with a Pr value close to 1 and the structural integrity of the 3D constructs were significantly *improved within a matter of seconds. The printed constructs had a Young's modulus of around 250 kPa, making them suitable for keratinocyte and myoblast cell culture. Additionally, the high cell adhesiveness and viability (exceeding 98%) of the encapsulated cells demonstrated the significant potential of this 3D cellular scaffold for applications in skin and muscle tissues, which can be easily managed with an extrusion-based bioprinter.*

Encoding Shape, Structure, Mechanics and Dynamics of a Soft Solid with an Active Fluid *Zvonimir Dogic[1], John Berezney[2], Ray Sattvic[1], Itamar Kolvin[3] and Seth Fraden[2]; [1]University of California, Santa Barbara, United States; [2]Brandeis University, United States; [3]Georgia Institute of Technology, United States*

Statistical mechanics describes how one can design targeted macroscale properties of equilibrium assemblages by controlling microscopic interactions. In comparison, our understanding of how large-scale structure and dynamics occur away from equilibrium is less complete. We describe a hierarchical self-organizing process of remarkable complexity. Starting with a uniform mixture of microtubule-based active fluid and passive actin filaments, we observe the emergence of complex structures and dynamical patterns on length scales ranging from nanometers to millimeters. Active fluids sculpt the structure, shape, mechanics, and dynamics of the actin network. Eventually, one observes the formation of macroscopically large actin-based thermalized membranes whose out-of-plane bending rigidity and in-plane oscillatory patterns are driven by the enveloping microtubule-based active fluid. Taken together, these experiments demonstrate a need for developing a theoretical understanding of out-of-equilibrium self-organizing processes.

The Use of Magnetic Fields to Spatially and Temporally Control Fiber Alignment Within Fiber-Hydrogel Composites *Julianne L. Holloway; Arizona State University, United States*

Approximately 14 million connective tissue injuries occur each year in the United States. Following injury, disorganized tissue is typically formed with inferior mechanical properties and impaired function. Within connective tissues, it is well known that fiber morphology serves as a critical signaling cue to direct cell behavior. Nonetheless, additional research is needed to better understand the spatiotemporal role of these cues on cell behavior and tissue repair. To address this challenge, we designed a magneto-responsive fiber-hydrogel composite system to enable in situ fiber alignment with control in both space and time. A polycaprolactone solution containing superparamagnetic iron oxide nanoparticles (SPIONs) was electrospun into a fibrous mat and cut into short fibers. The resulting magneto-responsive short fibers were embedded within static, covalently crosslinked hydrogels or dynamic, reversibly crosslinked hydrogels. Fiber alignment within the hydrogels was tuned via exposure to a magnetic field. Fiber alignment was characterized as a function of material formulation, magnetic field strength, and magnetic field exposure time. For static hydrogels, fibers aligned rapidly within the uncrosslinked polymer solution during magnetic field exposure and alignment was locked in place via crosslinking. This mechanism enabled three-dimensional spatial control over fiber alignment using layer-by-layer stacking. For dynamic hydrogels, fibers aligned within guest-host hydrogels at user-defined timepoints, which allowed for temporal control over fiber alignment. The ability of fibers to align within dynamic hydrogels indicates the magnetic field generated sufficient shear stress at the fiber-hydrogel interface to break the dynamic crosslinks and enable fiber movement. For both systems, alignment occurred more rapidly with increased magnetic field exposure and SPION content. This system will allow us to investigate the spatiotemporal role of fiber alignment on cell behavior and tissue repair. Ongoing work is evaluating gene expression as a function of fiber alignment within these materials.

Biopolymer-Based Electroconductive Hydrogels for Soft Robotic Systems *Didem Aycan[1,2], Mona M. Haemmerle[1] and Christine Selhuber-Unkel[1]; [1]Heidelberg University, Germany; [2]Marmara University, Turkey*

Soft robotics defined as the integration of state-of-the-art engineering and flexibility of nature has emerged as a promising field with applications ranging from healthcare to industry. They can negotiate complex situations with precision owing to their extraordinary capacity to bend and stretch in contrast to traditional-rigid robotics. Since usage of materials with compliance similar to that of soft biological matter is the most crucial parameter to the construction of soft robotics, electroconductive hydrogels (ECHs), a class of materials with their hydrophilic, conductive and biocompatible characteristics, have gained significant attention for their potential to revolutionize soft robotic systems.

The unique combination of mechanical compliance, biocompatibility, and electrical conductivity in hydrogels offers numerous advantages for soft robotic design. These materials exhibit tunable mechanical properties, allowing for the precise control over stiffness and elasticity, which are crucial for mimicking natural movement and interactions. Furthermore, ECHs offer opportunities for advanced functionalities such as stimuli-responsive behavior and self-healing capabilities. Owing to these properties, researchers can design robots that adapt to changing environmental conditions or external stimuli.

ECHs can be produced by either using conductive particles or intrinsically conductive polymers. However, in recent years, the combined strategy involving the incorporation of conductive particles into conjugated conducting polymer matrices is commonly preferred as an effective alternative to endow adjustable and improved properties to hydrogels for the proposed applications. Considering these, it is proposed to the development of novel biopolymer-based ECHs by using an integrated conductivity mechanism including both silver nanoparticles and polyaniline for the soft robotic applications in the current study. Further research and development in this study are expected to drive continued advancements in soft robotics, leading to the transformative applications including sensors, delivery of therapeutics, organ-on-a-chip platforms, biomedical implants and beyond.

Additive Manufacturing of Bioelectronics for Biomedical Applications *John G. Hardy; Lancaster University, United Kingdom*

Stimuli-responsive biomaterials have significant potential for the development of systems capable of the controlled delivery of drugs, neuromodulation and tissue engineering. We are interested in the development of smart biomaterials capable of responding to one or more stimuli (typically electricity, light and magnetism), and demonstrating their efficacy in vitro/vivo. We employ an interdisciplinary approach (combining chemistry, materials science, biology, engineering and medicine) to generate biomaterials with task-specific properties, 3D printing non-degradable materials designed for neuromodulation (in vitro, ex vivo and in vivo), and developing degradable/transient electronics for drug delivery and tissue scaffolds to control cell behaviour.

The focus of this presentation is the development of 3D objects with integrated electronics produced using an additive manufacturing approach relying on multiphoton fabrication (direct laser writing, DLW). Conducting polymer-based structures (with micrometer-millimeter scale features) are printed within various matrices *(including an polydimethylsiloxane which has been widely investigated for biomedical applications), the fidelity of the printing process was assessed by optical coherence tomography, and the conducting polymer structures were demonstrated to be capable of stimulating mouse brain tissue in vitro. Furthermore, the applicability of the approach to printing structures in vivo is demonstrated in live nematodes (Caenorhabditis elegans). These results highlight the potential for such additive manufacturing approaches to produce next-generation advanced material technologies, notably integrated electronics for technical and medical applications (e.g., human-computer interfaces).*

9:00 AM *SB07.03.02

Molecular Mechanisms to Control 3D Biomaterial Viscoelasticity *Adrianne M. Rosales; The University of Texas at Austin, United States*

Engineered extracellular matrices (ECMs) are important for therapeutic cell manufacturing and tissue engineering applications; however, synthetic ECMs remain less structurally and biologically complex than natural ECM. One key difference is that synthetic ECM tends to be static in nature, whereas the natural ECM exhibits dynamic behavior across multiple length scales. Hence, hydrogels with dynamic linkers have garnered intense interest as extracellular matrix (ECM) mimics and injectable delivery vehicles due to their tailorable viscoelasticity, stress relaxation, and self-healing behavior. However, to fully enable biomaterial applications, there remains a need to understand how linking chemistry affects gelation and nonlinear rheological properties. In this context, we have developed synthetic multi-arm poly(ethylene glycol) (PEG) hydrogels with three different dynamic covalent linking chemistries. This suite of dynamic covalent linkages allows control over the bond exchange kinetics across three orders of magnitude, which dictates hydrogel viscoelasticity under small amplitude oscillatory shear. Interestingly, the hydrogel moduli demonstrate unique scaling behavior at low concentrations, indicating heterogeneous networks. Furthermore, they exhibit non-monotonic flow curves under steady shear, with shear thickening behavior that depends on the crosslinking bond exchange kinetics and polymer concentration. At high shear, the dynamic hydrogels are injectable, with faster bond exchange kinetics leading to lower injection forces. Overall, these results provide insight to the molecular and structural characteristics that govern dynamic covalent PEG gelation, mechanics, and flow, while also expanding the types of scaffolds applicable to tissue engineering and therapeutic delivery.

9:30 AM SB07.03.03

Optical Characterization of 3D Light-Driven Bio-Hybrid Actuators *Andrea Pianetti[1], Ilaria Venturino[1], Valentina Sesti[1], Paola Moretti[2], Chiara Bertarelli[1,2] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy*

Bio-hybrid actuators represent a promising field in robotics. The advantage of a 3-dimensional device is that it can better mimic a human muscle and achieve high performance, adaptability, and complexity of movement, matching the standards required in the robotics field [1].
Muscle-based biohybrid systems are typically triggered electrically using electrodes. However, this approach has limitations, such as low spatial resolution and selectivity, potential tissue damage from inflammatory responses, and cumbersome wiring [2]. To address these issues, scientists are exploring light as an alternative trigger. Light stimulation offers high spatial and temporal resolution, low invasiveness, and can be controlled remotely. Methods like infrared radiation, semiconductor interfaces, and optogenetics have been successfully used to induce light-cell sensitivity. Another promising approach is the use of photoactive molecules. Recently, it has been demonstrated that an azobenzene molecule called Ziapin2 can modulate membrane capacitance and trigger muscle cells' contraction upon light stimulation in 2D systems [3], due to its light-triggered isomeratation process in the cell's membrane. Starting from this promising result, we infer that this stimulation approach may be used to

induce the deformation and contraction of a 3D bio-hybrid actuator.
Here we describe an example of a 3D bio-hybrid structure treated with Ziapin2 that is capable of contracting upon light stimulation. We studied and characterized the optical properties first of a 3D-printed hydrogel based on gelatin methacrylate. Subsequently, we encapsulated the skeletal cells inside the hydrogel to study Ziapin2 uptake and diffusion inside the cells and the hydrogel. Our focus was on optimizing the uptake of Ziapin2 to enhance its interaction with light, thereby achieving the most effective contractions. This study represents a significant step towards developing light-sensitive bio-hybrid actuators and a fundamental study of their optical properties.

Programmable Strain-Responsive Biopolymer Networks Adapt to High Magnitudes of Mechanical Loading

Yan Luo, Yuntao Hu, Prashant Purohit and Kyle Vining; University of Pennsylvania, United States

Biopolymer hydrogel materials typically exhibit relatively low range of programmable modulus less than 100 kPa, which limits their biomedical applications, such as in articular cartilage and synthetic joints, where tissues are cyclically loaded with high magnitudes of peak stress on the order of 10MPa, and applications in soft robotics require moduli across orders of magnitude from 1 kPa to 100 MPa. Here, we achieved a wide range of mechanical properties with double network biopolymer hydrogels that can sustain over 10-100 MPa peak stress under repeated axial unconfined compression. Previous systems use double-network to enhance hydrogel's toughness and strength. Here, cryogelation generates a foam network that undergoes a rarefied to densified phase transition, which is reinforced with a second dissipative network to yield highly tunable properties across orders of magnitude of applied stress. The foam network is formed by cryogelation of a covalently crosslinked collagen-glutaraldehyde (GA) biopolymer network that can sustain repeated loading through phase transition of its porous foam structure. Interpenetrating ionically-crosslinked alginate biopolymers tune the final modulus to make the hydrogel programmable in a high range of mechanical performance. This dual-network composite hydrogel system also exhibits reversible properties, achieved by chelating ions to reduce ionic crosslinks or restoring crosslinks by supplying additional ions. Together, these data demonstrate a robust hydrogel composite system adaptable to wide ranges of mechanical loading.
First, the mechanical properties of collagen-GA cryogel network were evaluated by the influence of gelation temperature, freezing rate, and GA concentration. Cryogel samples prepared under -20°C with 0.15% w/v GA and -2°C/min freezing rate exhibited the best balance of stiffness and flexibility. Detailed mechanical characterizations, including single axial compression and hysteresis testing, revealed nonlinear behaviors and significant phase transition dynamics under compression. A continuum theory of phase transition was employed to model the inelasticity, which showed the cryogel with 0.15% GA had 2 times higher peak stress and almost 10% lower transformation strain, compared to no GA one. This suggests covalent crosslinking during cryogelation leads to stiffer and less brittle structure. The micro-structure under axial strains of 0%, 50%, and 90% were characterized using second harmonic generation (SHG) imaging, which showed significant fiber reorientation and densification under increasing strain. Further, 20 loops of hysteresis tests revealed the cryogel's ability to withstand repetitive loading cycles, with mechanical properties stabilizing after 10 cycles.
Next, the cryogel was pre-compressed at different axial strain and infiltrated with an ionically-crosslinked alginate network which "locked" this state to achieve enhanced mechanical properties. Reversibility was achieved by adding ion chelator, ethylenediaminetetraacetic acid (EDTA), which disrupted the ionic crosslinks in alginate

matrix, allowing the hydrogel to return to an "unlocked" state. 20 loops hysteresis testing (0% to 90% strain) showed mechanical responses due to different pre-strain conditions, and higher pre-strain has higher peak stress and better mechanical properties with resistance to fatigue and stabilized properties after repeated loading cycles. In summary, the development of a double-network biopolymer hydrogel system with programmable mechanical properties offers significant advancements for biomedical applications and soft robotics. This system not only demonstrates robustness and adaptability through repeated loading cycles but also exhibits reversible and strain-responsive behavior by modulating ionic crosslinks. These characteristics highlight its potential as a versatile material for applications requiring precise mechanical performance and durability under dynamic conditions.

Multifunctional Hydrogel Foams for Crohn's Fistula Healing *Mary B. Monroe, Nghia L. Thai, Henry T. Beaman, Samara Tomlinson, Emily Fittante, Megan Perlman and Owen Salius; Syracuse University, United States*

Introduction: Crohn's disease (CD) can lead to fistula formation between portions of the urinary, reproductive, and digestive systems. These abnormal connections cause severe pain, infections, and abscess formation and occur in ~1/3 of CD patients. The majority of fistulizing Crohn's patients undergo surgical intervention, which has some short-term effectiveness. However, ~23% of these patients ultimately require bowel resections.
Fistula healing is hindered by infection, inflammation, and an observed epithelial to mesenchymal transition (EMT). Mesenchymal stem cells (MSCs) delivered to the fistula tract have shown some success in closing fistulas, which may be due in part to their ability to reverse the EMT. However, a lack of proper scaffolding for these cells likely reduces their retention in the fistula site and overall efficacy. Current fistula filling treatments fail to heal fistulas because they do not address infection and the EMT, and MSC treatments that may reverse the EMT are limited by poor delivery vehicles.
To address this clinical need, we developed a hydrogel foam platform that locally delivers cues aimed to reverse the EMT and support wound healing to drive fistula closure. These hydrogels are easily modified with bioactive compounds (gallic acid and/or MSCs) to enable control over the EMT, infection prevention, and healing.

Methods: Poly(vinyl alcohol) (PVA) was modified with methacrylate (PVAMA) and thiol (TPVA) groups using standard protocols. Gelatin was methacrylated to provide GelMA using standard protocols. Solutions of PVAMA, TPVA, and GelMA were mixed with varying concentrations of curcumin and/or MSCs in cell culture media with lithium phenyl (2,4,6-trimethylbenzoyl) phosphinate (LAP) as a photoinitator. Sodium bicarbonate was added, and then citric acid was mixed in to induce bubbling within the solutions. Hydrogels were crosslinked under UV light for 6 minutes during bubble formation to produce porous hydrogel foams. Control solid hydrogels were fabricated without sodium bicarbonate or citric acid. Resulting samples were characterized in terms of swelling, mechanical properties, degradation behavior, and cytocompatibility of encapsulated and surrounding cells. Effects on the EMT were evaluated using HT-29 intestinal epithelial cells (IECs) based on cell morphology and expression of fibronectin and E-cadherin. Wound healing capabilities were assessed in an ex vivo porcine skin wound model.

Antimicrobial activity was measured against S. aureus and E. coli.

Results: A library of PVA-based hydrogels was synthesized with tunable degradation rates (complete dissolution ranging from ~15-50 days in 3% hydrogen peroxide). Samples were cytocompatible, and hydrogels including both pores and GelMA enabled high encapsulated cell viability (~100%) over 2 weeks of culture in large (10 mm height X 8 mm diameter cylinders) scaffolds. These hydrogels also supported encapsulated cell proliferation and spreading over 2 weeks while maintaining MSC markers (Actin and CD90). Improved healing was observed in a 2D scratch assay and an ex vivo pig wound model after treatment with MSC-containing hydrogels. Both curcumin and MSCs showed effects on preventing the EMT in IECs based on cell morphology (rounded, denser (epithelial) vs. spindle-shaped, less dense(mesenchymal)), reduced fibronectin expression, and increased E-cadherin expression.

Conclusions and Future Work: This tunable hydrogel platform could enable scaffolds that fill, seal, and heal Crohn's fistulas to improve clinical outcomes relative to previously developed fistula plugs. Current work is focused on expanding characterization of the effects of scaffold variables on the EMT, antimicrobial properties, and healing in ex vivo and in vivo models.

11:00 AM *SB07.04.02

Designing Tough and Elastic Conductive Bioadhesive Hydrogels for Tissue Engineering *Nasim Annabi; University of California, Los Angeles, United States*

Hydrogels have been extensively used for various biomedical applications, ranging from tissue engineering to matrices for drug delivery, as well as substrates for biosensing, due to their versatility in structure and physical properties. Although significant progress has been made towards designing hydrogels with tunable properties, engineering tough and elastic hydrogels that resemble native tissue mechano-physical properties is still considered a great challenge. In addition, for many tissue engineering applications as well as biosensing, the conductivity of hydrogels is an important factor. Many attempts have been made to engineer conductive hydrogels through the incorporation of external conductive fillers such as carbon nanotubes, graphene, MXenes, metallic micro/nanoparticles, and intrinsically conductive polymers such as polyaniline and polypyrrole. However, the engineered conductive composites require a high concentration of conductive fillers, leading to inconsistent dispersion and agglomeration, as well as toxicity, limiting their biomedical applications. To address these limitations, our lab has focused on engineering multifunctional naturally-derived hydrogels with combined properties of high toughness, flexibility, adhesion, high elasticity, and conductivity through tuning various molecular interactions among the building blocks of the hydrogel network. In addition, the use of natural polymers as the backbone endows the engineered hydrogels with improved biocompatibility and biodegradability, which have been extensively tested in various in vitro and in vivo models. Due to the tunability of the physio-chemical properties of the engineered hydrogel networks, we have applied them for various applications ranging from tough and ultra-strong tissue adhesives for surgical applications to highly stretchable and conductive flexible sensors for real-time human health monitoring. In this presentation, I will outline our recent works on the design of tough bioadhesive hydrogels for soft tissue sealing and regeneration as well as their application as wearable biosensors.

11:30 AM SB07.04.03

Surface-Functionalized Microgels as Artificial Antigen-Presenting Cells to Regulate Expansion of T Cells

Junzhe Lou, Charlotte Meyer and David Mooney; Harvard University, United States

Artificial antigen-presenting cells (aAPCs) are currently used to manufacture T cells for adoptive therapy in cancer treatment, but a readily tunable and modular system could enable both rapid T cell expansion and control over T cell phenotype. Here, we show that microgels with tailored surface biochemical properties can serve as aAPCs to *mediate T cell activation and expansion. Surface functionalization of microgels was achieved via layer-by-layer coating using oppositely charged polymers, forming a thin but dense polymer layer on the surface. This facile and versatile approach is compatible with a variety of coating polymers and allows efficient and flexible surface-specific conjugation of defined peptides or proteins. We demonstrate that tethering appropriate stimulatory ligands on the microgel surface efficiently activates T cells for polyclonal and antigen-specific expansion. The expansion, phenotype and functional outcome of primary mouse and human T cells can be regulated by modulating the concentration, ratio and distribution of stimulatory ligands presented on microgel surfaces as well as the stiffness and viscoelasticity of the microgels.*

Buckling Microchannels of Porous Hydrogel Films for Vessel-on-a-Chip Fabrication *Riku Takahashi[1], Aya Tanaka[1], Tomoki Saito[2], Shinya Ohashi[2], Manabu Muto[2] and Masumi Yamaguchi[1]; [1]NTT Basic Research Laboratories, Japan; [2]Kyoto University, Japan*

The trend in constructing 3D human tissue/organ models in vitro for developing accurate diagnosis and effective treatments has been gaining momentum in recent years in a wide range of biological research fields, such as tissue engineering, biomedicine, and drug discovery. Here, hydrogel-based microchannels with high water content have recently attracted attention as an alternative platform that can faithfully reproduce the natural in vivo environment with high biocompatibility, ex vivo matrix (ECM)-like elastic modulus, permeability of bioactive substances, and biomimetic motion through stimuli-responsiveness.

We have previously reported a fabrication method in which the swelling of a common polyacrylamide (PAAm) hydrogel film is controlled on a support substrate to fabricate microchannel in an easy-to-use manner.[1] The method is based on the swelling of the laminate, with the interface between the PAAm hydrogel film and the support substrate given an arbitrary adhesion/non-adhesion pattern. Swelling-induced pressure selectively delaminates and buckles the hydrogel on the non-adhesive region, forming a space between the hydrogel and the support substrate that can be used as a microchannel. By using PAAm hydrogel with a high polymer concentration, this thin-film, tubular microchannel structure, similar to that of blood vessels and gastrointestinal tracts, is strong enough and flexible enough to withstand large deformations under pressure, even with film thicknesses less than 100 μm.[2] In addition, it can be made to reproduce intestinal peristalsis/segmentation by utilizing stimuli-responsive hydrogels, and thus, it may be a highly expandable platform that can mimic the dynamic stimulation environment of a living body.[3] However, while a high polymer concentration is an important factor in creating a tough and functional hydrogel, the high density of the hydrogel mesh reduces the permeability of the material.

In this study, we propose a novel and versatile method that couples cononsolvency photopolymerization, which enables the incorporation of porous structures into hydrogels, with on-chip microchannels formed by buckling of a thin film. This method provides a hydrogel-based microchannel with improved permeability while maintaining its mechanical properties by incorporating a continuous porous structure into a synthetic polymer network with excellent mechanical properties and easy functionalization. Specifically, the open-porous PAAm hydrogel fabricated by cononsolvency photopolymerization exhibited nearly five times better permeability than those of conventional PAAm hydrogels and was comparable to other materials commonly used as substrates for hydrogel-based microchannels. Furthermore, by coating the permeable microchannel with vascular endothelial cells, we proved the feasibility of evaluating the barrier function, fabricating a variety of channel geometries, and developing the technique into a co-culture system. Both the cononsolvency photopolymerization and on-chip structure formation methods used in this research are universal ones based on physical phenomena, so they can be used for various other types of swellable functional hydrogels. Therefore, we believe that the vast library of synthetic hydrogels can be used for fabricating microfluidic platforms that have the appropriate physical properties, responsiveness, and chemical composition for the target tissue/organ.

1:30 PM *SB07.05.01
Engineering Biomaterials for Regeneration, Therapy and Beyond *Akhilesh K. Gaharwar; Texas A&M University, United States*

Engineered biomaterials have emerged as powerful tools for a range of biomedical applications, including regenerative medicine, drug delivery, and additive manufacturing. These engineered biomaterials possess tunable biophysical properties, specific biochemical cues, and complex architecture, enabling precise control over cellular behavior. In this talk, I will outline three biomaterials-based approaches developed in our lab for biomedical applications. Firstly, I will highlight how engineered biomaterials can be used to control and direct cellular functions. Our work has resulted in a new class of biomaterials for bone regeneration, and mitochondrial biogenesis. The second approach emphasizes the design of biomaterials tailored for the sustained and controlled release of therapeutics, targeting osteoarthritis treatment, angiogenesis promotion, and wound healing. We have pioneered a suite of nano-toolkits adept at delivering both small molecular drugs and sizeable proteins, characterized by efficient loading and adaptable release dynamics. Lastly, I will demonstrate the design of 3D printing bioelectronics and anatomical-size tissue constructs. These advanced tissue structures enable the creation of physiologically accurate tissue models, replicating complex disease conditions like vascular pathophysiology and intricate vascularized tumor representations.

2:00 PM *SB07.05.02
Biomimetic Polymer Composites with Piezoelectric and Conductive Particles for Tissue Engineering
Humberto Palza[1,2], Francisco Fernandez[1,2,3], Sarah Cartmell[4] and José Aguilar-Cosme[4]; [1]Universidad de Chile, Chile; [2]IMPACT, Center of Interventional Medicine for Precision and Advanced Cellular Therapy, Santiago, Chile, Chile; [3]Universidad de la Frontera, Chile; [4]The University of Manchester, United Kingdom

Electroactive polymers emerged as a proper route to develop novel scaffolds for tissue engineering bio-mimicking the intrinsic electrostimulation occurring in our organism, such as in bone and cardiac tissues. Different approaches can be found to design these electroactive polymers, such as the use of intrinsic conductive biocompatible polymers (i.e., polypyrrole), and mixing a bioactive polymer with conductive nanoparticles (such as carbon derivatives including nanotubes and graphene). Nanogenerators had recently emerged in this context as the proper transducer technology able to deliver directly an electrical signal onto a tissue using a mechanical stimulus (for instance from biomechanical movements or a remote device). As cited by Wang, "nanogenerator is a field that uses the Maxwell's displacement current as the driving force for converting mechanical energy into electric power using either piezoelectric or triboelectric effect, whether we use nanomaterials or not". In particular, piezoelectric nanogenerators (PENG) are based on a phenomenon associated with the intrinsic property of some materials having non-centrosymmetric structures to create a polarization under mechanical *strain. Beside the need to enhance the voltage/current output of PENG, today the main challenge for tissue engineering is to increase their bioactivity, flexibility, and mechanical stability, motivating the development of polymer films containing piezoelectric particles. This strategy allows the design of novel multifunctional PENG devices with a synergy effect arising from the properties of the polymer matrix (i.e., biocompatibility and processability) and from the piezoelectric filler. During the last years relevant evidence had shown that the presence of conductive nanoparticles in polymer/piezoelectric composites can drastically improve the piezoelectric behavior. For instance, conductive particles can overcome issues related with the high permittivity from the charge density at the polymer/piezoelectric interface generated by the Maxwell-Wagner-Sillar effect. Indeed, conductive fillers at low amount can easily propagate the charges generated on the surface of individual piezoelectric particles through the whole material.*

In this contribution, 3D printed TENG scaffolds based on polycaprolactone (PCL) having piezoelectric Zinc Oxide (ZnO) rods and electrically conductive Thermally Reduced Graphene Oxide (TrGO) particles were developed and characterized as a biomimetic material for bone tissue engineering. Our results show that the ternary PCL/ZnO/TrGO composites presented a much higher dielectric permittivity and piezoelectric coefficient than binary PCL/ZnO composites, that results in a higher voltage generation. These results show that the ZnO-TrGO interaction forms a micro-capacitor network, boosting dielectric properties by charge accumulation at these interfaces. Simultaneously, TrGO creates conductive pathways for efficient piezoelectric charge transport, achieving bone-like properties that make scaffolds suitable for bone tissue engineering. Under 1 MHz ultrasound stimulation at 0.4 W/cm2, the peak-to-peak voltage generation of PCL/ZnO increased from 41.0 ± 3.7 mV to 105.3 ± 7.4 mV due to TrGO. Scaffolds containing ZnO demonstrated accelerated hydrolytic degradation, while both binary and ternary composites showed good MC3T3 cell adhesion, viability, and enhanced ALP activity under both non-ultrasound and ultrasound conditions. 3D printed PENG scaffolds further exhibited improved hMSCs adhesion and viability. Other examples showing that conductive particles can increase the output of PENG based on polymers having piezoelectric particles will be further presented.

2:30 PM SB07.05.03
Metamaterials Based Mechanically Adaptive Scaffolds for Cells *Gaurav Dave, Barbara Schamberger, Sophie Geiger, Venera Weinhardt, Federico Colombo, Malin Schmidt, Sadaf Pashapour, Fereydoon Taheri, Ankit Mishra and Christine Selhuber-Unkel; Universität Heidelberg, Germany*

Cells are known to have an active participation in shaping their environment. It has been shown that there is a two-way communication between cells and the scaffold/extra-cellular matrix. It is well established that cells respond to the stiffness of their surrounding matrix. For example cell differentiation and morphology are impacted based on the substrate stiffness. It has been shown how geometry and topographical features have an impact. Different tissues also show diverse mechanical behaviour depending on their functions. However, most of the approaches have been towards manipulation of cells via either chemical modification of surfaces or static 3D patterns. Majority of the research discussing these aspects with reference to cell behaviour have a major disconnect in term of the scale at which the scaffolds or the investigated features are fabricated. In most studies in the past the feature sizes have been at least an order of magnitude larger than the cells. With currently present advances in additive manufacturing technology as well as implementation of design concepts from metamaterial designs, this gap can be narrowed. With techniques like two-photon polymerization-based printing combined with mechanical

meta-materials like auxetics we can achieve scaffolds that have geometrical features that are relevant to individual cells (1-5 µm) and with tuneable mechanical responses as well as the surface area available for cells to adhere to.
The aim of this project is to design and fabricate structures which can be actively deformed by traction forces applied by cells. To achieve a cell induced deformation of 3D printed structures, an auxetic design called the snakeskin kirigami pattern is selected as the principle design to build up on. The advantage with a design-based approach is that we do not rely on material chemistry. The mechanics and the deformation profile of the scaffold can be tuned by changing the geometrical aspects. Herein, 3D scaffolds based on snakeskin kirigami pattern were designed and fabricated via two-photon polymerization-based printing. Mechanical characterization of the 2D patterns on different scales (mm & µm) show ~90% drop in effective Young's modulus in comparison to the bulk material. Preliminary cell experiments show a bioactive micro-scaffold with active deformation in the structure post cell seeding.

Three-Dimensional Magnetic Polymeric Constructs for Magnetothermal Stimulation and Tissue Engineering
Ekaterina Kuznetsova and Dekel Rosenfeld; Tel Aviv University, Israel

Magnetothermal stimulation for cell modulation is based on heat dissipation from 20 nm iron oxide magnetic nanoparticles (MNPs) exposed to alternating magnetic fields with frequencies of 100-600 kHz and 10-60 mT. Such stimulation offers the ability to perform tumor ablation for cancer hyperthermia or neuromodulation via stimulation of heat-sensitive ion channels, such as the transient receptor potential vanilloid family member 1 (TRPV1), which has a temperature threshold of 42 °C.
Previous studies have primarily utilized MNPs as ferrofluid embedded in the cell medium for in vitro analysis or injected into the organ of interest. Our work introduces a novel method for constructing three-dimensional polymeric structures that can accommodate cells and MNPs. We comprehensively analyze the magnetic gel, including the MNP's impact on the microstructure, mechanical properties, heat dissipation, and biocompatibility. This magnetic gel acts as a functional scaffold, offering potential applications in regenerative medicine and in vitro examination of MNP's functionality. Moreover, we present optional tuning of the scaffold's properties for neuroscience applications by examining the functionality of neuronal cells seeded within the scaffold. Our results suggest the potential of the magnetic gel for tissue engineering, bioelectronic implants, and drug delivery.

Mimics of Natural Matrices Through Supramolecular Assembly *Kristopher Kilian and Ashley Nguyen; University of New South Wales Sydney, Australia*

Soft structures in nature reversibly assemble into hierarchical networks with non-linear viscoelastic properties that are central to directing cell activity and tissue assembly. Supramolecular assembly has been used to create *hydrogels that mimic the structural aspects of natural materials. However, synthetic approaches generally fall short in replicating the dynamic behaviour of native tissue. Here I will present our work designing supramolecular materials to serve as scaffolding for 3D cell culture and biofabrication. Using coarse grain molecular dynamics, we discovered a novel short peptide based on the "tryptophan zipper" (Trpzip) motif that self-assembles into a hierarchically ordered nanofibrous hydrogel. Trpzip gels display tunable modulus, self-healing characteristics, stress-relaxation behavior, with inherent bioactivity that promotes matrix deposition and cell proliferation. The low yield point and self-healing properties facilitate syringe extrusion with cytoprotection, while also providing scope for use as a support matrix for suspension bioprinting. Integrating complementary polymer networks can expand the range of mechanical properties, allowing increased strength and toughness, while maintaining desirable viscous characteristics. Overall, harnessing supramolecular assembly with careful design of network architecture holds promise for advancing our goal of mimicking the complex attributes of natures soft materials.*

4:00 PM *SB07.06.02

Transient Polymer Interactions for Dynamic and Reversible Hydrogel Viscoelastic Tuning and Cell Adhesion Control *Shane Scott[1], Maria Villiou[2,2], Federico Colombo[2], Angeles De la Cruz-García[2], Leon Tydecks[2], Lotta Toelke[2], Katharina Siemsen[3] and Christine Selhuber-Unkel[2,2]; [1]McMaster University, Canada; [2]Heidelberg University, Germany; [3]Kiel University, Germany*

Cells in multicellular organisms, such as humans, have evolved a mechanically-sensitive signalling pathway called mechanotransduction. Interestingly, mechanotransduction has been shown to direct stem cell differentiation towards different cell types, such as muscle or bone cells, simply by changing the environmental elasticity. It also plays an important role in tumour progression. Despite its importance to cellular and physiological systems, the effect of environmental viscoelasticity on mechanotransduction is still not well understood. While complex, light-based or other polymer-based techniques exist to tune environmental stiffness, they require complex setups or are only useable on a narrow range of hydrogels.

Here, we present a simple, cost-effective means of dynamically and reversibly tuning polymer hydrogel viscoelasticity using transient interactions using poly(ethylene glycol), or PEG. PEG polymers in solution with a hydrodynamic radius below the size of the hydrogel's pores can infiltrate it, dynamically interacting with hydrogel polymers. Alginate, a polymeric hydrogel derived from algae, is an ideal candidate for this transient polymer control: at 2% (w/v), alginate has a relatively large (~5 nm) pore size, allowing PEG of molecular weight up to at least 8 kDa to infiltrate and stiffen it. Using rheometry, we demonstrate that PEG interactions can increase hydrogel stiffness by as much as hundreds of kPa. Local elastic modulus measurements confirm rheometry measurements of alginate hydrogel stiffness increase in the presence of PEG. Despite the addition of interacting PEG polymers to the hydrogels, hydrogel viscosity does not increase, further reinforcing the idea that the interactions between PEG and the hydrogel polymers cause the material to stiffen. To determine that this stiffening effect is not due to an increase in alginate hydrogel concentration due to solvent being forced out of the hydrogel from osmotic pressure, we show that stiffness for alginate hydrogels exposed to 300 Da vs. 8 kDa PEG are vastly different, despite similar increases in alginate concentration. PEG uptake into alginate hydrogels is also confirmed using fluorescently tagged PEG, with both confocal microscopy and HPLC demonstrating a change in fluorescence intensity. Interestingly, this dynamic stiffening effect is a function of PEG molecular weight, indicating a size-dependent interaction between PEG molecules and polymer hydrogel molecules. We postulate that this interaction is due to hydrogen bonding between the PEG and hydrogel polymers. Furthermore, we demonstrate the reversibility of the process, an important application as it allows for both stiffening and weakening effects. This reversible and dynamic PEG interaction with hydrogel polymers is also possible with other kinds of hydrogels, such as agarose.

We also demonstrate the clear effect on the morphology of rat embryonic fibroblast (REF) cells grown on PEG-exposed alginate hydrogels, with cells displaying a stretched-out morphology on PEG-interacting hydrogels that is not present in alginate hydrogels not exposed to PEG. This cell morphology difference is shown to be the result of alginate hydrogel stiffening, as REF cells grown on a very stiff 7% (w/v) alginate hydrogels that are not exposed to PEG show similar cell morphologies as those grown on 2% (w/v) alginate hydrogels exposed to 8 kDa PEG. As a further control to determine that cell morphology differences are due to changes in substrate stiffness, cells grown in the same well as those grown on hydrogels and exposed to the same PEG-containing solution demonstrate similar morphologies to cells grown on alginate but not exposed to PEG. This study is of interest to the biomaterials and polymer materials community, demonstrating a simple means of tuning the cellular environment.

4:30 PM SB07.06.03

A Click-Based Strategy to Customize Polymer–Nanoparticle Hydrogel Properties for Versatile Biomedical Applications *Sophia J. Bailey, Noah Eckman and Eric A. Appel; Stanford University, United States*

Polymer–nanoparticle (PNP) hydrogels consist of a unique type of water-rich polymer network formed by dynamic, supramolecular bridging interactions between polymers and nanoparticles. Previous work by Appel and colleagues has demonstrated that dodecyl-modified hydroxymethylcellulose (C12-HPMC) can form supramolecular hydrophobic interactions with poly(ethylene glycol)-b-poly(lactic acid) nanoparticles (PEG-PLA NPs), providing injectable hydrogels well-suited for the sustained delivery of pharmaceuticals and cell-based therapies. Although other polymer–nanoparticle pairs have been investigated, including hexyl- and adamantyl-modified HPMC or various block copolymer nanoparticles, tuning PNP properties has largely been limited to altering the concentration of C12-HPMC and PEG-PLA NPs in solution. Thus, "stiff" PNP hydrogels are often prepared by mixing 2 wt% C12-HPMC with 10 wt% PEG-PLA NPs, while "soft" hydrogels will be prepared by mixing 1 wt% and 5 wt%, respectively. Although much successful work has been demonstrated by this simple concentration-based method, strategies to independently modulate concentrations, polymer–nanoparticle interactions, and hydrogel mechanics would enable better customization for broad biomedical applications.

Previous methods to prepare PNP hydrogel derivatives have been limited by the arduous synthetic requirements of block copolymer libraries or the limited scope of the reported HPMC modification strategy. Here, we leverage a robust click reaction that is compatible with a multitude of commercially available thiols and cysteine-bearing peptides to prepare a library of modified HPMC derivatives. We will demonstrate how systematically altering the hydrophobic or steric character of modifications can be used to tailor the mechanical properties of subsequent PNP hydrogels and how those mechanical properties relate to cell compatibility, hydrogel lifetime, and drug retention in vivo. We will also highlight how this strategy can be used to incorporate bioactive moieties within the PNP system to optimize cellular interactions. This ongoing work offers a route to optimize PNP hydrogels for a variety of translational applications and holds particular promise in the highly tunable delivery of pharmaceuticals and adoptive cells.

4:45 PM SB07.06.04

Multifunctional Hydrogel Foam Wound Dressings *Elizabeth Cosgriff-Hernandez; The University of Texas at Austin, United States*

A major challenge in chronic wound treatment is maintaining an appropriate wound moisture balance throughout the healing process. Wound dehydration hinders wound healing due to impeded molecule transport and cell migration with associated tissue necrosis. In contrast, wounds that produce excess fluid contain high levels of reactive oxygen species and matrix metalloproteases that impede cell recruitment, extracellular matrix reconstruction, and angiogenesis. Dressings are currently selected based on the relative amount of wound *exudate with no universal dressing available that can maintain appropriate wound moisture balance to enhance healing. This work aimed to develop a high porosity poly(ethylene glycol) diacrylate hydrogel foam that can both rapidly remove exudate and provide self-tuning moisture control to prevent wound dehydration. A custom foaming device was used to vary hydrogel foam porosity from 25% to 75% by adjusting the initial air-to-solution volume ratio. Hydrogel foams demonstrated substantial improvements in water uptake volume and rate as compared to bulk hydrogels while maintaining similar hydration benefits with slow dehydration rates. The hydrogel foam with the highest porosity (~75%) demonstrated the greatest water uptake and rate, which outperformed commercial dressing products, Curafoam® and Silvercel®, in water absorption, moisture retention, and exudate management. Investigation of the water vapor transmission rates of each dressing at varied hydration levels was characterized and demonstrated the dynamic moisture-controlling capability of the hydrogel foam dressing. Overall, the self-tuning moisture control of this hydrogel foam dressing holds great promise to improve healing outcomes for both dry and exudative chronic wounds. To confer infection control to these hydrogel foam dressings, we investigated a novel antimicrobial agent, Gallium maltolate (GaM). First, the minimal inhibitory and bactericidal concentrations (MIC and MBC, respectively) of GaM against two Staphylococcus aureus strains were identified. No significant adverse effects of GaM on dermal fibroblasts were shown at MIC, showing an acceptable selectivity index. For the sustained release of GaM, electrospraying was employed to fabricate microspheres with different release kinetics. The systematic studies indicated that the larger microsphere size and lower GaM loading resulted in more sustained GaM release profiles. The evaluation of the GaM-loaded hydrogel dressing has demonstrated its biocompatibility and antibacterial activities with a zone of inhibition test. An equine distal limb wound model was developed and utilized to demonstrate the efficacy of GaM-loaded hydrogel foam in vivo. This antimicrobial hydrogel foam dressing demonstrates the potential to combat methicillin-resistant S. aureus (MRSA) infection with controlled GaM release to improve chronic wound healing. Finally, we investigated a cost-effective means to confer active wound healing to the hydrogel foam dressings. Bioactive factors isolated from apopotic mesenchymal stem cells (MSCs) were loaded into a hydrogel foam to harness immunomodulatory and angiogenic properties from MSC components to facilitate chronic wound healing without the high cost and translational challenges of cell therapies. After incorporation of bioactive factors, the hydrogel foam retained high absorbency, moisture retention, and target water vapor transmission rate. High loading efficiency was confirmed and bioactivity retention of the released factors was also confirmed for as-sterilized, 4°C-stored, and -20°C-stored bioactive hydrogel foams as determined by relevant gene expression levels in treated pro-inflammatory (M1) macrophages. These results support the use of the bioactive dressings as an off-the-shelf product. Overall, this work reports a new method to achieve a first-line wound dressing with the potential to reduce persistent inflammation and promote angiogenesis in chronic wounds.*

SESSION SB07.07: Hydrogels for Medical Applications III

Recapitulating Transport Properties of the Human Blood Brain Barrier in an Isogenic Microphysiological Model *Sarah Spitz, Francsca Pramotton and Roger Kamm; Massachusetts Institute of Technology, United States*

Introduction. There has been a recent and dramatic interest in the development of models capable of recapitulating the unique characteristics of the human blood-brain barrier. This comes both from the development *of several new antibody drugs for neurodegenerative diseases such as Alzheimer's disease and from the desire to utilize the membrane-bound transporters unique to the brain endothelium for targeted delivery of drugs to treat cerebral diseases such as glioblastoma. To meet the need to understand the mechanisms of transport and use that understanding to develop new drugs and modes of delivery to the brain, researchers and the pharmaceutical and biotech industries have accelerated efforts to develop in vitro models of the BBB. Numerous models now exist ranging from 2D monolayer systems with a single (endothelial) cell type to more complex 3D models consisting of multiple cell types felt to be instrumental in determining the transport properties of the BBB. Among the approaches used in the complex model, ones that utilize the natural self-assembly properties of the BBB cell types (endothelial, pericyte, and astrocyte) appear capable of growing in vitro models with in vivo-like morphology and function that closely parallel those of the human brain.*

While these models have demonstrated their potential, they suffer from relatively high variability due both to the natural biological diversity of the self-organized vascular networks and to the lack of a consistent, long-term cell source. This has led to several groups seeking to develop models that can be generated entirely from induced pluripotent cells that have the combined advantages of being derivable from patient-specific cells and, in principle, constitute an inexhaustible supply thereby representing a long-term consistent source for models.

Methods and Results. Here we report on one such model that combines iPSC-derived endothelial cells, pericytes and astrocytes from a single cell line (Alstem iPS11) widely available to both the research community and industry. Published protocols are used to derive pericytes and astrocytes, and a protocol for endothelial cells using inducible ETV2 has been adapted from prior publication [ref]. Using methods developed in our lab for generating a 3D BBB model [Hajal, et al., Nat Prot, 2022], the tri-ulture system is developed in a perfusable microfluidic platform using cell ratios that have been optimized to closely match those found in the human brain. Both the morphology (characterized by quantitative analysis of the network and interactions between the different cell types) and function (reflected by vascular permeability) were quantitatively assessed for direct comparisons to in vivo data. Transcriptional analysis and immunohistochemistry are used to determine the expression levels of key brain-specific markers, including the various transporter proteins found in the endothelial cells, and compared to human cell lines. In particular, genes associated with brain endothelial phenotype appear to be highly expressed whereas there is an absence of those genes that tend to be expressed in cells with an epithelial phenotype. Vascular permeability for a 10 kDa dextran (2.0 x 10^{-7} *cm/sec) matches in vivo measurements in rats. High resolution 3D imaging and multi-photon metabolic imaging demonstrate tight endothelial cell junctions marked by ZO-1 and claudin-5 along with a uniform distribution of vasculature throughout the full 500 mm height of the vascularized gel region.*

Conclusions. An isogenic model of the human blood-brain barrier can be produced from a tri-culture of endothelial cells, pericytes and astrocytes with physiological morphology and barrier function similar to in vivo. This system offers long-term consistency for use in models of neurovascular diseases such as cerebral amyloid angiopathy and for the screening of molecular therapeutics that utilize transporter proteins specific to the brain.

Dynamic Adhesive Fibers for Remote Capturing of Objects *Marco Lo Presti[1], Marina Portoghese[2] and Fiorenzo Omenetto[1]; [1]Tufts University, United States; [2]University of Cambridge, United Kingdom*

B. Mori silk has been extensively utilized to create Regenerated Silk Fibroin solutions (RSF) for a wide range of technological applications, including tissue engineering, drug delivery, biomaterials, and adhesives. In this study, we introduce a RSF-dopamine (DA) composite that yields easily deployable hydrogel fibers possessing adhesive properties that can be released on demand to capture and retrieve loads from a distance. The RSF-DA serves as an artificial dope, combining the functional attributes of silk fibroin (i.e. hydrogel formation) and dopamine (i.e.

adhesion) to instantly generate adjustable fiber-like hydrogels displaying a sticky behavior. The mechanical strength and adhesive characteristics of the fibers are assessed using tensile and lap-shear tests. Furthermore, we demonstrate the possibility of tuning these properties by adding chitosan (Ch) and borate ions (BB), leading to remarkable mechanical and adhesive performances up to 107 MPa and 280 kPa, respectively, which allows the retrieval of objects from the ejected structure. This process could be finely tuned to achieve a controlled fabrication of instantaneously formed adhesive fiber-like hydrogels for manifold applications, mimicking living organisms' ability to eject tunable adhesive functional threads.

9:45 AM SB07.07.04

Formulation of a Lubricating, Self-Healing Gellan Gum Eyedrop to Prevent Corneal Scarring in Epidermolysis Bullosa Patients *Sam Moxon[1], Richard Williams[2], Anthony Metcalfe[1], Richard Moakes[1] and Liam Grover[1]; [1]University of Birmingham, United States; [2]Healome Therapeutics, United Kingdom*

Epidermolysis bullosa (EB) is a rare genetic disorder caused by mutations in genes encoding for components of skin extracellular matrix (ECM) with the most severe symptoms arising from collagen-VII mutations. Consequently, the ECM integrity is compromised and patients experience skin fragility and blistering in response to minor trauma or friction. The severity of EB varies widely between patients but at its most severe, the blistering occurs over the whole body and results in internal, potentially fatal fibrosis. Treatments for EB primarily focus on managing symptoms/preventing infections. Patient quality of life is, however, still severely compromised and current treatments often fail to provide sufficient relief.
Safeguarding ocular function in EB patients is particularly challenging. EB-associated mutations can manifest in the eyelid and cornea. Even the act of blinking can then trigger extensive corneal scarring, resulting in severe eye pain and impaired vision.
This project is developing a lubricating, self-healing gellan-gum fluid gel eye drop that patients can purchase at low cost and apply daily to prevent ocular friction and scarring. Fluid gels were formulated at a variety of shear rates to evaluate the impact of formulation parameters on fluid gel rheology and lubrication. All samples exhibited a friction coefficient comparable to current eye drops. Moreover, the applied shear rate was found to directly influence fluid gel stiffness and stress responses without impacting viscosity. The changes in rheology also translated into alterations in the lubricating properties of the fluid gel, with increases in gel stiffness correlating with decreases in friction coefficients. Furthermore, we have successfully decoupled high viscosity from functionality by controlling the structuring of the material. This allows us to generate optimal rheological properties for eye drop retention without impairing the ability to extrude the solution through an eye dropper
Additionally, our formulation has been shown to protect cultured fibroblasts from undergoing differentiation into myofibroblasts in response to shear—a key mechanism of fibrosis. The fluid gel eye drop also sequesters pro-fibrotic factors like TGF-beta and inhibits downstream expression of pro-fibrotic genes. This highlights the significant potential of our formulation to not only provide lubrication but also actively prevent fibrosis, a major concern in ocular health.

10:30 AM *SB07.07.05

Exploring Stem Cell Niches with Bone Marrow-Inspired Materials *Cornelia Lee-Thedieck; Leibniz University Hannover, Germany*

Stem cells are tightly regulated by their direct microenvironment, so-called niches, through biological, chemical, and physical factors. The bone marrow harbors niches for the stem cells of the blood and the bone regenerating systems, with hematopoietic stem cells (HSCs) as the source of all types of blood cells and mesenchymal *stem/stromal cells (MSCs) from which bone cells are derived. Both regenerating systems interact closely in the rich environment of the bone marrow.*

Using scaffold-based 3D in vitro models of the bone marrow, we investigate the interplay of stem cells with their niches under healthy, physiological, and diseased conditions such as leukemia, bone metastasis, and large bone defects. In this way, we contribute to the fundamental understanding of both healthy and malignant niches, revealing significant inter-individual differences.

The acquired knowledge can be used to expand or selectively differentiate HSCs, an important goal of stem cell research aimed at HSC transplantation for treating patients with hematological diseases or other cellular therapies relying on blood cells, such as CAR-T cells. Furthermore, we have demonstrated in proof-of-principle studies the applicability of the developed models as drug testing platforms, allowing us to assess the efficiency and potential toxic side effects of treatments like chemotherapeutics. Finally, 3D printable formulations to mimic the stiff calcified bone and the soft bone marrow have been developed and are being optimized to improve the treatment of critical-size bone defects.

In conclusion, 3D bone marrow-inspired materials, created via conventional or printing technology, pave the way for fundamental studies on stem cell-niche interactions. Their multifaceted application potential includes pharmacological drug testing, bone tissue engineering, and cell production for cellular therapies.

11:00 AM SB07.07.06

Physico-Chemical Investigations of the Deeper Osteoid Tissue *Camille Chareyron and Nadine Nassif; Sorbonne Université, France*

Bone tissue is responsible for skeletal structure and function. The tissue undergoes dynamic remodeling characterized by a complex matrix of mineralized collagen fibrils. Recent studies on sheep bone biopsies have investigated the deeper osteoid (1) at the interface between osteoid and mature bone. It was identified as a distinct zone exhibiting an acidic pH (~ 5-6). This deeper domain was named acidic osteoid, and was shown to be highly structured by collagen molecules rather than fibrils. Further, it was characterized as a mesophase (liquid crystal analogues) with a continuous birefringence texture similar to that of mature bone (2). This observation strongly suggests that this domain is responsible for the formation of the twisted plywood structure in bone (3). This work aims to characterize this specific domain in different bone pathologies.

To this end, we use sections from physiological and pathological human biopsies, as well as collagen matrices as a biomimetic model of this acidic osteoid. The synthetic acidic osteoid is synthesized using an injection/dialysis process (4) to understand the mechanisms involved in the formation of this zone. The collagen solution is implemented with organic additives identified in bone (i.e., glycosaminoglycans (5) and citrate (6)) and inorganic ions to precipitate carbonated apatite. In parallel, an in-depth investigation of this domain in a series of histological sections from different pathologies that are extracted from human iliac crests was carried out. Characterizations were conducted focusing on the acid osteoid density, composition, spreading, pH, and organization. Experimental characterizations imply an interdisciplinary approach, combining analytical techniques from the fields of biology and materials science including multi-scale microscopic observations (MOLP, SEM, and TEM) with different pathologist-related staining, microstructure characterization (SAXS/WAXS), and 1H and 31P environment analysis (solid-state NMR). Collaboration with medical experts and physicists was crucial for this original approach.

We show that models of the acidic osteoid domain can be synthesized in vitro in the presence of citrate and glycosaminoglycans. The additives tend to stabilize a lower pH and lead to differences in macroscopic, *microscopic, and mineralization aspects. Moreover, analyses of the pathological histological sections revealed both qualitative and quantitative destabilization of the acidic non-fibrillar domain in some of the selected bone pathologies. Strikingly, this is also observed in the adjacent mature bone. The results strengthen the idea that the organization of mature bone directly depends on that of the deeper osteoid, which might be involved in the development of bone pathologies.*

This interdisciplinary work contributes to a better understanding of the physico-chemical processes underlying bone formation. The aim is to validate the feasibility of a physico-chemical diagnosis that would complement the anatomo-pathological and genetic analyses that focus on bone quantity and quality. These advances could open up new prospects for the development of therapeutic targets (e.g., organ-on-chip).

Tissue-Mimetic Tough and Poroviscoelastic Hydrogel Biomaterial for Tissue Engineering *Ismael Lamas[1], Michelle L. Oyen[2] and Mohammad R. Islam[1]; [1]The University of Texas at Rio Grande Valley, United States; [2]Washington University in St. Louis, United States*

Hydrogel-based tissue engineering is a promising strategy for damaged tissue regeneration. Hydrogels with highly swollen and three-dimensional (3D) polymer networks are ideal scaffolds for cell attachment and proliferation. While hydrogels can recapitulate the physical attributes of the tissue extracellular matrix (ECM), they are limited in terms of mechanical properties. Load-bearing tissues like articular cartilage or tendon possess remarkable mechanical properties, including good strength and large fracture toughness. Biological tissues are also time-dependent materials with strong load-relaxation ability due to poroviscoelasticity. They are also highly porous materials to accommodate cells and support cellular processes. Mimicking this combination of mechanical and structural properties in hydrogel biomaterials is important for tissue engineering applications but remains challenging. In this work, we experimentally characterized a double network (DN) hydrogel that combines excellent mechanical properties with meso-scale porosity for tissue engineering applications. The double-network hydrogel consists of polyvinyl alcohol (PVA) and agar, two commonly used polymers in biomedical applications. The DN gel consists of an entangled network of agar double helices as the first system and a semi-crystalline PVA network as the second one. It is a fully physically cross-linked DN gel, unlike the conventional DN gels with one or both covalent networks. It was observed that the PVA-agar DN gels are highly swellable with an equilibrium water content comparable to soft tissues, not affected by the agar content. However, the addition of agar induces sub-millimeter-sized pores in the DN gel, and the density of meso-scale pores increases with agar content. The hybrid gels exhibit synergistically increased fracture toughness comparable to soft tissues like articular cartilage, which increases linearly with agar content. Agar further provides enhanced time-dependent load-relaxation in the double-network gels. The load-relaxation data of the DN gels were analyzed using an analytical poroviscoelastic model. The model effectively identified the dominant relaxation mechanisms in the hydrogels at different time scales. The viscoelastic relaxation dominated the rapid load-relaxation at the initial stage, but the long-term relaxation behavior of the gels was dictated by poroelastic relaxation. The fundamental design strategy of most DN gels is to sacrifice the strong network to achieve high fracture toughness and use the second soft and ductile network to preserve structural integrity. An opposite design strategy is observed in the PVA-agar DN gels, where the *weak network (agar) is sacrificed, whereas the strong network (PVA) is retained. This unique strategy provides excellent ability to resist cyclic loading and improved load-relaxation properties, in addition to large fracture toughness. Overall, these promising characteristics demonstrate the potential of PVA-agar gels for clinical studies on the repair and regeneration of load-bearing tissues.*

11:30 AM SB07.07.08

Mimicking Dynamic Changes in the Lung Extracellular Matrix with Visible Light-Responsive Materials to Understand Lung Injury and Fibrosis *Samantha L. Swedzinski, Lina Pradhan, Jodi Graf, Catherine Fromen and April M. Kloxin; University of Delaware, United States*

Microinjuries to cells and extracellular matrix (ECM) in the lung can induce maladaptive wound healing that lead to disease, from fibrosis to late cancer recurrence. These events are associated with changes in the mechanical properties of the cellular microenvironment that are known to greatly impact cellular functions although underlying mechanisms are not fully understood. Cell culture platforms that synthetically mimic these changes in mechanical properties are needed to study and understand these diseases toward ultimately designing improved treatment strategies. Using visible light as an external stimulus, this work aims to fabricate a platform that mimics the mechanical property changes associated with maladaptive wound healing, from injury to subsequent stiffening, to study the cellular responses to these dynamic changes in the microenvironment. Strain-promoted azide-alkyne cycloaddition hydrogels were formed using a coumarin-containing linker to enable injury-mimetic properties. The stiffening mimetic properties were then enabled by triggering thiol-yne reactions via visible-light photoinitiation. Changes in viscoelastic properties were also triggered. The biomechanical properties of this hydrogel-based synthetic ECM were modulated to mimic injury and repair processes via selective photodegradation and subsequent photoreactions. Assessment of these mechanical changes was performed with rheometry and confocal imaging. Relevant cell types (e.g., epithelial cells, macrophages) were cultured on these synthetic ECMs and then subjected to injury, stiffening, and injury-stiffening, and cellular responses were assessed via immunostaining and imaging. The use of this photoresponsive hydrogel-based synthetic ECM platform to probe cellular response to injury and fibrosis aims to provide new tools for probing cellular responses to dynamic biomechanical changes and mechanistic insights toward modulating these complex processes and preventing disease.

SESSION SB07.08: Instructive Cues to Guide Cell Behavior I

Biometamaterials—A New Tool to Stimulate and Regulate Single Cells and Cell Ensembles *Motomu Tanaka[1,2]; [1]Heidelberg University, Germany; [2]Kyoto University, Japan*

Metamaterials offer unique advantages over plastic- or hydrogel-based substrates, because the effective elastic properties can be adjusted flexibly by the unit cell arrangement. However, most of the studies so far have been using them merely as "scaffolds" that are far stiffer than the mechanical enviromnets of cells in vivo. The major challenges are to fabricate the metamaterial unit cell smaller than the size of biological cells, and to make the metamaterials deformable by the active cell contraction. We fabricated metamaterials based on a soft elastomer-

like photoresist using two-photon laser printing, and applied them to regulate the morphology and mechanosensing functions of human mesenchymal stem cells. "Biometamaterials" with tailor-made mechanical properties open a new possibility towards the mechanical regulation of not only single cells but also multicellular ensembles.

2:00 PM *SB07.08.02

Growing Fibres on Curved Surfaces—Towards an Understanding of Tissue Growth in Bone *John W. Dunlop[1], Parvathy Anoop[1], Thomas Antretter[2], Paula Belska[1], Franz Dieter Fischer[2], Heidi Pertl-Obermeyer[1], Andreas Roschger[1], Barbara Schamberger[3] and Peter Fratzl[4]; [1]Universität Salzburg, Austria; [2]Montanuniversität Leoben, Austria; [3]Heidelberg University, Germany; [4]Max Planck Institute of Colloids and Interfaces, Germany*

Biological materials display an enormous range of material properties ranging from soft flexible connective tissues to hard mineralised materials such as bone and shell. The diversity in (structural) properties is attained through the clever arrangement of a relatively small range of building blocks, being fibres (collagen, cellulose or chitin), matrices and minerals. Although much is known about the link between structrure and function, relatively little is known about how these materials grow and are organised over length scales much larger than that of a single cell. Many biological materials grow on or at an interface, the shape of which can also determine the orientation and arrangement of the growing elements, cells and extra cellular matrix. The interface itself will also change shape due to growth resulting in a complex coupling between changing geometry and the patterning of cells. This presentation will present theoretical and experimental explorations into the 3D pattern formation of growing fibrous materials and give insights into how surface curvature can influence the alignment of cells and extracellular matrix. The focus will be on 3D cell cultures of pre-osteoblast cell lines and simulations of tissue patterning on surfaces of different curvature. It is hoped that the knowledge gained will assist in the design of new substrates for tissue regeneration and allow us to use surface geometry as a tool to direct cells to produce tissues with tailored properties.

3D-Printed, Bioinspired and Tunable Strain-Stiffening Structures as a Candidate for Cell Studies and Tissue Engineering *Malin Schmidt, Mohammadreza Taale, Gaurav Dave and Christine Selhuber-Unkel; Heidelberg University, Germany*

2-photon-polymerization (2PP) based 3D printing is a technique that enables the fabrication of highly complex micro- and nanostructures with high spatial control in all three dimensions. Therefore, 2PP direct laser writing gives rise to structures mimicking the microenvironment of cells and their extracellular matrix (ECM), which is highly interesting for the field of cell studies, tissue engineering and biomedical applications.
One very important property of cells, ECM and soft tissues like tendons, skin, muscles or ligaments is the nonlinear strain-stiffening behavior: They become stiffer with an increasing strain, leading to a J-shaped curve in the stress-strain diagram. We mimicked this mechanical phenomenon by developing a metamaterial, that increases its stiffness at a certain strain rate by simple design features. The obtained structure has a highly nonlinear, adjustable, rate-independent and reversible strain-stiffening behavior that can be implemented into various elastic materials and hence is not material depended. Changes in geometry affect the point of stiffening as well as the initial and final stiffness of the material. In addition, the strain-stiffening mechanics can also be used in complex three-dimensional arrangements like sheets, tubes or 3D networks. [1]
In this work, we now study the miniaturization of our metamaterial. Using 2PP direct laser writing with different materials ranging from hydrogels to acrylate-based materials and silicones, allows us to study our design in the

micron range. We evaluate the 3D printed structures in the means of shape accuracy, size limitations, force range and their stability in 3D. Materials, which we found very promising are hydrogels and highly elastic resins. By using materials which moreover allow cell adhesion, the behavior of cells can be studied. In future, our design will be used to study the mechanosensing and mechanotransduction of cells in a 3D network, that truly resembles the mechanics of soft tissue and the ECM.

Alginate Hydrogel Characteristics Regulate Human Fibroblasts in 2D and 3D Culture *Margrethe C. Stahl[1], Aman Chahal[1,2], Daria Zaitseva-Zotova[1,3], Hanne Haslene-Hox[2], Robin Mjelle[1], Øystein Arlov[2], Øyvind Halaas[1], Pål Sætrom[1] and Berit L. Strand[1]; [1]Norwegian University of Science and Technology, Norway; [2]Sintef Industry, Norway; [3]University of Oslo, Norway*

2D cell culture has been an indispensable tool to study cells and tissue, however 3D cell culture, matching the cell microenvironment, are believed to closer replicate in vivo complexities. Fibroblasts are present in the interstitial spaces of vital organs and typically reside close to the tissue epithelium. They are an important component of the microenvironment, where they contribute to barrier support, adjacent cell maintenance and overall tissue homeostasis. However, fibroblasts are most popularly known for regulating the production, turnover, and composition of the extracellular matrix (ECM) within tissue. As a result, maintaining normal fibroblast function is critical for the overall health and function of the organ it is housed in. Derived from the mesenchymal lineage, fibroblasts exhibit spindle like morphologies and are susceptible to physical and chemical changes in their microenvironment. We explore both 3D and 2D culture of human primary fibroblasts within and on top of alginate hydrogels. We optimize soft and stable alginate hydrogels for 3D culture and study fibroblast transcriptome and proteome when cultured in peptide-grafted and sulfated alginate hydrogels. We also use alginate hydrogel microspheres for the culture of fibroblasts in 2.5D environment aiming for the formation of complex in vitro tissue structures with the focus on the interstitial space.

4:15 PM SB07.08.05
Novel Protein-Based Bioadhesive Hydrogel with Tunable Material Properties *Juya Jeon and Fuzhong Zhang; Washington University in St. Louis, United States*

Synthetic biology offers the opportunity to design and produce novel protein-based materials with tunable properties. One type of such protein is silk-amyloid-mussel foot proteins (SAMs) consisting of β-amyloid peptide, spider silk domain, and mussel foot protein (Mfp). Hydrogels of SAMs display unique tunability, biocompatibility, bio-absorbability, strong cohesion, and underwater adhesion, making them attractive candidates for various biological surfaces. Understanding the relationships between protein sequence and hydrogel properties is important to designing tunable SAM hydrogels for different biomedical applications. Here, we fabricated SAM hydrogels using hybrid proteins of varying lengths of silk-amyloid repeats and Mfps and characterized their structure and properties. We found that increasing silk-amyloid repeats enhanced hydrogel's β-sheet content ($r = 0.74$), leading to higher cohesive strength and toughness. Additionally, increasing Mfp length beyond half-length of the full Mfp sequence (½Mfp) decreased β-sheet content ($r = -0.47$), leading to higher cohesive strength and toughness. Among different variants, hydrogel made of 16xKLV-2Mfp displayed a high ultimate strength of 3.0±0.3MPa, an ultimate strain of 664±119%, and an attractive underwater adhesivity of 416±20kPa to porcine *skin. In summary, the sequence-structure-property relationships learned from this project will be useful to guide the design of future protein adhesives with tunable properties for tailored surgical applications.*

4:30 PM SB07.08.06

How Neuromorphic Microstructures Control In Vitro Neuronal Outgrowth *Claudia Latte Bovio[1,2,3], Esther Matamoros[4,3] and Francesca Santoro[1,4,3]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Naples Federico II, Italy; [3]Forschungszentrum Jülich GmbH, Germany; [4]RWTH Aachen University, Germany*

In tissue engineering and bioelectronics, neuromorphic materials represent a new class of materials that mimic neuronal architectures and features to better replicate the physiological environment of native neuronal tissue. Biomimetic micro- and nanostructures can provide physical support and guidance for neurons, aiming to engineer chip-based platforms capable of monitoring and stimulating neuronal networks. Two major challenges remain: controlling the morphology of neuromorphic materials and understanding how these materials affect neural network development during different outgrowth phases.

Here, we present ad hoc biomimetic microstructure arrays fabricated via two-photon polymerization to resemble various morphologies and spatial arrangements of neuronal dendritic spines, with fixed material. We identified three geometries: thin shapes that initiate contacts with presynaptic terminals, crucial in early spinogenesis; mushroom shapes resulting from the dynamic reshaping of neuronal circuits during synaptic development; and stubby forms. The experimental approach involved primary cortical neurons. Our work demonstrated mechanical interactions at focal adhesion sites, which oversee the continuous remodeling and adjustment of cells on the material's surface and generate localized traction forces. Neurons utilize these forces for directed movement through contact guidance and for membrane invagination during engulfment, leading to precise localization of transmembrane proteins, including integrins, and specific cytoskeletal arrangements.

The integration of non-conductive polymers in neural recording devices is pivotal for advancing the field of bioelectronic interfaces. Our recent research underscores the profound impact these materials have on the mechanical rearrangement and the overall recording quality.

Microelectrodes, when combined with non-conductive polymers, significantly influence the directionality and remodeling of neural networks. This effect is particularly noticeable during the growth cone phase, where the transition from pausing to a resting state is critical. Our findings indicate that different pitch configurations of microelectrodes can alter the growth cone rate, emphasizing the importance of precise design in neural recording systems.

One of the key discoveries of our research is the role of biomimetic topographical cues. These cues rapidly affect membrane adhesion proteins, thereby enhancing the efficiency of neural recordings. Through advanced techniques like 3D reconstruction integrated into an electrical equivalent model, we've demonstrated that these topographical cues can significantly improve membrane interactions and overall signal integrity.

Looking ahead, the insights gained from our study hold promise for future applications in controlling signal dissipation. By leveraging the unique properties of non-conductive polymers and the strategic design of microelectrodes, it is possible to enhance the recording capabilities of devices used with electrogenic cells. This can lead to more accurate and reliable data collection, ultimately benefiting various fields such as neuroscience, bioengineering, and medical diagnostics.

We characterized the cell response considering neuronal-material interface processes such as adhesion, endocytosis, polarity, and network development. These new platforms pave the way for improved biomaterial-neuronal coupling aimed at neuroengineering and monitoring/stimulation.

In summary, the utilization of non-conductive polymers in recording technologies not only improves mechanical rearrangement but also enhances the overall efficiency and accuracy of neural recordings. Our research highlights the importance of material choice and design in developing advanced bioelectronic interfaces, paving the way for future innovations in the field.

Studying Bladder Cancer Spheroids in 3D Collagen-Hyaluronic Hydrogel Exposed to Shear Forces *Malgorzata Lekka and Sara Metwally; Institute of Nuclear Physics PAN, Poland*

Cells in tissues are subjected to a variety of mechanical forces generated by their microenvironment, which regulate and influence their properties and behavior. Understanding how cells respond to mechanically altered environments is especially critical in cancer research, as migrating and invading cancer cells can actively modify the viscoelastic properties of surrounding tissues. To fully comprehend metastasis, it is essential to evaluate the dynamic interactions between cells and the mechanics of the extracellular matrix (ECM). Recently, 3D spheroids have been widely used as tumor models because they can mimic the complex physiological properties of living tissues.
In this study, collagen-hyaluronic acid (Col-HA) hydrogels with embedded spheroids were used as a model to study cell migration in a complex 3D environment mimicking the ECM. Spheroids were formed from human non-malignant ureter cells (HCV29), transitional cell carcinoma cells (T24), and bladder carcinoma cells (HT1376). The study aimed to analyze the viscoelastic properties of Col-HA hydrogels and their effect on spheroid deformation and cell migration into the surrounding 3D scaffolds. We used a rheometer to study the elasticity and fluidity of the spheroids, quantified by the storage (G') and loss (G") moduli and the transition frequency f_T (G'=G"). The stiffer and softer hydrogels were characterized by G' of 28.8 ± 1.1 Pa and 0.84 ± 0.01 kPa and by G" of 7.6 ± 1.8 Pa and 0.15 ± 0.0 kPa, respectively. They were subjected to shear strain ($\gamma = 1\%$) and frequency ($f = 0.1 \div 10$ Hz), simulating the strength of physiologically relevant mechanical forces. Incorporating spheroids into Col-HA hydrogel changed the rheological behaviors of the Col-HA 3D system, depending on the spheroid type and Col-HA mechanics. Moreover, our study showed that increased mechanical properties of the hydrogels inhibited spheroid deformation. Cell migration was significantly higher for the highly invasive T24 cells compared to HCV29 and HT1376 cells. These results indicate that Col-HA-based hydrogels are a suitable model for studying the mechanical resistance of spheroids under applied shear forces. We showed that cell escape from the spheroids' surface into the 3D Col-HA matrix depends on both the hydrogel mechanics and cell type. These results may help in understanding the relationship between physicochemical and biological properties at the cell-ECM interface.

SESSION SB07.09: Poster Session: 3D Bioinspired Biomaterials
Session Chairs: Elizabeth Cosgriff-Hernandez, Markus Muellner and Christine Selhuber-Unkel

Clarification of Cuticle Characteristics Based on Wettability and Frictional Properties of a Single Hair *Sora Shibata and Daisuke Ishii; Nagoya Institute of Technology, Japan*

The outermost surface of the hair of living creatures is covered with cuticles made of keratin proteins. The cuticle is an important factor in determining the texture and beauty of hair and is known to play other roles such as protecting hair from external stimuli and regulating the amount of moisture. The mechanism by which hair absorbs water, one of its functions, has not been thoroughly clarified. Therefore, in this study, our objective was to clarify the mechanism by which water is absorbed into the hair. In addition, our objective was to quantify the state of the *cuticle structure, as we believe that the state of the cuticle on the outermost surface has a significant effect on how hair gets wet.*

For the hair samples, commercially available human hair (Beaulax: The same Human Hair BS-PG) was used. First, the hair was thoroughly cleaned by ultrasonic cleaning, and then subjected to multiple surface treatments, such as heat treatment, freeze-drying, or bleaching, and then divided into samples for each treatment. After that, surface structure observation, wettability evaluation, and friction evaluation were performed for each hair.

For surface structure observation, scanning electron microscopy (SEM) and atomic force microscopy (AFM) were used to confirm the state of the hair surface before and after each treatment. The SEM observations showed differences in the surface condition between the untreated hair and each treated hair. The cuticle of the treated hair appeared to be open. In particular, hair treated with bleach, a chemical treatment, showed that the cuticle melted according to the degree of bleaching. (We also confirmed that some hairs had lost all their cuticles due to a strong bleaching treatment.) The AFM observations measured the step of the cuticle, which cannot be identified from the SEM image. It was confirmed that the degree of cuticle opening varies depending on the type of surface treatment.

In the wettability evaluation, an automatic ultra-small contact angle meter (Kyowa Interface Science Co., Ltd.: MCA-3 type I) was used. A drop of water of approximately 30 pl was dropped on the hair surface under each condition and the wetting behavior of the droplet was observed from a direction perpendicular to the hair. When the change in the contact angle over time was focused on, the amount of decrease in the contact angle immediately after the liquid was applied was different depending on the treatment conditions. This difference is thought to be due to the absorption of water into the hair and the spreading of the water droplet on the hair surface. In particular, the decrease in the contact angle was greater for bleached hair compared to untreated hair. This was thought to be due to the fact that water penetrates more easily into bleached hair and that the discontinuous cuticle structure promotes the spreading of water droplets.

The purpose of friction evaluation was to quantify the state of the cuticle observed in the SEM images. For measurement, a static and dynamic friction measuring device (Trinity Labs: TL201Tt) was used to assess the friction of a single hair. A contactor with a hardness equivalent to that of a fingertip was used and the kinetic friction coefficients in the hair tip and root directions were measured for hair under each treatment condition with loads of 10g, 50g and 100g. As a result, firstly, the kinetic friction coefficient in the root direction was greater than in the tip direction under all conditions. In addition, differences in the kinetic friction coefficient were observed depending on the treatment condition.

From these results, we discovered that the tendency of water absorption differs depending on the state of the cuticle. In addition, the results suggest the possibility of quantifying the state of the cuticle in terms of wettability and friction properties.

SB07.09.02

Tau Amyloid Corona-Shelled Nanoparticle-Based Drug Screening Platform for Discovering Tau Oligomer-Degrading Drugs

Junho Bang and Dae Sung Yoon; Korea University, Korea (the Republic of)

Tau oligomers have been known to play a crucial role in neuronal toxicity and synaptic dysfunction in a heterogeneous group of neurodegenerative diseases collectively known as tauopathies. However, the discovery of drugs that specifically target tau oligomers has been impeded by the lack of appropriate screening methods. Here, we suggest a drug screening platform based on tau amyloid corona-shelled nanoparticles (TACONs) to assess the efficacy of tau oligomer-degrading compounds through aggregation-induced colorimetric responses of TACONs. TACONs were engineered via the encapsulation of gold nanoparticles with homogeneous tau oligomers by leveraging heparin as a co-factor. Further, to validate the proposed strategy, we employed tau oligomer-degrading proteases (protease XIV and plasmin) and various small molecules that have been demonstrated to aid in the treatment of tauopathies. We demonstrated that the proposed strategy with TACON can discover tau oligomer-

degrading agents, thereby potentially reducing the attritive problem encountered in drug discovery for tauopathies.

SB07.09.03

Free Energy Factors that Regulate Permeability Through Bacterial Microcompartment Shells Using Molecular Dynamics Simulations *Hayley Norton, Emiel Kram and Alexander Pak; Colorado School of Mines, United States*

Bacterial microcompartments (BMCs) are proteinaceous organelles that selectively encapsulate enzymes and control metabolite flux. Re-engineering the permeability of BMC shell proteins to extend to non-native metabolites will enable broad biotechnological outcomes, for example as part of a new circular carbon economy. However, rational engineering of BMC permeability requires knowledge on the molecular factors that contribute to selective pore permeability, which are difficult to observe using experimental methods alone. Molecular dynamics (MD) simulations are a complementary approach to investigate BMC permeability at atomic resolution. In this work, we model the permeability of acetate and carbonic acid, two precursors for fatty acid synthesis, through Haliangium ochraceum BMC hexamers, a model BMC system for protein engineering. To probe the free energy factors contributing to the permeability of metabolites through the BMC pore, we use umbrella sampling and metadynamics to quantify the potential of mean force (PMF) describing permeation. The PMF reveals free energy barriers from which specific protein residues can be inferred as targets for engineering. We aim to mutate these residues to increase permeability of target metabolites for carbon fixation and reduce efflux of potential intermediates, ultimately leading to new strategies for carbon capture and utilization from the atmosphere.

SB07.09.04

Biomimetic High-Throughput Screening Platform for SGLT-2 Inhibitors Using HK-2 Cell Membrane *YeonHo Kim and Dae Sung Yoon; Korea University, Korea (the Republic of)*

Sodium glucose co-transporter-2 (SGLT-2) is a membrane transporter protein that is utilized for glucose reabsorption in the kidneys. SGLT-2 inhibitors have been widely used in the treatment of type 2 diabetes. Moreover, SGLT-2 inhibitors have demonstrated efficacy in the treatment of non-alcoholic fatty liver disease and heart failure, with an increasing utilization of these agents. This has resulted in an increasing necessity for a precise and high-throughput SGLT-2 inhibitor screening platform. In this study, we present a biomimetic, high-throughput SGLT-2 inhibitor screening platform. The platform employs glucose oxidase immobilized gold nanoparticles coated with human kidney 2 (HK-2) cell membrane (HK-GOx-AuNPs). Upon the addition of a solution comprising glucose, ABTS, and horseradish peroxidase (HRP) to the HK-GOx-AuNP solution, an absorbance peak at a wavelength of 535 nm is observed, resulting from the oxidation of ABTS. However, the absorbance intensity is significantly reduced in the case of HK-GOx-AuNPs that have undergone reaction with SGLT-2 inhibitors. The difference in absorbance intensity between the presence and absence of the inhibitor can be used to quantify the efficacy of the inhibitor, with the evaluation of inhibitor candidates completed in 20 minutes.

SB07.09.05

Advanced Drug Screening Platform Utilizing Capillary and Artery Models Based on Tumor-Vessel Interactions *Jihyeon Song, Yeji Lee and Junmin Lee; Pohang University of Science and Technology, Korea (the Republic of)*

One of the hallmarks of tumors is angiogenesis, which involves forming new blood vessels around the tumor to provide it with oxygen and nutrients, thus supporting tumor growth and metastasis. In this study, we created a tumor-vessel spheroid model that can be used for high-throughput screening using microwells. The cancer spheroid model is an inverted version of a native environment with glioblastoma (GBM) at the center, the artery *model is human smooth muscle cells (SMCs) and human umbilical vein endothelial cells (HUVECs) surrounding the GBM, and the capillary model is surrounded by a layer of HUVECs only. We observed differential characteristics in the interaction between tumors and these blood vessels through junction markers and revealed strong expression of platelet endothelial cell adhesion molecule (PECAM) with the interaction of GBM and HUVECs. Comparisons with tumors derived from different organs and cytokine array analysis revealed expression of PECAM was brain-specific. Anti-cancer drug testing with doxorubicin and bevacizumab showed an increase in PECAM-associated proteins and drug resistance cytokines, and that adding flow to the drug environment increased viability compared to static conditions, further confirming that our model mimics the native model well. This demonstrates that our model shows that PECAM influences the interaction of tumors and blood vessels, advancing our understanding of the interaction between different tumor types and adjacent blood vessels and could serve as a platform for personalized devices using patient-derived cells.*

SB07.09.07

Investigating Mechanical Stimulation on Angiogenesis for Vascularized Brain Models *Sina Kheiri, Jessica Shah, Roger Kamm and Ritu Raman; Massachusetts Institute of Technology, United States*

***Introduction**: Neurodegenerative disorders are caused by the progressive loss of structural brain tissue and the death of neurons, which lead to devastating conditions and diseases such as Alzheimer's disease (AD). Although the mechanisms underlying AD have been extensively studied, there are currently no treatments proven to stop or reduce neurodegeneration. One of the main contributing reasons is that the current models poorly represent the physiology of the human brain. While brain organoids hold great potential for understanding the development of neurodegeneration, current organoid models still have important limitations, the absence of functional vascularization. This limitation not only restricts the supply of nutrient transport, delivery of oxygen, and waste removal to/from organoids but also hinders the recapitulation of the blood-brain barrier (BBB), an essential component in AD progression. Despite a wide range of biochemical and biological approaches to promote vascularization, there remains a need for fully perfusable systems developed in a controlled manner. While mechanical cues are as important as biochemical factors in developing vascularized organoids, they are much less studied due to the complexity of platforms. There is thus a critical need for a bioengineering approach to control mechanical cues and study their impacts on the vascularization of brain organoids, with the ultimate goal of developing fully vascularized AD models.*

***Methods**: Our lab has previously demonstrated that a magnetically actuated matrix (MagMA) embedded in an extracellular matrix can be controlled by a permanent magnet, enabling non-invasive mechanical stimulation. We integrated MagMA into a 3D tubular perfusable vasculature on a microfluidics platform to investigate the impacts of mechanical stimulations on angiogenesis and vascularization of brain organoids. The embedded MagMA was fabricated by mixing iron microparticles with poly(dimethyl siloxane) (PDMS). This microfluidics platform is composed of two hollow cylindrical vessels (600 μm in diameter) lined with human umbilical vein endothelial cells (HUVECs), positioned on either side of the brain organoid culture site. Programmable mechanical stimulation on this platform was achieved by embedding MagMA into the collagen-based hydrogel bed. This straightforward 3D platform allows for studying the effects of dynamic mechanical stimulation on angiogenesis and vessel alignment.*

***Results:** We demonstrated that our microfluidics platform is capable of forming perfusable feed vasculature in a 3D setting after 5 days of cell culture. Additionally, we showed that this platform can effectively investigate the effects of controlled mechanical stimulation on angiogenic sprouting from existing endothelial channels. As a proof of concept, we studied the impacts of different regimes of mechanical stimulation using embedded MagMA on angiogenic sprouting. We examined the effects of duration and frequency of mechanical deformation on the formation and alignment of sprouts from endothelial channels using deep learning-based image processing* *algorithms (Angio-Net). Furthermore, we characterized the effects of mechanical stimulation on molecular permeability in the vessels, a key application for BBB models. Two molecular weights (10 and 40 kDa) of FITC-Dextran were used to model vessel permeability for both small and large molecules. Molecular permeability was investigated via confocal imaging of FITC-Dextran molecules.*

Conclusion: *We have developed a novel platform for investigating the impact of controlled mechanical stimulation on the formation of new vessels in a 3D setting. Our microfluidic platform has the potential to generate new fundamental knowledge on the sole effects of mechanical factors in the formation and alignment of angiogenesis, with the ultimate goal of developing fully vascularized brain organoids.*

SB07.09.08

Imprinting Synthetic Polyphenols on Hair and Their Progressive Oxidative Browning

Eunu Kim[1], Jungwoo Hong[1], Jinjae Lee[2], Hee-Seung Lee[1] and Haeshin Lee[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Dermameal Co., Ltd, Korea (the Republic of)

The astringent tastes of wine or green tea and the spiciness of capsaicin persist on the tongue due to their strong binding to mucosal proteins, making them difficult to remove by rinsing. Polyphenols in those plants, in general, robustly bind with proteins exhibiting non-washable and water-resistant coating properties. In this study, we introduce a imprintably strong, non-washable synthetic polyphenols for hair browning through in situ spontaneous polyphenol oxidation under washable conditions. Specifically, a synthetic polyphenol, dimeric 1,2,4-benzenetriol (diBTO), demonstrates an immediate and rapid adherence to hair keratin, forming a non-washable polyphenol layer resistant against detergent washing. The nearly imprinted polyphenols on the hair surface can undergo progressive further oxidation, resulting in gradual color development, which is similar browning phenomenon shown in apples and bananas. Moreover, Cu(II) ions serve as crucial and responsive coordinating linkers between diBTO ligands, significantly increasing the amount of diBTO adhesion and resulting in a rich brown polyphenolic color. Cysteine on the hair surface also acts as an extra ligand to facilitate rapid adhesion between the hair surface and the polyphenol ligand. This study reduces the long exposure time required for dyeing in professional settings, a routine aspect of traditional hair dyeing methods, and demonstrates that gray hair care can be effectively managed through Cu(II)-dependent polyphenol browning in everyday life. Furthermore, this innovative polyphenol implantation holds significant potential for future applications, including immediate use in 3D scaffolds for controlling the wettability of porous surfaces and introducing responsive polymers, underscoring its versatility and broad applicability across various fields.

Optimization of Cryomill Settings to Create Extrudable Decellularized Extracellular Matrix for Bioink Applications

Catherine Whitehead, Larry Stevens, Babak Safavieh and Mora Melican; Tides Medical, United States

As the field of tissue engineering continues to revolutionize treatment strategies for a variety of conditions, 3D bioprinting platforms have driven advancements in recapitulating physiologically relevant characteristics of the native tissue microenvironment to support the regeneration of various tissues. Similarly, advancements in bioink formulations have allowed for greater biocompatibility, especially via the incorporation of decellularized extracellular matrix (dECM) to preserve the native and biochemically complex composition of the ECM. Decellularized ECM grafts derived from porcine small intestinal submucosa (SIS) are commercially available and have been widely used to promote healing in multiple clinical settings including orthopedics, gastrointestinal surgery, and cardiovascular surgery. This ECM's biodegradability and favorable composition of fibrous proteins, glycosaminoglycans, and other bioactive molecules make it a promising candidate for use as a bioink component to promote wound healing.

One strategy for incorporating a porcine SIS-derived graft into a bioink formulation involves processing the graft into a particulate with a sufficiently small particle size distribution to allow for controlled extrusion through a bioprinter's nozzle. This micronization may be effectively performed using a cryomill, as cooling with liquid nitrogen allows the intact graft to be embrittled for efficient milling into a fine particulate. Unsurprisingly, variations in cryomilling parameters impact the final particle size and, furthermore, the extrudability of resuspended porcine SIS particulate. In this study, various milling parameters were assessed for generating porcine SIS-derived particulate capable of passing through a 25-gauge needle upon resuspension with saline. Parameters of precooling time, milling time, grinding ball size, and grinding ball number were varied across multiple cryomill cycles to generate particulates and maximize the flow of solids through a 25-gauge needle. This study underscores the importance of optimizing cryomill cycle parameters to achieve particle size distributions appropriate for 3D bioprinting skin grafts from decellularized ECM.

SB07.09.10

Hybrid 3D Printed Bioink for Chronic Wound Regeneration Laura K. Rivera Tarazona, Babak Safavieh and Mora Melican; *Tides Medical, United States*

Chronic wounds face significant obstacles during the natural healing process. Current treatment options, such as autologous skin grafts, are often limited in availability and may not fully address the complex needs of these wounds. To overcome these limitations, we developed a novel wound dressing utilizing a 3D Printed hybrid bioink. This approach leverages the versatility of synthetic biomaterials to create a scaffold that integrates with the wound bed and can be tailored to patient-specific requirements using 3D printing.

The use of synthetic polymers as components of the bioink offers precise control over the mechanical properties and elasticity of the graft, ensuring optimal handling and performance. Moreover, the scaffold can be incorporated with autologous or allogeneic adipose tissue to create a hybrid bioink that could potentially enhance biocompatibility. These bioinks can be 3D printed into scaffolds, providing a supportive structure for tissue regeneration. Further, control over the structure and porosity of the material could enhance the healing process by promoting cell proliferation, angiogenesis, and extracellular matrix deposition. Lastly, the scaffold's architecture can be customized to match the specific requirements of different chronic wound types, enabling a personalized approach to wound care.

In the current study, an in vivo full thickness skin defect model demonstrates the efficacy of this 3D-printed wound dressing to accelerate wound closure and improve healing outcomes. While further research is needed to optimize material properties and healing strategies, this innovative approach holds promise for revolutionizing the treatment of challenging wounds and improving patient outcomes.

SB07.09.12

Development of a 3D Computational Cell Model for Understanding Membrane-Cytoskeleton Interaction
Donyoung Kang and Hyungsuk Lee; *Yonsei University, Korea (the Republic of)*

Active biomaterials have unique properties such as high biocompatibility, biodegradability, and the ability to consume biological energy sources. The cytoskeletal network in a cell is a representative active biomaterial. The network is consisting of cytoskeletal proteins, cytoskeleton crosslinkers, and motor proteins. Sliding motion of the cytoskeletal filament is generated by the motor protein and developed into the network contraction.
The cell membrane is an interface between cell and its external environment. Cell motions are determined by the deformation of the cell membrane. The deformation of the cell membrane is induced by the contraction of the

cytoskeletal network which is connected to the membrane. The interaction between the membrane and the cytoskeletal network is a key factor for understanding cell deformation. However, the complexity of cellular components makes it difficult to understand how the contraction of the cytoskeletal network is developed into cell deformation via the cell membrane.

Computational modeling is an effective approach for building a simplified system of cell. Some studies reported that the crosslinking degree of cytoskeletal filaments in the network defined by the ratio of cytoskeletal protein to cytoskeleton crosslinkers is closely related to the contractility of cytoskeletal network. However, it remains unclear the exact process by which the membrane transmits the mechanical force from the contractile cytoskeletal network to induce cell contraction.

In our study, we developed a 3D computation model of cell membrane-cytoskeleton interaction including cytoskeletal filaments, motor proteins, cytoskeleton crosslinkers, the cell membrane, and membrane-cytoskeleton linkers on the membrane. We assessed membrane rigidity through thermal fluctuation analysis and replicated the rigidity of cell membrane by adjusting the stiffness of fiber linkers consisting of the membrane. Cytoskeletal filaments were attached to the membrane via membrane-cytoskeleton linker. We explored how the contraction shape changes based on the membrane properties, cytoskeleton crosslinking degree, and membrane-cytoskeleton linker concentration.

Our simplified 3D cell model provides an insight for understanding the interactions between active components and membrane generating cell deformation. Our model and approaches for membrane modeling can help elucidate the mechanisms of cell functions such as division and migration in biological tissues. Additionally, we propose a design concept for a 3D cell-sized, stimuli-responsive smart material.

SB07.09.13

SERS-Based Sensors for Drug Monitoring in a 3D Tumor-Stroma Breast Cancer Model *Lara Troncoso Afonso[1], Patricia González-Callejo[1,2], Paula Vázquez-Aristizábal[1], Pablo S. Valera[1,2], Malou Henriksen-Lacey[1,2], Clara García-Astrain[1,2] and Luis Liz-Marzán[1,2,3]; [1]CIC biomaGUNE, Spain; [2]Centro de Investigación Biomédica en Red de Bioingeniería Biomateriales, y Nanomedicina, Spain; [3]Ikerbasque Basque Foundation for Science, Spain*

Drug and therapy discovery against cancer are limited by the default of cellular models able to mimic tumoral growth and tumoral interactions with the environment.[1] Conventional 2D cellular models are suboptimal and, therefore, more complex 3D in vitro models are required to have closer conditions to those inside living beings. Moreover, to study cellular behaviour in such three-dimensional environments, sensitive and non-invasive techniques are needed as for example Surface-Enhanced Raman Spectroscopy (SERS) which allows to detect low concentrated metabolites located on or next to metallic nanostructures.[2] Therefore, incorporating these nanostructures into 3D cellular models would allow for in situ detection of metabolites and biomarkers secreted by tumoral cells. Herein, plasmonic nanoparticles are combined with different hydrogels to obtain hybrid bioinks that could be used for printing sensing materials within a 3D cell model. The main goal of this work is to use the hybrid bioinks to print the sensor inside a decellularized extracellular matrix (dECM) bath containing different cancer cell types to support tumoral cell culture and monitor cell behaviour over time. The tumor compartment of the 3D model comprises MDA-MB-231 cells while the stromal compartment comprises human breast fibroblasts (HBF). Therefore, the tumoral model is first obtained by directly bioprinting the tumor core within a supportive bath of breast dECM containing the stromal cells and then the sensors are printed inside. Preliminary results show that the sensor can be tuned to sense different metabolites in a hydrogel dependent manner. Moreover, 3D printing of the hydrogel-based sensors in tumor-stroma model does not affect the integrity of the system and allows cell growth and spreading overtime.[3] The distribution of different sensors across the model allows for the spatial and temporal monitoring of antitumoral drug consumption by the different cell populations, using 6-thioguanine as a model drug. Further characterization will involve in situ SERS sensing of cell-secreted metabolites related to tumoral death.

Anchoring Effect of Microneedle Stent in Intravascular Implantation

GeonA Kim and KangJu Lee; Chonnam National University, Korea (the Republic of)

Vascular diseases caused by blockages or disruptions in blood flow within blood vessels are among the deadliest conditions. Treatment options include surgical vascular bypass and non-surgical interventional procedures, with many patients favoring the latter. Interventional techniques have evolved from balloon angioplasty to stent implantation. During stent implantation, a stent attached to a balloon catheter is positioned at the coronary artery lesion and then expanded to improve blood flow. However, this procedure can lead to various complications, with stent dislodgement posing a significant, albeit less common, life-threatening risk. To address these challenges and prevent complications, this study proposes enhancing stent anchorage using a microneedle stent (MNS) featuring an array of microneedles (MN) on its surface. MNs penetrate tissue minimally invasively, promoting secure tissue adherence without causing damage. The MNS is fabricated using a conformal transfer molding process, comprising a 3D-printed stent made from biodegradable polycaprolactone (PCL) and MNs composed of UV resin. Detachment or breakage of MNs on the stent could introduce impurities into the bloodstream, further complicating matters. Therefore, the mechanical strength and strong attachment of the MNs is crucial for their efficacy during deployment and implantation to vascular lesions. MNs were fabricated on PCL film and arranged horizontally and vertically for testing under compression. Using a universal testing machine, MNs were subjected to controlled compression to evaluate shape changes and detachment under simulated conditions. Results confirmed MNs can be applied without tissue damage, ensuring proper insertion into the vessel wall without undue strain.
To validate the anchoring effect of the fabricated MNS, vascular tissue phantom was fabricated using gelatin Methacryloyl (GelMA) and connected to a peristaltic pump to simulate an in vitro circulation system. The MNS and conventional PCL stents were mounted on the GelMA vascular tissue and subjected to various RPM settings. While PCL stents dislodged in all scenarios, the MNS remained firmly anchored, demonstrating its superior anchoring capability within blood vessel compared to conventional stents. Further validation was conducted by implanting the stents in the right carotid artery of rabbits using a 6 Fr sheath. After 1-week follow-up, including H&E staining to assess anchoring and inflammatory response, it is concluded that MNS stents effectively penetrated and anchored in the vessel wall without causing damage or significant inflammatory response, in contrast to conventional PCL stents. Resultingly, this study introduces the innovative application of MNs to stents, highlighting their anchoring effect in stent implantation.

Bioinspired Ecoflex-Based Skin Models for Investigating Catheter-Related Bloodstream Infections

Majed Althumayri, Azra Tarman and Hatice C. Koydemir; Texas A&M University, United States

Catheter-related bloodstream infections (CRBSIs) are life-threatening and a significant cause of healthcare-associated infections. Intravenous catheters, essential for delivering medications and nutrients, can serve as conduits for bacteria to enter the bloodstream. These infections are mostly caused by microorganisms on the patient's skin microbiome (e.g., Staphylococcus epidermidis) at the catheter insertion site. Catheter dressings prevent microorganism growth. The persistence of CRBSIs, with approximately 250,000 cases annually in the United States, highlights the need for innovative research models to understand microorganism dynamics and

develop new sensing devices for early infection alerts.
Various polymers, such as PDMS and PVA, have been used to create skin phantoms for testing wearable and implantable sensors. They provide optical and mechanical properties similar to human skin, but there's an unmet need for quick and easy human skin replicas with highly reproducible and accurate surface properties to study new diagnostic tools for early CRBSI detection. Here, we present bioinspired in vitro model using Ecoflex, a silicone-based material known for its flexibility, durability, and biocompatibility, to mimic human skin properties. The process involved creating detailed molds of human skin to ensure the Ecoflex-0035 models accurately replicate texture, surface roughness, and behavior of real skin. It takes 15 minutes to create the molds and 10 minutes to have the in vitro model ready for testing.
We conducted thorough characterizations of these models, measuring their surface roughness and wettability. Using an optical profiler, we ensured the surface roughness of the Ecoflex models was within 7.5% replication error, in the range of 0.05 μm to 6.2 μm surface roughness, matching the detailed microtopography of human skin. Wettability tests using a contact angle goniometer demonstrated that applying artificial sebum, which simulates natural human skin oils, significantly decreased the static contact angles for deionized water and artificial sweat. This finding highlights the role of sebum in modulating skin surface properties, crucial for realistic bacterial adhesion studies. We imaged areas with different textures to observe pathogen presence, revealing how different surface roughness levels influence initial adhesion and subsequent bacterial colony formation. The images showed that surface roughness contributes to bacterial colony formation by providing more surface area and microenvironments for bacterial attachment and proliferation. This visual evidence underscores the need to optimize surface textures to minimize bacterial colonization.
To replicate clinical conditions, we used a tube as a vein and artificial bones while replicating an in vitro human arm model for our validation studies. Ultrasound imaging captured in-depth images of these forearm replicas. After intentionally contaminating the skin replica surface with S. epidermidis suspension, we mimicked intravenous catheter insertion on the in-vitro model and applied catheter dressing. We used a liquid bacterial growth medium and a peristaltic pump system to simulate blood flow through the vein of the Ecoflex model in a temperature-controlled environment at 37°C. Samples were collected and analyzed using the plate counting method to monitor bacterial growth dynamics over time, highlighting the importance of catheter insertion sites in bacterial proliferation. Our results showed a typical bacterial growth pattern with distinct lag, exponential, and stationary phases, emphasizing the critical role of catheter design and insertion techniques in minimizing infection risks. In conclusion, Ecoflex-based skin models represent a promising in vitro tool for investigating CRBSIs and evaluating new catheter designs. These models provide a controlled, realistic environment for studying bacteria-catheter interactions and exploring modifications to reduce infection rates.

SB07.09.16
Single-Step Nucleic Acid Assay for On-Site Molecular Diagnostics *Jae Chul Park and Hojun Kim; Korea Institute of Science and Technology, Korea (the Republic of)*

Nucleic acid biosensors often require ultrasensitivity due to the low abundance of target in biofluids. In this context, Quantitative polymerase chain reaction (qPCR) is widely regarded as the gold standard. However, such ultrasensitivity resulted in requiring skilled experts and equipment for sample preparation and nucleic acid amplification, restricting its application to centralized labs. Recent advancements have focused on simplifying and streamlining the procedures within the devices, enabling frequent and decentralized testing. However, the current approach requires expensive equipment with complex designs, which still poses a hurdle for point-of-care testing. In this study, we suggest a nature-inspired CRISPR-based system design as an sample preparation-free and enzymatic amplification-free approach to facilitate point-of-care testing. Since the whole assay occurs in a single-step reaction, the detection was very rapid while maintaining the high sensitivity of CRISPR-based detection (sub-femtomolar). Moreover, the assay operates at room temperature. These advancements significantly reduce assay *complexity and allow for a straightforward design of a smartphone-based fluorescence reader, enhancing its accessibility and distribution.*

Biomimetic Cerium Metal-Organic Frameworks Biosensor for Hydrogen Peroxide Detection *Hamidreza Ghaedamini and Dong-Shik Kim; The University of Toledo, United States*

Hydrogen peroxide (H_2O_2) plays a crucial role in cellular signaling and regulation. However, excessive H_2O_2 concentrations may lead to various diseases such as cardiovascular disorders, cancers, and neurodegenerative conditions. Therefore, it is necessary to detect H_2O_2 as a biomarker in order to diagnose these serious health conditions at an early stage. This study presents a novel electrochemical biosensor for sensitive H_2O_2 detection using a composite of cerium metal-organic frameworks (Ce-MOFs), hemin, and graphene oxide (GO). The Ce-MOFs@hemin/GO-modified electrode exhibited excellent electrochemical performance for detecting H_2O_2, with a wide range of linearity from 0.05 to 10 mM and a limit of detection (LOD) of 9.3 μM. This is attributed to the synergistic effect of the composite components. It is found that the Ce-MOFs served as an efficient matrix for hemin encapsulation, preventing its self-degradation while maintaining its peroxidase-like activity. In addition, hemin significantly enhanced the electrocatalytic activity for the reduction of H_2O_2. Meanwhile, GO was observed to increase the overall conductivity of the composite, facilitating rapid electron transfer. The sensor successfully detected H_2O_2 released from human prostate carcinoma cells, demonstrating its capability for real-time monitoring of H_2O_2 release in living cells. Moreover, human serum sample recovery values ranged from 94.50% to 103.29%, highlighting the practical applicability of the sensor.

SB07.09.18

Fabrication of Janus Membranes Mimicking Biological Leathers and Evaluation of Their Specific Wettability Behaviors in Water *Yuki Ishikawa and Daisuke Ishii; Nagoya Institute of Technology, Japan*

Recently, Janus membranes, which have hydrophilic and hydrophobic surfaces and exhibit unique wettability, have attracted attention from various research fields because they enable applications that are difficult with conventional membrane materials, such as one-way transport of liquids, oil-water separation, and fresh water supply by fog collection. However, the structure of Janus membranes and the wetting mechanisms of different surface wettability have not been fully elucidated, making the design and control of Janus membranes to optimize their performance a challenge. In this study, we focus on biological leathers, which exhibit different wettability on the front and back surfaces for organisms to maintain internal water content and manage permeation to and from the outside. Specifically, we devised an original preparation method for Janus membranes that mimics the common feature of biological leather, which has a fiber surface on the more hydrophilic inner surface, and fabricated and evaluated the membranes.

The materials used were nonwoven fabrics (PP) and polydimethylsiloxane (PDMS). Fabrication was carried out as follows. First, the PP fabrics were fixed on the water surface and PDMS (main material: hardener: solvent = 10:1:30, solvent: hexane) was applied from its atmospheric side and cured at the liquid-liquid interface to prepare a mimetic sample (PP-PDMS). After curing, the surface side of the PP fiber of the sample, from which water was removed after curing, was treated with plasma irradiation to hydrophilize one side of the sample as a Janus film. By this method, only one side of the nonwoven fabric was successfully coated with PDMS. The pore size on the PDMS coated surface was controlled by adjusting the PDMS concentration.

The prepared samples were subjected to liquid permeation tests and friction measurements in water. In the permeation test, the vertical water permeation time of a fixed amount of water or hexadecane was measured from the front and back sides of the sample, respectively. For PP-PDMS, which is hydrophobic on both sides, permeation from the PP side took longer, with a water permeation time ratio of 1.3 between the front and back

sides. On the other hand, for Janus membranes with asymmetric wettability, permeation from the PP side, which is the hydrophilic surface, was slower and the permeation time ratio was 2.2. This result may be attributed to the formation of a water film on the PP surface due to hydrophilicity. Therefore, permeation from the PP side is significantly suppressed by the two-layer structure of the PDMS layer, which supports the water film with limited pore size. In contrast, permeation from the PDMS side of Janus membranes is considered to have little permeation suppression because there is no layer to support the water film. The asymmetric wettability of the PP nonwoven fabrics did not show any difference in permeation time compared to the Janus membrane, suggesting that the biomimetics enhances the properties of the Janus membrane. For underwater friction measurement, we attempted to evaluate the characteristics of the air layer in water by focusing on the fact that the prepared samples restrict the outflow direction of the air contained in the sample due to the presence of a PDMS layer covering only one side of the sample, thus retaining the air layer in the water. As a result, the dynamic coefficient of friction increased in the sample with an air layer under water conditions, where the coefficient of dynamic friction is generally lower. This suggests that the presence of an air layer plays a role as an antislip agent that increases the frictional force in water.
As described above, the biomimetic Janus membranes have specific wetting behavior, and the optimization of Janus membranes on the basis of the evaluation of their physical properties can be expected to advance the field of engineering in the future.

SB07.09.19
PEG-Containing Hydrogel Graft for Highly Exudating Wounds *Haylee Coupal, Babak Safavieh and Mora Melican; Tides Medical, United States*

Highly exudating wounds are particularly challenging to treat because the exudate can harbor bacteria and pathogens, promoting infection. It is known that chronic wounds are associated with higher levels of exudate production, which may impede healing because excess exudate slows down cell proliferation, interferes with growth factor availability, and contains elevated levels of inflammatory mediators and proteases.
In this study, we developed a novel antimicrobial hydrogel from hybrid water soluble polyethylene glycol (PEG)-driven polymers to control moisture of the wound exudate with extended stability. Exudate control is demonstrated for two weeks periods across a range of pH values relevant to wounded and healing skin. Swelling analysis of the graft showed that the hydrogel can absorb 15-20 times its initial weight in PBS buffer at pH 5.5-8.5.

The hydrogel material was then used to create a multilayer wound dressing graft that helps tissue regeneration by controling exudate levels of the wound. This novel graft has the potential to be used in a variety of wounds ranging from ulcers in diabetics to burns in which excess amount of exudate is preventing the wound from healing in an effective manner.

SB07.09.20
Heterostructured Mechanical Metamaterials Inspired by the Shell of Strombus Gigas *Juzheng Chen[1], Jingzhuo Zhou[1], Roberto Ballarini[2] and Yang Lu[3]; [1]City University of Hong Kong, China; [2]University of Houston, United States; [3]The University of Hong Kong, Hong Kong*

The shells of molluscs have been shown to be strong and tough, despite being highly mineralised, as a result of various types of architectural design that effectively control the development of shear bands and cracks during deformation. The crossed-lamellar design of the shell of Strombus gigas, whose hierarchy consists of four distinct lamellar-shaped features, represents the toughest of all seashells. A mechanical metamaterial that replicates the natural structure of this queen conch is anticipated to circumvent the renowned trade-off between strength-ductility and strength-density. Here we introduce the architectural concepts of dimensional discreteness and *interactive discreteness, inspired by the crossed-lamellar design, to instruct the design of bio-inspired metamaterials. Inspired by the crossed-lamellar microstructure, we introduce its three-dimensional hierarchical and interactive architecture concept to instruct the design of bio-inspired metamaterials that mitigate failure from the extension of a single shear band and instead develop numerous smaller bands confined within the individual plank-like zones introduced in their layered geometric design. The results have far-reaching implications for the design of strong mechanical metamaterials from a brand-new perspective.*

SB07.09.21
3D Printing of Bio-Inspired Amorphous Calcium Carbonate Composites *Hadar Shaked, Daniela Dobrynin, Iryna Polishchuk, Alexander Katsman and Boaz Pokroy; Technion-Israel Institute of Technology, Israel*

Composites in nature are often formed in the course of biomineralization. These biocomposites are usually produced via an amorphous precursor such as amorphous calcium carbonate (ACC), demonstrating a layered structure. These layered composites have inspired us to form 3D-printed layered structures via robocasting, following the mineralized tissues of Ophiomastix wendtii and Odontodactylus scyllarus. We compared various bio-degradable organic matrices and studied their mechanical properties. Characterized and proved the extended stabilization of the ACC. We investigated the 3D-printed structures' mechanical properties to weigh the benefits an amorphous precursor may offer in the 3D printing processes of ceramic materials. The fracture interface presented bulk behavior with no distinct layering, resembling the formation of mineral single crystalline tissue in nature and overcoming one of the most critical challenges in 3D printing, namely the inter-layer interfaces. This research presents a bio-inspired, low-temperature route to form layered structures. By fusing the layers following low-temperature sintering, a composite structure composed of stabilized ACC integrated with biodegradable, environmentally friendly matrices can be obtained.

SB07.09.22
Novel Volumetric Mapping of 3D Nanomechanical Heterogeneities in Gelatin, Collagen and Polypeptide Hydrogels and Films *Fei Wang, Kevin Grassie, Jianan Mao, Yao Lin, Yusuf Khan and Bryan D. Huey; University of Connecticut, United States*

Porous and fibrous hydrogels and films are promising scaffolds for tissue engineering and drug delivery. To assess their nanovolumetric mechanical properties, far-field longitudinal ultrasonic excitation and simultaneous 3D optical mapping are employed to detect down to picometer scale displacement vectors throughout a uniformly loaded gel or film using up to thousands of fluorescent markers as beacons. This allows local distortions within the hydrogel, and even incorporated cells, to be volumetrically mapped and the force distribution to even be back-calculated. Results are reported for a range of gelatin, collagen, and polypeptide compositions, as well as applied acoustic power and load duration, and compared to macroscopic storage and loss moduli determined by rheology. Spatial variations in local magnitudes and vectorial directionality, as well as elastic recovery, are also visualized and statistically analyzed by specimen and depth. Collectively, this approach reveals 3D nanomechanical heterogeneities resulting from local differences in hydrogel cross-linking, density, hydration, and/or cellular mechanical structures and active adhesion.

SB07.09.23
Wettability and Anisotropic Friction Properties of Fish-Scale-Mimetic Structures Fabricated by a 3D Printer *Tomoki M. Tanaka and Daisuke Ishii; Nagoya Institute of Technology, Japan*

In an increasing awareness of environmental issues and the need to strengthen the international competitiveness of the manufacturing industry, there is a demand for energy efficiency, high functionality, and high added value in *transportation machinery and industrial machinery. In response to this, extensive research has been conducted on the surface structures and forms of various marine organisms, such as sharks, tuna, and dolphins. Recently, attention has also begun to be paid to the surface structures of small fish inhabiting low-velocity water regions, and research has been conducted on reducing fluid friction and fluid drag. There are few studies on the effects of fish scale structures on solid friction, the friction in the presence of liquids, and their anisotropy. In this study, we focused on Plecoglossus altivelis as a small fish upstream, and aimed to evaluate not only the ability to reduce fluid drag due to fluid friction on solid surfaces but also the anisotropic solid friction in air and the anisotropic friction in the presence of water.*

Commercially available natural fish was used as materials. A mimic structure was fabricated and fluid drag measurements were performed. They were performed on four samples: flat, mimicked surface head-to-tail (H.T.T), tail-to-head (T.T.H), and H.T.T hydrophilized by plasma treatment. The results showed that at low flow speeds, H.T.T required less pressure to flow water than the flat and T.T.H, confirming the anisotropy in flow ease. This is thought to be due to the water layer formed by vortices that occur in the recesses when the water flows smoothly along the structure in the HTT. This water layer moves the high-velocity region away from the surface, reducing the velocity gradient near the surface and consequently decreasing the frictional force exerted by the water on the solid surface. It was also confirmed that the hydrophilic treatment reduced fluid drag. We think there are two reasons. First, in the untreated condition, air bubbles remained in the gaps of the structure, but the hydrophilic treatment allowed for the formation of a stable water layer. Second, the hydrophilic treatment created a robust water layer near the surface, increasing the overall thickness of the water film.

Regarding friction measurements, static and dynamic frictions were measured for three samples (flat, H.T.T, and T.T.H) under three conditions: in air, in the presence of water, and in the presence of water when the samples were hydrophilic. As a result of static friction, the friction coefficient of H.T.T was smaller than that of T.T.H in air and in the presence of water when the samples were hydrophilic. We think there are two reasons. First, in both conditions, the contactor is trapped by the convexity of the structure in T.T.H. Second, in the presence of water when the samples were hydrophilic, water in the vicinity of the contactor trying to move smoothly along the structure in H.T.T but get caught on the protruding parts in T.T.H, like fluid drag measurements. As a result of dynamic friction, the structured samples had lower friction coefficients than the flat ones. This is thought to be due to a decrease in the contact area in the air and in the presence of water, and a change from solid-solid friction to solid-liquid friction in the presence of water when the samples were hydrophilic.

Additionally, similar measurements were conducted when the height of the scales was varying was varying from 50μm to 1000μm. The results confirmed that the height of the structure influences anisotropic friction.

These results suggest that they can not only contribute to reducing energy consumption in various devices but also have the potential to provide high added value through changes in surface structure, particularly in situations or products where directional slipperiness is required.

SB07.09.24

Strong and Tough Hydrogel Enhanced by Aligned Microfibers and Confined Interconnected Polymer

Jiazheng Bao, Bin Lian, Zixiang Tong, Jin Yang and Donglei (Emma) Fan; The University of Texas at Austin, United States

Engineering hydrogels with high strength and toughness are rare and represent an important technological challenge. One conventional way to address this challenge is to use solvents such as salt, deep eutectic solvent, and ionic liquids to improve the strength and fracture tolerance of weak and brittle polymers. The marked changes arise from locally aggregated polymer chain whiles increasing polymer-polymer interactions. Here, we demonstrate a different strategy, where substituting conventional solvent with polar solvents in microfiber channels can produce multiscale hierarchical hydrogels with desirable mechanical properties of both toughness and strength, exhibiting an ultimate stress of 31.2 MPa, strain levels of 3100%, and toughness of 410 MJ/cm^3. Molecular simulation and experiment results attribute the multiscale mechanisms to aligned fibrous structures at *the microscale, and the strong intermolecular interactions formed in situ and the sliding of molecules with PVA chains in polar solvents. This mechanism is general and could be explored to various hydrogels made of commercially available and natural polymers, important for biomedicine, soft robotics, wearable electronics, and tissue engineering.*

SB07.09.25

Sepia Melanin for the Local Deactivation of Matrix Metalloproteinases *Seth Edwards, Zhen Tian, Young Jo Kim and Kyung Jae Jeong; University of New Hampshire, United States*

Matrix metalloproteinases (MMPs) are a family of zinc-dependent enzymes that degrade the extracellular matrix, and serve essential functions in wound healing and tissue remodeling. However, overexpression of MMPs is implicated in chronic wound environments and cancer metastasis. Systemic circulation of MMP inhibitors causes severe side effects, and therefore, local deactivation of MMPs is highly desirable. In this research, sepia melanin, a natural biopigment, is explored for deactivation of MMPs, through chelation of zinc ions. Melanins have high affinities toward metal ions through various chemical functional groups, which we demonstrate can be exploited for the deactivation of MMPs. Zinc binding to melanin and MMP deactivation in the presence of melanin are examined using zinc binding and MMP activity assays, in addition to functional in vitro tissue degradation studies. Our findings indicate that melanin has high potential to be used for biomedical applications that require local MMP deactivation.

SB07.09.26

Aiding Arthritis Research—A 3D Cell Culture of Human Fibroblast-Like Synoviocytes Encapsulated in a Chitosan-Based Hydrogel *Francesco Bisconti[1], Beatrice Vilardo[2,3], Gaia Corallo[1,4], Francesca Scalera[1], Giuseppe Gigli[1,4], Annalisa Chiocchetti[2,3], Francesca Gervaso[1] and Alessandro Polini[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università del Piemonte Orientale, Italy; [3]University of Piemonte Orientale, Italy; [4]Università del Salento, Italy*

Osteoarthritis (OA) and Rheumatoid Arthritis (RA) are the most prevalent types of arthritis. OA affects approximately 7% of the global population annually, while RA affects about 1% of the population.[1] Both conditions impact the joints, but RA is an autoimmune disease that also causes systemic symptoms alongside joint inflammation. The primary tissues involved are the synovium, bone, and cartilage. The synovium, which plays a significant role in RA, consists of fibroblast-like synoviocytes (FLS) and synovial tissue resident macrophages (STM).[2] A realistic in vitro system for FLS is essential for pathophysiological studies and drug screening. Despite the known benefits of three-dimensional (3D) in vitro cell cultures over traditional two-dimensional (2D) systems, there are few reports on culturing human FLS in 3D.[3]

Matrigel, a commonly used but expensive commercially available product, is among the various hydrogel materials employed for human FLS 3D culture. Derived from Engelbreth–Holm–Swarm mouse sarcomas, Matrigel mainly comprises laminin, collagen IV, entactin, and various growth factors, and it is known for its significant lot-to-lot variation. Reducing or partially replacing Matrigel could offer significant advantages for standardizing human FLS 3D culture and lowering costs.[4] To achieve this, we developed thermoresponsive chitosan (Cs) formulations by combining different hydrogel precursors and testing them for culturing human FLS, using cells derived from the synovial tissue of both non-RA and RA-positive patients. Chitosan,[5] a linear polysaccharide known for its high biocompatibility, low immunogenicity, affordability, and high commercial availability, was chosen to reduce the need for Matrigel in the system.

Hydrogel formulations based on pure Matrigel, 50% and 70% chitosan, and pure chitosan were synthesized and characterized morphologically and mechanically using Scanning Electron Microscopy and compression tests, respectively. Subsequently, non-RA and RA FLS were encapsulated in these hydrogels, followed by live/dead assays and DAPI-Phalloidin immunofluorescence staining. The live/dead assay on day 1 showed an ideal cell *distribution throughout the hydrogel structure and high cell viability in all the formulations. DAPI-Phalloidin staining indicated that FLS elongated, acquiring a typical fibroblast morphology after 4 days, and formed a complex and dense 3D network after 7 days in all hydrogel formulations except the pure chitosan. Similar results in terms of cell viability and morphology were observed for both non-RA and RA patient-derived cells. Notably, chitosan-based hydrogels demonstrated greater stability throughout the experiments compared to Matrigel. Thus, given the low cost and high availability of chitosan, this system offers a viable alternative to pure Matrigel for human FLS encapsulation.*

3D Printing of Biohybrid Silica Composites

Olivia Pear[1], Dylan Moss[2], Arjun Khakhar[2] and R. Konane Bay[1]; [1]University of Colorado Boulder, United States; [2]Colorado State University, United States

Recently, additive manufacturing has emerged as a technique to fabricate engineered living materials (ELMs). Most 3D printed ELMs are composites of polymers and living cells, and inorganic-organic living composites have not been widely explored. Here, we 3D print fibers composed of the fungus, Aspergillus niger, into granular hydrogel matrices swollen in liquid growth media. The A. niger cells are engineered to express silicatein on the cell surface, which acts as a template for silica mineralization. After incubation, printed fungal spores display radial hyphal growth, extending from the core printed fiber. The radial growth of hyphae depends on oxygen and nutrient availability. We characterize the mechanical properties of the fibers pre- and post-biomineralization. Overall, this work demonstrates that material properties of 3D printed inorganic-organic engineered living materials can be tuned by oxygen and nutrient availability.

SB07.09.28

Engineering Vessel Walls of Increased Stiffness in Microvascular Channels Within Hydrogels

Victoria Vest, Isabella K. Holtz, Katherine J. Young and Leon M. Bellan; Vanderbilt University, United States

Vascular networks extend throughout most tissues in the human body and are heavily involved in biological functions in both healthy and diseased states. The inclusion of perfusable vasculature is therefore key to producing engineered tissue constructs either for implantation or as in vitro disease models. Many approaches have been employed to pattern hollow channels within hydrogels, and these channels are often then lined with cells to mimic the architecture of the native vessel wall. While these methods do an excellent job of producing vessels that support nutrient and oxygen exchange (i.e. capillary-like function) and therefore support cell survival, when applied to resistance vessel-sized channels this approach does not properly recapitulate native vessel walls in several key ways. In vivo, in such vessels (the non-capillary microvasculature) there is a distinct difference in the structure and mechanical properties of the vessel wall and those of the tissue through which it extends. Soft

tissues such as brain, kidney and lung, have elastic moduli of 5kPa or less, while the walls of small resistance arteries have moduli on the order of 10s to 100s of kPa. For such structures, instead of the "channels in a gel" architecture formed by traditional approaches, a better model of the natural tissue stiffness heterogeneity would be a relatively stiff, thin-walled tube through a relatively soft hydrogel ("tubes in a gel"). This configuration would allow the vessels to distend in a way similar to those in vivo and provide cells at the vessel wall and cells deeper within the surrounding hydrogel distinct environments with appropriate local stiffness. To mimic this stiffness heterogeneity, we seek to create a tube-like channel through a soft hydrogel by perfusing the channel lumen with a large molecule crosslinker which can slowly diffuse into the hydrogel and locally enhance crosslinking density. Experiments were performed using 10% w/v gelatin dissolved in DI water, enzymatically crosslinked with 0.1% w/v microbial transglutaminase (mTg) at 37°C as the primary crosslinking step (to yield a soft gel). Secondary crosslinking steps used a 1% w/v mTg solution. To confirm that secondary crosslinking could be achieved, 2 mm-thick slabs of gelatin were cast; after primary crosslinking, 1% mTg was added on top and allowed to incubate for 8 hours. After incubation, the gelatin was bisected, creating two 1-mm slabs - one proximal and one distal to the mTg/gelatin interface on the top surface. A rheometer was used to measure the elastic modulus of each disc. In a second series of experiments, straight channels with a diameter of 350 µm were formed in a gelatin hydrogel using nylon monofilament as a removable template. MTg conjugated with AF488 fluorophore was perfused into the channels, and diffusion of the fluorescent mTg normal to the channel wall into the hydrogel was observed using a confocal microscope. Enzymatically-crosslinked gelatin exhibits increased elastic modulus after a secondary mTg crosslinking step, in a manner dependent on the distance from the surface where the crosslinker is applied. Fluorescent mTg injected into a microchannel patterned through gelatin was observed to diffuse radially outward tens of microns into the gelatin hydrogel bulk, defining a fluorescent "cylinder" around the channel lumen. These preliminary results show that enzymatically-crosslinked gelatin can be further crosslinked by a second application of crosslinker, and that crosslinker can diffuse radially out of a patterned channel into the bulk hydrogel. This suggests it will be feasible to leverage large molecule crosslinker diffusion to create a tube-like region of enhanced stiffness surrounding a channel through a soft hydrogel, thereby forming a vessel wall with mechanical properties distinct from the bulk hydrogel. Importantly, this approach could be applied to branching channel networks that mimic the architecture of the natural microcirculation.

Development of Bioinspired Scaffolds for Producing Cultured Meat Embodying the Organoleptic Properties of Conventional Meat

Milae Lee and Jinkee Hong; Yonsei University, Korea (the Republic of)

Cultured meat has been gaining attention as a new type of food that can provide animal-derived nutrients in a sustainable way. Recently, edible scaffolds have been studied to develop muscle tissues in vitro for mimicking the biological and physical properties of conventional meat. Organoleptic characteristics are critical in cultured meat, but they are relatively under-explored. Here, we suggest strategies of fabricating bioinspired scaffolds which provide meat-like organoleptic properties such as texture, flavor, and taste in cultured meat. By engineering the structure of scaffold as well as the interactions of polymers constituting the scaffold, we developed various types of scaffolds to mimic the organoleptic characteristics of conventional meat in cultured meat system. Specifically, edible coating, bulk gelatin hydrogel, and hydrogel releasing flavor molecules were studied.

Edible coating for inducing cell adhesion was fabricated on the surface of soy protein meat to produce hybrid-type of cultured meat. The soy protein meat was dipped into the hydrogel composed of gelatin and agar. Because gelatin can specifically interact with cell, the coating can induce stable cellular adhesion and proliferation on the surface of soy protein meat. Also, gelatin can interact with agar at high temperature to produce Maillard reaction products which also occur in conventional meat cooking. Due to this coating, the cultured meat expressed meaty flavor and taste after cooking. This hydrogel-type coating can be introduced on the surface of any type of edible substrate to produce flavor-enriched hybrid type of cultured meat.

Bulk hydrogel composed of gelatin and alginate was developed to investigate the relationship between cellular behavior and organoleptic properties of cultured meat. By regulating the interaction between alginate and calcium ions, hydrogel scaffolds with different stiffness were fabricated. Since cellular differentiation depends greatly on the mechanical properties of scaffold, we cultured muscle and fat cells on the scaffolds with different stiffness to diversify the degree of differentiation. Then, the texture and flavor of cell-scaffold complex were investigated for each specimen. Interestingly, it was confirmed that cultured meat with higher cell differentiation embodies more similiar sensorial properties with conventional meat because of the high quantity of muscle proteins and fatty acids. As a result, we could conclude that the material engineering for regulating cell differentiation has significant impact in cultured meat development.
Lastly, we studied a three-dimensional scaffold which can release flavor molecules under cooking temperature to mimic the grilling flavors of conventional meat in cultured meat system. By conjugating Maillard flavor molecule into the gelatin-based hydrogel, the flavor-enriching scaffold can be produced. The disulfide bond between the flavor molecule and the polymer backbone can change temperature responsively, releasing the molecule from the scaffold. We confirmed that this flavor releasing scaffold can provide meaty and savory flavors in cultured meat. Combining materials engineering and food science, we have developed a variety of innovative strategies to produce the scaffolds which not only function to provide an environment for cell proliferation and differentiation, but also mimic the organoleptic properties of conventional meat. We believe that these bioinspired scaffolds can contribute to the sustainable food system by reducing the gap between the cultured meat and the conventional meat.

SB07.09.30
Ascidian Derived Tunicine Hydrogel Patches for Enhanced Wound Healing *Mano Govindharaj, Rodaina Ahmed, Khulood H. Alshehhi, Deema K. Islayem, Akbar Ali, Blaise L. Tardy, Sung Mun Lee and Charalampos Pitsalidis; Khalifa University of Science and Technology, United Arab Emirates*

Rapid closure of tissue gaps during wound healing is crucial to restore the skin's barrier function, preventing infection and fluid loss. This involves a sophisticated process where cells at the wound migrate, proliferate, and differentiate to cover the ruptured area. This study investigates the potential of marine tunicate-derived tunicin (a cellulose-protein complex)-based scaffolds from poriferans for enhanced drug delivery, wound healing, and tissue regeneration. Specifically, Phallusia nigra stands out due to its renewable source of unique 3D nanocellulosic-protein hydrogel scaffolds. These scaffolds are easily prepared, maintain excellent shape-retention properties at physiological conditions, and are suitable for in vivo applications. Our findings show that tunicin scaffolds are cytocompatible, supporting human fibroblast cell attachment, growth, and proliferation in vitro. After seven days of cultivation on the scaffolds, fibroblasts exhibited a two-fold increase in metabolic activity, indicating cell proliferation. Additionally, cells near the gaps in both control and test samples demonstrated actomyosin contractility, bridging the gaps within 30 hours of incubation. Animal studies demonstrated an accelerated recovery rate compared to traditional wound care methods, with observable healing within a markedly shorter time frame. Moreover, applying the bioderived wound patch resulted in minimal inflammation markers, indicating a reduced inflammatory response and a favorable biocompatibility profile. These results highlight tunicate-derived tunicin as a novel and promising material for developing advanced wound-healing strategies.

SESSION SB07.10: Instructive Cues to Guide Cell Behavior II
Session Chairs: Cécile Bidan and Cornelia Lee-Thedieck
Thursday Morning, December 5, 2024
Hynes, Level 1, Room 101

8:30 AM *SB07.10.01

A Resurfacing-Regenerative Approach to Repair Osteochondral Defects *Melissa Grunlan; Texas A&M University, United States*

Osteochondral defects (OCDs), areas of localized joint damage to articular cartilage and underlying subchondral bone, often lead to pain, loss of joint function, and osteoarthritis. Clinical repair is focused on biological grafting procedures but are innately limited by graft availability and donor site morbidity. We have developed a bioprosthetic implant, combining articular cartilage resurfacing and osseous tissue regeneration, as a new method for OCD repair. These implants – "cartilage-capped, regenerative osteochondral plugs (CC-ROPs)" - combine a multi-network hydrogel (cartilage cap) and osseous scaffold (base). The cartilage cap is prepared from a multi-network, electrostatic hydrogel that gives rise to articular cartilage-like mechanical, hydration, and tribological properties. The osseous scaffold base is prepared from a semi-interpenetrating polymer network (semi-IPN) of poly(ε-caprolactone)-diacrylate (PCL-DA) and poly(L-lactic acid) (PLLA). The scaffold is intrinsically osteoinductive and has a trabecular bone-like modulus as well as robust degradation rates to facilitate bone ingrowth. Formed as cylindrical plugs, CC-ROPs may be implanted into OCDs using existing grafting techniques and be fabricated in a range of sizes. In vitro and in vivo performance of the cartilage cap, osseous scaffold, and CC-ROP device demonstrate encouraging results towards development of an alternative OCD treatment.

9:00 AM *SB07.10.02

Shaping Slime—How to Guide Bacterial Biofilm Architecture via Substrate Properties *Cécile Bidan; Max Planck Institute of Colloids and Interfaces, Germany*

As bio-sourced materials are raising interest for their sustainability, using bacteria to produce biofilms made of a protein and polysaccharide matrix has become a new strategy to make engineered living materials. Our group contributes to this emerging field by clarifying how bacteria adapt biofilm materials properties to their environment. For this, we culture E. coli producing curli amyloid and phosphoethanolamine-cellulose fibers on nutritive agar substrates. The resulting microbial tissue forms a film that expands at the surface of the agar and acquires a complex morphology through wrinkling and folding. We first demonstrated that varying physico-chemical properties of the agar substrates with polyelectrolyte coatings or by changing their water content, affects E. coli biofilm growth kinetics, wrinkling patterns and mechanical properties. We also explored how tuning the chemical environment of the bacteria can lead to biofilm biomineralization and expand the range of materials properties reachable with biofilm-based materials. We are now adapting fabrication methods to shape hydrogels and combining them with live and static microscopy techniques to explore if and how geometrical features of the agar substrates influence biofilm growth, morphology and matrix fiber orientation. Producing microbial tissues with various properties in an anisotropic and controlled manner could greatly enlarge the possibilities offered by synthetic biology to engineer living materials with broad functionalities.

9:30 AM SB07.10.03

Photoswitchable Hydrogels for Biomedical Applications *Maria Regato Herbella, Chantal Barwig, Sophie Geiger, Krishna Ramesh, Qiyang Jiang and Christine Selhuber-Unkel; Universität Heidelberg, Germany*

Multi-responsive synthetic hydrogels are very versatile three-dimensional network capable to respond simultaneously to multiple relevant stimuli i.e., temperature, pH, light, redox activity, enzymes, etc. These polymeric tunable materials have the capability to retain large amounts of water, controlling the biodegradability, biocompatibility and mechanical strength, which makes them excellent candidates to be widely used in *biomedical applications such as tissue engineering, biosensing and drug delivery, among others. The most outstanding used thermo-responsive monomer in biomedical field is the N-Isopropylacrylamide (NIPAM) whose reversible volume phase transition is shown by swelling at temperature below the lower critical solution temperature (LCST ≈ 32 C) and shrinking above it. NIPAM can be copolymerized with other monomers, for example methacrylic acid (MAA), a pH-responsive monomer whose carboxylic acid moiety deprotonates at pH higher than 4.8, generating the ionic interaction with water and ensuing swelling of the hydrogel. The stimuli, in this case, are found in our body, in the difference of temperature and pH between diseased and healthy tissue, or between organs. However, external stimuli, i.e., magnetic field, electric field, light and ultrasound have advantageous features. From these stimuli, light can be considered the most promising, being non-invasive, tunable and easy manipulated stimulus to produce a change in the hydrogel properties. Photoswitchable monomers are very versatile light-sensitive molecules that can be photopolymerized in presence of other sensitive monomers to modify their response. Spiropyranes, Diaryethenes and Azobenzenes are some of the traditional Photoswitchable molecules used in biomedical applications. Azobenzenes, and more specifically, Push-Pull azobenzenes, are extensively studied due to the thermal isomerization reducing the light cytotoxicity and the possibility of functionalization with biological molecules such as peptides, to regulate the cell attachment and increase the biocompatibility.*

In this work, a Push-Pull Azobenzene monomer (PPm) and azobenzene crosslinker (PPc) are produced by Williamson ether synthesis and posterior diazotization reaction. Subsequently, the carboxylic acid moiety of the monomer is functionalized by Steglich esterification with RGD cyclic peptide (PPmp). Moreover, the monomer (PPm) is functionalized with acrylamide by amide formation in presence of DCC to obtain the azobencene crosslinker (PPc). The triple-responsive hydrogels of N-Isopropylacrylamide (NIPAM), Methacrylic acid (MAA) and PPmp or PPc were synthesized using led light in few minutes or by thermal reaction. The exposition of the PPmp containing hydrogels to low energetic light, produces a change in the conformation of the azobenzene molecule modulating the interaction of the peptide with the mammalian cells. However, the exposition of the PPc to light modifies the conformation producing changes on the scaffold structure possibly reducing the pore size and modifying the mechanical properties along with the cell attachment.

9:45 AM SB07.10.04

Tunable Platform for Drug Eluting Stents *Haritosh Patel[1], Duygu Deniz[2,1], Olivia Snapper[1], Pierce Cousins[1], Jack Alvarenga[1], Eckhard Quandt[2] and Joanna Aizenberg[1]; [1]Harvard University, United States; [2]Kiel University, Germany*

Coronary artery disease (CAD) remains the leading cause of morbidity and mortality claiming 610,000 lives and 200 billion dollars annually in the United States. Driven by atherosclerosis, CAD manifests as thickening and stiffening of the arterial walls due to plaque buildup. To recover normal blood flow, stents emerged as a pivotal instrument to reopen constricted arteries. While revolutionary at the time of discovery, there are significant issues that are still present. Specifically, there are four common complications: restenosis, infection, thrombus, and inflammation. To mitigate these, drug-eluting stents (DES) were developed, adding a coating loaded with anti-proliferating drugs to deliver locally. Despite the advantages of DES, clinical complications continued. Primarily, low drug loading capacity, poor temporal tunability, and sub-optimal compatibility of the polymer-coating lead to late-stage thrombosis and low reendothelialization. ***Given this, there is an urgent need for a DES that provides a programmable passive drug release while minimizing adverse effects.***

Here, we removed the less-biocompatible coating altogether, instead, adding a slippery liquid-infused porous surface (SLIPS) – a novel biocompatible coating – where the drug can reside in the matrix of the sintered nanoparticles or the lubricant, specifically termed infused DES (iDES). This design results in decreased foreign body response (FBR) due to the anti-biofouling effects of SLIPS and increased drug loading with bimodal release capacities tuned through the tailoring of chemistries. ***Unique to iDES, the platform design offers three***

independently tunable parameters – stent material, coating properties, and drug delivery kinetics – creating a solution that can be precisely tailored to each patient. *The stent material, Nitinol, is commonly used in implants, as it is a super elastic metal that can withstand high intrinsic strain. The mechanical tunability comes from the geometry of the design such as pitch, width, and thickness. Moreover, the design imparts the base stent regions of stress-prone and stress-free drug-loadable islands capable of varied kinetics under blood flow's fluid shear forces depending on the specific geometry chosen. The coating comes from the SLIPS technology, an anti-biofouling surface that significantly reduces infection risk. The tunability comes from the option to load the drug in the nanoparticle's matrix or the lubricant, with varying release and customization for both. The lubricant offers a faster release, with the phobicity and viscosity affecting the kinetics. Due to the longer diffusion, loading the drug into the matrix gives a slower release with the nanoparticles' size, functionalization, and porosity determining the kinetics. The ability to load drugs into two matrices allows for a patient-targeted approach, without the concern for poor biocompatibility. In tailoring medical devices to individual patients, kinetics and drug selection adaptability become essential, allowing for personalized adjustments that align with a patient's physiological and therapeutic needs. iDES aims to be the next generation of medical devices that can be catered for each patient's needs minimizing revision surgeries and unnecessary visits.*

SESSION SB07.11: Poster Session II

8:00PM - 10:00PM
Hynes, Level 1, Hall A

SB07.11.01
Designing and Preparation of Virus Like Particle Based Recombinant Biomaterials for Targeted Drug Delivery Purpose *Tapan K. Chaudhuri; Indian Institute of Technology Delhi, India*

Protein particles that self-assemble serve as important Nano carriers with a wide range of industrial and biomedical uses. Viral capsid proteins, whether from infectious or non-infectious viruses, can naturally form virus-like particles (VLPs), replicating viral structures and facilitating the study of their properties, and potential as drug delivery vehicles.

MS2 bacteriophage VLPs, which are non-enveloped, are commonly utilized in a variety of biotechnological applications and structural research. The capsid protein (CP) of bacteriophage MS2 assembles into uniform quasi-icosahedral VLPs with a diameter of 27.5 nm through recombinant expression in E. coli.

MS2 VLPs are biocompatible, biodegradable, and easy to engineer. Studies suggest that MS2 VLPs can serve as platforms for targeted drug delivery. Their advantage as delivery vectors lies in their 27 nm size and the presence of surface-accessible amino acids on the capsid protein for conjugation. Additionally, a single amino acid mutation in the capsid protein has reduced the size of MS2 VLPs from 27.5 nm to approximately 17 nm, which may improve enhanced permeability (EPR) and half-life. Thus the engineered version of the Bio-Nano material is a good model for further investigation to explore for the drug loading capacity and delivery profiles of these smaller MS2 particles, along with their physicochemical properties.

This study focuses on engineering the wild-type (WT) capsid protein to explore the stability and physicochemical *properties of mutant MS2 VLPs, as well as the potential use of these mutants as targeted drug delivery Nano-carriers. Experimental results highlight the critical role of inter-subunit and inter/intra-dimer interactions in maintaining the overall stability of these particles. We observed significant differences in thermal unfolding between the WT and a mini variant of the VLPs, likely due to their variations in symmetry and size. Additionally, we propose that the heat-induced melting of MS2 VLPs is a complex process involving capsid disassembly, nucleic acid exposure, protein unfolding, and aggregation. Overall, our thermal unfolding data demonstrate the enhanced stability of the mini MS2 VLP compared to the larger WT VLP. This information is valuable for using non-enveloped VLPs as improved models for biomedical applications, such as antigen display, vaccine development, and drug delivery.*

We investigated the drug encapsulation and delivery efficiency of mutant VLPs in vitro, and the results revealed lower encapsulation in the mutant VLPs compared to the wild-type (WT), due to their smaller interior volume. However, the mutant VLPs demonstrated a higher peptide conjugation ratio per particle compared to the WT, leading to increased interaction with cell receptors and improved internalization. Overall, the study suggests that mutant VLPs, with their enhanced stability, could be utilized in the future for developing potential Nano-carriers or other biomedical applications.

SB07.11.02

Extracellular Silica Nanomatrices Promote In Vitro Maturation of Anti-Tumor Dendritic Cells Via Activation of Focal Adhesion Kinase *Zhifeng Huang; The Chinese University of Hong Kong, Hong Kong*

The efficacy of dendritic cell (DC)–based cancer vaccines is critically determined by the functionalities of in vitro maturated DCs. The maturation of DCs typically relies on chemicals that are cytotoxic or hinder the ability of DCs to efficiently activate the antigen–specific cytotoxic T–lymphocytes (CTLs) against tumor. Herein, we replace the maturation chemicals with extracellular silica nanomatrices, fabricated by glancing angle deposition, to promote in vitro maturation of murine bone marrow–derived DCs (mBMDCs). The extracellular nanomatrices composed of silica nanozigzags (NZs) enable the generation of mature mBMDCs with upregulated levels of co–stimulatory molecules, CCR7, XCR1, DC-SIGN, and enhanced endocytic capacity. The in vitro maturation is partially governed by focal adhesion kinase that is mechanically activated in the curved cell adhesions formed at the DC–NZ interfaces. The NZ–maturated mBMDCs can prime the antigen–specific CTLs into PD–1^{low}CD44^{high} memory phenotypes in vitro and suppress the growth of tumors in vivo. Meanwhile, the NZ–mediated beneficial effects are also observed in human monocyte–derived DCs. This work demonstrates that the silica NZs promote the anti–tumor capacity of in vitro maturated DCs via the mechanoactivation of FAK, supporting the potential of silica NZs being a promising biomaterial for cancer immunotherapy.

SB07.11.03

Development of an In Vitro Platform for Analyzing the Correlation Between Matrix Stiffness and Cancer Stemness Using In-Bath 3D Bioprinting Technique *Won-Woo Cho[1], Seok-Hyun Lee[2], Minjun Ahn[2] and Byoung Soo Kim[2]; [1]Yonsei University, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)*

Cancer stemness refers to the phenomenon where cancer cells acquire stem cell-like phenotypes, which are known to significantly influence carcinogenesis and contribute to poor prognosis. The stiffness of the extracellular matrix (ECM) surrounding tumor changes during the cancer progression. It has been reported that the increase of ECM stiffness can activate cancer stemness, leading to enhancement of cancer progression and acquisition of drug resistance. Therefore, to better understand the relationship between cancer stemness and matrix stiffness, developing an in vitro platform that elaborately recapitulates the heterogeneity of the mechanobiological environment of cancer is necessary. In this study, we developed an in-bath 3D bioprinting technique and stiffness-

tunable hybrid bioink to fabricate an in vitro cancer platform that recapitulates complex tumor microenvironment and effectively stimulates cancer stem cells (CSCs). In the platform, PC3 prostate cancer cell line is printed as a form of spheroid. By adjusting the bioink composition, stiffness gradients are created to determine the optimal mechanical environment in which CSCs are stimulated. We found that PC3 cells are actively stimulated in the stiff matrix, exhibiting dynamic changes in cellular organization from epithelial to mesenchymal phenotypes and acquiring drug resistance. Specifically, cancer cells cultured in a stiff matrix exhibited a significant increase in the expression of the transmembrane receptor integrin and focal adhesion kinase. Moreover, next-generation sequencing revealed elevated activation of the phosphatidylinositol 3-kinase (PI3K)/Akt pathway in cancer cells within this stiff matrix, with nuclear factor kappa B (NF-κB) being the most significantly activated downstream target of the PI3K/Akt pathway. Through the development of this platform, we were able to confirm stiffness-enhanced prostate cancer cell progression mediated via the PI3K/Akt/NF-κB signaling pathway. These results suggest that the developed platform holds strong potential for understanding the mechanobiological aspects of cancer stemness activation and could be utilized as a drug screening platform to identify optimal drug candidates for personalized cancer treatment.

SB07.11.04

Generalizable 3D Bioprinting Using Universal Fugitive Network Bioinks *Aneela Davuluri, Hakan Arslan, Hiephoang Nguyen, Byung Ran So, Juhyun Lee, Junha Jeon and Kyungsuk Yum; The University of Texas at Arlington, United States*

Three-dimensional (3D) bioprinting has emerged with the potential for creating functional 3D tissues with customized geometries. However, the limited availability of bioinks capable of printing 3D structures with both high shape fidelity and desired biological environments for encapsulated cells remains a key challenge. Here we present a 3D bioprinting approach that uses universal fugitive network bioinks prepared by loading cells and hydrogel precursors (bioink base materials) into a 3D-printable fugitive carrier. This approach constructs 3D structures of cell-encapsulated hydrogels by printing 3D structures using fugitive network bioinks, followed by crosslinking printed structures and removing the carrier from them. The use of the fugitive carrier decouples 3D printability of bioinks from the material properties of bioink base materials, making this approach readily applicable to a range of hydrogel systems. The decoupling also enables the design of bioinks for the biological functionality of the final printed constructs without compromising 3D printability. We demonstrate the generalizable 3D printability by printing self-supporting 3D structures of various hydrogels, including conventionally non-3D printable hydrogels and those with low polymer content. We conduct pre-printing screening of bioink base materials through 3D cell culture to select bioinks with high cell compatibility. The selected bioinks produce 3D constructs of cell-encapsulated hydrogels with both high shape fidelity and cell viability and proliferation. The universal fugitive network bioink platform could significantly expand 3D printable bioinks with customizable biological functionalities and the adoption of 3D bioprinting in diverse research and applied settings.

SB07.11.05

An Electrically Conductive DNA-Inspired Coating for Neural MEA Interfaces *Ian Sands[1], Wuxia Zhang[1], Alpaslan Ersoz[1], Sabato Santaniello[1], Pengju Li[2], Huijing Xu[3], Bozhi Tian[2], Ellis Meng[3], Martin Han[1] and Yupeng Chen[1]; [1]University of Connecticut, United States; [2]The University of Chicago, United States; [3]University of Southern California, United States*

MEAs provide crucial insight into the electrical function of the nervous system and other electrically excitable tissue types. However, poor bio-integration remains a major challenge for intracortical microelectrodes due to lack of biocompatibility between implanted electrode materials and native neural tissue. Poor biocompatibility will *result in a reduction in healthy neuron attachment following acute-phase implantation, which will impact the chronic-term success of the MEA. Families of MEA coatings have been developed to facilitate the integration of brain and device including, conductive polymers, carbon nanotubes, and bioactive hydrogels. Many of these coating materials possess biological, functional or electrochemical disadvantages that impede microelectrode efficacy. Herein lies the incentive to develop novel nanomaterials capable of coating MEAs to improve tissue integration while maintaining the functionality of bioelectronic interfaces.*

Therefore, we developed Janus base nanotubes (JBNts), a family of Janus base nanomaterials (JBNs) self-assembled from G^C or A^T units mimicking DNA base pairs. The G^C monomers may also be conjugated with amino acid moieties that influence supramolecular chirality and electrostatic properties upon self-assembly into rosettes. Non-covalent interactions including hydrogen bonding, the hydrophobic effect, and the π-π stacking effect drives rosettes on top of one another forming a nanotubular structure with a high density of outfacing amino acids. These nanotubes (JBNts) are <1nm in diameter and can self-assemble upwards to multiple microns in length. A key feature of JBNt self-assembly lies between the aromatic rings that constitute the nanotubes core. Core aromaticity allows π electron mobility around the 10-carbon system, effectively creating π electron clouds below and above each assembled JBNt rosette, enabling electrical conductivity. Our results demonstrate that JBNts utilize long-distance electron dislocation via π-π rosette stacking to maintain electrochemical activity during cyclic voltammetry, impedance testing and pseudo-neural signal recording on MEAt. JBNTs also enhance interface integration including differential protein expression that encourage neural outgrowth and neuron maturation. In vivo results demonstrate JBNt biocompatibility during in vivo interface studies. We anticipate these results will serve as a benchmark for the continued development and study of JBNt to enhance interface dynamics and ultimately the performance and reliability of brain microelectrodes.

8:45 AM SB08.01.01

Understanding the Influence of Polymer Mechanical Properties on Mechanochromic Behavior of Cholesteric Liquid Crystals *Tim Lawton[1], Andrew Nguyen[2], Kris Senecal[1], Paola D'Angelo[1], Victoria Ayotte[1], Todd Alexander[1], Walter Zukas[1], Hong Zhao[2] and Christina Tang[2]; [1]U.S. Army, United States; [2]Virginia Commonwealth University, United States*

Mechanically responsive materials show promise in many areas including smart textiles and flexible displays. In certain applications like sensing, it is desirable for materials to respond to an external or environmental stimulus with a macroscopic color change. Military applications can take place in extreme temperature environments where power sources are limited, so having a material that responds to mechanical stimulus is desirable. One interesting class of mechanically responsive materials are mechanochromic cholesteric liquid crystals (CLC). These molecules form helical structures that reflect a wavelength of light proportional to their helical pitch. While interesting, the utility of these molecules is limited, requiring them to be blended into polymers for many applications. Previous studies have shown this approach still allows for the inherent mechanochromic behavior. What remains is the question of how the polymer matrix viscoelastic properties affect the selective reflection band (SRB) of the blended CLC molecules. In the present study, we first conducted design-of-experiments and machine learning to predict the macroscopic color of a three-component CLC mixture. Rheological experiments were then conducted to understand the effect of strain rate and oscillation on color change. Finally, visible reflection spectroscopy on CLC-polymer blends suggest differences in SRB depending on the mechanical properties of the polymer matrix.

9:00 AM SB08.01.02

Transforming Fluid Instabilities into Smart Materials—Non-Equilibrium Pattern Dynamics for Thermoregulatory Homeostasis *Raphael Kay[1,2], Ross Cocks[2], Charlie Katrycz[2], Alstan Jakubiec[2], Atalaya M. Wilborn[1], Joanna Aizenberg[1] and Benjamin Hatton[2]; [1]Harvard University, United States; [2]University of Toronto, Canada*

Emerging pattern dynamics in natural systems have fascinated materials scientists for decades. Ordered patterns can evolve within non-equilibrium systems when driven to instability, where emergent instability-mediated phenomena underly the morphology of snowflake crystals, bacterial colonies, microorganisms, and retinal vessels.

In this talk, I will discuss our recent efforts to harness pattern dynamics and instability to develop smart, bio-inspired, self-regulating materials, toward addressing one of our largest sustainability challenges of the day: keeping humans comfortable. Specifically, I will explain how to exploit the Saffman-Taylor hydrodynamic instability to achieve thermoregulatory homeostasis in rationally-engineered devices, where the calibration of rheology, chemistry, and geometry gives rise to intelligent and versatile thermo-responsive behaviors that parallel those observed in nature.

First, I will introduce a platform we call HISTEMI (Homeostatic Interface for Solar and Thermal Environmental Management using Instability), after the Greek root for homeostasis; I will then demonstrate some of the unique environmental management behaviors enabled by the non-linear temperature-dependence of the underlying hydrodynamic instability.

Next, I will discuss the implications of this class of smart materials for accessing what we call 'customizable homeostasis' – a new temperature management paradigm that fuses the benefits of typical passive systems (low-energy feedback) with those of typical active systems (high-precision control). Results from a set of optical and thermodynamic energy-balance models will reveal the potential energy savings of this thermoregulatory modality across global sectors, from transportation to agriculture, residential housing, and power generation.

Finally, I will make the case for 'engineered-instability' as a paradigm to access new functions that unconventionally address challenges in energy management, human comfort, and sustainability.

9:15 AM SB08.01.03

Magnetic Nanoparticles Coupled to Cadherins as Smart Materials to Activate Mechanoreceptors and Intracellular Pathways *Christian Castro-Hinojosa[1], Pilar Gomollon-Zueco[1], Susel del Sol-Fernandez[1], Raluca Maria Fratila[1], Pablo Martínez-Vicente[1] and Maria Moros[1,2]; [1]Instituto de Nanociencia y Materiales de Aragón, Spain; [2]Centro de Investigación Biomédica en Red de Bioingeniería, Biomateriales y Nanomedicina, Spain*

Magnetic particles are stimuli-responsive materials, that coupled to magnetic fields can be used as a tool to precisely manipulate mechanoreceptors by converting mechanical cues into biochemical signals. Compared to other techniques, the use of magnetic fields offers some advantages such as deep-tissue penetration, the possibility to apply a wide range of stresses and forces (fN to nN) without damaging the sample and the possibility to manipulate the receptors in a remote fashion.
Although magnetic microparticles are widely used for this purpose, their large size might result in multivalent binding, causing clustering of receptors and activation of intracellular signalling even in the absence of a magnetic field. Alternatively, smaller magnetic nanoparticles (MNPs) offer undeniable advantages for manipulating mechanoreceptors as they show spatial control at the molecular level. However, MNPs exert smaller forces (in the range of fN or pN), that might be low to activate a mechanoreceptor. Therefore, a full optimization of the magnetic properties of the MNPs (through control of their size, shape and composition) and a correct design of the magnetic field applicator are crucial to reach this threshold.
Cadherin fragments immobilized on magnetic nanoparticles can be used to selectively target cadherin expressing cells and to activate intracellular pathways if the fragments are correctly oriented on the nanoparticle surface. Critical factors that can ultimately affect cellular recognition are the orientation and density of the biomolecule on the MNP surface as the interaction between two E-cadherins depends on a correct spatial position. We will discuss how MNPs attached to cellular cadherins can be used to selectively stimulate important intracellular pathways related to cellular proliferation and the advantages of using these smart materials

9:30 AM *SB08.01.04

Dissipative Self-Assembly of Active Supramolecular Materials Fueled by Chemical and Electrochemical Redox Reaction Networks *Zhibin Guan; University of California, Irvine, United States*

Fuel-driven dissipative self-assemblies (e.g., microtubules) play essential roles in living systems, contributing both to their complex, dynamic structures and emergent functions. Several dissipative supramolecular materials have been created using chemicals or light as fuel. Recently, we demonstrated a new platform for creating dissipative self-assembled supramolecular materials fueled by chemical and electrical redox reaction networks. Through chemical and electrochemical redox reaction networks, several active supramolecular assemblies have been achieved with rapid kinetics, directionality, and precise spatiotemporal control. In this talk, I will share our recent studies and collaborative work in designing dissipative self-assembly of active supramolecular materials using different building blocks ranging from amino acid derivatives, peptides, nanoparticles, and even living cells. As *electronic signals are the default information carriers in modern technology, the described approach offers a potential opportunity to integrate active materials into electronic devices for bioelectronics applications.*

10:00 AM BREAK

SESSION SB08.02: Smart Materials: Shape Memory Materials
Session Chairs: Carmelo De Maria and Andres Diaz Lantada
Tuesday Morning, December 3, 2024
Hynes, Level 2, Room 202

10:30 AM *SB08.02.01
4D Printing of Shape Morphing Devices Using Shape Memory and Superelastic Metallic Alloys *Jon M. Molina-Aldareguia[1], Carlos Aguilar[1], Oscar Contreras[2], Muzi Li[2] and Andres Diaz Lantada[1]; [1]Universidad Politécnica de Madrid, Spain; [2]IMDEA Materials Institute, Spain*

Additive manufacturing (AM) technologies have reinvented many areas of product development. The use of "smart" devices, obtained through the emerging concept of "4D printing", capable of undergoing progressive metamorphosis is still a dream, especially in metallic materials that offer substantial load bearing capabilities. In this context, we investigate the use of active materials, such as shape memory alloys (SMA), capable to undergoing shape changes upon a thermal stimulus. Laser powder bed fusion (LPBF) might offer the degree of dimensional precision and manufacturing control required to achieve this goal, provided the metallurgical changes that take place during processing are well understood and that effective post-processing methods are developed to control the final surface condition, which is critical for many applications. Several examples will be presented on the effect of processing parameters on the chemical composition, microstructure and properties of several SMAs of the nitinol family.

11:00 AM SB08.02.02
Development of Smart Memory Polymers for Implantable Devices *Zoe Schofield, Arjan Sall, Georgios Mikalef, James Churm, Atif Shahzad and Liam Grover; University of Birmingham, United Kingdom*

There is a growing body of research on the integration of sensing systems for measuring blood pressure by integrating sensors into vascular stents [1–3]. Using implantable sensors enables for continuous sensing of diseases such as hypertension, neurological disorders, diabetes, and other cardiovascular diseases situated in vivo will allow for better therapeutic management and diagnosis of patients. One such sensor has been developed by our team using polydimethylsiloxane (PDMS) and a capacitor electrode, however the sensor will need an invasive procedure for implantation, limiting its widespread uptake. Here we report on the development of an implantable blood pressure sensor that can be delivered using minimally invasive methods. The delivery of this sensor system is enabled through the use of a Smart Memory Polymer (SMP), which can change conformation on elevation to body temperature. Smart memory polymers (SMPs) were first introduced to biomedical engineering in 1988 with polyurethane based SMPs [4]. The SMP reported here consists of a combination of PDMS and PCL [5]. When formed correctly, this SMP is soft at room temperature and then uncoils at 37 °C to enable deployment. Both PDMS and PCL are already used in the body and have an established safety profile. However, we have confirmed that the polymer blend system is non-toxic to cells in vitro, with in vivo experiments currently underway. We were able to deposit the sensor electrodes on the surface of the PDMS-PCL blend using photolithography [6]. Using this polymer *and deposition method, it was possible to miniaturise the current capacitor electrode design from 8x14 mm to 2x4 mm while maintaining sensor function.*

Shape-Memory-Based Smart Materials for Endovascular and Cochlear Navigation *Daniella R. DeVries[1], Maxwell L. Salter[1], Stephen E. Balzora[1], Jeffrey S. Olafsen[1], Keith E. Schubert[1], Yang-Soo Yoon[1], Samuel A. Gearhart[2], Jason H. Huang[2,3] and Linda J. Olafsen[1]; [1]Baylor University, United States; [2]Baylor Scott and White Medical Center, United States; [3]Baylor College of Medicine, United States*

Smart materials offer opportunities for navigating arteries or other body passages to deliver biomedical devices for sensing, diagnosis, and treatment. Shape-memory alloys can be programmed to useful geometries such as a bend or a coil in a wire to steer through a desired vessel or cavity. In this work, heat activation of the programmed shape into the austenite phase of Nitinol is achieved by passing current through the wire to generate resistive heating. Two primary applications of smart shape-memory alloy wires will be presented: (1) endovascular navigation and (2) guided insertion of electrode arrays and their placement for cochlear implantation.

At present, neurosurgeons and cardiothoracic surgeons utilize guidewires that typically are inserted in the groin and guided to the treatment site by feel, advancing or retracting by twisting or angling the wire manually. To facilitate navigation, shape-memory alloys, such as Nitinol, can be trained to bend at the tip or in a specific section of the wire in order to steer or select a branch of an artery. One of the challenges of this smart endovascular navigation is location of the guidewire, particularly as the diameters of the wire are reduced to reach narrow capillaries. While current practice is to use repeated x-ray fluoroscopy, we present results of successfully locating small-diameter wires (50–250 μm) using ultrasound and differential imaging techniques. Successful navigation and localization have been demonstrated in gelatin phantoms and a manikin forearm.

We also present programming of shape-memory alloys into coil shapes, with the long-term goal of enhanced insertion depth of the electrode array and its placement in cochlear implantation. While the human cochlea has a snail shape that spirals 2.5 turns (900°) as the chamber elevates from base to apex, insertion of the electrodes for cochlear implants typically is limited to 1–1.5 turns (<540°), as the physician will stop at the first sign of resistance in order to avoid injury or trauma. This shallower insertion results in a frequency mismatch between the clinically mapped frequencies on electrodes and corresponding cochlear frequencies, particularly affecting low-frequency *processing and perception. An additional challenge can occur due to poor lateral placement of the electrode array relative to the cochlea's ganglion cells as well as insertion depth, and these shape-memory alloys offer an opportunity to enable lateral control for better placement in addition to deeper insertion, which may result in enhanced spectral and temporal transmission to central auditory pathway. Results will be presented for training and relaxation of the programmed coil shapes as well as engineering the coils for sectional activation to achieve deeper insertion.*

11:30 AM SB08.02.04

Smart Polymeric Micro/Nanosystems with Programmable and Recoverable Functions Juhyuk Park*; Seoul National University, Korea (the Republic of)*

In recent years, the versatility and potential of shape memory polymers (SMPs) have expanded dramatically, driven by advancements in chemical design, finite-element modeling, and rheology-based precision polymer processing techniques. Our work leverages these advancements to create solutions that address complex challenges in multiple domains. Ss matrix materials for smart systems, we designed, synthesized, and used shape memory copolyacrylates (SMCPAc) and shape memory polyurethanes (SMPU) that exhibit unique physicochemical properties. Using the SMPs, we developed functional micro/nanostructures, such as nanopattern arrays, microcellular foams, and microfluidic channels. In this talk, first, the smart nanopattern arrays are introduced, which not only enhance antireflection capabilities and biometric sensing performance but also offer sustainable nanofunctions. Second, the smart microcellular foams for sound absorption and thermal insulation are demonstrated. These foams can be tuned to adjust their functions based on the programmed microcellular shapes, such as tuning working noise frequency and the level of thermal insulation. Lastly, our work on smart microfluidic devices demonstrates the potential of SMPs in creating fluidic logic devices. The multidisciplinary approach to developing SMP-based micro/nanostructures introduced in this talk has the potential to revolutionize current technologies and introduce groundbreaking capabilities.

SESSION SB08.03: Fundamentals of Engineered Living Materials
Session Chairs: Chelsea Heveran and Monsur Islam
Tuesday Afternoon, December 3, 2024
Hynes, Level 2, Room 202

1:30 PM *SB08.03.01

De Novo Engineered Living Materials from Bacteria Sara Molinari*; University of Maryland, United States*

Engineered living materials – ELMs – are composites of living cells embedded into a biopolymer matrix. They are inspired by naturally occurring living materials, such as bones, wood, and biofilms, but use synthetic biology to introduce tailored non-natural properties to function as living sensors, therapeutics, biomanufacturing platforms, electronics, energy converters, and structural materials. While cells confer functionality to ELMs, the matrix assembles the material and defines its mechanical and physical properties, by controlling the bulk material composition, structure, and function. For this reason, the ability to engineer the collective self-organization of cells through a genetically encoded synthetic matrix has been a longstanding challenge in the ELM field. Prior to my work, most macroscopic ELMs either required significant processing to be assembled, or were based on natural biomaterials, such as the bacterial nanocellulose, and hence minimally tunable. Here, I present the first macroscopic de novo ELM, which grows from genetically engineered bacteria. I achieved this goal by engineering

Caulobacter crescentus to display self-interacting proteins. In this way, I created a synthetic extracellular matrix that mediates the hierarchical organization of cells over four orders of magnitude, resulting in the growth of centimeter-scale living materials. The most remarkable and unique feature of the de novo ELMs is that their mechanical properties can be controlled through genetic modifications. I showed that this living material can be functionalized from complex enzyme mixtures, allowing it to perform biological catalysis. Moreover, it retained the natural ability of single C. crescentus cells to bind cadmium from contaminated solutions, demonstrating the potential to be a much more useful tool for heavy metal removal than a suspension of single cells by virtue of being macroscopic, solid materials. De novo ELMs can be reshaped and used as cementing agents, forming hard hybrid materials; they can also be desiccated at room temperature and reseeded into fresh medium to form new material, facilitating their transport and storage. This study lays the foundation for growing ELMs with defined physical and mechanical properties, thus paving the way toward growing multifunctional, self-regenerating materials.

2:00 PM *SB08.03.02

***Cellular Proliferation Within Engineered Living Materials Enables Material Growth and Cell Delivery** Taylor H. Ware; Texas A&M University, United States*

Engineered living materials derive functionality from the characteristics of living and non-living components. We will describe two unique functions, programmed growth and controlled cell delivery, driven by the proliferation of embedded microorganisms within covalently crosslinked hydrogels. Living yeast–hydrogel and bacteria-hydrogel composites are capable of undergoing programmed shape change. As the cells are higher modulus (~100×) than the gel, cell proliferation results in a macroscopic shape change of the composite. This growth can be used to create stimuli-responsive materials or to manufacture components with >95% biomass. When the proliferating colonies of cells get large enough, the hydrogel locally fractures and these cells are released to the surrounding environment. We will describe systematic relationships that govern cell release. For example, the elastic modulus of the hydrogel can be used to tune the rate of cell release over a range of four orders of magnitude. The use of these composites to deliver probiotic bacteria in a controlled fashion will be described.

2:30 PM SB08.03.03

***Mechanics of Microbial Granular Hydrogel Composites** Samson O. Adelani, Morgan Riffe, Jason Burdick and R. Konane Bay; University of Colorado Boulder, United States*

To fabricate scalable engineered living materials (ELMs), researchers often embed living cells within artificial scaffolds and substrates. In hydrogel systems, this approach often results in the formation of fixed-sized microcolonies due to the confinement effect of the hydrogel matrix. These microcolonies can enhance the stiffness of the hydrogel by acting as reinforcing organic microparticles. Tuning the mechanical properties of these ELMs typically involves either increasing the cell density within the material before crosslinking or altering the crosslinking density of the hydrogel. Consequently, the final mechanical properties of these materials are fixed during the crosslinking process. In this study, we will overcome these challenges by fabricating microbial granular hydrogel composites by combining jammed microgel with photocrosslinkable methacrylate hyaluronic acid (MEHA) and Escherichia coli. The jammed microgels serve as a scaffold supporting cell growth before crosslinking, while MEHA immobilizes the cells post-crosslinking. We demonstrate how crosslinking after incubating the composites affects the final cell density and stiffness of the microbial hydrogel composites. Our findings provide fundamental insights into how cell growth in granular environments can influence the mechanical properties of microbial hydrogel composites.

2:45 PM SB08.03.04

Microbialites as Self-Assembling and Self-Repairing Building Materials *Hossein Khadivar[1,2], Erika Espinosa-Ortiz[3], Chelsea Heveran[2,1] and Robin Gerlach[2,1]; [1]Center for Biofilm Engineering, United States; [2]Montana State University, United States; [3]Utah State University, United States*

Living materials, an innovative and emergent class of materials, are expanding our opportunities to construct, maintain, and repair buildings as well as produce materials in resource-scarce locations, such as in space. Natural materials, including bone, wood, and bacterial biofilms, adapt their properties based on environmental factors. These materials naturally exhibit autonomous growth, sensing, metabolite secretion and regeneration. Engineered living materials aim to mimic these characteristics to create functional, stimuli-responsive materials. Lichen are an example of synergistic microbial communities with a heterotrophic fungal partner (mycobiont) and a photoautotrophic partner (photobiont, either an alga or a cyanobacterium). When lichen form minerals, they could also be considered microbialites, generally defined here as microbial communities with lithification capacity. Using microbialites for manufacturing applications has the potential to harness the progress of millions of years of evolution to improve sustainable biomanufacturing strategies.

We hypothesize that by leveraging the synergy between the mycobiont and the photobiont, materials and structures can be grown, which are also capable of self-repair. Here, we present work, which uses organisms capable of forming lichen to produce living materials for prospective infrastructural applications. In lichen, only the co-culture of the two partners is capable of producing the emergent lichen structure, while neither partner alone is capable of doing so. Furthermore, lichen are resilient and can grow (albeit slowly) using carbon dioxide as the sole carbon source.

Our primary goals are (1) designing self-sustaining co-cultures capable of biomineralization, (2) understanding and controlling the contribution of each community member to the overall biomineralization process, and (3) optimizing the material properties of the biomineralized products. Initial efforts have identified promising myco- and photobionts, including Aspergillus niger, Neurospora crassa, Aureobasidium pullulans, Nostoc sp. PCC 6720, and a high pH-tolerant green alga (Chlorella sp.). These selections are based on existing evidence of mutualistic relationships and their potential for contributing to biomineralization.

By manipulating environmental parameters such as pH, light, nutrient availability (incl. CO2), and temperature, we aim to understand and ultimately control the mechanisms through which these organisms contribute to biomineralization and the creation of structures. The produced structures and materials will be examined in terms of hardness and strength using nanoindentation and compression testing, respectively. Scanning Electron Microscopy combined with Energy Dispersive X-ray Spectroscopy and X-Ray Diffraction techniques assist with material characterization such as assessing the composition and structure of the produced material.

In summary, the integration of our insights gained from the sustainable microbial co-cultures and our material characterizations will contribute to the development of novel materials that meet specific structural and environmental requirements, paving the way for their application in sustainable construction and beyond.

3:00 PM BREAK

SESSION SB08.04: Applications of BioELMs
Session Chairs: Carmelo De Maria and Monsur Islam
Tuesday Afternoon, December 3, 2024
Hynes, Level 2, Room 202

3:30 PM *SB08.04.01

Self-Assembled, Living Bacterial Microlenses that Capture and Focus Light *Anne S. Meyer; University of Rochester, United States*

Microlenses are a cutting-edge technology for focusing, imaging, detecting, and coupling light in advanced optical applications. However, current fabrication methods require expensive, labor-intensive manufacturing techniques that often require and/or produce toxic chemicals. Additionally, microlens fabrication can require further processing that introduces defects such as etching into the lenses themselves. We have employed a synthetic biology approach to develop biological microlenses by engineering bacteria that display the natural silica biomineralization enzyme silicatein found in aquatic sea sponges. The silicatein enzyme can catalyze the polymerization of monomeric silica into polysilicate layers at physiological pH and temperature. We have engineered Escherichia coli bacteria to express silicatein fused to outer membrane protein OmpA at the surface of the bacteria, so that the silicatein enzyme can polymerize a layer of polysilicate surrounding the cell. Fluorescence confocal microscopy of silicatein-expressing bacterial cells stained with Rhodamine123, which binds polysilicate, revealed a highly stained cell boundary with little internal staining. This result indicates that the E. coli are encapsulated with polysilicate. To measure the light-focusing behavior of the polysilicate-coated bacterial cells, we illuminated them with total internal fluorescence microscopy and detected the pattern of light that was scattered into a fluorescent agarose pad. The bioglass-coated bacteria scattered light off their surface that illuminated a larger area with a brighter intensity compared to bacteria not expressing silicatein, indicating that the engineered bacteria can both capture and focus light. Our bacterial microlenses are metabolically active for four months, creating the possibility for the living, encapsulated bacteria to alter their optical properties in response to environmental cues. Our bacterial microlenses are sustainably self-assembled without expensive machinery or harsh chemicals and have wide-ranging applications in the optical and biomedical industries, such as compact image sensors, 3D displays, concentrators for photovoltaics, solar cell technologies, and more.

4:00 PM *SB08.04.02

Getting Cells into Engineered Living Materials and Keeping Them Alive *Christopher Hernandez[1,2,3]; [1]University of California, San Francisco, United States; [2]Chan Zuckerberg Biohub, United States; [3]University of California, Berkeley, United States*

Engineered living materials (ELMs) are a new class of materials synthesized by and/or populated by living cells. While early demonstrations of ELMs have been promising, they have been limited in application because they are predominately soft (Young's modulus < 1 GPa), and they have a short service life, often single-use, due to the limited lifespan of resident cells. These two facts limit the ability of ELMs to replace most traditional engineering materials. Our goal is to make engineered living materials with sufficient stiffness and service life to replace traditional engineering materials in durable devices. We have therefore focused on populating traditional engineering materials with living cells and on technologies that make it possible to replenish the cell populations within the material. Inspired by nutrient transport mechanisms to cells within bone matrix, we recently demonstrated an approach to deliver nutrients to cells entombed within a network of small channels punctuated by larger pores where cells reside [1]. An open question is how to populate and/or replace dead cells in the pores of such a matrix. Here we use microfluidic systems to explore the mechanical properties of individual bacteria and understand how their deformability enables the colonization of submicron scale pores within a solid matrix. We find that the mechanical properties of bacteria are highly tunable and that appropriate external mechanical loading can enable the population of a channel-pore system by cells in the absence of net flow through.

4:30 PM SB08.04.03

Materials-Driven Strategies to Engineer Bacterial Motile Behaviour—Using Light to Understand and Control Dynamic Membrane Potential Modulation *Andrea Pianetti[1], Pietro Bertolotti[1], Cosimo D'Andrea[2], Giuseppe Maria Paternò[1,2] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy*

Understanding and controlling bacterial motility and response to external stimuli is indeed pivotal for leveraging bacteria in the creation of smart and living materials. Recent studies have unveiled the dynamic nature of bacterial membrane potential: it is now evident that membrane potential regulates a wide array of bacterial physiological processes and behaviors, including membrane transport, motility, antibiotic resistance, communication, and environmental sensing. Despite these advancements, numerous questions remain. These include the information encoding capacity of membrane potential dynamics, the origins of excitability and electrical signaling, the feasibility of artificial control of membrane potential, and many others [1].

Traditional patch-clamp techniques, while effective for certain applications, are inadequate for studying dynamic changes in bacterial membrane potential due to the requirement for cell immobilization and the diminutive size of bacterial cells. Consequently, there is an urgent need for developing novel, minimally invasive methods to measure membrane potential dynamics [2].

Fluorescent molecular probes with voltage-dependent optical properties have emerged as a promising solution for noninvasive studies of membrane voltage. Recent advancements that optical electrophysiology measurements will soon become routine in human cell electrophysiology [3]. This approach is now being extended to non-eukaryotic cells, such as bacteria. In this context, Nernstian dyes have been widely employed due to their high efficency and low toxicity. However, estimating membrane potential based solely on fluorescence intensity is fraught with challenges due to various factors such as spatial uniformity of excitation and fluctuations in light source power, which can lead to significant experimental errors. In contrast, fluorescence lifetime is an intrinsic property that depends solely on the local environment of the dye and is independent of many external experimental parameters. Thus, measuring both fluorescence intensity and lifetime can provide more accurate and reliable data.

In this study, we investigated the dependency of the fluorescence lifetime of the TMRM dye on the progressive depolarization of membrane potential in both gram-positive and gram-negative bacteria. Our findings demonstrate that this phenomenon is ubiquitous across different bacterial types, underscoring its potential as a robust tool for electrophysiological studies of motile and free-living bacteria in various environments. Furthermore, we employed Fluorescence Lifetime Imaging Microscopy (FLIM) to precisely correlate bacterial motility behavior with membrane potential modulation, using both intensity and lifetime as observables. Additionally, we demonstrated the internalization of DIANEP dyes in bacterial membranes, which have primarily been used in eukaryotic cells, to evaluate membrane potential based on variations in spectral characteristics beyond photoluminescence dynamics.

These advancements enable the use of optical methods in bacterial electrophysiology, providing new insights into the dynamic processes of bacterial behavior and physiology. This approach could also be extended to study the detailed electrophysiology of other small motile cells, such as algae and viruses, which have not been extensively explored before but might serve as a new foundation for developing living materials.

4:45 PM SB08.04.04

Time-Dependent Assessment of Fibril Assembly and Order by Light Polarization *Chris Zhou, Chenglong Zhang, Xin Lu, Yi Lu, Xuetong Shi, Farhad Ahmadijokani, Frank Ko, John D. Madden and Orlando J. Rojas; The University of British Columbia, Canada*

Microfibrillar structures are fundamental to the dynamics of both biological and physical systems, most relevant to materials based on polysaccharides (cellulose, chitin) and proteins (collagen), including filaments, textiles, sensors and actuators, as well as data/electric/magnetic channels. Among the various properties, alignment (order) is an important factor defining structural, mechanical and functional features. Currently, measurements of fibril order in the nano and microscales rely on scattering and 2D imaging data that is fed to mathematical models, which compromise precision and generality across diverse fibril organizations and applications. For example, studies on fibril order in cellulose biofilms produced by microorganisms is challenged by the random distribution of features in space, including length, diameter, density, orientation, and morphologic or topologic dynamics, which are not considered in conventional approaches. The level of complexity is further increased considering the dynamics of the system, e.g., spatial-temporal factors. To address these challenges and better understand the impact of fibril order on the assembly in living systems, we propose a non-invasive technique utilizing three-dimensional imaging and light polarization analyses. This approach allows us to precisely assess the structural order using a matrix representation and correlating it with responses under different conditions (e.g. mechanical strains). We have synthesized fibers featuring various materials, alignment angles, structures, and organizations—including aligned, semi-aligned, random alignments, and helical configurations. By using a custom-made polarization matrix detection platform, we quantified order in the time domain. The polarization detection enables real-time observation and detailed quantification of the changes in fiber order under mechanical strain. This work provides fundamental support relevant to current efforts related to living matter, self-assembly, energy and health-materials.

SESSION SB08.05: Programmable Materials
Session Chairs: Carmelo De Maria and Monsur Islam
Wednesday Morning, December 4, 2024

8:45 AM *SB08.05.01
Mechanisms and Algorithms for Shape Morphing and Self-Sealing Programmable Materials *Naeim Ghavidelnia[1], Franziska Wenz[2] and Christoph Eberl[2,1]; [1]Universität Freiburg, Germany; [2]Fraunhofer Institute for Mechanics of Materials, Germany*

Programmable Materials are a novel research field in materials science and engineering, as their inner structure represents the instantiation of algorithms, thus enhancing them to have functionalities and abilities instead of just physical properties. Programmable Materials facilitate molecular and mesoscopic meta materials' mechanisms to interact with the environment e.g. react on thermal or mechanical inputs. Here, inspiration can be drawn from biological systems, which evolved to incorporate complex physical computing abilities, allowing them to adapt to changing environments, self-repair, and train or lean from external stimuli. In this talk the scientific opportunities enabled by Programmable Materials, their inner workings and possible design tools shall be discussed. The focus will be on the meta material unit cell designs and their concerted interaction, as well as the achievable functionalities. Examples of adaptive stiffness, damping and shape morphing will be shown as well as complex processes to implement e.g. self sealing. The related challenges and possible applications shall be discussed.

9:15 AM SB08.05.02

Dynamically and Reversibly pH-Repsonsive Poly(amine) Capsules *Zhang Wu[1], Joerg G. Werner[2] and David Weitz[1]; [1]Harvard University, United States; [2]Boston University, United States*

Microcapsules featuring an aqueous core and a shell responsive to stimuli hold appeal as delivery vehicles for loading and unloading cargo in drug delivery systems. In complex scenarios, there is a growing demand for intelligent capsules capable of adapting to environmental changes dynamically. However, there remains a dearth of dynamic capsules tailored for drug delivery in acidic environments. This study presents a new approach to designing dynamic capsule shells using crosslinked poly(amine) to achieve pH-responsive hydrogel microcapsules that can reversibly swell and shrink. The poly(amine) hydrogel capsules demonstrate dynamic behavior, including changes in shell network mesh size upon pH shifts, enabling cyclic capture, trapping, and release of cargo. These newly designed poly(amine) capsules enhance the diversity of smart capsule options and expand their potential applications.

9:30 AM SB08.05.03

Magneto-Responsive, Hyperelastic and Self-Healing Ionoelastomers *Xuan Zhang and Yu Jun Tan; National University of Singapore, Singapore*

Magneto-responsive soft materials with self-healing properties are highly desirable for wearable electronics and soft robotics. However, traditional magnetic materials using metal particles always limit transparency and elasticity despite offering high magnetization. We present a novel Magneto-IoNo-Elastomer (MINE) that overcomes these limitations. MINE combines exceptional magnetization with hyperelasticity and self-healability, while possessing ionic conductivity and transparency. This is achieved through a unique polymer design with urethane groups that effectively confines magnetic anions from magnetic ionic liquids (MILs) via potential hydrogen bonds and metal-coordination bonds. The strong interactions between polymer chains and magnetic anions allow for high MIL loading (up to 80 wt%) while maintaining the material's structural integrity. The versatility of MINE, stemming from multiple reversible bonds, holds great promise for wearable strain sensors, contactless magneto-responsive electronics, and see-through touch panels. The discovery of MINEs will shed new light on applications bridging optics, electricity, magnetism, and stretchability.

9:45 AM SB08.05.04

The Physical Limits of Self-Healing Materials *Grady Iliff, Lin Wang, Alexander Myers and Tak-Sing Wong; The Pennsylvania State University, United States*

Self-healing materials demonstrate the ability to automatically repair damage similar to the healing process found in nearly all biological materials [1]. While most reported self-healing materials rely on slow diffusion-driven mass transport to achieve healing, stabilized liquid materials represent a class of materials which can self-heal at unprecedented speeds (~1 m/s), nearly three orders of magnitude faster than conventional diffusion-driven self-healing materials [2]. Such an ultrafast self-healing response has enabled engineering applications that were previously unachievable such as reverse filtration where large particles can pass through the material while retaining smaller ones [3]. In order to engineer self-healing materials capable of ultrafast self-healing, it is essential to understand the physical limits of the self-healing mechanisms involved. Here we show that inertial-capillary self-healing is the fastest mode of self-healing in functional materials. Our results suggest that the inertial-capillary self-healing rate of a liquid film scales with its Taylor-Culick rupture speed, an intrinsic material property of the system. We also provide a relationship for the critical impact speed of an impinging object, beyond which the film will rupture instead of self-heal, defining the functional regime of self-healing liquid films. Our findings offer the first *physical design principles for engineering ultrafast self-healing materials that surpass the current state-of-the-art self-healing materials.*

Tetrapods Based Smart Materials for Advanced Technologies *Fateme Mirsafi, Elham Chamanehpour, Humaira Asghar, Mustafa Ismael, Till Leissner and* <u>*Yogendra K. Mishra*</u>*; University of Southern Denmark, Denmark*

Considering the size dependent utilization complexities of nanoscopic dimensions tin real technologies, the focus of nanomaterials community is converging to three-dimensional (3D) nanomaterials which are built out of interconnected nanostructures building blocks. This talk will briefly introduce the importance of tetrapod nanostructures towards smart 3D nanostructuring via a simple and single step flame-based approach for synthesis of zinc oxide tetrapods. These tetrapods have already demonstrated their potential roles in many different technologies. These zinc oxide tetrapods can be used as solid backbone or sacrificial templates to design hybrid or new tetrapods as smart materials. These smart 3D nanomaterials offer many applications in engineering and advanced technologies. Application examples of 3D tetrapods in nanosensing, composite engineering, antiviral candidates, water purification, piezotronics, and in several other applications will be demonstrated [1-10]. The integration of tetrapods in electrospun fibers offer many advantages in biomedical engineering and few examples about nano-engineered electrospun fibers will be presented as recent developments.

Smart Windows Using Thermochromic VO_2 Coatings for Autonomous Adaptation of Solar Heat Gain for Optimized Energy Efficiency in Buildings *Roberto Habets and Daniel Mann; TNO, Netherlands*

Crystalline vanadium dioxide is a naturally occurring smart material that reacts on a number of different stimuli with a structural phase transition (STP) that changes the optical, electrical and physical properties of the material. This phase and property change can be used in smart applications, such as thermochromic glass coatings for smart windows. Here a thermal and optical stimulus is used to switch the solar infrared transmission of a coated glass plate between a transparent and a blocking state. Integrated into a window this enables the autonomous adaptation of its solar heat gain based on a buildings energy and comfort needs. This significantly reduces the energy demand of a building on heating and cooling simultaneously and increases comfort levels for occupants. Furthermore, smart windows using thermochromic VO_2 coatings can reduce the CO_2 emissions of buildings and add to the transition towards a climate neutral built environment.
In the past years, we have developed a process to synthesize doped thermochromic VO_2 nanoparticles at high purity, crystallinity and precise size and shape.[1] We integrated this functional smart material into a coating on glass, resulting in thermochroic smart window coatings with optimized optical properties, combining high visible transmission >60% with high solar modulation >20%.[2] Here we present the importance of the functional materials characteristics on the smart properties. Various parameters, such as crystallinity, size and compatibility between functional nanoparticles and coating matrix, are crucial to optimize functional performance. To influence the STP towards application oriented requirements, we used precise meatal ion doping to reduce the phase transition temperature from 68°C for regular VO_2 to application oriented region between 20 – 30°C.[3] The technology has been scaled up to 1 m^2 sized glass plates using an industrial roller coater and the coated glass plates have been integrated into insulating glass units. We further investigated the combination of the smart window coating with industrial low emissivity coatings, adding insulating properties to the adaptive solar heat gain properties of the smart window coating. Synergistic and parasitic effects of both coatings have been investigated to find the correct balance between both effects.[2] Full sized window demonstrators have been installed in test buildings, monitoring the thermochromic effect dependent on the glass and outdoor temperature, as well as the solar irradiance.[4] Using the gained insight into the smart window behavior in a real life setup, the thermochromic properties and phase transition temperature could be further optimized. Finally, we present the energy and CO_2 emission savings potential of the new smart window via building energy simulations. Here we show that in a regular Dutch household energy savings of approximately 9% in comparison to existing highly energy efficient windows can be achieved and that the Dutch built environment may save up to 5.8 Mt in CO_2 emissions per year using widespread implementation of the new smart window.[2,3] Overarching, we present the development of a new smart product, from conceptualization, to lab scale optimization, scale up, system integration, real life testing and impact analysis. The knowledge gained during this multi-year development can be transferred towards other smart material developments.

Thermoresponsive Hydrogel Composite Devices for Cooling-Triggered Release of Therapeutics for Pain Relief *Romario Lobban, Michael Carroll, Isabel Madrid, Andrew Ray, Mailee Srilouangkhol and Leon M. Bellan;*

Vanderbilt University, United States

Easy, on-demand treatment of pain is achieved primarily by opioids, which are frequently administered orally (for on-demand relief) and have systemic effects. Unfortunately, these drugs are highly addictive; over 5 people per hour die from opioid abuse in the US alone. A safer, non-systemic mechanism for pain relief is therefore needed. Local anesthetics and nonsteroidal anti-inflammatory drugs (NSAIDs) have been explored for this purpose; they are non-addictive, provide excellent pain relief, and can (local anesthetics must) be delivered locally to minimize dosage and systemic side effects. However, an on-demand, minimally invasive method for local delivery is needed to enable these drugs to serve as a convenient replacement for opioids; external stimulus-triggered release from an implanted depot is one approach. Stimuli like light and ultrasound have been used to trigger drug release from implanted depots, however, these rely on energy input to tissue (provided by complex apparatus) and are thus not comparable to the ease of oral administration. We propose localized cooling as a stimulus. As icepacks are already applied to ease local pain, introducing a drug delivery mechanism switched "ON" by cooling would enable long duration, enhanced pain relief triggered by a method with which patients are already familiar. Herein, we demonstrate that cooling-triggered release of both local anesthetics and NSAIDs can be achieved using the well-known gel-to-sol transition that physically crosslinked thermoresponsive polymer hydrogels undergo upon being cooled below their LCST. We show that said hydrogels, loaded with a given anesthetic or NSAID, can be combined with a non-thermoresponsive membrane material to create implantable devices that demonstrate up to a ~40x increase in drug release rate upon cooling below body temperature.

We designed two separate thermoresponsive hydrogel composite devices. In the first, an aqueous solution of 35 w/v% Soluplus (a polyvinyl caprolactam-polyvinyl acetate-polyethylene glycol graft copolymer made by BASF) loaded with the NSAID Celecoxib (CXB) (8 $w/w_{Soluplus}$%) or Nile red (0.4 $w/w_{Soluplus}$%) was combined at various ratios with 3.1 w/v% sodium alginate (with 0.1% linear polyethyleneimine (LPEI) to enhance crosslinking). We then poured this mixture into a mold, and placed said mold into 3 w/v% calcium chloride for 30 minutes. The resulting gel device was composed of a crosslinked alginate matrix with scattered ~20-micron diameter domains of CXB-laden Soluplus. We explored the microstructure of these devices using scanning electron and confocal microscopy. We also explored cooling-triggered release of CXB or Nile red from them in-vitro and in cadavers. The second hydrogel composite device was made by creating solutions of 6 w/v% poly-n-isopropylacrylamide (PNIPAM) and either 2 w/v% Bupivacaine hydrochloride (BUP) or 0.2 w/v% fluorescein sodium (FL), allowing these solutions to physically gel at 31.5 °C for 48 hours, and encapsulating the resulting physical hydrogels inside chemically welded regenerated cellulose membranes. We then explored in-vitro cooling-triggered release of BUP and FL from these devices.

The alginate/Soluplus composites released Nile red and CXB ~100x faster ON (at 23 °C) vs. OFF (at 37 °C) in-vitro; a ~40x difference was seen when 29 °C and 35 °C were used as the ON and OFF temperatures, respectively. The latter temperatures represent icepack-cooled and uncooled temperatures 1 cm below the skin, as described in literature. Results in cadavers were similarly conclusive. The PNIPAM/cellulose composites released FL >100x and BUP ~30x faster ON (at 25 °C) vs. OFF (at 31.5 °C). These temperatures represent icepack-cooled and uncooled temperatures in the subcutaneous layer. Hence, we have demonstrated in-vitro cooling triggered release of both an NSAID and a local anesthetic at temperatures achievable in-vivo. We are currently working to demonstrate this behavior in live Sprague-Dawley rats.

Development of Smart Fractal Nanostructure for Promoting Heterogeneous Ice Nucleation *Minjun Ko[1], Sanghee Lee[1], Yoo Sang Jeon[2] and Dong-Hyun Kim[1]; [1]Northwestern University, United States; [2]Korea University, Korea (the Republic of)*

Our development of smart fractal ice nano-nucleators (SF-INNs) leverages their structural advantages, which inherently maximizes the number of active sites for heterogeneous ice nucleation. Owing to their radially attached nanocrystalline structure, SF-INNs expose an extensive array of grain boundaries. The rapid precipitation and subsequent radial attachments of nanocrystallites promote the exposure of facets with high Miller indices, intrinsically strained, five-fold twinned nanocrystals, and increasing point defects due to kinetically-limited precipitation. This unique fractal structure culminates in the elevating of freezing temperature compared to Euclidean-shaped ice nucleators. Additionally, the branched fractal structure of SF-INNs facilitates heterogenic ice formation within its nanoconfined region, leading to the production of numerous self-similar small fractal fragments. This fragmentation is primarily driven by nanoconfinement-induced delayed ice nucleation, similar to frost heaving. The shear stress can be easily relieved through grain boundary sliding within the radially stacked SF-INN, making itself prone to cryo-responsive fragmentation. Such cold-responsive attributes significantly enhance ice nucleating activity, presenting a powerful strategy to increase the efficacy of cryotherapy by enhancing cellular ice formation and in vivo tumor coverage. This research marks a paradigmatic leap in utilizing fractal nanoparticles for ice nano-nucleators.

Interactive Robust and Resilient Life-Like Materials Systems Inspired by Plants for Applications in Architecture, Medical Technology and Soft Robotics *Thomas Speck[1,2,2]; [1]Universität Freiburg, Germany; [2]University of Freiburg, Germany*

Plant tissues and organs are hierarchically organised fibre-reinforced polymeric materials consisting of polysaccharide fibres (cellulose microfibrils and fibres) embedded in a complex polymer matrix of hemicellulose, pectins and lignin. In addition to excellent mechanical properties, they often exhibit high robustness and resilience. These properties are based - in addition to various effective forms of self-repair - on various forms of damage prevention, damage control and damage management that allow these tissues and organs to function fully even after (sometimes severe) injury. The evolution of effective ways of dealing with damage is not only of high selective advantage for plants (and all other living beings), but also provides excellent concept generators for the development of robust and resilient interactive life-like materials systems of interest for application in various fields of technology and architecture.
Over the last decade, the Plant Biomechanics Group Freiburg has investigated several types of plant tissues and organs for their ability to prevent, control and manage damage. Examples include pine cone scales, cactus branchings, citrus fruit peels and the stems and tendrils of climbing lianas. The structural composition and function of liana tendrils and their adhesive pads, pine cone scales and self-healing latex plants are presented to demonstrate their extreme resilience and robustness even in the face of major damage. In addition, citrus fruit peels are shown as highly efficient structures for preventing damage to the fruit's internal parts and seeds. Selected examples demonstrate how these biological systems can be used as a source of inspiration for the design of robust and resilient interactive materials systems for applications in architecture, medical technology and soft robotics. Examples include autonomous hygroscopically actuated façade shading systems inspired by

the structure and function of pine cone scales and silver thistle bracts, highly shock-absorbing paddings for protective helmets inspired by citrus peels, and fail-safe technical attachment structures inspired by liana tendrils with adhesive pads.

2:00 PM *SB08.07.02
Self-Oscillating Polymer Gels, Vesicles, Micelles, Coacervates, Linear Polymers Exhibiting Life-Like Autonomous Behaviors *Ryo Yoshida; The University of Tokyo, Japan*

In 1996 [1], the author reported "self-oscillating" polymer gels that spontaneously repeat swelling–deswelling changes in a closed solution without any on–off switching by external stimuli, such as heart muscle. The gel has an energy-conversion system involving an oscillatory chemical reaction (called the Belousov–Zhabotinsky (BZ) reaction), which allows periodic mechanical motion of the polymer chain. Since the first report, the author has systematically developed self-oscillating polymer gels from fundamental behavior to construction and demonstration of material systems for potential applications in biomimetic materials, such as autonomous soft actuators, automatic transport systems, and functional fluids exhibiting autonomous sol–gel oscillations similar to those of amoeba [2]. BZ gels with similar properties have sometimes been called "Yoshida gels" [3]. Further optimal design such as direction control of movement were carried out. In particular, the myocardium repeats expansion and contraction in a uniaxial direction. In order to give the self-oscillating gel such anisotropic deformation, by introducing a layered structure like muscle fibers, the direction of contraction was controlled [4]. Further, by cyclically applying external mechanical stimulation to the BZ gels, it was possible to find resonance, either with the stimulation's fundamental frequency or an n × or (1/n) × harmonic of it, and then the system kept a "memory" of the resonant oscillation period and maintained it post stimulation, demonstrating an entrainment effect [5]. These findings help bridge the functions of biological systems with nonequilibrium chemical physics and pave the pathway to study the complicated biological problems using simpler biomimicking chemophysical systems.
Cell membranes in living organisms exhibit a fluctuating phenomenon with marginal undulations. Since this phenomenon is closely related to many important life phenomena such as cell motility, transport of intercellular substances, and cell division, many attempts have been made to artificially reproduce and understand the membrane fluctuation phenomenon. When a large hollow capsule-type self-oscillating gel is fabricated, the propagation of chemical waves on the surface causes a unique cell-like fluctuation and buckling of the gel [6]. By analyzing the fluctuation in detail, we will explore the meaning of the biomembrane fluctuation phenomenon and its application as an artificial cell.

Multifunctional Engineered Materials Inspired by Plants, Insects and Microorganisms *Tak-Sing Wong; The Pennsylvania State University, United States*

Numerous biological organisms have demonstrated how the diversity of surface architectures at the micrometer, nanometer, and molecular scales can yield a range of unique functions, including stimuli-responsiveness, self-healing, and special interfacial properties. Incorporating these functions into engineering materials enables novel functionalities that cannot be found in conventional materials. In this talk, I will discuss several examples of our recent biologically inspired materials, drawing inspiration from plants, insects, and microorganisms. These examples include the development of stimuli-responsive liquid-repellent materials inspired by the slippery liquid-infused peristome of Nepenthes pitcher plants [1 – 4], ultra-antireflective materials inspired by the three-dimensional, buckyball-shaped leafhopper-produced brochosomes [5, 6], and a self-healing reverse filter inspired by the self-healing and fluid mosaic nature of cellular membranes [7].

Geometric-Thermodynamic Modelling of the Isotropic-to-Smectic A Phase— Collagen-Based Material as an Inspiration for Fibre Manufacturing *David U. Zamora Cisneros, Noemie-Manuelle Dorval Courchesne, Matthew J. Harrington and Alejandro D. Rey; McGill University, Canada*

Functionalities in biological materials and Nature's manufacturing processes are heavily influenced by order, structure, and organization such as position, alignment, and chirality. Liquid Crystals (LCs) are materials presenting these structural details, like orientational and positional order while being found in synthetic and biological settings. The order and alignment in LCs are maintained until a phase transition is induced by a gradient in a driving force (e.g. temperature, concentration, pH). One example in Nature, and the motivation of this work, is the collagen-based tethering system used by marine mussels: the mussel byssus or byssal thread. This smart material, fabricated in seawater environments, features high-toughness, self-assembly and self-healing properties. As building blocks, mussels use collagenous molecules packed in a liquid crystalline layered fashion inside tactoid-shaped vesicles. These tactoids offer rich storage principles and mechanisms to be extruded into the green tough functional and composite material used by the mussel. The organization of the byssal thread precursor is a smectic semisolid with oriented molecules perpendicular to the layers, which has been hypothesized to play a major role in the pre-organization and formation of the fibre.

For the characterization of the liquid crystalline precursor structure, and the description of the roles of the LC in the formation of this collagen-based material from its pre-transitional state, it is essential to understand the assembly and phase transition mechanisms that govern the highly organized hierarchical molecular organization. The self-organization, self-assembly, and phase kinetics processes can be studied through the Landau-de Gennes (LdG) model. This model uses two non-conserved order parameters to describe the positional and orientational order and correlates them to the free energy of the system with phenomenological parameters. First, the energy landscape is developed to give an insight into the self-organization scheme. It provides information about the possible phases, or critical points, that exist at different conditions, which in this work are different temperatures or quenching regimes. In addition, the stability of the critical points has a predominant influence on the phase

kinetics. It has been seen that is involved in drop formation systems where there is a presence of stable phases within a matrix of an unstable phase, ultimately showing a thin layered-like film structure. Finally, the decomposition of the contributions from all the critical points enables the study of the self-assembly process. The manifestation of these processes by nucleation and growth and spinodal transformation are studied by decomposing the index of the free energy landscape into the contributions of the different critical points and their respective phase under different quenching regimes.
We present a new method to study the isotropic-to-smectic A liquid crystal phase transition by integrating thermodynamic stability modelling, polynomial index, non-linear differential equations and differential geometry to provide an insight into the multiple stable and unstable states and their dynamics as the quench regime changes, thus unravelling fundamental principles and roles of the LC in the formation of the multi-hierarchical structure. It was found that the emergence of different states which stability was then characterized as stable, unstable, and metastable using the energy landscape and their evolution through it. Consequently, it was observed that smectic ordering promotes nematic alignment. Ultimately, the understanding of the evolution and behaviour of the phases will pave the way for the development of green engineering principles, storage and delivery technologies, and advances in the processing of materials offering a greater comprehension of the tuning capabilities according to the material hierarchical organization.

Injectable Living Therapeutic Matrix—Nucleic Acid-Based Unit-Assembly of Cell-Microgels *Hyangsu Nam[1,2] and Jong Bum Lee[2]; [1]Harvard University, United States; [2]University of Seoul, Korea (the Republic of)*

Cell-to-cell communication is essential for coordinating fundamental biological processes. The extracellular matrix (ECM) plays a crucial role in this complex process by providing a stable structure that supports migration, differentiation, and cell behavior. In this study, we present an innovative injectable therapeutic matrix designed to enhance cellular networks through biorthogonal click cross-linking with a nucleic-acid scaffold. In our system, cells act as both active building blocks and therapeutic agents for the final construct. Additionally, the nucleic-acid substrate-mediated clickable moiety utilized in this study serves as a depot for cells, ensuring stable maintenance of cellular functions for subsequent in vivo delivery. Our system demonstrates that evaluating cell-substrate properties and cellular functions is effective, resulting in improved cell linking, proliferation, and precise control of stiffness. This platform showcases the potential of nucleic acid-based nanotechnology in the regenerative biomedical field, offering promising solutions for the restoration of full function in damaged tissues or organs.

SB08.08.02
Biohybrid Toggle Switches *Ronald Heisser and Ritu Raman; Massachusetts Institute of Technology, United States*

INTRODUCTION
Modern automation technologies continue to push the limits of engineering design by packing higher degrees of

freedom—actuation freedom—into smaller machine enclosures. Our prospects of producing many life-changing technologies including multi-line braille displays, high-resolution haptic feedback suits, microfluidic single-cell analyzers, and high-dexterity robotic end effectors critically depend on the number of compact actuators which can fit in the given device.

With muscle, Nature provides an elegant solution problem for all animals, even using its actomyosin parts to provide high-DOF motion to cells. Human beings have over 640 skeletal muscles, enabling the wealth of gracefully dexterous and precise motions we can do. Muscle's hierarchical structure frees limitations of size and arrangement; caterpillars have over 4000 muscles. Given muscle's clear actuation advantages, the burgeoning field of biohybrid robotics aims to fabricate in-vitro, 3D muscle tissue to expand its applications beyond animal locomotion.

Currently, biohybrid robotic actuators are cell-gel composites formed in a ring shape with bounding box dimensions of 5 mm x 10 mm and a radius of ~0.5 mm. Muscle constructions are limited to forces of up to 0.5 mN for C2C12-derived tissues and ~5 mN for primary skeletal muscle tissues. Researchers have used these nascent constructs to make simple walkers and microgrippers which deform an elastic flexural structure. Walking and gripping demonstrations show biohybrid robotic proof of concept, yet we seek to design a mechanism which we can more generally apply to machine components for future high-DOF actuation systems.

A common actuator design requirement is the control of two or more discreet position states. Switches and valves flip between on/off and open/closed states. Clutches flip between engaged/disengaged states in power transmissions. Though not mechanical, transistors flip between on/off voltage states to form the heart of the computer. Aside from functional necessity, switching mechanisms often have the advantage of only consuming power during state change. Muscle-powered systems would benefit from holding a position without the need for constant exertion. To our knowledge, no biohybrid systems in the literature have this capability.

RESULTS
With our previously developed C2C12-derived 3D muscle constructs, we have integrated our actuators with a bistable flexure to form a biohybrid toggle switch. The flexure is a molded soft polymer shuttle connected to a base with two beams on either side of the shuttle. Pushing one side inwards slightly preloads the flexure, moving the shuttle upwards. Pulling the shuttle downwards causes compressive stresses on the beams until the shuttle is in line with beams, where an instability causes the beams to push the shuttle downward with any further motion. Operating near the instability, electrical or optical stimulation of a muscle actuator triggers the toggle motion. We are currently tuning system stiffness and setpoints to obtain consistent actuations with muscle actuators. Rational design of the flexure including first order analysis, finite element simulations, and rapid iterative prototyping with 3D printed molds help to match the muscle contractile performance with bistable flexure behavior.

OUTLOOK
The first instantiation of our system features micron positioners to account for muscle actuator manufacturing variability and to tune the flexure preload. Once geometric specifications are computationally and experimentally verified, we can design a compact device which matches the actuator's own length scale. Ideally, this device would have an antagonistic pair of muscle actuators to enable cyclic toggle actions, and we will demonstrate this in future experiments.

SB08.08.03

Noise-Actuated Assembly in Active Matter *Emma M. Goyette, Caroline Desgranges and Jerome Delhommelle; University of Massachusetts Lowell, United States*

Biomimetic active matter has drawn considerable interest in recent years. Such systems give rise to unusual, out-of-equilibrium, assembly pathways as shown, for instance, by the formation of living crystals [1] and smart templated active self-assembly [2,3]. These unexpected assembly pathways, as well as the motility-induced phase separation (MIPS) process, can be traced back to the intrinsically non-equilibrium nature of active matter and the underlying energy transduction at the center of their operation. Building on the Active Brownian Particles model [4], we perform extensive simulations of systems of self-propelled particles to explore the impact of noise on assembly and phase separation and determine their phase diagram as a function of motility and packing fraction.

Collective Learning During Assembly and Navigation in Active Matter *Thomas D. O'Connor, Caroline Desgranges and Jerome Delhommelle; University of Massachusetts Lowell, United States*

In nature, the existence of complex environments with intricate topologies has prompted the development of navigation strategies in biological active matter[1]. Recent work on E.coli bacteria has revealed that these strategies emerge not only at the individual level[2], but also as a collective response[3]. This includes, for instance, the development of collective waves and bet-hedging at path nodes that enable active matter to solve environmental puzzles and challenges[4]. Complex environments may also be leveraged to probe communication mechanisms between different types of active matter or promote self-organization and new assembly pathways. Here we propose a comprehensive computational framework that leverages particle-based simulation methods as well as machine learning to shed light on how collective learning impacts navigation and assembly in active matter.

SB08.08.05

Structural Color Elastomer Based on Two Different Mechanisms *Cong Yue, Jialei He and Yukikazu Takeoka; Nagoya University, Japan*

Organisms capable of changing their body color generate color through a variety of mechanisms in response to environmental shifts and stimuli, resulting in color transformation. Inspired by these color changes, we can create sensors and optical materials that alter their color in response to various stimuli, such as mechanical and optical triggers.
Using submicron-sized spherical silica particles as fillers and arranging them in a periodic structure within an elastomer can result in a silica composite elastomer with structural color changes. When this composite

elastomer is stretched, its periodic structure changes, thereby affecting the structural color produced by the elastomer. According to Bragg's law, which takes into account Snell's equation, a blueshift occurs in silica composite elastomers when the distance between silica particles changes after stretching.
Additionally, cholesteric liquid crystal elastomers (CLCEs) with helical structures can selectively reflect circularly polarized light, resulting in interesting optical effects. When the CLCEs are stretched, the change in pitch also produces a blue shift which is similar to silica the composite elastomer.However, the rate of change in blueshift is not synchronised between silica elastomers and CLCE due to different structural changes in blueshift caused by stretching. Moreover, the unique circular polarization of the CLCEs makes it possible to distinguish between the two different structural color change mechanisms.
In this study, we report on a bioinspired composite elastomer that combines the helical structure of CLCEs with the periodic structure of the silica composite elastomer, enriching the chromatic effects of the composite elastomer and fabricating a cholesteric liquid crystal-silica (CLC-silica) composite elastomer with mechanochromism. This mechanochromism can be used to develop a unique strain sensor based on the CLC-silica composite elastomer, displaying complex color patterns upon stretching, with significant application potential in encryption, anti-counterfeiting, and other areas.

SB08.08.06
3D-Printable Intelligent Polymers Based on Dynamic Reversible Urea Bonds *Patrick Fesser[1,1], Michael Klein[1,1], Julius Bartels[1], Stefan Zechel[1,1] and Martin D. Hager[1,1,2]; [1]Friedrich-Schiller-Universität Jena, Germany; [2]Helmholtz Institute for Polymers in Energy Applications Jena, Germany*

The limited availability of oil and therefore oil-based polymers leads to an investigation of more sustainable materials. For this purpose, longer polymer lifetimes are crucial. One approach to solve this challenge are self-healing materials, which are able to recover mechanical damage or certain properties. Self-healing polymers can be divided into extrinsic and intrinsic healing polymers. Extrinsic healing polymers are based on healing agents inside of, e.g., microcapsules in order to heal damages. The downside is the decreasing amount of microcapsules over multiple healing cycles. Intrinsic healing, on the other hand, is usually based on reversible bonds with the benefit of multiple healing cycles at the same location. This study represents the synthesis and investigation of intelligent abilities of 3D-printable polymers based on dynamic reversible urea bonds. Particular noteworthy is the intrinsic self-healing ability in complex 3D-printed structures.
The synthesized polymers contain sterically hindered urea molecules with the aim to weaken the amide bond by disrupting the co-planarity due to the bulky substituent with the ultimate goal of bond reversibility. Commercially available monomers undergo light-induced polymerization, resulting in networks that are crosslinked by hindered urea bonds. For this purpose, the polymers were either casted in a PTFE-mold or DLP-3D-printed and afterwards thermally annealed for 24 h at 100 °C. These moieties are reversible and can therefore be converted back into the starting compounds (i.e. isocyanate and amine) through thermal treatment or undergo exchange reactions.
The resulting polymers were analyzed by various techniques such as mechanical testing (tensile strength, 3-point-flexure, (dynamic) thermo-mechanical analysis) or the self-healing quantification by indentation. Furthermore, a comparison between casted and 3D-printed polymers was performed.
Besides, all polymers reveal a self-healing behavior even in complex, hollow structured printed specimens with healing efficiencies up to 100%. However, 3D-printed polymers showed a worse self-healing-effect compared to the casted equivalent. This may be caused by the layered structure of 3D-printed polymers which would lead to a less dense material.
Furthermore, dynamic thermal-mechanical analysis was performed to investigate the shape-memory behavior of the polymers, since these polymers should be able to possess this intelligent ability due to the highly dynamic bond at elevated temperatures. The specimens were twisted at 80 °C and cooled down to room temperature in order to fix the temporary shape. The following heating process recovers the specimen to its original shape. The

fixity rate of the temporary shape and the recovery rate of the original shape were calculated. The fixity rate revealed, that casted polymers showed an overall better performance. The recovery rate on the other hand was better with shape recoveries near 100%. The resulting polymers showed excellent mechanical properties with tensile E-moduli between 0.34 GPa up to 3.43 GPa and flexural moduli between 0.44 GPa up to 0.76 GPa. Additionally, during these tests, the casted polymers performed better (2.5 GPa vs. 1.0 GPa for tensile- and 0.71 GPa vs. 0.52 GPa for flexure E-moduli in general).
In summary, the materials are able to be DLP-3D-printed in complex structures and still reveal good thermal, intelligent and mechanical properties. Although 3D-printed specimens show slightly worse properties compared to their casted equivalents, the ability to print complex structures with intelligent properties is a great addition to the current state of research on more sustainable polymers. In the future, this system can be further investigated in terms of faster printing time, better specimen resolution and faster self-healing.

SB08.08.07

Silica Fume Rich, Low-Cement Mixes to Extend the Applications and Sustainability of Hempcrete *Leah K. Davidson, Emma Morgan, Riffat Farjana, Kirsten Matteson and Chelsea Heveran; Montana State University, United States*

Building-related operations, such as heating and cooling, account for 28% of anthropogenic carbon emissions, alongside the carbon cost of the materials [1]. Hempcrete, a carbon-neutral to carbon-negative insulation material consisting of hemp hurd, lime, and potentially other binder materials, offers a sustainable alternative but has poor load-bearing properties. Including cement and increasing density through compaction can improve strength but reduce bulk porosity, which lowers thermal resistivity and increases the material requirement to achieve the same insulation level. Higher cement content also elevates embodied carbon, reducing hempcrete's sustainability. This research aims to enhance hempcrete's utility by using microbially induced calcium carbonate precipitation (MICP) and examining how cement additives, silica fume and metakaolin improve microbial viability. Incorporating MICP-capable bacteria can potentially increase hempcrete's strength while preserving its thermal properties through targeted biomineralization, expanding its applications without compromising its insulation properties and sustainability. However, modifications need to be made to hempcrete paste to promote microbial viability, such as reduced pH.

This study aimed to investigate the impacts of commonly available, sustainable fillers on paste pH and strength to improve the properties of hempcrete and create environments more suitable for microbial viability (i.e., lower pH). Silica fume, a byproduct of the ferrosilicon industry, and metakaolin, a pozzolana, were chosen for their potential to reduce pH by decreasing free portlandite and increasing the relative amount of calcium silicate hydrate. Central composite designs of experiments were used to determine silica fume's and metakaolin's impact on hempcrete paste pH and strength. We found that increased cement replacement with silica fume and metakaolin reduced the pH of hempcrete paste, reaching as low as ~10 at the highest replacement levels. Silica fume was the primary driver of pH reduction. Higher cement replacement inversely affected strength. Our results demonstrate that increased silica fume replacement decreased strength while incorporating metakaolin slightly improved strength in high silica fume replacement mixes. Additionally, we used the most probable number (MPN) method to assess the viability of the MICP-capable bacterium Sporosarcina pasteurii in cement and low pH mixes both immediately and 24 hours after mixing. Our preliminary results showed increased bacterial viability immediately after mixing, rising from ~10^4 MPN/g paste in ordinary Portland cement (OPC) to ~10^6 MPN/g paste in high silica fume mixes. This is significant because high pH, temperature, and nutrient depletion challenge bacterial viability in cementitious materials, and previous methods to protect microbes, such as expanded clay and glass beads, have been costly and only moderately successful. Increased viability was not observed at 24 hours after mixing compared with OPC, demonstrating that other stressors still impact microbial viability in these pastes.

These results are significant for several reasons, including (1) generating hempcrete where sustainable fillers replace significant amounts (up to 80%) of cement, (2) improving early microbial viability in paste compared with OPC, and (3) producing building materials with less potential for leaching of high-pH fluid to the surrounding environments. The next steps are to explore further how cement additives influence microbes' metabolic and biomineralization activities.

Thursday Morning, December 5, 2024
Hynes, Level 2, Room 202

8:30 AM *SB08.09.01
Growing Diverse Macroscopic Living Materials from Engineered Bacteria *Esther Jimenez, Robert F. Tesoriero and Caroline Ajo-Franklin; Rice University, United States*

Challenged by a changing climate, dwindling natural resources, and a growing global population, we need advanced, renewable materials that meld the sustainability of biological materials with the functionality of conventional materials. To help address this need, my research group creates sustainable and environmentally-responsive living materials by engineering microorganisms to synthesize such materials.
Living materials synthesized by organisms, such as bones and shells, exhibit remarkable mechanical properties due to their hierarchical assembly of hard and soft components across the nanometer to the centimeter scales. While engineering macroscopic analogs to these materials would open new frontiers, there is currently no bottom-up route to do so that enables control of the composition, hierarchical structure, and mechanical properties of living materials. In this talk, I will describe our approach to constructing such hierarchically ordered materials by programming bacteria. First, I will describe how macroscopic materials can be grown from bacteria engineered to display and secrete a self-interacting protein. This protein formed an extracellular protein matrix and assembled cells into hierarchically ordered, centimeter-scale materials. Next, I will report on how genetic modification of this self-interacting protein, specifically changing the length of its biopolymer segment, can tune the microstructural properties of these materials. While these modest changes in the biopolymer region have unexpectedly complex effects on the microstructure, the changes in microstructure impact the mechanical properties of the material much like other non-living composites. Lastly, I will present on how changing the growth media affects the macroscopic structure of these materials, forming rope-like structures that are both stretchy and strong. Altogether, these studies show a complex relationship between protein matrix sequence, the resulting structure, and properties while introducing new materials with high elasticity and strength. We envision specific matrix properties that can be combined synergistically with existing cellular functions to greatly expand the opportunities for biological materials in human health, energy, and the environment.

9:00 AM SB08.09.02
3D Printed Engineered Living Materials for High Performance Bioplastics *Alshakim Nelson; University of Washington, United States*

Engineered living materials (ELMs) are a class of materials that integrate genetically modified microorganisms within a polymer network, yielding versatile functional objects. Here, we introduce ELMs comprising cells with inducible genes that enable external control of mechanical stiffness of the matrix and the degradation time point. Specifically, the induced metabolite production can signficantly impact the encapsulating polymer matrices. Our ELMs can be 3D printed via Direct Ink Write extrusion or light-based vat photopolymerization to fabricate functional objects. The innovative features of our approach are the genetic programming of material properties and their temporal control using inducible genes. The advanced bio-manufacturing and the bio-degradability of the ELM bioplastics addresses the need for sustainable production methods with end-of-use considerations for future plastic materials.

9:15 AM SB08.09.03

Topology Optimization of 3D Printed Hierarchical Porous Mycelium Hydrogels *Winston Lindqwister, Kunal Masania, Iuri Rocha and Martin Lesueur; Delft University of Technology, Netherlands*

The regenerative and adaptive properties of biological living materials make them an exciting candidate for sustainable and resilient material design. Mycelial hydrogels—hydrogels loaded with Ganoderma lucidum for 3D-printing applications—have shown to be mechanically robust, with their printability allowing for complex geometric control of the material lattice. As printable hierarchical porous materials, the tunable porosity of these lattices opens a new dimension of customizability for a wide array of structural applications, leveraging differing geometric and topological features across multiple scales. However, with such design freedom in terms of material shape, microstructure, and functionality, topology optimization is the key to effectively utilizing the full potential of this material. In this work we describe a framework for optimizing the topology of 3D printed mycelium hydrogel structures. This system considers engineered and natural parameters, manipulating print design and spacing as well as mycelial growth patterns to optimize the mechanical strength of a given design configuration for strength-to-weight optimization. By identifying morphologic descriptors that link microstructural geometry and topology to macroscale functionality, we unlock a high degree of multiscale control for this class of porous materials, allowing for a complex and flexible design scheme for these novel printed systems.

9:30 AM SB08.09.04

Mycelium Scaffolds for Improved Viability and Control over Interior Microarchitecture of Biomineralized Engineered Living Materials *Ethan T. Viles[1,2], Ethan Heyneman[1,2], Shuyi Lin[2,3], Virgina Montague[2,3], Amir Darabi[1], Lewis M. Cox[1], Adrienne Phillips[1,2], Robin Gerlach[1,2], Erika Espinosa Ortix[4] and Chelsea Heveran[1,2]; [1]Montana State University, United States; [2]Center for Biofilm Engineering, United States; [3]Middlebury College, United States; [4]Utah State University, United States*

Engineered living materials (ELMs) offer new strategies for manufacturing more sustainable building materials. ELMs that are biomineralized by leveraging the metabolism of microbes can generate simple, low-load bearing structures. Biomineralized ELMs may be useful for more complex applications if they surmount two major limitations. The first limitation is transient cell viability. Cells in previous biomineralized ELMs did not survive more than a few days to weeks limiting limits how long these cells could perform desirable functions (self-healing or environmental sensing). A second limitation is a lack of control over internal microarchitecture. Biomineralized composites in nature can optimize their strength while remaining lightweight due to specialized microarchitecture (bone, coral, nacre). Fungal mycelium used as a scaffold for biomineralization might address both limitations. Some fungi, including Neurospora crassa, can perform biomineralization. N. crassa scaffolds may have excellent viability characteristics, since N. crassa is able to survive a wide range of environmental conditions. The scaffold may also protect the viability of other biomineralizing microorganisms, such as the bacterium Sporosarcina pasteurii. Fungal scaffolds may also introduce new strategies to design the internal geometries of biomineralized *materials, as these scaffolds can be grown and then shaped.*

We created biomineralized, fungally-scaffolded ELMs using two strategies. The first strategy employed a living mycelium scaffold that mineralizes itself. The second uses a non-viable mycelium scaffold that is mineralized by S. pasteurii. The viability of living components (N. crassa or S. pasteurii) within these biomineralized ELMs was analyzed after drying for 4-weeks at either room temperature or elevated temperature (30°C). Both biomineralized ELMs showed abundant culturable cells after drying for 4-weeks at either temperature condition. Mineralization efficiency, determined by comparing calcium and urea usage over time, was greater for the bacterially-mineralized fungal scaffolds. Biomineral microscale morphology and moduli were analyzed using scanning electron microscopy with elemental dispersive spectroscopy and nanoindentation, respectively. Bacterially-mineralized ELMs had more mineral accumulation and both larger and stiffer biomineral crystals than fungally-mineralized scaffolds. These results demonstrate that biomineralized ELMs with excellent viability can be created using fungal scaffolds mineralized either by the fungus or by bacteria, but bacterial biomineralization generates mineralized material more efficiently.

Bacterial biomineralization of mycelium was then used to create mineralized fungal scaffolds with a complex interior microarchitecture inspired by osteons within cortical bone. Osteons were chosen as a model since this structure optimizes mechanical and biological performance in the skeleton. Mycelium scaffolds were shaped and then mineralized with S. pasteurii to form artificial osteons from columns with concentric rings and a central canal. Sand was used as an interphase between the osteons and the entire structure was biomineralized using S. pasteurii. This strategy created biocemented specimens (4”x1”x1”) with a designed internal microarchitecture, as demonstrated by electron microscopy and microCT.

This work establishes the potential of fungal scaffolds for the manufacturing of biomineralized ELMs with improved viability and designability. Both types of ELMs (self-mineralized living fungal scaffolds or bacterially-mineralized killed fungal scaffolds) have potential as useful ELMs with excellent viability characteristics. The improved viability characteristics of these scaffolds, together with the formability of mycelium into useful shapes that confer control over internal microarchitecture, may enable the design of new materials that surmount design limitations of previous biomineralized ELMs.

Engineering 3D Tissue Models to Study Vascular Dysfunction in Disease *Alisa Clyne; University of Maryland, United States*

The vascular system is essential for nearly every tissue in both health and disease, and it is therefore important to engineer a functional vasculature into in vitro tissues and on-chip systems. Yet the vasculature itself is diverse, so engineering strategies must be tailored to each vascular system type. In this talk, I’ll describe our work to engineer functional in vitro peripheral microvasculature and microvasculature, as well as cerebral microvasculature.

We first bioprinted a 3D in vitro system to examine interactions between the microvasculature and breast cancer cells. We bioprinted 3D breast spheroids composed of non-tumorigenic MCF-10A cells and tumorigenic MCF10A-NeuN cells onto endothelial tube-like structures using a multi-nozzle solid freeform fabrication-based computer controlled direct cell writing system. Surprisingly, the breast spheroids preferentially attached to the endothelial tubes and maintained endothelial viability. Within 24 hours, the MCF10A-NeuN breast epithelial cells grew out of the spheroids and migrated along the endothelial networks, while the MCF10A cells remained in the spheroids for up to 72 hours of co-culture. This 3D multicellular structure bioprinting method has potential to rapidly create vascularized tissue models, perhaps directly from patient cells, which better replicate the structure and function of the in vivo tumor microenvironment.

Vasoconstriction and vasodilation are essential macrovascular functions and are used to determine vascular

health with drug treatment or in conditions that promote atherosclerosis. Vascular contractility can be measured in humans in vivo and in animals ex vivo. However, human studies require a skilled technician and have limited ability to vary physiological stimuli, whereas animal studies are time consuming and have limited applicability to human vascular function. We are therefore creating a human artery-on-a-chip that contracts and dilates. Vascular contractility requires that vascular smooth muscle cells be circumferentially aligned around the vessel lumen, which is challenging to achieve in a soft blood vessel model. To circumferentially align smooth muscle cells inside a hydrogel channel, we wrapped gelatin microribbons around a needle and encapsulated them in a gelatin methacryloyl hydrogel, forming a microribbon-lined channel. We then seeded smooth muscle cells inside the channel and showed that they circumferentially aligned in response to the microribbons. This technique can be used to create a human artery-on-a-chip to assess vasodilation via pressure myography, which will enable researchers and pharmaceutical companies to quantify vascular health in response to a disease or drug.
Brain microvascular endothelial cells tightly control transport from the blood into the brain, which is essential to cerebral health. In vitro systems often use human primary brain microvascular endothelial cells (hpBMEC), which are more endothelial but do not form a good barrier, or induced pluripotent stem cell derived brain microvascular endothelial cells (hiBMEC), which form a good barrier but have an underlying epithelial signature. To assess the use of these two cells types in in vitro metabolic models, we examined differences between hpBMEC and hiBMEC glucose and glutamine metabolism. hiBMEC had decreased glycolytic flux and lower overall levels of glucose-derived metabolites relative to hpBMEC. Despite these differences, hpBMEC and hiBMEC glucose metabolism responded similarly to treatment with astrocyte conditioned media and high glucose. In contrast, hpBMEC and hiBMEC had distinct glutamine metabolism, with hpBMEC having a higher mitochondrial metabolic rate, more branched mitochondria, and different glutamine-derived metabolites than hiBMEC. Thus, when considering an in vitro brain model, the endothelial cells should be carefully engineered to closely match the in vivo function.

10:45 AM *SB08.09.06
Building Synthetic Biofilm with Laser Lithography-Based 3D Bioprinting *Isaak Thornton, Kathryn Zimlich, Matthew W. Fields and James Wilking; Montana State University, United States*

Biofilms are ecologically and physically complex biomaterials that attach to abiotic and biotic interfaces and develop three-dimensional, heterogenous structure. Biofilms play vital roles in ecosystem functions, industrial processes, and human health that have profound implications for the grand societal challenges of water, food, energy, and health. Biofilm growth has unique physiology, ecology, and evolution that requires deeper investigation to improve our understanding of the microbial world and to drive biotechnological innovation. However, biofilms are typically defined and studied as self-assembled systems and the underlying mechanisms that drive biofilm formation and behavior are often difficult to systematically manipulate. To understand these complex biomaterials, methods of controlling and manipulating biofilm structure and composition are needed. We have developed a laser lithography-based 3D bioprinting method that provides control over the structure and composition of living materials at the submillimeter scale. Hydrogels were 3D printed with the bacterium Pseudomonas fluorescens and growth was spatially and temporally quantified throughout the matrix based upon the expression of mCherry fluorescence. Cell populations encapsulated in the printed films developed drastically different biovolume spatial distributions depending on initial cell volume fraction and depth of the printed hydrogels. More homogeneous biovolume distribution was observed at lower cell densities, with increasing heterogeneity at increasing cell densities. These results suggest that heterogeneous structural features can develop in 3D printed biofilms from an initially homogeneous distribution of cells, with differences in population distribution likely partially driven by overall reaction and diffusion rates.

11:15 AM SB08.09.07
4D Printing Self-Deploying Bio-Based Structure for the Non-Invasive Treatment of Intestinal Ulcers *Irene*

Chiesa[1], Andrea Guerra[1], Laura Fazzini[1], Leonardo Beati[1], Giuseppe Raffaele[1], Silvia Bittolo Bon[2], Rocco Malaspina[2], Luca Valentini[2], Maria Rachele Ceccarini[2], Paolo Rovero[3], Antonino Morabito[3,4] and Carmelo De Maria[1]; [1]University of Pisa, Italy; [2]Università degli Studi di Perugia, Italy; [3]Università di Firenze, Italy; [4]Azienda Ospedaliera Universitaria Meyer, Italy

Ulcers are a breach in the membrane of the stomach or intestine caused by inflamed necrotic tissue. When they develop in the ileum and jejunum, ulcers represent a burden clinical challenge, since they are not accessible through regular colon- or gastroscopy. Here, we envision the design and fabrication via 4D printing of a self-deployable microfabricated and multi-layered structure, physically programmed to reach a mild bleeding chronic ulcer, wirelessly communicate, and locally promote the tissue regeneration, thanks to bio-enabled materials processed via 4D printing (i.e. the fabrication via additive manufacturing of active structure characterized by a programmed change, over time, under a predefined stimulus) for the non-invasive treatment of ulcers.

The self-deploying over time can be achieved through the differential swelling properties of a bilayer C-shaped cylindrical structure. The swelling mismatch creates a deformation gradient in the structure that drives its deploy when hydrated. The two layer of the structure are made of the same bulk material, i.e., (3-Glycidoxypropyl) methyldiethoxysilane crosslinked gelatin in PBS (GPTMS-GEL), and the swelling behavior was tuned through the material concentration.

Finite element modeling has been exploited to study the interactions between structural mechanics and the hygroscopic swelling, and to predict the humidity-triggered shape change of the structure according to its geometry, properties and arrangement of materials. Preliminary models shown that the aforementioned difference in swelling lead to the desired self-deploying of the structure when the materials are properly arranged in space. Then, we fabricated a proof of concept of the self-deployable structure (i.e., C-shape with an internal Ø of 12 mm and a length of 20 mm) using a custom 3D printer equipped with a piston driven extruder and a rotating spindle. The inner layer of the structure was made by the high swelling solution, extruded on a spindle, purposely fabricated via stereolithography, to form 2.4 mm spaced lines with a width of 1.6 mm. The second layer was made of low swelling material and was deposited on the previous one to create a continuous layer. The structure was then dried for 48h, removed from the spindle, and finally its humidity-triggered self-deploying was analyzed by dipping the structure into a PBS 1X solution. Those tests showed the structure ability to self-deploy in a water-based solutions, in around 100 sec., thus enlarging its surface and potentially cover an ulcer.

Finally, we designed and fabricated a sacrificial spindle to be used as printing support, able to degrade once hydrating, thus realizing the 4D printed structure. This sacrificial spindle (internal Ø = 3mm, external Ø = 6mm, length = 20 mm) was fabricated via fused deposition modeling in Polyvinyl alcohol (PVA) using a spiral vise slicing approach. Its degradation profile was evaluated at different pH (i.e., 7.4 and 6.2), that represents the pH range encountered in the intestinal tract of interest. Those tests showed that the PVA spindle is able to completely dissolve in around 110 minutes, in both tested solutions.

We are currently optimizing the inclusion of peptides-enriched regenerated silk into the gelatin-based solution to allow the localization and adhesion of the structure to a bleeding ulcer and to promote tissue regeneration. In this context, infrared spectroscopy will be used to assess the role of the folding of the secondary structures on the swelling properties of the gelatin-based structure and the citotoxicity of structure in vitro by Caco2 culture. Moreover, we are miniaturizing the device to be easily swallowable, and we are implementing the addition of an external gastro-resistant layer (e.g., alginate) to cover the smart structure and protect it from the acid pH of the stomach, thus enabling the administration of the device orally.

11:30 AM SB08.09.08

Development of a Self-Folding Engineered Trachea by 4D Bioprinting *Irene Chiesa[1], Alessio Esposito[1], Giovanni Vozzi[1], Riccardo Gottardi[2,3] and Carmelo De Maria[1]; [1]University of Pisa, Italy; [2]The Children's Hospital of Philadelphia, United States; [3]University of Pennsylvania, United States*

***INTRODUCTION**: Four-dimensional (4D) bioprinting (i.e., fabrication via additive manufacturing of scaffolds characterized by a programmed change, over time, under a predefined stimulus) can be exploited to produce active scaffolds with several advantages for tissue engineering applications: 1)recapitulating of biological dynamic processes, 2)easiness of cell seeding and achievement of 3D complex organization; 3)exerting of forces on the seeded cells. Here, we exploited the 4D bioprinting approach to design and develop an innovative smart scaffold able to fold in time when hydrated, to be used for trachea engineering. **MATERIALS AND METHODS**: The folding in time is achieved exploiting the differential swelling properties of bilayer films. This mismatch creates a deformation gradient in the film that drives the folding of the film. The two layers of the scaffold were made of the same bulk material, i.e., (3-Glycidoxypropyl) methyldiethoxysilane crosslinked gelatin, GPTMS-GEL), thus guaranteeing a chemical bond between the layers. The swelling behavior of the layers is tuned through the modification of the GPTMS and GEL concentrations. GPTMS-GEL-1 monolayer films (i.e., higher volumetric swelling, 15% w/v GEL in PBS with 92 µl/g of GPTMS) were fabricated by solvent casting. Then, 1 mm wide lines of GPTMS-GEL-2 (i.e., lower volumetric swelling, 5% w/v GEL in PBS with 368 µl/g of GPTMS), were deposited on the GPTMS-GEL-1 film by Extrusion-Based Bioprinting. The scaffold was then dried for 48 hours at room temperature. Scaffold folding behavior was tested in PBS 1X. Then, preliminary in vitro tests were performed. 10 mm x 5 mm rectangular scaffolds were fabricated as described above, sterilized by 1h of UV light and incubated in cell culture media for 2h. Then, 20k cells (see below) were seeded on each scaffold in its initial flat position. After 30 mins, 2 ml of cell culture media was added for each scaffold and changed every 3 days. Three different cell types were tested: human vocal folds fibroblasts and human lung endothelial cells, that mimic the internal epithelial and endothelial layer of the trachea, and human ear chondral progenitor cells that mimic the chondrocytes of the trachea cartilage rings. Cell proliferation via Alamar Blue Assay were evaluated for all the cell types and materials 24h, 72h and 5 days after the seeding. Finally, the ability of eCPCs to differentiate towards mature cartialge was evaluated. Briefly, cells were seeded as described before, and culture for 7 days to allow the complete coverage of the scaffold. Then, medium was switch to chondrogenic medium and cells were cultured for additional 21 days. Histological Assay and Real time PCR were performed to verify the chondral commitment of cells. Monolayer static scaffold made of the same materials were used as control. **RESULTS AND DISCUSSION**: In vitro tests showed the ability of cells to adhere on scaffolds in its flat position, maintain their adhesion during scaffold folding, that occurs 24h after seeding, and confirmed the biocompatibility of the GPTMS-GEL materials, that promotes viability, proliferation, and metabolic activity of all the tested cell types. Regarding the cartialge differentiation analysis, Alcian Blue histological analysis confirmed the deposition of cartilaginous matrix in the external layer of the scaffold. Moreover, an overexpression of SOX9, ACAN e COLII was observed on the 4D scaffold, when compared with static monolayer films. No differences arise in the expression of PRG4 and COLX, suggesting the establishment of a stable chondral phenotype on the 4D scaffolds. **CONCLUSION**: In this study, we exploited the 4D bioprinting approach to fabricate a self-folding bilayer scaffold for trachea engineering. The reported results represent an important milestone for 4D bioprinting, quantitatively showing that shape-morphing scaffolds in the millimeter scale can promote cells activity and differentiation.*

SESSION SB08.10: ELMs to Biohybrid Materials I

Bacterial Multiphysical Interactions with Hard and Soft Materials Interfaces—Towards Computational Design of Engineered Living Materials *Jingjie Yeo; Cornell University, United States*

Many mechanisms underpin bacterial interactions with surfaces to allow adhesion and proliferation. By adhering to concrete, microbially induced carbonate precipitation can help create new building materials that are less energy-intensive to manufacture and repair. We computationally coupled multiphysical interactions in agent-based models to determine how bacteria form biofilm and biomineralize on patterned surfaces and in porous structures. Structural designs were proposed using data-driven modeling to optimize targeted biofilm properties. Differences in the molecular structures of healthy and diseased mucus in the human gut can also alter the adhesion of bacteria on mucus. We developed a coarse-grained mucus model that captured the molecular structures of two glycoproteins abundant in human gut mucus. We studied the dependence of nanoparticle diffusion on the particle size. Machine-learned fingerprints were employed to provide a mechanistic understanding of nanoparticle diffusion.

2:00 PM *SB08.10.02

Living Therapeutic Materials for Zero-waste Therapeutics *Aránzazu Del Campo; INM–Leibniz Institute for New Materials, Germany*

In many therapeutic treatments, only a small fraction of the administered drug is uptaken, and a large part is wasted and released to the environment. One example of inefficient drug delivery are eye drops, the delivery vehicle for 85% of ocular treatments, where less than 5% of the administered drug is uptaken by the eye and the remaining 95% is wasted. Drug waste means economic loss and an environmental risk. We present drug eluting materials with the unique property to self-produce biopharmaceuticals directly at the therapeutic site. The materials are designed to host biofactories of natural therapeutics, and to maintain and control their productivity in-vivo long term. The biofactories produce and deliver the drug using energy sources from body fluids. These self-replenishable drug eluting devices can deliver the drug continuously at the required concentration and improve therapeutic outcome at zero-waste. We demonstrate the potential of this concept in a contact lens prototype that contains biofactories of hyaluronic acid and can self-lubricate.

Biohybrid Microrobots Locally and Actively Deliver Drug-Loaded Nanoparticles to Inhibit the Progression of Lung Metastasis *Zhengxing Li; University of California, San Diego, United States*

Lung metastasis poses a formidable challenge in the realm of cancer treatment, with conventional chemotherapy often falling short due to limited targeting and low accumulation in the lungs. Here, we show a microrobot approach using motile algae for localized delivery of drug-loaded nanoparticles to address lung metastasis challenges. The biohybrid microrobot [denoted "algae-NP(DOX)-robot"] combines green microalgae with red blood cell membrane–coated nanoparticles containing doxorubicin, a representative chemotherapeutic drug. Microalgae provide autonomous propulsion in the lungs, leveraging controlled drug release and enhanced drug dispersion to exert antimetastatic effects. Upon intratracheal administration, algae-NP(DOX)-robots efficiently transport their drug payload deep into the lungs while maintaining continuous motility. This strategy leads to rapid drug distribution, improved tissue accumulation, and prolonged retention compared to passive drug-loaded *nanoparticles and free drug controls. In a melanoma lung metastasis model, algae-NP(DOX)-robots exhibit substantial improvement in therapeutic efficacy, reducing metastatic burden and extending survival compared to control groups.*

From Bioinspired to Biohybrid—Design, Microfabrication and Advanced Engineering Applications of Plant-Like Miniature Machines *Isabella Fiorello[1,2]; [1]Albert-Ludwigs-Universität Freiburg, Germany; [2]California Institute of Technology, United States*

Plants have developed efficient evolutionary adaptations to almost all environments, inspiring scientists to prototype ingenious bioinspired and biohybrid machines(1, 2). When miniaturized, these machines can access confined and/or targeted unstructured three-dimensional (3D) scenarios. By combining nature and technology, we propose a new class of biologically inspired, microfabricated hybrid machines that can be used as multifunctional tools for in situ monitoring and/or cargo delivery in complex 3D environments(3-5). Here, we briefly introduce our recent results on plant-like machines, focusing on their design, microfabrication, and advanced engineering applications.

These machines are designed using both biohybrid and bioinspired approaches. This involves extracting the main morphological and biomechanical features of selected plant species (including terrestrial and aquatic plants) and embedding plant tissues directly within the material matrix. They were prototyped by combining microcomputed tomography with advanced high-resolution microfabrication techniques, such as two-photon lithography and bioprinting. These methods enabled us to produce multiple low-cost, sustainable, and scalable machines, offering promising avenues for the next generation of living materials in advanced engineering systems.

The mechanical performance and behavior of our prototypes were tested in various real-world scenarios, including soil terrains, leaf tissues and aquatic habitats. Specifically, we have developed various prototypes at small scales, including: (i) climbing plant-inspired machines for reversible attachment, which have been applied in climbing robots(5, 6), controllable manipulators(7), and sensors for leaf microclimate monitoring and localized delivery of plants(4); (ii) fruit-inspired hybrid machines for soil exploration and reforestation applications(3); and (iii) aquatic plant-inspired hybrid machines for underwater sensing.

These technologies hold promise for developing next-generation materials that integrate living components with synthetic frameworks, highlighting the potential of using plant-like biohybrid machines in real-world scenarios, such as for environmental protection and conservation. Our results can have a multidisciplinary impact on material science, soft robotics, and precision agriculture, paving the way for pilot studies in segmented markets and advancing the frontiers of engineering applications.

Iterative Refinement of Biohybrid Swimming Devices Using Neural Networks *John Zimmerman[1], Daniel J. Drennan[1,2], James Ikeda[1], Qianru Jin[1], Herdeline Ann Ardoña[1,3], Sean Kim[1], Ryoma Ishii[1,4] and Kevin K. Parker[1]; [1]Harvard University, United States; [2]Texas A&M University, United States; [3]University of California, Irvine, United States; [4]NTT Research Inc, United States*

Biohybrid swimmers have recently emerged as a new form of self-powered swimming device that combines living tissue with artificial components. Built at the millimeter scale, these devices have proposed applications in remote sensing, medical procedures, and for studying muscle regeneration and development. In building these devices, researchers often employ a 'biomimetic' design strategy, which attempts to recreate the specific shape or design of a naturally occurring marine lifeforms. However, in nature marine lifeforms display a wide range of different fin shapes and muscular structures depending on their local swimming environment. To select from among these various swimming strategies for use in biohybrid swimmers, here we will discuss how machine learning can be used to guide the engineering-design process. Starting from random initial configurations, fin performance can first be approximated using computational fluid dynamics (CFD) simulations. The resulting data can then be used to train a neural network model, which can make informed predictions about how different fin geometries will perform as biohybrid swimmers. Testing these predictions using experimentally realized tissue engineered devices, we then plan to show how machine learning can be used to improve biohybrid performance, resulting in faster swimming velocities at the millimeter length scale. Overall, by using a machine learning directed process we hope to gain a better quantitative understanding of muscular structure-function relationships, while providing a novel tool for designing biohybrid robotic systems.

The Surface Geometry and Self-Assembly of Bio-Inspired Cholesteric Liquid Crystals *Ziheng Wang, Phillip Servio and Alejandro D. Rey; McGill University, Canada*

Surface corrugations driven by molecular self-assembly is a ubiquitous pattern observed in nature. Those anisotropic molecules can be found in collagen fibres from human bones, chitin fibres from beetles' exoskeletons and celluloses in biological plywood. They are responsible for multifunctionalities, for example, the diffraction gratings in tulip petals, and mantis shrimps' strong endurance to mechanical damage. Closed surface corrugation patterns exhibited in lipid-based droplets have applications in messenger RNA encapsulation, which plays an important role in synthesizing proteins. In this presentation, we study the mechanism and the surface geometry of molecular self-assembly responsible for the self-assembly-driven wrinkling phenomenon in cholesteric liquid crystals. This theoretical study is analyzed under an integrated geometric framework, where the dimensionless *shape parameter and the dimensional curvedness are decoupled from the classical curvature tensor. Addressing these complexities will not only enhance our understanding of chiral liquid crystals but also the scientific advancements in various domains.*

SB08.11.02

Self-Assembled Nanoparticles for Targeted Protein Degradation Using Hydrophobic Tag Through Hydrophobic Polymer *SeoHee Lee and Won Jong Kim; Pohang University of Science and Technology, Korea (the Republic of)*

Targeted protein degradation (TPD) strategies offer a promising approach in drug development by selectively degrading disease-causing proteins, providing an advantage over small molecule inhibitors. However, small molecule-based degraders are rapidly excreted from the body due to their low water solubility and instability in the bloodstream, and they also have poor tumor specificity. Here, we developed hydrophobic polymer tagging nanoparticles, called ARL-PLA-SS-PEG NPs, which use a hydrophobic tagging strategy on oncogenic proteins. The platform was constructed by conjugating an androgen receptor (AR) ligand to a PLA-PEG block copolymer containing disulfide bonds. The targeted protein degradation of ARL-PLA-SS-PEG NPs operates in response to glutathione (GSH) in cancer cells, exposing the hydrophobic polymer due to nanoparticle collapse. The ARL-PLA effectively degrades the AR through two proteolytic pathways, namely the ubiquitin-proteasome system (UPS) and autophagy-lysosome pathway (ALP). The ARL-PLA-SS-PEG NPs have demonstrated their ability to inhibit tumors in in vivo models, highlighting their potential as a pioneering platform in targeted protein degradation.

SB08.11.03

Dissipative Thioester Peptide Assemblies with Tuneable Lifetimes *Maximilian Schuler, Jiaqi Xing, Christopher V. Synatschke, David Ng and Tanja Weil; Max Planck Institute for Polymer Research, Germany*

In nature, biological function of enzymes, membranes, or viruses is grounded in supramolecular self–assembly. This phenomenon is ubiquitous and observable across various length scales. Inspired by this concept, supramolecular self–assembly has gained increasing attention in peptide chemistry in the last decades. Due to their inherent versatility and straightforward synthesis, self–assembling peptides are widely employed in biomedicine with great success[1]. Stimuli–responsive systems reacting to endogenous or external triggers were implemented to increase spatial–temporal control over peptide assemblies[2]. However, despite responsivity, the resulting nanostructures are often static due to kinetic trapping or the reaching of the thermodynamic equilibrium. To overcome this hurdle and approximate natural self-assembling systems, researchers have developed transient peptide assemblies that form far from thermodynamic equilibrium (out–of–equilibrium systems)[3]. This phenomenon is prominently observable in processes such as microtubular self–assembly where dynamic instability dictates biological function. Studying these phenomena strengthens the fundamental understanding of natural dissipative assembly types, sheds light on the origin of life and allows the development of more sophisticated materials[4]. In the lab, these energy states are often accessed through high–energy fuels such as carbodiimides[5]. We present here a novel combinational approach that may approximate natural systems through high–energy peptide fuels. The reaction between activated peptides and thiol–containing peptide derivatives gives rise to new chemical reaction networks that are tuneable in their dissipation pathway kinetics.

DNA Information-Editing Tools for Reconfigurable Nanoparticle Architectures *Elad Arad[1] and Oleg Gang[1,1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States*

Biological organisms have developed comprehensive machinery for organizing matter into structures with specific functions and for reconfiguring their states in response to external signals. Unlike biology, most nanomaterials remain static, unable to adapt, change or reconfigure in response to stimulation. Transforming materials into molecular machines requires a dynamic nature with precise activation mechanisms and behavior. DNA nanotechnology methods offer a powerful means of controlling matter at the nanoscale, especially when combined with other types of nanoparticles. However, there are no methods of orchestrating reconfiguration of these complex nanostructures. Herein we aim to unravel the principles for transforming static DNA-origami into dynamic material using CRISPR-Cas technology. Controlling and editing the DNA backbone using CRISPR-Cas sequence-editing, reconfiguration of the DNA scaffold will exert control over its covalent bonds, conformation, and states. As a proof of concept, we aim to create a DNA/nanoparticle lattice with reconfigurable d-spacings. Using Cas editing we aim to achieve supramolecular asymmetry in the DNA-crystal. This goal converges biological methods and nanotechnology, achieving precise and dynamic structures while applying specific-editing tools to manipulate biopolymer system (the DNA origami).

SB08.11.05

Targeting Bacterial Biofilms with Magnetic Nanoparticles *Mastoure Shirjandi; University of Rhode Island, United States*

Bacterial biofilms provide protective environments for bacteria, blocking antimicrobial agents and significantly hindering treatment efforts. contribute to chronic infections and often increase resistance to conventional therapies. Understanding the mechanisms behind biofilm formation and persistence is crucial for developing more effective therapeutic strategies. Magnetic nanoparticles (MNPs) have unique properties, such as generating heat under alternating magnetic fields, which have been extensively studied in cancer treatment for their ability to target and destroy cancer cells. However, the potential impact of MNPs on bacterial biofilms has not been thoroughly explored, presenting a promising area for research. This study aims to investigate the ability of MNPs to disrupt bacterial biofilms through localized temperature increases. The primary objectives are to evaluate the impact of MNP-induced hyperthermia on bacterial survival within biofilms and to explore the potential use of MNPs as a standalone treatment or in combination with existing antimicrobial therapies. This research could lead to innovative solutions for treating biofilm-related infections, improving patient outcomes, and addressing the growing concern of antimicrobial resistance.

SB08.11.06

Mathematical Modeling and Design for Alignment of Active Nematic Liquid Crystals and Its Application to Alignment Control of Cellular Sheets on a Large Scale *Hiroki Miyazako, Yota Fujii, Hiroyuki Miyoshi and Takaaki Nara; The University of Tokyo, Japan*

Cardiac and skeletal muscular cells have been widely applied to driving forces of biohybrid actuators and *biohybrid robots. Since these cells are elongated along specific directions at a confluent state and can generate contractile forces along their cell alignment, it is important to predict and control the alignment of the muscular cells in preparation for cell culture experiments because of the high cost of the experiments. One theoretical approach for the prediction of the cell alignment is to model the elongated muscular cells as living nematic liquid crystals, which are known as "active nematics" in the fields of biophysics and non-equilibrium physics.*

For the mathematical prediction and control of the muscular cell alignment, our research group has developed explicit formulas of nematic cell alignment based on complex function theories [1-3] and confirmed the validity of the developed formulas by doing cell culturing experiments for mouse myoblast cells (C2C12) [4]. However, our previous studies are limited to the prediction of cell alignment on single and confined domains. To achieve reproducible and large-scale fabrication of biohybrid actuators based on muscular cells, it is necessary to extend the formulas for two-dimensional sheets.

In this study, we propose a new design method for controlling cell alignment of two-dimensional cellular sheets on a large scale based on our developed formulas for nematic cell alignment. In the proposed method, we consider unit circular triangles, which have positive and negative curvatures, and divide the two-dimensional sheets by the unit circular triangles. Such division is experimentally achieved by making micro-grooves on the sheets. Since the cell alignment in each unit circular triangle can be easily predicted based on the explicit formulas of the nematic cell alignment, we can achieve the control and prediction of the cell alignment of the entire cell sheets. In this presentation, we first show how to calculate the cell alignment on the unit circular triangles and then optimize the geometry of the unit circular triangles by numerical calculations and optimization. The optimality of the geometry was also experimentally verified by culturing C2C12 cells on PDMS substrates which have micro-grooves.

Can Self-Healing Concrete Self-Destruct? *Caitlin Adams, Cansu Acarturk and Wil V. Srubar III; University of Colorado Boulder, United States*

Biological self-healing of cementitious materials has the potential to increase the sustainability, durability, and service life of concrete infrastructure by reducing the impact of crack-induced losses in performance.

Biomineralization via microbially-induced calcium carbonate precipitation (MICP), one such "healing" method, leverages biomineralizing capabilities of certain microorganisms to mediate the production of new minerals, thus repairing cracking damage. The most used form of MICP leverages ureolytic microorganisms delivered in a treatment media consisting of urea and often a calcium salt. Despite some notable advances, there is still no fundamental understanding of the physical and chemical limits of this technology, nor of potential urea hydrolysis side reactions in a cementitious environment. This study investigated the effects of treatment media concentration both on MICP yield and on portland cement (OPC) paste properties. Sporosarcina pasteurii was selected as a representative ureolytic bacteria for cementitious healing. Aqueous media consisting of urea, calcium acetate, and yeast extract were prepared in equimolar concentrations as well as in molar excesses of urea and calcium acetate. Deionized water was used as a control treatment. Ex situ experiments quantified the potential calcium carbonate production as a function of media concentration using thermogravimetric analysis (TGA). One-centimeter OPC paste cubes (0.5 w/c) were immersed in either S. pasteurii-loaded treatment media or abiotic media and re-treated three times weekly until characterization at 7 and 28 days. To elucidate any effects of treatment on OPC paste phases, immersed paste cubes were characterized using X-ray diffraction, scanning electron microscopy, and TGA while the supernatant was characterized via inductively coupled plasma-optical emission spectroscopy. These results will provide perspective on the limits and side effects of ureolytic self-healing and will enable optimized media concentration for efficient crack healing in OPC systems.

Development of a Biohybrid Tendon Interface for Muscle-Powered Robots *Nicolas Castro, Maheera Bawa, Sarah Wu, Laura Rosado, Annika Marschner, Bastien F. Aymon, Sonika Kohli, Martin Culpepper, Xuanhe Zhao and Ritu Raman; Massachusetts Institute of Technology, United States*

Unlike metal and plastic, biological materials can communicate with their surroundings, adapt to stimuli, and self-repair damage. Thus, incorporating these materials into engineered systems could foster smarter, more adaptable machines. Our lab has shown that a ring of engineered skeletal muscle stretched around a flexible 'skeleton' can generate force and drive motion (Raman et al, PNAS 2016). However, the interface between the biotic and abiotic components of this robotic system are friction-based, leading to inefficient force transmission. The ring morphology of the biological actuator also restricts its applicability and modularity in more complex system setups. To solve these issues, we have taken a bioinspired approach. In the body, muscle is covalently tethered to bone via tendons, which efficiently transmit force. Thus, we have developed a bioinspired synthetic tendon to act as a biohybrid stiffness-gradient interface, enabling the design of more modular and efficient bioactuators for adaptive biohybrid machines.

We developed an adhesive hydrogel tendon, composed of a poly(acrylic acid) hydrogel functionalized for tissue adhesion with N-Hydroxysuccinimide esters, in collaboration with the Zhao Lab at MIT. Its characteristics as a tendon material were evaluated. Muscle tissues were manufactured from optogenetic C2C12 mouse myoblasts seeded into a fibrin and Matrigel matrix, and were then differentiated with horse serum. Peel tests of muscle bound between two synthetic tendon sections revealed the biotic-abiotic interface could withstand forces >500mN before breaking. This is significantly greater than force generated from the contraction of engineered muscle (~300uN), demonstrating a robust binding. A cell viability assay and synthetic tendon exposure test confirmed that the hydrogel had no significant impact on muscle health.

Furthermore, we combined this tendon with our engineered muscle to evaluate a new bioactuator composition. We have bound a strip of muscle between two strips of tendon, akin to myotendinous junctions in vivo. Thus, we are leveraging this tendon-muscle-tendon (TMT) construct as a modular actuator that can be mechanically coupled to robotic skeletons to generate force and motion. TMT constructs were mounted onto flexure skeletons *to determine force production capabilities (Lynch et al, Adv. Intell. Syst. 2024). In addition, these trials were repeated with tendons backed by two types of polyurethane, Hydromed D3 and hydrothane, with mean stiffnesses of ~900kPa and ~2700kPa, respectively, which are ~7x and ~21x the stiffness of our muscle sections (~130kPa). In all cases, mounted TMTs were variously pretensioned by sweeping across the entire adjustable pin-to-pin distance range (8-14mm) of the flexure skeleton resulting in a general TMT strain of 0-27%. This range corresponds to a rotation angle of the adjustable cam on this skeleton.*

We have first evaluated the compatibility of a synthetic tendon material with our bioactuators, finding suitable binding strength and biocompatibility. In addition, we have evaluated the effects of varying synthetic tendon stiffness and preload tension on the force production capability of TMT units, enabling the optimized design and deployment of TMT actuators in untethered machines. Currently, our TMT constructs are being deployed in a robotic gripper skeleton to demonstrate its applicability in isolated robotic systems. Our TMT studies have shown the ability to generate comparable contractile strokes from ~1/2 the volume of previous muscle ring configurations, thus increasing power-to-weight ratio by ~2X. In essence, we have developed a hydrogel tendon system that serves as a robust biocompatible musculoskeletal interface that expands the implementation of biological materials into engineered systems. In addition to robotics, we anticipate future application of our system as an implantable muscle graft with suturable tendons to repair injured and diseased muscle in vivo.

Turning Waste into Wealth—Microbe-Semiconductor Biohybrids for Sustainable Chemical Production *Yiliang Lin[1] and Xiang Gao[2]; [1]National University of Singapore, Singapore; [2]Shenzhen Institute of Synthetic Biology, China*

Semiconductors biohybrids, integrating the best of biological catalysts and semiconductor nanomaterials, holds promise for revolutionizing sustainable chemical production. Here, we present novel semiconductor biohybrids that integrate the capabilities of living cells with semiconductor materials to enable sustainable chemical production through efficient solar-to-chemical conversion. By exploiting the periplasmic space in Gram-negative bacteria, we achieve biomineralization of semiconductor nanoclusters, containing single- and multiple-metal elements. These periplasmic semiconductors are metastable and exhibit defect-dominant fluorescent properties, enhancing ATP levels and malate production under photosensitization. In a following study, we further explored the combination with engineered bacterial strain to facilitate the biosynthesis of functional semiconductor nanoparticles from heavy metal ions, sulfate, and organics present in wastewater. Life-cycle assessment indicates significant sustainability improvements over traditional methods. The biohybrids can turn waste into wealth and achieve sustainable chemical production combining material science and synthetic biology.

9:45 AM SB08.12.04

Living Electroactive Microorganism-Based Biohybrid Microbial Fuel Cell Biosensor for Formaldehyde in Water Monitoring and Dose-Response Curve Determination *Hao Ren; ShanghaiTech University, China*

In this abstract, we present utilizing living electroactive microorganism-based biohybrid microbial fuel cell biosensor for formaldehyde in water monitoring and dose-response curve determination. We have built microfluidic MFCs with anode and cathode chambers of 100μL. Start-up process of the microfluidic MFC biosensor takes 3-5 days and we utilize the MFC biosensor for formaldehyde in water monitoring as well as determining the dose-response curve. It is found that when the MFC biosensor is exposed to a large formaldehyde concentration range from a low concentration of 1x10^{-3} mg/L to a high concentration of 3 mg/L in water, a real-time current drop is observed after each formaldehyde injection, and a higher formaldehyde concentration results in a higher current drop percentage, which makes the biosensor suitable for measuring formaldehyde concentration. Analyzing the experimental results shows a sigmoid relationship between the output current and the formaldehyde

concentration, and the experimental results are in agreement with traditional toxicology dose-response curve obtained by other measurement techniques.
Water pollution is a global health threat affecting 2 billion people, causing significant health issues. Traditional non-real-time methods are time-consuming and expensive. Therefore, a real-time and low-cost sensor for toxic chemical in water monitoring is needed. In addition, traditional dose-response curve determination methods are time-consuming and requires expensive equipment. In this abstract, we report utilizing living electroactive bacteria based microfluidic MFC biosensor as a low-cost and real-time platform to monitor toxic chemical concentration and determine dose-response curve.
The microfluidic MFC biosensor is composed of anode, cathode and proton exchange membrane (PEM) with a chamber volume of 100 μL. The anode/cathode are 100nm-thick Pt thin films deposited by magnetic sputtering. The start-up process of the MFC biosensor takes approximately 3-5 days. We perform polarization characterization, which shows that the MFC biosensor operates normally. Afterwards, we inject formaldehyde into the MFC biosensor to test the capability of the MFC biosensors for monitoring formaldehyde in water. When the MFC biosensor is exposed to a large formaldehyde concentration range from a low concentration of $1x10^{-3}$ mg/L to a high concentration of 3 mg/L in water, it is found that a real-time current drop is observed after each formaldehyde injection. Afterwards, the current does not recover, which indicate that the formaldehyde kills some electroactive bacteria. Furthermore, measurement results show that a higher formaldehyde concentration results in a larger current drop percentage. By fitting the experimental results, we obtain a mathematical relationship between the formaldehyde concentration and normalized current drop percentage, which can be utilized for measuring the concentration of formaldehyde in water. Further analyzing the normalized current drop percentage versus formaldehyde concentration shows a sigmoid dose-response relationship, which is in agreement with traditional toxicology dose-response curve obtained by other measurement techniques. As a result, besides being utilized as biosensor for determining the concentration of formaldehyde, the biosensor can be utilized to monitor the dose-response curve of toxic chemicals in water. Due to the low-cost and real-time monitoring capability, the microfluidic MFC biosensor has potential for toxic pollutant in water monitoring and dose response-curve determination.

The Ethics of Engineered Living Materials Mette Ebbesen; *Aalborg University, Denmark*

Engineered living materials (ELMs) are developing in materials science and engineering pointing towards applications in fields such as materials and energy production, biotechnology, and tissue engineering. An ethics-guided research approach in the field of ELMs will promote successful and sustainable development and implementation.
This presentation explains why it is important for nanoscience researchers to become ethically competent. It is not only a moral imperative to conduct socially responsible research – it is an opportunity for researchers to research even better solutions. Ethics-guided research is not only good for science but for society as a whole.
This presentation argues that ethical issues of nanotechnology and synthetic biology are not new and unique. Hence, similar basic ethical principles are at stake in nanotechnology and biotechnology. These basic ethical principles are beneficence, nonmaleficence, respect for autonomy, and justice as defined by American ethicists Tom Beauchamp and James Childress. To inform the community of ELMs, this presentation introduces the ethical theory of principles by Beauchamp and Childress and shows how these principles are useful in the field of ELMs to conduct ethics-guided research.

11:00 AM *SB08.12.06

Engineering Protein-Based Biomaterials—Versatile Applications in Biocatalysis, Bioelectronics, Sensing, Imaging and Therapy *Aitziber L. Cortajarena; CIC biomaGUNE, Spain*

Ordered protein-based biomaterials are highly desirable for a wide range of applications including templating, coating, sensing, bioelectronics, catalysis, and biomedicine. This has recently spurred the development, among others, of novel self-assembled materials and supramolecular nanostructures based on biomolecules. Inspired by nature, we explore biomolecules and their derivatives as novel biomedical and technological tools. Among biomolecules, proteins rise huge interest due to their high structural and functional versatility, biocompatibility, and biodegradability. In particular, we mainly focus on a class of engineered repeat proteins, due to their stability and robustness as a base scaffold that can be easily tailored to endow desired functions to the protein and to encode defined supramolecular assembly properties resulting into functional biomaterials.

We have explored strategies that rely on rational design of protein self-assembly and the re-engineering interactions within innate protein-protein contacts in crystalline lattices. On one hand, we demonstrate the potential to generate diverse crystalline protein frameworks by tuning the innate metal coordination preferences, guiding protein assembly for engineered consensus tetratricopeptide repeat (CTPR) proteins.[1] *On the other hand, we have developed strategies to create ordered protein-based biomaterials by re-engineering protein-protein interactions that maintain the crystalline lattices, and by interfacing proteins with other self-assembly elements such as amyloid-derived peptides. Through these methods, we direct the assembly of proteins into structured thin films, 2D monolayers, or 3D tubular architectures.*[2]

Additionally, we have developed protein-metal hybrids by engineering metal-binding residues, and the subsequent formation of tailored nanomaterials stabilized by proteins with unique luminescent, magnetic, or catalytic properties. Generally, the fusion of two distinct materials exploits the best properties of each, however, in protein-nanomaterial hybrids, the fusion takes on a new dimension as new properties arise. Overall, the rational engineering of protein-based materials offers a promising approach for biomolecular materials with defined structural and functional properties. We present selected applications of these materials in the fields of bioelectronics,[3,4] *and biomedicine.*[5,6]

Multifunctional Conductive Hydrogels for Next Generation Bioelectronics *Teuku Fawzul Akbar[1], Carlos A. Jimenez-Rodriguez[1], Carsten Werner[1,2], Ivan Minev[1,2] and Christoph Tondera[1,2]; [1]Leibniz Institute of Polymer Research Dresden, Germany; [2]Technische Universität Dresden, Germany*

The mismatch between electronic devices and biological tissue is based on two fundamental differences in their mechanical and functional properties causing a separation between the two worlds. While intensive research has been conducted to reduce the mechanical mismatch, reducing the functional disparity has been largely neglected. In biological systems, electrical and biomolecular signals are closely interconnected. Electronic devices on the other hand rely purely on electronic signal transmission. A technological recapitulation of the biological principle in one soft materials system could bridge both the mechanical and the functional gap between

electronics and living matter and could enable seamless integration of electronic devices into biological tissues. Targeting that challenge, we developed a new class of conductive metamaterials which mimic but also transcend the natural extracellular matrix. We synthesized a semi-interpenetrating network of the electroconductive polymer poly(3,4-ethylenedioxythiophene) (PEDOT) within sulfated/sulfonated polymer hydrogels (SSPH). Due to the modular character of the hydrogel system, the PEDOT:SSPH materials are tunable in their electrical properties such as impedance and charge storage capacity. Charge storage capacities of more than 1100 mC/ml could be reached enabling highly efficient electrical stimulation using these materials as electrodes or electrode coatings. Furthermore, by tuning the integral and local anionic charge density of the doping SSPH matrix, the specific affinity of the hydrogel to differently charged biomolecules could be varied. In combination with PEDOT, which has an electrically tunable redox state, the PEDOT:SSPH materials are capable of delivering differentially charged small molecules and proteins in electronically controlled ways. Depending on the polarity of the applied potential differently charged molecules could be released. Furthermore, by tuning the amplitude of the applied potential, the amount of the released molecules could be precisely controlled. By fabricating organic electrochemical transistors (OECTs) we demonstrated the feasibility of creating hydrogel sensor units from the PEDOT:SSPH materials. We showcased the potential of the sensors to act in direct combination with the biomolecule release system. Using the hydrogel OECTs low oxygen levels could be measured in physiological solutions. Subsequently an active release of Vascular Endothelial Growth Factor (VEGF) was induced. This caused the formation of blood vessel like structures in a 3D HUVEC cell culture embedded in the biomimetic hydrogel.
With this, our newly developed biomimetic metamaterials combine and link tunable electrical conductivity and specific biomolecular affinity. Applying these materials to design multimodal tissue interfaces that are able to stimulate and sense biological signals, we aim to further push the boundaries between living matter and electronic devices.

11:45 AM SB08.12.08
Enabling Torque-Based Magnetic Control of Living Bacteria for Targeted Drug Delivery Through Advanced Membrane-Bound Functionalization *Lisa Regazzoni, Ines Oberhuber, Pascal Poc, Xiang Wang, Fan Li, Stefano Menghini, Elena Totter, Cameron Forbrigger, Michael G. Christiansen and Simone Schuerle; ETH Zürich, Switzerland*

Biohybrid microrobots combining living microorganisms such as bacteria with nanomaterials are poised to contribute to future cancer treatments by enabling tailored therapeutic functions and targeted non-invasive controllability. Magnetic materials are of particular interest to provide means for wireless magnetic control. Torque-based magnetic actuation using rotating magnetic fields (RMFs) is an advantageous strategy for remote control, as it can be implemented at clinically relevant scales, does not rely on positional feedback, and can be spatially focused.

However, such an actuation strategy requires robust, high-throughput functionalization capable of attaching several hundred of magnetic nanoparticles (MNPs) to the bacteria while leveraging magnetic anisotropy. Additionally, to ensure controllability, these strategies must remain stable and robust when exposed to physiological conditions.
Previous biohybrid designs that have considered the introduction of magnetic material to the surface of clinically relevant bacterial strains have lacked adequate magnetic nanoparticle coverage to enable torque-based actuation.

Here, we present an efficient magnetic functionalization strategy for Escherichia coli that enables the application of sufficient torque to override natural locomotion at frequencies of several Hz. By studying the role of lipopolysaccharide in hindering the attachment of iron oxide nanoparticles and identifying a strategy employing *calcium ions to mitigate this challenge, we were able to attach on the order of 10^3 MNPs per bacterium. Moreover, by leveraging magnetic anisotropy, approximately 60% of the bacterial population became responsive to a 20 mT 2 Hz RMF. The resulting torques were on the same order of magnitude as magnetotactic bacteria, and exhibited a higher fraction of magnetic responsiveness. These biohybrid microrobots efficiently infiltrated the core region of 3D tumor spheroids, exhibiting up to a 5-fold enhancement of colonization under RMF exposure, highlighting their potential for enhancing tumor targeting and treatment efficacy.*

Tough and Stretchable Conductive Polymers Synthesized Using Controlled Radical Polymerization for Haptics and Human-Machine Interfaces *Darren J. Lipomi[1,2]; [1]University of California, San Diego, United States; [2]University of Rochester, United States*

In this talk, I will describe my group's interest in the materials science of stretchable, biocompatible conductive polymers and their microstructures. In particular, the conductive polymer PEDOT:PSS-b-PPEGMEA. This polymer has been specially designed to facilitate lower activation thresholds for neural stimulation, a crucial factor in making transcutaneous "electrotactile" stimulation more efficient and less invasive. We have achieved this *through molecular-level tuning that couples the well-known conductive properties of PEDOT:PSS with the biocompatibility and aqueous dispersibility conferred by PPEGMEA blocks. This strategic combination not only enhances the electrical characteristics of the polymer but also improves its mechanical properties, making it suitable for flexible and wearable formats. Utilizing these attributes, we have integrated PEDOT:PSS-b-PPEGMEA into a variety of device architectures, such as epidermal electronics and swallowing monitors, that have been evaluated in clinical contexts. This presentation will focus on the synthesis, characterization, and device integration of this unique conductive polymer, exemplifying the materials science contributions to remote health monitoring and human-machine interfaces.*

More than Flexible—Soft Electronics for Seamless Integration with the Human Body *Fabrizio A. Viola[1,2], David Mecerreyes[3] and Annalisa Bonfiglio[4]; [1]Università degli Studi di Cagliari, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]University of the Basque Country, Spain; [4]Scuola Superiore Studi Pavia IUSS, Italy*

Soft electronics is an exciting research field that aims to seamlessly integrate electronic components and devices onto non-rigid, non-planar, complex 3D surfaces and objects. The research on soft electronics has been mainly driven by the increasing request for a new category of portable and ubiquitous electronic systems capable of bridging the gap between biology and electronics, and of being integrated with the human body, with non-conventional features such as conformability. One of the most interesting field of applications of epidermal electronics is undoubtedly the engineering of bioelectrodes for monitoring biopotentials, such as electrocardiography (ECG), electromyography (EMG), electrooculography (EOG) and electroencefalography (EEG) signals from the surface of the skin.
The main challenge today lies in the methods of connecting such imperceptible films to external electronics, a problem that effectively voids some of the main advantages of having an ultra-thin and conformable device. On the other hand, another important issue to be solved is related to the improvement of the conformability of such electrodes in order to maximize their signal recording capabilities.

We here present our recent results on the engineering of soft bioelectrodes, utilizing cost-effective conductive polymers functionalized with a new category of ionic liquids and ferromagnetic nanoparticles.
We propose a simple, cost-effective approach using low-resolution, large-area manufacturing techniques for the fabrication of tattoo bioelectrodes based on biocompatible materials such as PEDOT:PSS and ionic liquids.
Thanks to the ionic liquids, we demonstrate an impressive level of conformability and mechanical stability of the electrodes, enabling them to record biopotentials (ECG, EMG, EOG, and EEG) for several hours with performance (i.e., signal-to-noise ratio) comparable to that of commercial wet electrodes.
Moreover, thanks to the functionalization of the proposed ultra-thin tattoos inexpensive ferromagnetic nanoparticles, they can be directly interfaced with the read-out electronics using magnetic connectors without compromising their conformability.
This approach, at the intersection of epidermal and organic electronics, offers high-performing and conformable soft bioelectrodes, while overcoming important issues related to interfacing electronics and the human body.

11:15 AM SB10.01.03

Blending Polymers for Improved Organic Thin Film Transistors *Benoit Lessard; University of Ottawa, Canada*

The deployment of smart packaging and wearable electronics depends on stable, low cost and high-performing electronics. Blending of polymers can provide a simple and low cost route towards obtaining optimized performance. This presentation will discuss our recent contributions towards 1) improving air stability and b) reducing operating voltage of n-type OTFTs using polymer blends.

1) N-type organic semiconductors are particularly susceptible to degradation by ambient air. we report the stabilization of n-type performance of the semiconductor poly{[N,N'-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-alt-5,5'-(2,29-bisthiophene)} (P(NDI2OD-T2)) when it is blended with an increasing proportion by weight of poly(2-vinylpyridine) (P2VP). The simple synthesis of P2VP also makes it an ideal candidate material for large-scale applications. Concentrations as low as 0.1% P2VP incorporated into the P(NDI2OD-T2) blends provided an immediate stabilization effect, and at 10% and 50%, longer-term stability after one week was observed.

Mater. Adv., 2023, 4, 4707-4711
Adv. Electron. Mater. 2024, 10, 2300660. https://doi.org/10.1002/aelm.202300660

2) Incorporating Poly methylmethacrylate (PMMA) as the dielectric successfully reduced the threshold voltage (VT) of bispentafluorophenoxy SiPc (F10-SiPc) based OTFTs from 14.9V to 7.3V while retaining a high mobility. Further reduction in VT was obtained by using copolymers and blends of PMMA and dimethylamino ethyl methacrylate (DMAEMA)-containing polymers where more mole fraction of DMAEMA led to a consistent drop in VT to 0.7 V. The electron donating groups of the tertiary amines in the DMAEMA show a clear interfacial doping of the semiconductor reducing the voltage required to populate the dielectric/semiconductor interface which charge carriers and turn on the device. Blending trace amounts of DMAEMA-containing copolymers with PMMA proved to be an effective strategy for reducing the VT while keeping the charge mobility high, unlike when using pure copolymers with elevated DMAEMA content. Time of flight secondary ion mass spectroscopy (ToF-SIMS) and X-ray photoelectron spectroscopy (XPS) demonstrated the DMAEMA containing copolymer is floating to the surface of the PMMA blend at the dielectric-semiconductor interface which explains the reduced VT. This study demonstrates a straightforward process for designing dielectric polymers and their blends for the reduction in VT for n-type OTFTs.

Adv. Electron. Mater. 2024, 2300810. https://doi.org/10.1002/aelm.202300810

Overall, these studies demonstrate simple approaches to obtaining high performance OTFTs through simple functional polymer blending.

11:30 AM *SB10.01.04
Textile Actuators (and Sensors) Based on Conjugated Polymers *Jose G. Martinez; Linköping University, Sweden*

Conjugated polymers are soft and compliant materials that can actuate (change their volume). When an electrical current is passed through the material, a reversible electrochemical reaction is promoted. Such electrochemical reaction changes the composition of the material and with that its volume, by incorporating or removing ions and solvent to or from the material. This electrochemically-driven actuation requires only a low potential of 1-2 V and is silent. During the last years we have merged conjugated polymers with textiles and textile processing to develop textile actuators. The fabrication of textiles is highly optimized in a vastly automated industry. Besides, textiles are ubiquitous and very well accepted by humans: Textile are the ultimate wearables. By merging both technologies, we are providing the textiles with mechanical actuation which will be of great interest for different applications such as wearable haptic devices, rehabilitation wearables or textile exoskeletons. Besides, conjugated polymers can also be used as sensors, and when merged with textiles, this results in textile sensors. In this invited talk, I will cover the working principles, latest progress and challenges of textile actuators (and sensors) based on conjugated polymers, including some application examples.

SESSION SB10.02: Materials for e-Textiles and e-Skins II

Multifunctional Liquid Metal Materials for Integration of Soft Electronics *Michael D. Bartlett; Virginia Tech, United States*

Multifunctional soft materials and interfaces create intriguing new opportunities for electronics, robots, and human-machine interfaces through e-textiles and e-skins. However, one of the largest challenges in this area is the robust mechanical and electrical integration across heterogeneous interfaces. In this presentation, I will address this challenge with several recent advances utilizing liquid metal-based composites to enable a spectrum of reversible to permanent attachment and integration with programmable electrical, thermal, and adhesive behavior. I will discuss how control over composite microstructure can dramatically tune functional, mechanical, and adhesive properties of these systems. This includes material and fabrication strategies to interface soft electronics with rigid functional components both in-plane and thru-plane for soft and flexible devices. Fundamental adhesion mechanisms will also be highlighted with discussion of design strategies for adhesion performance. These approaches provide model systems to study fundamental material properties while enabling soft electronics, soft robots, and advanced adhesives for a variety of applications.

2:00 PM SB10.02.02
Wireless Vagus Nerve Stimulation Patch with 3D Liquid Metal Electrodes—A Non-Surgical Solution for Treatment-Resistant Depression *Wonjung Park, Jinyong Park and Jang-ung Park; Yonsei University, Korea (the Republic of)*

Depression is one of the most serious mental diseases, affecting approximately 280 million people in the modern population. Alleviating depression is crucial as it often leads to other severe conditions through complex biological connections. Various treatments for depression have been researched and are currently utilized in clinical practice. However, some patients suffer from treatment-resistant depression, which does not respond to conventional antidepressants. To address these challenges, several electrical stimulation treatments such as electroconvulsive therapy have been developed. However, electroconvulsive therapy necessitates anesthesia for the electrical stimulation of the brain and is associated with temporary memory loss. Consequently, vagus nerve stimulation (VNS) has emerged as a promising alternative treatment capable of overcoming these limitations. VNS involves electrical stimulation of the vagus nerve, which modulates brain regions such as the hippocampus and prefrontal cortex. However, traditional VNS systems require surgical implantation of cuff electrodes around the vagus nerve under anesthesia. Transcutaneous auricular VNS has been proposed as a non-invasive alternative, but it has limited efficacy with only 27-50% of patients responding to the treatment. Here, we introduce a skin-attachable, surgery-free, wireless VNS patch with 3D liquid metal electrodes. This VNS patch is applied to the skin on the left cervical region, targeting the vagus nerve. It can operate wirelessly to provide treatment without spatial constraints and enable on-demand activation. Specifically, we determined the optimal stimulation parameters through in-vivo animal experiments, establishing 1 mA, 30 Hz, and 30 minutes as an ideal setting. The alleviation of depression was proven in all 10 mice tested with our VNS system. Additionally, our skin-attachable VNS patch *demonstrated rapid tissue recovery in mice with complete healing within seven days and no signs of prolonged immune response, highlighting its potential for safe and minimally invasive therapeutic applications. Electrophysiological analysis, such as phase-amplitude coupling and phase-locking measurements, demonstrated that VNS significantly modulated neural activity and functional connectivity in the hippocampus and prefrontal cortex. These changes led to the normalization of neural circuits involved in mood regulation and facilitated the recovery of cognitive function in depression models. Key biomarkers of neuroplasticity and inflammation, such as brain-derived neurotrophic factor and interleukin-6, were investigated in the hippocampus and the prefrontal cortex. Our research also indicated that VNS treatment can normalize immune function as demonstrated by the assessment of lymph node volume. This VNS system offers a novel therapeutic option for treatment-resistant depression, providing three major advantages: 1) no requirement for surgery, 2) wireless functionality, and 3) proven efficacy.*

2:15 PM SB10.02.03
Smart Textiles for Human Body Physiological Signal Monitoring and Personalized Thermoregulation *Ronghui Wu and Po-Chun Hsu; The University of Chicago, United States*

Global warming has increased the direct heat-related illnesses or even death. One innovative method to reduce the impact on health is using wearable technology for diagnostic, therapeutic, and post-care rehabilitative employment. Currently, the adoption of wearable sensors and therapeutic materials onto human body remains a considerable challenge because of the device bulkiness, power supply restrictions, ergonomic comfort limitations, and variations in quality and durability. To address these issues, we incorporate sensing and therapeutic capabilities into wearing textiles by nano- to macro-scale material design and multiscale textile engineering from fibers to cloths. We developed a 3D braided stretchable hierarchical interlocking fancy-yarn triboelectric nanogenerators (3D HIFY-TENG) with deoxyribonucleic acid-like double-wing spiral structure for multifunctional energy harvesting modes and self-powered biomechanical sensing. The 3D HIFY-TENG can generate self-driven triboelectrical outputs without relying on other objects by body movements. In addition, we developed a spectrally engineered textile for personalized thermoregulation, with mid-infrared spectrally selective hierarchical fabric (SSHF) with emissivity greatly dominant in the atmospheric transmission window through molecular design. SSHF minimizes the net heat gain from the surrounding buildings and ground and shows a 2.3°C cooler than a solar-reflecting broadband emitter when placed vertically in simulated outdoor urban scenarios during the day. The smart textiles show mechanical robustness, flexibility, washability, and human-body comfort. The electronic diagnostic and thermal therapeutic textiles provide great potential in promoting personalized healthcare.

2:30 PM SB10.02.04
Stimuli-Responsive Microfibers *Xin Hu and Alfred J. Crosby; University of Massachusetts Amherst, United States*

Microfibers, characterized by micron-scale diameters and lengths of up to several centimeters, play pivotal roles in natural structures. For example, plant tendrils use their microstructure and responsiveness to the environment to climb and provide support during growth. Their microstructures enable twisting and initiating helical chirality for bundles, providing significant performance at larger scales.[1] *This study presents a new approach for preparing microfibers utilizing nanoimprint lithography (NIL) and reactive ion etching (RIE). This method has been successfully employed to fabricate microfibers from polydimethylsiloxane (PDMS) elastomers and poly(acrylic acid)--based copolymer (PAA) hydrogels. The prepared microfibers exhibit exceptional responsiveness to stimuli such as pH, solvent, and electric fields.*

The responsive control of microfiber morphologies is dictated by the surface and near-surface chemical and *mechanical properties induced by RIE. For PDMS microfibers, their surface tension and near-surface moduli increase after RIE treatment. These modifications provide the driving force for coiling into curved structures with size scales set by the balance of elastic and interfacial interactions when the microfibers are released in a liquid environment. Their curvature can reversibly change when switching between different liquids. Likewise, RIE treatment stiffens PAA microfibers' surface, resulting in less swelling in water compared to the subsurface region. This difference creates a helical structure when swollen. When placed near the anode, mobile protons in the gel migrate toward the cathode with water molecules due to Coulomb forces. This electro-osmotic flow causes the microfiber to shrink and straighten.[2,3] Upon reversing the electric field's polarity, the microfibers revert to the swollen helical form. Through the control of the hydrogel's swollen and shrunken phase transition in electric fields,[4] the PAA microfibers realize the reversible transformations between coiled and straight configurations. Microfibers with stimuli-responsiveness exhibit the potential in sensors, actuators, electronics, mechanics, fluids, and photonics.[5]*

Self-Elongating Liquid Crystal Elastomer Fibers for Active Textiles—Beyond Thermotropic Contraction *Jin-Hyeong Lee, Seungjoon Oh and Suk-kyun Ahn; Pusan National University, Korea (the Republic of)*

Liquid crystal elastomers (LCEs) integrate the anisotropic properties of rod-like mesogens into a loosely cross-linked polymer network. When molecularly aligned, LCEs can undergo a large and reversible actuation upon heating, making them promising for applications such as artificial muscles and soft robots. Among various LCE geometries, 1D LCE fibers or filaments has received considerable attention due to their scalable production, rapid actuation, and flexibility in shaping through diverse fabric manufacturing processes. While recent studies have successfully demonstrated thermoresponsive active textiles based on LCE fibers, all these examples exhibit thermotropic contraction. In this study, we report unprecedented "self-elongation (30% in strain)" of LCE fibers upon heating, which was fabricated through the extrusion-based spinning combined with UV curing. The extraordinary thermal behavior originates from the unique microstructure of our LCE fibers evidenced by x-ray scattering and microscopy. As a proof of concept, we demonstrate active textiles that can increase the pore size (~50%) upon heating, offering potential applications in thermoregulation.

3:30 PM *SB10.02.06
Choline Based Ionic Liquid for Re-Shaping Bioelectronics *Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)*

As one of conducting polymers, PEDOT:PSS is commonly used in organic electronics, especially for bioelectronics due to its advantages such as high electrical and ionic conductivity, solution-processability and biocompatibility. Creating bioelectronics, for example organic electrochemical transistors (OECT), with the PEDOT:PSS requires advanced techniques to obtain physical/chemical modification of the PEDOT:PSS for improved performance and various applications.[1,2] To satisfy these demands, we demonstrated shape controllable gelation of PEDOT:PSS by injection to choline acetate, an ionic liquid, with a constant flow rate was used in this study to make a conductive fibers for textile OECT.[3] Conductive fibers by fibrillary gelation showed enhanced electrical conductivity of about 400 S cm^{-1} *and volumetric capacitance of about 154 F cm*$^{-3}$ *which would be strongly beneficial to be utilized for organic OECTs, resulting in a high transconductance of 19 mS in a depletion-mode. Moreover, high performance of enhancement-mode OECTs could be demonstrate by dedoping. [4] These results demonstrate that these conductive fibers and electronic-textiles are suitable candidates for applications in bio-integrated electronics.*

Zwitterionic Liquids and Elastomers with High Permittivity for Soft Dielectric Actuators *Dylan M. Barber, Michael D. Nelwood, Mady Corrigan, Andy J. Cohen, Robert J. Wood and Jennifer A. Lewis; Harvard University, United States*

Current interest in soft robotics, sensors, and shape-morphing materials have driven demand for mechanically compliant devices. While a broad palette of soft elastomers has emerged for these applications, dielectric materials remain limited to compositions with low elastic modulus Y (e.g., poly(dimethylsiloxane), Y ~ 10-1000 kPa) and permittivity (ε_r *= 2-10). A common strategy to increase permittivity is the incorporation of high-permittivity fillers, but this affords a concomitant increase in their stiffness. We posit that zwitterions, which are composed of charge pairs tethered by a covalent linker, offer a path to creating soft, high-permittivity dielectric liquids and elastomers. Unfortunately, most zwitterions synthesized to date possess high melting points,* $T_m > 200$ *°C, preventing field-mediated alignment under ambient conditions. Here, we report a new class of zwitterions that are stable liquids at room temperature and exhibit static dielectric constants* ε_r *as high as 420. Importantly, they also exhibit dramatically lower viscosity (~ 500x) compared to previously reported supercooled zwitterions. When incorporated as pendent groups on a flexible polymer backbone, they afford polymer melts; these can be crosslinked to form soft dielectric elastomers. These are the first examples, to our knowledge, of polyzwitterion melts and elastomers, making them ideal candidates for dielectric elastomer applications.*

4:15 PM SB10.02.08

Alkyl-π Liquids/Gels Electrets Toward Free-Deformable Motion Sensors *Takashi Nakanishi[1,2]; [1]National Institute for Materials Science, Japan; [2]Hokkaido University, Japan*

Interest in developing soft, lightweight, power-generating materials for soft electronics designed for healthcare applications has grown in recent years. Electrets capable of stably retaining electrostatic charge may be used to develop motion-powered devices without external power sources. We have led efforts to establish low-volatility, room-temperature alkyl–π liquids composed of a π-conjugated moiety and flexible yet branched alkyl chains. The alkyl–π liquids exhibit excellent charge retention properties, can be applied to other materials (e.g., through painting and impregnation), and are easily formable. However, when these alkyl–π liquids have been combined with electrodes to create flexible devices, they have proven challenging to immobilize and seal, resulting in leakage issues. Moreover, the electrostatic charge retention capacities of alkyl–π liquids needed to be increased to improve their power generation capabilities.

We recently developed an alkyl–π gel by adding a trace amount of a low-molecular-weight gelator to an alkyl–π liquid. The elastic storage modulus of this gel was found to be 40 million times that of its liquid counterpart, and it could be simplified fixation and sealed. Moreover, the gel-electret obtained by charging this gel achieved a 24% increase in charge amount compared to the base material (i.e., the alkyl–π liquid), thanks to the improved confinement of electrostatic charges within the gel. We then combined flexible electrodes with the gel-electret to architect a vibration (weak-motion) sensor. This sensor could perceive vibrations with frequencies as low as 17 Hz and convert them into an output voltage of 600 mV—83% higher than the voltage generated by an alkyl–π liquid electret-based sensor.

4:30 PM SB10.02.09

Self-Poled Piezoelectric Nanocomposite Fiber Sensor for Wireless Monitoring of Physiological Signals *Md Mehdi Hasan[1,2], Mahmudur Rahman[1,3], Md Sazid Bin Sadeque[1] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]University of Massachusetts Amherst, United States; [3]University of Southampton, United Kingdom*

Self-powered sensors have the potential to enable real-time health monitoring without contributing to the ever-growing demand for energy. Piezoelectric nanogenerators (PENGs) respond to mechanical deformations to produce electrical signals, imparting sensing capability without external power sources. Textiles conform to the human body and serve as an interactive biomechanical energy harvesting and sensing medium without compromising comfort. However, the textile-based PENGs fabrication process is complex and lacks scalability, making these devices impractical for mass production. Here, we demonstrate the fabrication of long-length PENG fiber compatible with industrial-scale manufacturing. The thermal drawing process enables the one-step fabrication of self-poled MoS_2-PVDF nanocomposite fiber devices integrated with electrodes. Heat and stress during thermal drawing and MoS_2 nanoparticle addition facilitate interfacial polarization and dielectric modulation to enhance output performance. The fibers show 57% and 70% increase in output voltage and current compared to the pristine PVDF fiber, respectively, at considerably low MoS_2 loading of 3 wt%. The low Young's modulus of outer cladding ensures effective stress transfer to the piezocomposite domain and allows minute motion detection. The flexible fibers demonstrate wireless, self-powered physiological sensing and biomotion analysis capability. The study aims to guide the large-scale production of highly sensitive integrated fibers to enable textile-based and plug-and-play wearable sensors.

***Hierarchical Strain Synergistic Sensitivity Strengthening of Flexible Strain Sensors** Weijuan Wang, Ting-yui Wong and Fangxin (Frank) Zou; The Hong Kong Polytechnic University, Hong Kong*

Flexible strain sensors have garnered substantial interest for their potential applications in the burgeoning field of soft electronics. However, the precise transduction of diverse mechanical stimuli into corresponding digital signals presents significant challenges to their sensitivity. Recent advances in designing intricate multi-layer composite sensors with microcrack structures have demonstrated exceptional sensitivity. Nevertheless, the complexities associated with assembly structures and interfacial interactions, along with the limitations inherent in sensing material selection, continue to hinder the development of highly sensitive strain sensors. To address these challenges, we propose a hierarchical strain synergistic strategy to enhance the sensitivity of flexible strain sensors made from a single material by decomposing applied strain into varying levels.

Firstly, we develop a Monte Carlo model to simulate the hierarchical strain synergistic strategy and investigate the effects of hierarchical strain parameters (distribution structures, proportions, and values) on the sensitivity of strain sensors. The results of numerous randomized experiments reveal that, compared to a uniform strain distribution, a hierarchical strain structure can either strengthen or weaken sensitivity. Additionally, for the optimal hierarchical strain architecture, the sensitivity of strain sensors is positively correlated with the proportion of small strains and inversely related to the magnitude of small strains. Both factors contribute to the amplification of large strains. The effectiveness of this strategy is underpinned by detailed mathematical theory, offering a robust theoretical foundation and guiding principles for sensor structure design within the hierarchical strain synergistic strategy.

As a proof-of-concept prototype, we designed, and established finite element analysis (FEA) models of, patterned graphene strain sensors (PGSSs) featuring the optimal hierarchical strain distribution, achieved by constructing and parameterizing grooves on flexible substrates. With the programmable computational approach that incorporates multiphysics coupling, strain sensing curves of constructed FEA models of the PGSSs could be quantitatively evaluated with high fidelity, which allows for virtual verification without conducting resource- and time-consuming experiments. The experimental sensing trends of the fabricated PGSSs align with the modeled results, showing that under 100% uniaxial tensile strain, reducing small strain values and increasing their proportions significantly boost sensitivity by factors of approximately 10.7 and 3.3, respectively. The maximum sensitivities of the two sets of PGSSs reach gauge factors as high as 25,600 and 17,800, respectively. The hierarchical strain synergistic strategy demonstrates broad applicability across various materials and offers adjustable sensitivity, presenting substantial potential for applications in soft electronics.

8:30 AM *SB10.03.02

***Dielectric Elastomer Fibers by the Meter** Magdalena Skowyra, Romisa Fakhari, Florina-Elena Comanici and Anne L. Skov; Technical University of Denmark, Denmark*

Since the 1990s, dielectric elastomer actuators (DEAs) have been developing as a potential solution for soft robotics, including artificial muscles. The intrinsic softness, lightweight, considerable actuation strain, fast response time, and high work densities distinguish them from other candidates. Currently, most DEAs have been fabricated in a planar format, where a pre-stretched elastomer is sandwiched between two compliant electrodes, allowing them to convert electrical energy into mechanical movement using electrostatic forces. Even though the fabrication of planar DEAs has been automated, they still cannot form complex three-dimensional geometries that mimic skeletal muscle displacement. Therefore, various geometrical configurations have been investigated, including stacks, rolls, and fiber actuators, with the latter showing the most significant potential as artificial

muscles due to the unidirectional actuation performance. So far, several research groups reported advancements in fiber format actuators; however, only with limited fiber length and low or unstable actuation strain.
We present a silicone (PDMS) fiber DEA, produced by the meter in a flexible wet-spinning process and turned into an actuator by applying ionic liquid-based electrodes in the fiber's inner core and outer layer. The fabrication method is based on a continuous spinning process of PDMS solution that undergoes a UV-curing reaction in a solvent bath to form a hollow fiber. Various fiber sizes can be prepared by varying the flow ratios of the coaxial needle constituents, i.e., inner solvent and outer PDMS solution. A single extrusion process can produce uniform fibers with an external diameter of 355-493 µm and uniform wall thickness of 67-129 µm of up to 10 m length. The fibers are extremely soft, with Young's modulus of 0.2 – 0.3 MPa and tensile strain up to 720%. The fiber actuator inner electrode – ionic liquid – is injected into the fiber core using a thin needle, and the fiber outer electrode – ionogel, a mixture of ionic liquid with a polymer and solvent – is applied by dip coating the fiber in the solution for 30 s.
The DEA fiber can lift up to 200 times its own weight and characterizes stable actuation strain of up to 9% at 2.7 kV, with a response time of 2 s. We studied multiple fiber geometries, intending to maximize actuation strain while improving fiber reliability. An improvement in the breakdown voltage value was observed for fibers with thicker walls and smaller inner diameters. Moreover, the fibers can be bundled for joint forces, allowing the freedom to operate the actuators in different architectures, including asymmetrical lifting systems. It is also possible to actuate the fibers in wet conditions, where ionic liquid or water act as external electrodes, with a similarly high actuation strain of 9.5% at 3.6 kV.
With the versatile and scalable fiber fabrication process, as well as stable actuation strain, we open up a wide range of potential soft robotics applications. Looking forward, the DEA fibers could serve as a fundamental component for body-compliant actuators, wearables or artificial muscles, among other innovative uses.

9:00 AM SB10.03.03
MoS_2-Integrated Polymer Nanocomposite Fibers for Triboelectric Generation via Thermal Drawing Technique *Md Sazid Bin Sadeque[1], Mahmudur Rahman[1,2], Md Mehdi Hasan[1,3] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]University of Southampton, United Kingdom; [3]University of Massachusetts Amherst, United States*

Triboelectric nanogenerators (TENGs) are green energy-generating devices that convert biomechanical energy into usable electrical energy by combining contact electrification and electrostatic induction phenomena. Recently, TENG devices have attracted significant interest due to their ability to be employed as self-powered smart sensing devices in biomedical applications. Polyvinylidene fluoride (PVDF) and its copolymers are attractive materials for flexible TENGs due to the presence of highly electronegative fluorine ions and high dielectric constant. Adding MoS_2 with PVDF is an efficient way to improve the triboelectric property of the composite fiber. The positively charged $-CH_2$ dipoles of PDVF can strongly interact with negatively charged MoS_2 layers, significantly enhancing the PVDF's ferroelectric properties. This study presents the scalable fabrication of MoS_2-embedded PVDF flexible nanocomposite triboelectric fibers at varying concentrations (1-5 wt%) via thermal drawing. The incorporation of MoS_2 into PVDF promoted the electroactive phase transition in triboelectric fibers. The β phase percentage of 3% MoS_2- PVDF fiber increased to 48%, which was 32.5% for pristine PVDF fiber. The phase transition in PVDF resulted in improved triboelectric output. The single fiber peak power output for 3% MoS_2 - PVDF fiber was measured as 17µW. Utilizing the flexible nature of the fiber, we integrated it as a wearable device for human respiration monitoring applications. The insights gained from this study will significantly contribute to our understanding of transition metal dichalcogenide-integrated fibers toward the scalable fabrication of high-performance textiles.

9:15 AM SB10.03.04

Enhancing Sensitivity Across Scales with Highly Sensitive Hall Effect-Based Auxetic Tactile Sensors
Youngheon Yun and Bumjin Jang; Hanyang University, Korea (the Republic of)

In recent years, Within such landscape of human–robot interaction (HRI) and human–machine interaction (HMI), tactile sensors have emerged as indispensable components, especially in fields requiring the exchange of tactile information among interacting entities. Diverse research initiatives have been initiated with the aim at enhancing sensitivity and resolution by delving into sensing mechanisms, coupled with the exploration of materials to increase the effectiveness of these mechanisms. Among these, Hall sensing-based (or magneto) tactile sensors have recently garnered significant attention due to the impressive spatial resolution achievable with a single Hall sensor: traditional resistive or capacitive tactile sensors, in contrast, require a substantial number of electrode arrays to achieve high spatial resolution, resulting in structural complexity with numerous input/output (I/O) elements. Moreover, these sensors face limitations in sensing range, as substantial external forces can interrupt their conductivity paths. Importantly, issues related to the reproducibility of stable sensing performance arise due to poor adhesion at the interface between electrode arrays and the underlying active soft layer composed of elastomers and receptors.

In wearable applications, there is a growing trend to directly integrate auxetic structures into tactile sensors, largely because of their crucial function in enhancing sensitivity and flexibility at the interface with human or robotic skin. Diverse auxetic structures have found application across various tactile sensing mechanisms. Nevertheless, challenges persist in addressing issues related to the interface of electrode arrays and the limited force range for interrupting the conductivity path. Ongoing efforts are dedicated to overcoming these challenges and further enhancing the performance of auxetic-based tactile sensors to ensure improved usability and effectiveness in diverse applications.

We present a Hall effect-based auxetic tactile sensor (HEATS) that integrates a magnetic auxetic structure with a negative Poisson's ratio into a homemade Hall sensor array for the first time, as we have recently published in ref.[1]. HEATS introduces the capability of real-time calibration of the Earth's magnetic field by integrating a reference Hall sensor near a measuring Hall sensor. This innovative approach enables the collection of signals solely from the structural deformation of the active soft layer, addressing a current weakness in Hall effect-based tactile sensors. Utilizing finite element analysis (FEA), we conducted a comprehensive analysis of the mechanical properties of various auxetic structures and identified the optimal pattern—a rotating square plate—that facilitated achieving higher sensitivity. Additionally, our observations indicate that as the Poisson's ratio of the auxetic structure becomes more negative, the sensor's sensitivity increases significantly. The experimental results showcase remarkable improvements in sensitivity for HEATS across a broad sensing range, with a 20-fold and 10-fold enhancement at tensile rates of 0.9% and 30%, respectively, compared to the non-auxetic sensor. Finally, our experiments demonstrated the successful detection of changes in muscle movement and motion associated with physical activities using HEATS. By strategically placing HEATS on various body parts, we established the feasibility of accurately capturing these changes in both humans and robots. Moreover, building upon the preceding findings, we conducted additional experiments to assess HEATS on the knee joint of a robot, where we verified that the values exhibited a linear change corresponding to the rotation angle of the robot's joint. Our technology represents a significant breakthrough in tactile sensor technology, offering the potential for enhanced sensitivity and versatility for diverse applications.

Highly Integrated Fibers and Textiles for Sensing and Actuation via Thermal Drawing *Fabien Sorin, Hritwick*

Banerjee, Stella Laperrousaz, Xin Chen, Yan Meng and Jinwon Song; École Polytechnique Fédérale de Lausanne, Switzerland

The integration of sensing and actuation within fibers and fabrics is at the heart of the technological developments for smart and e-textiles. Several approaches exist for functionalization via a direct and selective coating of the already made fiber and fabric. An alternative approach relies on thermally drawing a fiber from a preform that already contains the desired functional materials within a cladding. This approach enables to realize fiber-integrated devices with complex architectures and functionalities, at the scalability traditionally associated with optical fibers. Until recently however, the cladding materials have been made out of rigid thermoplastic or glasses that could not respond to most mechanical external stimuli. Moreover, actuation of such advanced fibers had not been demonstrated. In this presentation, we will present the latest developments in the multi-material functional fiber field and show in particular how we can provide fibers with novel structures and materials that can sense a variety of stimulations, while at the same time being mechanically actuated, for advanced diagnostic and therapeutic tools (Leber et. al., Advanced Science 2204016, 2023). We will in particular show the materials selection criteria, and processes at play to integrate polymer composites, liquid metal, optical fibers, piezo-resistive or piezoelectric materials, as well as hollow channels, at prescribed positions and of arbitrary size within thin and soft elastomeric fibers. We will show examples of highly soft functional catheter-like fiber systems, advanced fibers for drug delivery, as well as electronic fibers for strain or pressure sensing that can be integrated into textiles for large area mapping. With just a few connections at the fiber ends, we will show how a single fiber can functionalize an entire area in a robust way, paving the way towards novel opportunities for advanced yet simple and affordable smart textiles for health care applications. Adding Magnetic composites, we will show how advanced and soft fibers can be actuated magnetically (Banerjee et. al., Advanced Materials 2212202, 2023). Integrating such fibers into textiles, we will show examples of applications where soft textiles can be magnetically actuated, paving the way towards novel soft prosthesis.

9:45 AM SB10.03.06

Wearable Conductive Textile with Controllable Piezoresistivity and Transiency for Vibrotactile Haptics Systems Pietro Cataldi*; Istituto Italiano di Tecnologia, Italy*

Electronic waste is an exponentially increasing environmental issue, especially for wearable devices, due to their widespread diffusion into society and short life cycle.[1] To promote their enormous benefits, e.g., in assisting visually impaired individuals and making them more sustainable, biobased and/or biodegradable materials should be used instead of traditional components.

Thus, we functionalized cotton with diverse conductive coatings made by mixing biodegradable binders such as polybutylene adipate terephthalate and environmentally friendly solvents such as water, alcohol, and anisole with carbon-based nanomaterials. Doing that, we obtained isotropic or anisotropic electrical resistance change with bending, depending on the coating composition, the textile twill, and the stress direction. The obtained materials were functioning either as a bendable-compliant electrode or a tunable piezoresistor. Transiency of the coatings was tuned, changing the binder type and composition, allowing the coating to shift from entirely transient within minutes to resisting washing cycles for hours without losing its electrical conductivity. By controlling the material composition and deformation direction, these versatile green electrical conductors may be used in various applications, such as sensors, actuators, or human motion sensing.

Towards such vision, we engineered a specific class of inks to propose the first ECO-friendly wearable vibroTACtile device (Eco-Tac).[4] The design of Eco-Tac includes integration on a cotton T-shirt through the biodegradable conductive ink forming electrical tracks, a flexible commercially available solar panel, and the vibrotactile haptic device itself. As such, the feasibility of using a sustainable energy source to supply power to the device and the possibility of using biodegradable materials in its manufacturing are demonstrated. An experiment with twenty *blindfolded subjects is conducted, reporting the device's potential for assistance in manipulation tasks. Overall, the results of this work represent the first significant step towards creating wearable and sustainable haptic devices with green electronics and mechatronics approaches.*

Development of Grid-Structured Conductive Microfiber-Based Skin Electrodes for Facial Muscle Movement Detection *Myung-Han Yoon; Gwangju Institute of Science and Technology, Korea (the Republic of)*

In this research, we fabricated semi-transparent skin electrodes based on grid-structured PEDOT:PSS microfibers and ion gel-permeated electrospun polyvinyl alcohol (PVA) nanofibers. Grid-structured PEDOT:PSS microfibers exhibit high optical transparency, decent electrical/electrochemical characteristics, mechanical flexibility, and modest stretchability owing to large empty spaces between highly crystalline PEDOT:PSS microfibers. To enhance their adhesion to and electrochemical interfacing with skin, a thin layer of electrospun polyvinhyl alcohol (PVA) nanofibers was employed after being permeated with ion gels. The resultant skin electrodes enable the long-term high-fidelity measurement of various biological signals such as electrocardiogram, electromyogram, electrooculogram with minimal skin irritation and aesthetic concerns. Finally, it was demonstrated that grid-structured PEDOT:PSS microfibers are capable of detecting facial muscle movements which can be potentially translated into non-verbal communications such as emotional expression.

11:00 AM SB10.03.08
From Graphene Oxide Liquid Crystal to Artificial Muscle *Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Graphene Oxide Liquid Crystal (GOLC) is an intriguing 2D carbon based soft material, which exhibits nematic type colloidal discotic liquid crystallinity with the orientational ordering of graphene oxide flakes in good solvents, including water. Since our first discovery of GOLC in aqueous dispersion at 2009, this interesting mesophase has been utilized over world-wide for many different application fields, such as liquid crystalline graphene fiber spinning for wearable devices, highly ordered graphene membrane/film production for water treatment, and nanoporous graphene assembly for energy/environmental applications. Interestingly, GOLC also allow us a valuable opportunity for the highly ordered molecular scale assembly of functional nanoscale structures. This presentation will introduce our current status of GOLC and other 2D material research particularly focusing on the nanoscale assembly of functional nanostructures, including highly oriented 1D fibers, 2D films and 3D nanoporous structures. In particular, human muscle inspired graphene based nanocomposite fiber actuators will be highlighted along with its interesting demonstration for biomimetic behaviors.

11:15 AM SB10.03.09

Bio-Friendly Artificial Muscles for Electroactive Textiles Based on Carbon Nanotube Yarns *Gabriela Y. Ananieva[1], Cédric Vancaeyzeele[1], Giao T. Nguyen[1], Daniel Aguilera-Bulla[1], Frédéric Vidal[1], Mathieu Pinault[2] and Cédric Plesse[1]; [1]CY Cergy Paris Université, France; [2]Université Paris-Saclay, France*

Electrochemically driven coiled yarn actuators, which provide fast actuation and large contractile stroke, are promising soft transducers and could be considered precursors of artificial muscles for applications in smart textiles, prosthetics, soft robotics, and exoskeletons. These actuators are built on a coiled electroactive yarn and an electrolyte, serving respectively as the electrode and the ion source. Charging the electrochemical double layer (EDLC) at the interface of the yarn and the electrolyte promotes a local increase in volume as the ions swell the yarn's surface, leading to transversal expansion and longitudinal contraction. The most utilized type of yarns for these actuators is made of carbon nanotubes (CNTs) due to their high conductivity, high surface area, light weight, and excellent mechanical robustness. Air operation can be achieved by associating two coiled yarns with a gel electrolyte coating. The gel electrolyte plays a critical role in the ultimate performance of such actuators but usually suffers from issues such as air-drying for hydrogels, toxicity, or low conductivity in the case of organogels or ionic liquid-based gels.

In this work, we present eutectogels as gel electrolytes for fabricating bio-friendly, air-operating, rapid, coiled yarn actuators from commercially available CNT yarns. The eutectogels are synthesized using a deep eutectic solvent (DES), which is a multicomponent mixture of a hydrogen bond donor (HBD) and acceptor (HBA). DES presents properties similar to ionic liquids, such as air stability and high ionic conductivity, with additional desired features: biocompatibility, low cost, and facile synthesis. Coiled yarns are initially electromechanically characterized in a 3-electrode electrochemical setup using various DES dilutes. The effects of CNT surface treatments (chemical, thermal, etc.) and the composition of the DES are investigated to optimize the electromechanical performances, reaching a maximal strain rate of 1%/s and a maximal stroke of 5.3% in 15 seconds.

To enable air actuation, novel eutectogels were directly coated on the surface of coiled CNT yarns using UV-polymerization of liquid precursors. More specifically, two oppositely charged gels were developed to promote the so-called unipolar charging of yarns. The polyanionic gel contained grafted anions, while the polycationic one contained grafted cations, meaning that the anions and cations were respectively, blocked from participation in the intercalation process at the negative and the positive electrodes. This enabled unidirectional contractile stroke over the full electrochemical window. First characterizations of the resulting actuator in open air showed a contractile stroke of 3.6% in 30 seconds and a volumetric work capacity of up to 100 kJ/m^3.

The demonstrated coiled CNT yarn/gel actuators can be fabricated rapidly and can operate in open air, at an applied potential difference of less than 3V, using bio-friendly and biocompatible electrolytes and commercially available CNT yarns. Further development will include their integration into e-textile garments as soft actuators.

11:30 AM SB10.03.10

Thermoplastic Elastomers for Wireless, Skin-Interfaced Electronic and Microfluidic Devices *Yunyun Wu[1,2], Claire Liu[1], Jan-Kai Chang[1], Ralph Nuzzo[3] and John A. Rogers[1]; [1]Northwestern University, United States; [2]Dalhousie University, Canada; [3]University of Illinois at Urbana-Champaign, United States*

Wireless, skin-interfaced electronic and microfluidic devices have the potential to replace wired, bulky, and cumbersome technologies for personal and clinical health monitoring, allowing care to extend from hospital settings to the home. For use on skin, these devices commonly employ silicone-based thermoset elastomers (TSEs) as layers that encapsulate the electronics or serve as molded microchannels for biofluid (e.g., sweat) capture, storage, and analysis. Barriers to commercial adoption of such devices include difficulties in use of these elastomers in conventional practices for mass manufacturing. Their relatively high cost and inability to allow for *recycling represent additional disadvantages. By contrast, thermoplastic elastomers (TPEs) are fully compatible with industrial-scale manufacturing processes, low in cost, and recyclable. Like TSEs, TPEs are soft, stretchable, flexible, and optically transparent, while possessing other properties well-suited for applications in wireless, skin-interfaced devices. In this presentation, we report on the characteristics, processing, and application techniques for three commercially available TPEs, including two thermoplastic polyurethanes as encapsulation layers for a wireless skin hydration sensor and one thermoplastic styrenic block copolymer for a microfluidic sweat analysis platform. The results demonstrate that TPEs can be effectively integrated into these classes of devices, as a compelling alternative to TSEs, as a mass-manufacturable, sustainable materials option.*

Colorimetric pH Sensing and 3D Printable Hydrogels with Laponite® as Universal Rheology Modifier—A Value-Added Supplement for e-Skins and e-Textiles *Rayan Basodan, Ozge Z. Akca and Hyun-Joong Chung; University of Alberta, Canada*

Hydrogels contain water that often incorporates various solutes; unless hydrogels are encapsulated by a barrier, the solutes in the hydrogels reach an equilibrium with the environment. The most attractive feature of hydrogels is that the aqueous environment becomes a substantial part of the material itself, while the hydrogels maintain their mechanical consistency with a physical boundary. For these reasons, hydrogel is an ideal sensor platform in aqueous media. Colorimetric assays deliver information intuitively; keeping chromophores free from leaching has been a challenge in aqueous media. Direct ink writing is a versatile freeform manufacturing method for hydrogels; a generalizable formula to enable 3D printability can be impactful.
In this study, a dual network hydrogel of polyacrylamide and alginate with a backbone-incorporated modified pH sensing chromophore, methacrylated phenol red (MAPR), is printed by incorporating Laponite® as a universal rheological modifier. Here, a co-polymerization of MAPR with polyacrylamide enables colorimetric response to pH, ranging from yellow (pH=4) to fuchsia (pH=10) without leaching of the chromophore. Rheological analysis of the precursor solutions reveals that a critical content of Laponite® to achieve substantial shear thinning behaviour to be , which is consistent with a pervaded volume-based model. X-ray diffraction confirms the formation of 5-layer-thick Laponite® aggregates when their content exceeds the critical content. For printing, 8 wt% of Laponite® provides the optimal shear thinning and viscosity at rest for the best printing fidelity. While strong anisotropicity in printed strands leads to a contrast in mechanical properties with respect to the printing directions, optimized printing produces hydrogels that stretches 18 times the original length. This paves a way to incorporate structure based toughening mechanism by optimizing the raster direction of 3D printing.
Our 3D printed colorimetric pH sensing hydrogels combine sensitivity, intuitive data interpretation, mechanical strength, and structural integrity to operate in various aqueous environments while having arbitrary shapes to address various needs in environmental, underwater, and healthcare applications. We believe that our colorimetric hydrogel platform wherein the chromophore with environmental sensitivity is covalently integrated in the main chain of the polymeric backbones provides a robust and versatile platform to incorporate multifunctional sensitivity. These colorimetric hydrogel sensors can seamlessly blend into e-skins, e-textiles, actuators, coatings, optics, electronics, and water harvesters for boundless future applications
** Rayan Basodan and Ozge Zengin Akca contributed equally to this work.*

SESSION SB10.04: Fabrication and Integration of e-Textiles and e-Skins
Session Chairs: Hyun-Joong Chung and Ahyeon Koh
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 302

*1:30 PM *SB10.04.01*

Functionalizing e-Textiles Using Printed Films and Washable Flexible Filament Circuits *Stephen Beeby; University of Southampton, United Kingdom*

Electronic functionality can be added to textiles using printed functional materials or invisibly integrating flexible electronics with the yarn or fabric structure. This talk described a suite of textile-compatible screen printable inks that have been developed to achieve a variety of functions. The talk describes a range of example materials and devices along with a process based on domestic ironing as a repair mechanism to return the printed conductors to prime condition, enhancing lifetime and durability during extended stress cycles. Flexible filament circuits utilize bare-die components to realise functional circuits that can be integrated with a textile yarn or woven invisibly into an otherwise standard fabric. The circuits utilise a vacuum-forming packaging process that enables circuits to survive up to 50 machine wash cycles.

2:00 PM SB10.04.02

Textile-Based Supercapacitors with Integrated Electrode-Electrolyte Structure for E-Textile Applications

Dong Seok Lee and Jonathan Y. Chen; The University of Texas at Austin, United States

The rapid advancement of flexible and wearable electronics has created a substantial demand for equally flexible and lightweight energy storage devices. In this context, two innovative approaches were investigated to enhance the performance of textile-based supercapacitors, with a focus on their potential integration into a variety of applications, such as biomedical sensors, electronic textiles (E-textiles), healthcare monitoring, and human-machine interfaces.

First, a textile-based supercapacitor constructed from a fabric/film composition was studied. Activated carbon granule (ACG) was used as the electrode material due to its high surface area and excellent electrochemical properties. Polyvinyl alcohol (PVA) combined with phosphoric acid (H_3PO_4) was chosen to form a film composite functioning as both the polymer matrix and the electrolyte. This fabric/film layered structure was designed to maintain a solid state, ensuring essential mechanical robustness, while also rendering needed device flexibility. The as-prepared supercapacitor demonstrated typical double-layer electrostatic capacitive behavior, with a specific capacitance of 1.0 mF cm^{-2} at a scan rate of 10 mV s^{-1}. To further enhance the capacitor performance, ZnO nanoparticles were incorporated into the electrode/electrolyte matrix, resulting in an improved specific capacitance of 1.32 mF cm^{-2} under the same conditions. Remarkably, the supercapacitor maintained its performance even when bent at various angles and could power an LED for 30 minutes using four units after being charged by a solar cell for two hours. This indicated that the proposed supercapacitor fabrication process and structure were flexible, lightweight, and capable of being integrated into textile products.

Second, a supercapacitor based on a nanofiber structure was investigated, offering distinct advantages in terms of surface area and porosity. The aqueous PVA + H_3PO_4 solution was used as a dope solution for spinning, and PVA nanofibers were produced via a force-spinning method. ACG was subsequently added to the nanofibers to enhance their electrochemical performance. The resultant nanofiber was then configured into a non-woven structure, making it highly adaptable to produce flexible supercapacitors. The initial specific capacitance of the as-prepared supercapacitor was measured at 0.041 mF cm^{-2} at a scan rate of 10 mV s^{-1}. By increasing the amount of electrolyte (H_3PO_4) within the nanofiber matrix, the supercapacitor's performance was significantly enhanced, achieving a specific capacitance of 3.827 mF cm^{-2} at the same scan rate. Additionally, the proton ionic conductivity of the supercapacitor was dramatically increased by a thousand-fold, from 5.991×10^{-6} S cm^{-1} to 2.796×10^{-3} S cm^{-1}, demonstrating substantial improvements in ionic transport properties.

These studies underscore the versatility and effectiveness of the proposed supercapacitor fabrication processes *and structures, highlighting their potential for seamless integration into textile products. The ability to maintain high performance while being flexible and lightweight makes these supercapacitors promising candidates for next-generation wearable technologies. Furthermore, the integration of such supercapacitors into textile-based platforms offers a promising route for the development of self-powered smart textiles and wearable systems.*

2:15 PM SB10.04.03

Multi-Signal Collecting E-Textile System for Long-Term Maternal Health Monitoring via Sponge Electrode

Chansoo Kim, Junyi Zhao, Weilun Li, Ryan Andersen and Chuan Wang; Washington University in St. Louis, United States

Stretchable and flexible health monitoring systems have great potential for improving the accuracy of predicting arrhythmias or diagnosing peripheral nervous system disorders through long-term measurements. Moreover, these systems create synergy when applied to maternal health monitoring. In many developing countries or regions with underdeveloped infrastructure, many pregnant women are unable to reach the hospital at the appropriate time for childbirth, putting both the mother and child at risk. To predict childbirth, hospitals provide tocodynamometer (TOCO) system that collects pressure signal of uterine contraction and electromyography (EMG) electrodes that collect uterine muscle contraction signals, and these electrodes provide highly accurate information. Nevertheless, these systems are large and rigid, making it difficult to wear them in a wearable form for daily use.

Here, we propose an innovative approach for a wearable long-term maternal health monitoring system through integrated sponge and textile electrodes. The system consists of a soft and pliable polydimethylsiloxane (PDMS) sponge and stretchable textile electrodes coated with poly(3,4-ethylenedioxythiophene)polystyrene sulfonate (PEDOT:PSS). By adjusting the content of PEDOT:PSS and polyethylene oxide (PEO) that induce a cross-linking reaction in each electrode, we easily coated conductive ink on flexible substrates and adjusted the properties of two different types of electrodes: 1) those that respond sensitively to pressure (sponge) and 2) those that maintain stable electrical conductivity even during stretching (textile). Through this, the sponge electrode can keep the gel from drying out for a long time and drastically increase the contact area with the skin via its internal pores, achieving low contact impedance for collecting electrophysiological signals. Simultaneously, it can measure changes in resistance and capacitance in response to pressure, allowing the integration of bulky TOCO and EMG electrodes into a single small electrode that can capture both signals.

Consequently, this system demonstrates lower contact impedance 4.41×10^4 Ω cm^2, and an improved signal to noise ratio (SNR) up to 26.23 dB during electrophysiological signal collecting compared to flat textile electrode. In addition, it successfully collected wrist pulse signals, which are much weaker compared to uterine contraction signals. Finally, this electrode system was verified for maternal health monitoring capability through a clinical patient study. We strongly believe that this sponge electrode system can reliably monitor the health of pregnant women in everyday life.

2:30 PM SB10.04.04

Investigation on the Effect of Fabric Properties on the Performance of PEDOT-Based Textile Actuators *Louise Anne A. Furie, Shayan Mehraeen, Jose G. Martinez and Edwin Jager; Linköping University, Sweden*

Smart textile actuators have garnered increasing attention owing to their versatile applications in soft robotics and wearable electronics. These actuators exhibit the capability to undergo controllable and reversible deformation in response to external stimuli such as temperature variations or electric potential. The latest evolution in smart textiles involves the integration of smart yarn- and fiber-actuators, as well as the incorporation of smart materials onto textile substrates. The underlying mechanics of the textile substrate play a significant role in determining the overall performance of these actuators, offering opportunities to achieve intricate actuation modes effectively.

Moreover, the utilization of additive manufacturing techniques presents a promising avenue for the fabrication of these devices, enabling rapid customization and optimization of both active and passive material patterns to amplify their functionality. In this investigation, multi-layered poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) actuators were 3D printed on different textile fabrics using syringe-based extrusion, with the aim of investigating how different weave and knit patterns influenced bending actuation performance. Additionally, intricate patterns of passive materials were incorporated through printing methods, leveraging distributed compliance to program the movement capabilities of the actuators. This work sheds light on the interplay between textile substrate design, material composition, and fabrication techniques in enhancing the performance and functionality of smart textile actuators.

2:45 PM SB10.04.05

Mechanically Gradient and Electrically Conductive Structures for Soft-to-Hard Interface in E-Textiles and Other Soft Electronics *Akanksha Pragya; North Carolina State University, United States*

Mechanically gradient materials are a special class of advanced materials where the mechanical properties (most often, stiffness) gradually increase or decrease along one or more dimension(s). This allows for a more gradual transition between soft and hard phases as compared to an abrupt interface. Under an external deforming load, the spatial stiffness gradient enables the gradient to transfer loads between the two mechanically mismatched phases progressively. This maintains a local continuity in the materials' response to applied stress through the system. On the contrary, in the absence of a gradient, a sharp junction is formed at the interface of soft and hard phases. This leads to an abrupt change (or discontinuity) in the materials' response to the applied load across the soft-to-hard interface, leading to detrimental effects such as delamination, rupture, or cracking in the system. The concept of gradient is relevant in systems where mechanically mismatched materials form an interface. Some of the examples include soft robotics, electronic textiles, limb prosthetics, etc.

When it comes to soft and flexible electronic devices like wearable e-textiles and soft robotics, commercial viability requires a robust integration of soft (textile, polymer, or biological tissues) and traditional semiconductor-based hard components. Among many other issues caused by this integration, managing the interconnection between hard and soft components poses one of the most significant challenges. Here, the mismatch in the materials' response to bending, stretching, twisting, etc. soft-to-hard interface during use may cause the system to fail. Even though several soft and stretchable electronic devices (such as textiles- and polymer-based transistors, batteries, sensors, etc.) have been shown to survive clothing-like handling and laundering, they have little commercial success. Thus, the silicon-based electronic components of electronic devices remain an indispensable part of soft electronics because of their superior electrical performance. Consequently, the significant challenges in integrating hard electronics into soft substrates and devices continue to exist. A potential solution to this issue involves the development of a structure having spatially varying mechanical properties while simultaneously possessing uniform electrical conductivity.

In the present work, stiffness gradient structures prepared from elastomer-carbon nanoparticles composite are presented. Unlike conventional composites in which the number of nanoparticles dictates the mechanical properties and vice-versa, a novel composite has been proposed in this work. The mechanical and electrical properties in these novel composites have been decoupled i.e., the changing spatial stiffness will not change the corresponding electrical conductivity, and vice-versa. This decoupling has been achieved by in-situ foaming of the composites. Foaming (or foaming agent) causes (1) re-orientation of conductive carbon particles which improves or maintains electrical conductivity and (2) arrests local polymer chain mobility to impart stiffness. By carefully controlling the spatial foaming intensity longitudinally along the composite, stiffness can be gradually increased while bearing minimum impact on the electrical conductivity. The initial prototype extruded on a lab-made setup is *in a filament form and is capable of accommodating ~10X stiffness mismatch. However, this can be extended to accommodate up to 20-30X mismatch. The gradient capacity can be improved further by switching to a multi-polymer system in contrast to the single-polymer system currently. The presented work represents a potential avenue of research to strengthen soft-to-hard interface from a fundamental materials standpoint. The electro-mechanical decoupling in a conductive gradient composite holds promise to impart unprecedented durability to e-textiles and other soft electronics.*

***Advanced 3D Fibrous Biosensing System** Ahyeon Koh; Binghamton University, The State University of New York, United States*

Our research focuses on advanced fibrous bioelectronics, a novel field with enormous potential for biomedical sensor development. These bioelectronics, capable of biointegration for in situ quantitative analytical analysis, are a significant leap in improving the biocompatibility of the device's mechanical and physicochemical properties. The fibrous 3D nonwoven biosensors, for instance, enhance breathability and allow mass transfer, thereby improving the long-term reliability of sensor performance. Our research has led us to investigate silicone nanofibrous bioelectronics, stretchable paper-based electronics, nanofiber reinforced hydrophilic elastomeric biosensors, liquid-metal embedded electrospun fibers, and stretchable gold nanofibers for biosensing. Each sensing system was developed using a sustainable engineering solution, demonstrating the rigor of soft bioelectronic prototyping. These innovative approaches have far-reaching implications for biomedical and mobile health applications.

4:00 PM SB10.04.07
***3D Printed Electronic Skin for Strain, Pressure and Temperature Sensing** Akhilesh K. Gaharwar; Texas A&M University, United States*

Electronic skin (E-skin) that can mimic the flexibility and stretchability of human skin with sensing capabilities, holds transformative potential in robotics, wearable technology, and healthcare. However, developing E-skin poses significant challenges such as creating durable materials with skin-like flexibility, integrating biosensing abilities, and using advanced fabrication techniques for wearable or implantable applications. To overcome these hurdles, we have fabricated a 3D-printed electronic skin utilizing a novel class of nanoengineered hydrogels with tunable electronic and thermal biosensing capabilities. Our methodology takes advantage of shear-thinning behavior in hydrogel precursors, allowing us to construct intricate 2D and 3D electronic structures. We simulate the elasticity of skin using triple crosslinking in a robust fungal exopolysaccharide, pullulan, while defect-rich 2D molybdenum disulfide (MoS_2) nanoassemblies ensure high electrical conductivity. The addition of polydopamine nanoparticles enhances adhesion to wet tissue. The hydrogel exhibits outstanding flexibility, stretchability, adhesion, mouldability, and electrical conductivity. A distinctive feature of this technology is the precise detection of dynamic changes in strain, pressure, and temperature. As a human motion tracker, phonatory-recognition platform, flexible touchpad, and thermometer, this technology represents a breakthrough in flexible wearable skins and holds transformative potential for the future of robotics and human-machine interfaces.

4:15 PM SB10.04.08
***Stretchable Electronic Skin for Tactile Action Recognitions Assisted by Machine Learning** Yanpeng Li[1], Guren Matsumura[2], Yan Xuan[1], Satoko Honda[2] and Kuniharu Takei[1]; [1]Hokkaido University, Japan; [2]Osaka Metropolitan University, Japan*

Monitoring tactile pressure and action recognition are important functions of electronic skin (e-skin). To detect pressure distribution by attaching e-skin over three-dimensional objects conformably, e-skins need to be stretchable while maintaining output stability. To address this challenge, we develop a resistive-type tactile pressure sensor using laser-induced graphene (LIG) and liquid metal (GaInSn) patterned on a stretchable ecoflex film. To imitate a simple robotic sphere hand, a balloon structure integrated with a tactile pressure sensor array is demonstrated, allowing that the sensor can also be characterized as a function of stretching conditions by changing air pressure. Finally, echo state network (ESN), which is a reservoir computing framework, is applied for action recognition based on continuous tactile pressure changes and distribution results.

The fabrication process is briefly explained. First, ecoflex solution was poured onto a mold to make liquid metal channel patterns embedded in the ecoflex film and cured in an environmental oven at 90 °C. Laser-induced graphene (LIG) was formed on a PI film via CO_2 *laser exposure. Ecoflex solution was then poured over the LIG/PI film, followed by LIG transfer to the ecoflex film after curing it for 15 min in the oven at 90 °C. These two ecoflex films were bonded using ecoflex solution as glue. After lamination, GaInSn liquid metal was injected into the channels to form the electrodes. Finally, the injection ports were sealed with ecoflex solution to complete sensor fabrication.*

The real-time pressure sensor output and hysteresis show that the sensor has relatively stable operation during the application and release of pressure. The electrical resistance behaviors by applying pressure up to 140 kPa have two trends for low and high pressures. At pressures less than 80 kPa, the sensor sensitivity was 2.73 %/kPa, while the sensitivity was 10.49 % /kPa in the range of 80 ~ 140 kPa. This sensitivity difference is most likely caused by the structural deformation differences, which is confirmed by photos during applying pressure. For the stability test, cycle test was conducted by applying 4.3 kPa up to 10,000 cycles over 12 hours, and the results showed constant outputs, suggesting that this sensor has highly stable function. Since it was designed to be a stretchable e-skin, it was verified that the sensor could be stretched more than 200 % without electrical disconnection. The stabilities of the sensor against stimuli of partial surface damage, temperature change, humidity change, and pH change were also confirmed. After confirming stable operation as a stretchable tactile pressure sensor, a balloon-type 4×4 tactile pressure sensor array was fabricated to control the degree of expansion of the e-skin by injecting air. As a proof-of-concept, three actions of patting, sliding, and grabbing were performed with/without an air injection volume of 80 mL of the e-skin. By optimizing ESN algorithm, tactile pressure distribution and action recognition were successfully realized with average accuracy of >85 % regardless of stretching conditions.

In summary, a stretchable e-skin with good durability was demonstrated by optimizing and designing the structure and materials. In the future, as a practical application of electronic skin, it is expected to reduce the cost of device fabrication by optimizing the design and applying it to human-computer interaction by developing machine learning algorithms.

4:30 PM SB10.04.09

Translating Tattoo Electrodes in Biorobotics *Laura M. Ferrari[1,2], Marina Galliani[1], Michele Foggetti[1], Lorenzo Amati[1], Simona Crea[1] and Francesco Greco[1,1,3]; [1]Scuola Superiore Sant'Anna, Italy; [2]INRIA, France; [3]Graz University of Technology, Austria*

Tattoo electrodes are made by printing PEDOT:PSS onto commercially available temporary tattoo paper. The result is an ultra-thin and conformable dry electrode that can record high-quality surface electrophysiological signals. Tattoo electrodes have been compared with standard Ag/AgCl electrodes in many applications, for biomonitoring, and their internal structure and signal transmission mechanism have been fully detailed. [1]

We have started translating tattoo technology into real-life applications, showing their use in biomonitoring.

We have interfaced tattoos with multiple wearable devices [2], and we have used a learning approach (an autoencoder trained for one-class classification) on EEG tattoo data to identify the optimal wearable setup for

alpha wave detection. [3]
Now we are moving a step further in translating this technology into biorobotics applications.
We have applied tattoo electrodes under lower and upper-limb exoskeletons. The lower-limb exoskeleton used in this study is a robot that transfers assistive torques during hip flexion and extension through a human-robot interface (HRI) at the thigh level [4]. Whereas the upper-limb exoskeleton uses arm cuffs to transfer assistive torque to the user to help the shoulder flexion and extension [5]. Tattoos have been developed as bipolar electrodes and their interconnections have been optimized to reach the robot via a Serial Peripheral Interface (SPI) allowing synchronous and full-duplex data transmission. Thanks to the ultrathin and conformable nature of tattoos, EMG signals have been acquired in direct contact with the HRI, where the electrodes are subjected to high mechanical stress. Such an approach opens novel control algorithms that, by leveraging the information coming from muscles, can be adapted for locomotion recognition and generation of torque profiles. This allows for real-time, adaptive responses of exoskeletons and personalized assistance, crucial in rehabilitation, industrial tasks, and assistive devices. We have developed tattoo high-density electromyography (HD-EMG) matrices to study manipulation. The interconnections have been improved to enable a stable and reliable link with wearable electronics, guaranteeing high signal quality. Conformable HD-EMG matrices ensure a drastic reduction of movement artifacts, typical of other dry interfaces, and permit the reaching of complex anatomical regions. Thanks to these latest developments we investigate novel application scenarios of HD-EMG in free-moving humans for the understanding of finger movements and forces, related to manipulation.

Sweat-Enhanced Biocomposite Electrodes for Dynamic Skin Electrophysiology *Huarun Liang, Mengjia Zhu and Yingying Zhang; Tsinghua University, China*

Electrophysiological monitoring is essential in healthcare and life science research, yet conventional Ag/AgCl gel or dry electrodes face challenges such as interfacial instability and susceptibility to sweat and motion artifacts. Herein, we propose a sweat-enhanced electrode design with a double-network hydrogel, comprising Ca^{2+}-modified silk fibroin (SF) and poly(acrylic acid) grafted with N-hydroxysuccinimide ester (PAA-NHS). The obtained biocomposite SF-PAA-NHS (BioSP) forms robust skin adhesion through strong covalent crosslinking by NHS esters, along with other intermolecular forces at the BioSP/skin interface, leading to an interfacial toughness of 411 $J\ m^{-2}$. In the presence of sweat, SF enhances adhesion by increasing molecular chain mobility and facilitating mechanical interlock with the skin microstructure, resulting in a nearly 23% increase in interfacial toughness. Additionally, sweat electrolytes enhance the ionic conductivity of BioSP by about 45%, further improving its suitability for electrophysiological monitoring. Moreover, BioSP can be combined with elastomers to create electrodes with excellent anti-drying capability. Finally, high-fidelity and long-duration electrophysiological measurements validate the superior performance of the sweat-enhanced electrode during daily activities, such as exercise and perspiration. This work represents a significant step forward in skin electrode technology, promising improved reliability, longevity, and durability in electrophysiological monitoring systems, even on dynamic and sweaty tissue.

High-Accuracy Gesture Classification Using Biocompatible, Low Impedance Dry Electrodes *Ana Claudia Arias; University of California, Berkeley, United States*

Epidermal electronics match the mechanical properties of human skin, enhancing the coupling between electronics and biological tissues. Flexible functional materials and additive fabrication methods are used in developing dry electrodes for skin applications to enhance wearable devices for monitoring muscle activity and electrophysiological signals. Maintaining a consistently low impedance electrode-skin interface is crucial. Traditional wet electrodes use hydrogels and skin abrasion, which are impractical for self-administration and in-home care. These devices utilize machine-learning models for gesture classification and other monitoring tasks, achieving high accuracy with adaptive learning capabilities. A wearable surface electromyography (sEMG) biosensing system based on a screen-printed conformal electrode array implements a neuro-inspired hyperdimensional computing algorithm for real-time gesture classification and model training, achieving 97.12% accuracy for 13 hand gestures and 92.87% for 21 gestures, with adaptive updates enhancing performance under variable conditions. Using electroless copper and gold plating with 3D printing, biocompatible, low impedance dry electrodes that do not require hydrogels were demonstrated. These electrodes, tested alongside clinical-standard devices, show an average electrode-skin impedance of 66.7 kΩ at 50 Hz, comparable to wet electrodes. Strategies that use blown aerosol chemical vapor deposition to produce free-standing, conformal carbon nanotube (CNT) dry films will also be discussed.

9:00 AM SB10.05.02
Skin-Inspired All-Natural Biogel for Bioadhesive Interface *Lingyi Lan and Yibin Ying; Zhejiang University, China*

Natural material-based hydrogels are considered ideal candidates for constructing robust bio-interfaces due to their environmentally sustainable nature and biocompatibility. However, these hydrogels often encounter limitations such as weak mechanical strength, low water resistance, and poor ionic conductivity. Here, inspired by the role of natural moisturizing factor (NMF) in skin, we propose a straightforward yet versatile strategy for fabricating all-natural ionic biogels that exhibit high resilience, ionic conductivity, resistance to dehydration, and complete degradability, without necessitating any chemical modification. A well-balanced combination of gelatin and sodium pyrrolidone carboxylic acid (an NMF compound) gives rise to a significant enhancement in the mechanical strength, ionic conductivity, and water retention capacity of the biogel compared to pure gelatin hydrogel. The biogel manifests temperature-controlled reversible fluid-gel transition properties attributed to the triple-helix junctions of gelatin, which enables in situ gelation on diverse substrates, thereby ensuring conformal contact and dynamic compliance with curved surfaces. Due to its salutary properties, the biogel can serve as an effective and biocompatible interface for high-quality and long-term electrophysiological signal recording. These findings provide a general and scalable approach for designing natural material-based hydrogels with tailored functionalities to meet diverse application needs.

9:15 AM SB10.05.03

Ultrathin, Breathable and Self-Powered Electronic Tattoos with Graphene and Silk-Reinforced Cellulose Nanofibers for On-Skin Electronics *Shalik R. Joshi[1], Minjoo Lee[1], Hyun Young Lee[1], Mi-Eun Lee[2] and Sunghwan Kim[1,1]; [1]Hanyang University, Korea (the Republic of); [2]BJ Silk, Korea (the Republic of)*

Electronic skins and electronic tattoos (E-tattoos) represent notable advancements in wearable technology, offering benefits in healthcare monitoring, energy harvesting, human-machine interfaces, and artificial intelligence prostheses. These devices emulate human skin functionalities, enabling real-time, noninvasive detection of environmental stimuli like temperature, pressure, and vibrations. E-tattoos, particularly, are ultrathin, lightweight, and skin-adhesive, allowing seamless integration with human skin, making them valuable in clinical diagnostics, therapeutic applications, and real-time monitoring of physiological signals. Despite advancements, challenges remain in integrating these technologies with human skin while maintaining high sensitivity in sensing and minimal invasiveness.

To fabricate E-tattoos, synthetic polymers like poly(dimethyl siloxane), polyimide, and poly(ethylene terephthalate) are commonly used. However, these polymers lack biocompatibility and biodegradability. Conductive materials are often blended into these polymers to maintain skin adhesion and signal monitoring capabilities. Yet, the insulating nature of most polymers reduces overall conductivity, necessitating thick electrodes that compromise breathability, leading to sweat accumulation and potential skin issues. Addressing these limitations requires resilient, adaptable E-tattoos with multifunctionalities. Hybrid and nanostructured biomaterial composites can be viable solutions.

The present study reports an imperceptibly operable, skin-compatible, multifunctional E-tattoo based on a composite of silk sericin (SS), cellulose nanofiber (CNF), and graphene. CNFs provide mechanical stability, flexibility, biocompatibility, and porosity, while SS offers strong adhesion and skin compatibility. The hybrid biomaterial-based tattoo is ultrathin, lightweight, highly porous, and displays exceptional adherence to skin, mechanical robustness, and skin compatibility. Graphene provides favorable electrical and thermal properties, resulting in high electrical conductivity of ~0.16 S/cm, stable under various mechanical deformations. The E-tattoo also features high water-vapor transmission and no skin irritation. It facilitates temperature sensing and can function as a skin heat patch which can be activated by electrical and optical signals. The temperature can increase by more than 20 °C at a bias voltage of 3 V as well as under light-emitting diode (LED) illumination with a power density of ~34.5 mW/cm^2. Due to the tribopositive nature of cellulose, the E-tattoo generates a high open-circuit voltage (V_{oc}) of ~320 ± 20 V and a power density of ~7.2 mW/cm^2, sufficient to glow multi-LEDs, demonstrating its potential in self-powered sensory systems for Morse code transmission and real-time monitoring of body movements. Overall, the study presents a novel E-tattoo platform with potential applications in healthcare and secure communications, demonstrating significant advancements in wearable bioelectronics.

9:30 AM SB10.05.04

Transfer Printing Technology on 3D Curvilinear Surfaces Using Shape Deformable PVA-Based Stamp for e-Skins *Hyeon Ji Yang, Jun Hee Lee and Yei Hwan Jung; Hanyang University, Korea (the Republic of)*

Stretchable and flexible electronics have attractive applications in wearable devices by transforming rigid configurations into ultrathin, skin-like forms that wrap around the skin. Conventional planar elastomer stamp-based transfer printing techniques face significant challenges in printing onto complex curved surfaces, particularly in regions with small radii of curvature, such as the fingertips or the narrow spaces between fingers, while maintain conformal lamination. Here, we demonstrate a fabrication method for conformal printing on sophisticated three-dimensional(3D) curvilinear surfaces using shape deformable polyvinyl alcohol(PVA)-based *transfer printing. The proposed stamp enables the transfer of a pattern array from a negative surface to a positive surface by minimizing stress and conforming its shape to the receiver substrate, thereby ensuring conformal contact with the pattern array. Shape deformable stamp printing, which exhibits good adhesion and ease of deformation, provides significant advantages for printing on curvilinear surfaces and enables the creation of electronic skin(e-skin) by printing on low modulus substrates, such as skin. To illustrate the capabilities of this approach, we demonstrate the transfer onto highly contoured regions, such as the ear, fingerprints and skin wrinkles. This research presents potential application for 3D electronics, including innovative uses like skin displays with mini-LEDs and contact lenses integrated with antennas. Furthermore, the concept of electronic skin emerges as a prominent feature within our proposed applications. This study highlights the potential impact of this research on the future landscape of wearable electronic technology.*

9:45 AM SB10.05.05

Thin and Small Pressure Sensors Based on Ion-Infiltrating Piezo Capacitive (i-PIC) Film for Monolithic E-Skin Integration *Sehwan Park[1], Haechang Lee[2], Seonjeong Lee[3], Seunghyup Yoo[3] and Hanul Moon[1]; [1]Dong-A University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Flexible pressure sensors are essential elements for realizing artificial electronic skin, human-machine interfaces, and smart healthcare. The major development goal of the flexible pressure sensors has been improving sensitivity, and that was mostly achieved by introducing microstructures in a pressure-sensing film that can involve a large deformation when pressed. The strategy was successful, especially when it collaborated with an ionic gel film having a huge capacitance density of over 1 μF, and a capacitance change with pressure reached over 1000 times. Despite the success in sensitivity, the microstructures in the pressure-sensing film implied serious drawbacks in the flexible pressure sensors in terms of system integrity and scaling-down. The fabrication processes of the conventional sensing film and the sensor involved a molding process to make the microstructures and a laminating process for "bottom electrode/ sensing film/ top electrode" structure, thus it was very hard to secure reproducibility and collaborate with conventional processes of semiconductor devices or circuits. The scaling-down of the sensor was limited as well due to the feature size of the microstructure and the laminating processes, while a smaller pressure sensor is beneficial for many E-skin applications. These are significant drawbacks for flexible pressure sensors to be integrated into an E-skin system. To overcome these limitations, a high-performance flexible pressure sensor through monolithic stacking and micro-patterning processes, which are compatible with conventional fabrication processes, is needed, ensuring not only the integrity of a single sensor but also scaling-down and integration into a system for future applications.

In this study, we propose a new piezo-capacitive pressure-sensitive mechanism of a gradual electrical double layer (EDL) modulation based on an ion infiltrating piezo-capacitive (i-PIC) film, in which a very small amount of ionic liquid is included in a polymer network. The i-PIC film shows very small capacitance of about 100 pF/cm^2 that is of a neat polymer film without pressure due to the very small ion concentration. Its capacitance substantially increases with pressure near 1μF/cm^2, because the pressure causes thickness reduction and it causes a relative increase of the ion concentration and finally the gradual generation of EDL in the film. The i-PIC film with an optimal ion concentration of 0.2 mg/mg in the polymer film exhibited a high sensitivity of 3.94 kPa^{-1} over a wide pressure range of up to 1 MPa with a very high linearity of 0.999. Additionally, due to the absence of surface texturing, it showed excellent mechanical durability with identical characteristics for over 10,000 repeated pressure and release cycles for pressures of up to 1 MPa. The i-PIC film shows excellent properties with a thickness of below 10 μm and is fabricated by one-step spin-coating directly onto a bottom electrode without any molding or laminating processes, thus is compatible with monolithic fabrication processes. The i-PIC film involves very small pores of a few μm, thus the almost identical performance and high uniformity of the flexible pressure sensor was maintained for a scaling-down below 100 μm, and this small size is enough to mimic the detection *resolution of human skins that is about 50 ppi.*

Seeing Bodily Fluid Flow—Wearable Fluid Flow Sensing for Health Diagnostics *Richard C. Webb, Adam Zysk and Anna Lisa Somera; Rhaeos, Inc., United States*

The human body is comprised of a network of fluid flow systems such as those containing blood, lymph, urinary and cerebrospinal fluids (CSF). Many disease states induce shifts in fluid dynamics of one or more of these systems on a localized or system level. While various tools exist for monitoring specific physiological fluid flows, they commonly suffer from a combination of being motion sensitive, not portable, require tethering patients, and/or high cost. Further, fluids such as CSF generally lack substantial scattering centers or chromophores making them more difficult to measure via traditional optical or acoustic mechanisms. This talk will present commercial healthcare applications of wireless, noninvasive, wearable sensor systems based on spatial monitoring of thermal transport properties which are largely independent of fluid composition within physiological regimes. A recent 9-center clinical trial of 122 subjects demonstrates the viability of this thermal flow technique - deployed as FlowSense®, an FDA designated Breakthrough Technology - to noninvasively monitor CSF flow through implanted ventriculoperitoneal shunts used to treat the neurological condition hydrocephalus. Additional examples demonstrate use in remote, continuous monitoring formats, as well as designs directed towards monitoring hemodynamics, all in wireless noninvasive formats.

11:00 AM SB10.05.07
A Wearable Closed-Loop Haptic System Based on Ultra Light-Weight Textiles *Jin Hee Hwang, Sun Hong Kim and Yei Hwan Jung; Hanyang University, Korea (the Republic of)*

Advancements in haptic technology, such as electrical tactile stimulators, have opened up the possibility of not only reproducing artificial sounds for the ears but also delivering realistic tactile sensations to the skin. However, previously reported tactile feedback devices face several challenges due to the use of heavy and bulky actuators. These devices are often large, rigid, non-breathable, and encased in weighty packaging materials, resulting in discomfort and unstable sensations during prolonged wear. These issues hinder the integration of haptic systems over large areas of the body. To address these problems, we propose a new electrical haptic rendering system integrated with textiles, which offers higher resolution and faster response times while remaining lightweight and comfortable for the user. Inspired by everyday clothing, this system utilizes stretchy PU textiles to simulate a variety of tactile sensations, including touch, tickling, vibration, and rough textures. Garments covering significant portions of the body can provide consistent sensory feedback over the entire area and detect pressure across different body parts. This enables appropriate stimulus adjustments through a closed-loop control mechanism. This functionality not only holds potential for high-level medical services and data collection but also offers significant commercial value through the design of user-friendly wearable interfaces. This paper reports on an advanced wearable haptic system that provides enhanced user comfort, high resolution, and the ability to cover extensive areas of the body—features not found in previous studies.

11:15 AM SB10.05.08
Flexible Wearable for Addressing Health Disparities *Maral Mousavi, Farbod Amirghasemi, Abdulrahman Al-Shami, Melissa Banks and Mona Abdelmonem; University of Southern California, United States*

This work develops new electrochemical wearable sensors and systems. We developed these sensors from laser-

induced carbon. Laser-induced graphene (LIG) has become a focal point of recent research due to its promising applications in sensing devices. This material is produced by exposing carbon-rich polymers, especially polyimide, to a laser beam. The laser irradiation induces localized photothermal reactions, transforming SP3 carbon atom hybridization into a three-dimensional, graphitic-like structure. This method, which is maskless, scalable, straightforward, reproducible, cost-effective, and rapid, generates high-quality graphene layers. These layers possess remarkable flexibility, electrical conductivity, and electrocatalytic properties, offering advantages over traditional methods such as wet chemistry, ink-jet printing, and chemical vapor deposition, which are often more complex, time-consuming, and costly. In this work, we investigate the surface modification and properties of graphene to achieve a stable interfacial potential with a lipophilic sensing membrane in a potentiometric readout mode. We specifically examine how the material's surface topography and hydrophilicity affect the long-term and short-term properties of wearable sensors and explore use of redox mediators to address the sensor calibration drifts. Robust sensors are achieved through this engineering of the LIG surface. We demonstrate application of these sensors for development of wearable sensors tailored to address unmet needs in women's health.

***Cut-Pile Textiles as Transformative Substrates for Wearable Electronics** Tricia B. Carmichael, Fatemeh Motaghedi, Hannah Jessop, Yunyun Wu and Sara Mechael; University of Windsor, Canada*

Clothing is ubiquitous in daily life, making textiles an ideal platform for the next generation of wearable electronics. New electronic textiles (e-textiles) will incorporate sensors to detect biometric data, light-emitting devices to display data, and integrated wiring and power sources. The fabrication of these e-textiles requires the integration of functional materials into the textile, while maintaining wearability, softness, and stretchability. Our approach has relied on solution-based electroless metallization to fabricate conductive textiles, in which aqueous plating solutions can permeate into the textile structures to deposit conformal, uniform metallic coatings on the surfaces of individual fibers that comprise the yarns, preserving the mechanical properties of the fabric.
In this presentation, we focus on incorporating textile structures into the device design. In this textile-centric design paradigm, textiles play an integral role in the operation of e-textile devices rather than acting merely as passive device carriers. Specifically, we discuss the use of cut-pile fabrics in wearable pressure sensors and energy storage devices. Cut-pile fabrics consist of a knitted framework with cut yarn (piles) looped through at regular intervals. We present the use of solution-based metal deposition to selectively metallize the framework of this fabric structure to fabricate textile-based electrodes. We show the use of these electrodes in energy storage devices in which selectively coating the cut-pile fibers with electroactive materials forms the basis for an architectural engineering approach that isolates the brittle materials from strain. We furthermore demonstrate the use of uncoated cut piles as the dielectric medium for textile-based capacitive pressure sensors. The cut piles provide a structure that effectively traps air, which is integral to the sensor's functionality and performance, enhancing sensitivity, flexibility, breathability, mechanical response, and comfort.

2:00 PM SB10.06.02
***Nanostructured Honeycomb Film Architectures for Stretchable Opto-electronics** Antonio Facchetti; Georgia*

Institute of Technology, United States

In this presentation we report the fabrication of semiconducting and insulating nanostructured honeycomb films using the breath figure method technique and their use for demonstrating highly stretchable opto-electronic devices. This technique consists of spin-coating a polymer solution in a high relative humidity (>90%) atmosphere resulting in formation of cavities within the polymer film with controlled distribution, height and size. Thus, semiconductor films can be integrated into organic thin-film transistors for gas detection and organic electrochemical transistors for bio-electronic applications. Particularly, we demonstrate electrochemical transistors with excellent performance and strain-insensitive current-voltage characteristics up to ~ 90% strain and laminable on the skin and plants. Finally, we report the use of insulating polymers for fabricating stretchable photovoltaic devices.

2:15 PM SB10.06.03

Multi-Detection Electronic Brush *Haruki Nakamura[1], Satoko Honda[2], Guren Matsumura[2], Kohei Nakajima[3] and Kuniharu Takei[1]; [1]Hokkaido University, Japan; [2]Osaka Metropolitan University, Japan; [3]The University of Tokyo, Japan*

With the development of the Internet of Things (IoT) society, demand for a variety of sensors is increasing to collect many datasets for data analyses. Among them, whiskers or brush-type sensors have possibilities to contribute to the application of industry and robotics. Brush-type sensors can be used to detect the surface morphology and target shape by contacting the object like animal whiskers, which should be useful for the robotic applications. However, the sensor that can measure such whisker/brush movement has yet to be fully developed. Although some electronic whisker (e-whisker) concepts have been reported previously, a lot of challenges to detect the movement of whiskers/brushes still remain such as multi-detections including movement amplitude, speed, and directions etc. To overcome these challenges, this study proposed out-of-plane e-brush combined with 4 resistive tactile pressure sensors and machine learning system. E-brush is designed to collect multiple datasets precisely from the target. Due to movement of e-brush, tactile pressure sensors show different outputs that allow to distinguish bending amplitude, moving direction, and moving speed simultaneously. Furthermore, reservoir computing (RC), which is one of the recurrent neural networks, was introduced to make real-time data analyses, and it enables to classify 3 brush motion state (stop, move, and slip) and surface condition of contacting object. First, fundamental characteristics of the sensor were conducted. The brush on the tactile pressure sensor was moved from left to right with applied force from top, repeatedly. During the movement, resistance changes of 4 sensors were simultaneously measured. The tactile pressure sensors can measure a relatively wide range of pressure from 20 Pa to 5.5 kPa. The sensitivity is ~0.33 %/Pa from 0 to 190 Pa and ~0.002 %/Pa from 190 Pa to 5.5 kPa. Due to wide dynamic range and high sensitivity especially at low pressure range, integrated 4 tactile pressure sensors clearly show the output difference by changing the movement velocity (0~90 mm/s), bending distance (-7.5 ~ 7.5 mm), and directions (8 directions). In addition, applying force from top, states of brush movement and surface conditions of contacting object were detected by observing small change of sensor outputs. These results suggest that this platform can measure detail bending information like animal whiskers.
To abstract a lot of information from sensor signals, real-time and quick data analysis system using RC was adapted. By optimizing the RC algorithm, bending distance (-7.5~7.5 mm from the initial position), movement velocity (0~90 mm/s) and force from top (0~1.5 N) were successfully predicted with normalized mean absolute error <0.12 for bending amplitude, <0.20 for velocity, and <0.24 for force. This system also classified movement direction (8 directions), brush motion state (stop, move, and slip), and surface condition (acrylic plate with/without rough sticky tape) with accuracy of ~99 % for direction, ~86 % for motion states, and ~ 98 % for surface conditions. Importantly, this system allows to detect slip conditions of brush structure, continuous movements of brush can be tracked. By integrating all functionalities, as a proof-of-concept, handwriting and its conditions during writing

using this brush could be digitized successfully.
In summary, this study demonstrated the e-brush system using integrated tactile pressure sensor and reservoir computing. By optimizing the sensor design and data processing algorithm, the e-brush can detect a variety of datasets, which can be potentially used for the robotic applications.

In Air Actuating Textiles and Versatile Integration—Textiles in Actuation, Actuators in Textiles *Nils-Krister Persson[1,2,2]; [1]Smart Textiles, Sweden; [2]Swedish School of Textiles, Sweden*

Soft materials are by definition showing modulus matching with biological tissue. The by far most used technical soft material is textile with a large number of parameter overlap between these abiotic and the biotic materials. Thus, textile is potentially an interesting realm for soft electronics, including actuation.

We discuss a number of fundamental characteristics of textiles that are of relevance for actuation. Textile fabric making and other textile processes are inherently an additive manufacturing technology built upon the defining building blocks of any textiles, which are yarns.

We show how different functionalization of individual yarns facilitates the creation of complex patterns in both parallel and serial arrangement and how textile processes such as weaving can be adopted to actuating yarns, that behaves differently compared to standard yarns. This, in turn, enables making actuating devices directly in the loom. Except for minimizing post-processing and enable efficient production of actuators, this also opens up an interesting route for creating metamaterials.

Textiles, being polymer-based are shown compatible with the actuation mechanism given by electroactive polymers. By this the vision of all-polymeric-devices can be given support. We show how polymerbased in-air actuating yarns can be manufactured and how textile assembly strategies can amplify forces. By employing textile processes for actuation and introducing actuation for textile community, a novel scientific, technological and industrial field emerge.

4:00 PM SB10.06.05
Multi-Variate Bio Wearable Sensor Patch for Glucose, Lactate, pH and Temperature Sensing Using Human Sweat *Yuchen Shao, Paul Lavryshyn, Michelle Livojevic, Anoushka Ganguli, Lixin Zhang and Manisha Gupta; University of Alberta, Canada*

Wearable biosensors are gaining importance as they can now be more reliably used for detection of several biomarkers. Human sweat, which can be used non-invasively, has been shown to be rich in biomarkers with values in sweat showing a good correlation to the blood [1,2]. Glucose, lactate, pH and temperature are some of the important biomarkers which can indicate a lot about the individual's health. This type of multi-variate bio wearable has applications in athletes, diabetic patients and for monitoring other health conditions.

*Here, we present an integrated design for a bio wearable patch with glucose, lactate, pH and temperature detection. All the sensors are integrated in an area of 3cm*4cm on a 1mil Kapton patch which is integrated with a ZIF connector to the readout circuit. For the glucose and lactate sensors, we have utilized organic electrochemical transistors (OECTs) due their high transconductance and being able to work in aqueous environment. pH and temperature sensor were developed as resistive sensors using carbon nanotubes as the sensing element. The* *temperature sensor was developed using CNT with thermoplastic to develop a nanocomposite. The pH sensor was developed utilizing functionalized CNTs. All the sensors were printed using Optomec Aerosol Jet 5X printer with gold, Au, as the electrode material and platinum as the gate for the OECT devices. PEDOT:PSS was used as the channel material for the OECT and polyimide layer was used as the insulator layer to prevent the shorting in presence of aqueous media. Glucose oxidase (GOx) and lactate oxidase (LOx) were used for functionalizing the OECT gate for detection of glucose and lactate, respectively. Gelatin was dropped casted on glucose, lactate and pH sensors for increasing stability and repeatability of the device while temperature sensor was encapsulated with another piece of Kapton to prevent direct contamination with the skin. The optimized glucose sensor has a linear detection range between 1.3mM-50mM with a sensitivity of 0.317 NR/dec and the limit of detection (LoD) is 1uM. The lactate sensor demonstrated three linear ranges 0.1-1mM, 1-10mM and 10-50mM with a sensitivity of 87.5uA/mM, 8uA/mM and 0.72uA/mM. A sensitivity of 114 ohm/°C was extracted from the temperature sensor between 20°C and 60°C, while the pH sensor can detect a pH variation from 4 to 7 with a sensitivity of 439 ohm/pH and 7 to 10 with a sensitivity of 155 ohm/pH. All the detection ranges are sufficient for detection of these variables in human sweat (0.06-0.2mM, 16-30mM, 35.5-37.7°C, 4.5-7 for sweat glucose concentration, lactate concentration, temperature and pH, respectively [2-5]. The patch can be worn continuously for a several hours for continuous data which is transmitted via BLE or WIFI to a computer. Testing results from this integrated bio wearable patch will be presented.*

Engineering the Skin-Device Interface for Efficient Skin-Mounted Thermoelectric Generators *Francisco Molina-Lopez; KU Leuven, Belgium*

The recent advancements in skin electronics have led to complex devices capable of sensing, actuating, computing, and communication. Such an increase in functionality comes with a higher demand for power. Batteries alone cannot always fulfill this demand because frequent replacement might be unfeasible in many scenarios, or because the bulkiness of batteries might hinder wearability. Moreover, batteries often include toxic liquids that pose safety challenges for integration with the human body. In this context, energy harvesters hold promise to complement or even replace batteries. In particular, the body is a rich source of waste heat that could be harvested by thermoelectric (TE) devices to power wearable devices. An important challenge of TEs is the high thermal contact resistance between the device and its surroundings at its hot and cold sides. Such (parasitic) contact resistance leads to a large temperature drop at the surroundings-device interfaces that cannot be then utilized for electrical power generation. This challenge is accentuated for wearable TEs, where the dynamic nature of the skin makes it hard to optimize the thermal interface at the hot side, i.e., between the skin and the device. Moreover, wearability is not compatible with the use of bulky heat sinks, which results in a further increase of the thermal contact resistance at the cold side of the device, i.e., the device-air interface. Consequently, wearable TE

generators utilize only a very small fraction of the thermal gradient available to them, resulting in a disappointing value of skin heat-generated power.
In this work, I will present the last progress in my group on skin-mounted thermoelectrics with an emphasis on optimizing the skin-device thermal interface. First, I will emphasize the importance of using low thermal conductivity TE materials when high thermal contact resistances are present, like in wearables. To address this point, we are developing TE aerogels that are electrically conducting but present extremely low thermal conductivity. Those aerogels are to be integrated on soft substrates designed to minimize the thermal contact resistance with the skin. This device-skin thermal contact resistance minimization is achieved by promoting the substate tight mechanical compliance with the skin, and by enhancing the substrate thermal conductivity. Furthermore, the substrate will be engineered to channel skin lateral heat flows toward the TE generators to further improve power generation. This research will improve the efficiency of skin-mounted TE generators by tackling, from a material point of view, aspects related to their practical implementation. Our holistic approach includes not only developing innovative TE and substrate materials but also tuning their interface.

TouchpadAnyWear—Textile-Integrated Tactile Sensors for Multimodal High Spatial-Resolution Touch Inputs with Motion Artifacts Tolerance *Junyi Zhao[1,2] and Chuan Wang[1]; [1]Washington University in St. Louis, United States; [2]Facebook Reality Labs, United States*

Touch sensing is essential in human-computer interaction (HCI), the Internet of Things (IoT), and Augmented and Virtual Reality (AR/VR). The rapid proliferation of wearable devices, such as smart glasses and head-mounted displays, underscores the necessity of mobile touch input interfaces. In this study, we introduce TouchpadAnyWear, a novel series of textile-integrated force sensors capable of multi-modal touch input for detecting micro-gestures, two-dimensional (2D) continuous input, and force-sensitive strokes. This thin, conformal device (less than 1mm thick) provides high spatial resolution sensing and exhibits strong motion artifact tolerance due to its unique capacitive sensor architecture.

Compared with conventional gesture sensing techniques (e.g., IMU, magnetic, optical, camera), the E-textile tactile sensor exhibits several advantages, including reduced bulk, low power consumption, lightweight, skin conformability, and robustness against environmental interference. The sensor is composed of a knitted fabric dielectric core, sandwiched by printed silver electrodes and shielded by conductive fabrics on both sides. Featuring a high-density sensor pixel array (up to 49 pixels/cm^2), TouchpadAnyWear can detect the size, location, and pressure of touch inputs with sub-millimeter spatial resolution and accommodate a wide range of force inputs (0.05N to 20N). Inspired by mechanoreceptors (specifically the SA-1 type found in human skin), micro-structured silicone domes are patterned onto the knitted fabrics to locally stiffen sensing units, thereby reducing motion artifacts during deformation. These polymer domes also provide passive tactile feedback to users, facilitating eyes-free localization of the active sensing pixels. The patterning and fabrication of the silicone domes and silver electrodes were achieved via programmable direct-ink-writing (DIW).

Two distinct configurations have been developed: an 8-by-8 grid flexible sensor, demonstrated as a miniature high-resolution touchpad that can be attached to any ubiquitous object; and a T-shaped wearable sensor designed as a finger sleeve for thumb-to-finger micro-gesture input. A coin-sized, miniaturized flexible printed circuit board (FPCB) has been designed and fabricated for direct connection to the sensor device, enabling multichannel data acquisition and communication in a portable manner. Furthermore, fast and highly accurate gesture input recognition (over 95%) has been achieved using machine learning-assisted algorithms. User evaluations involving 35 participants were conducted to validate the effectiveness and usability of TouchpadAnyWear in daily human-computer interaction contexts, such as tapping, swiping, multi-touch, 2D cursor control, text input, and 2D stroke-

based gestures. This study also explores potential applications of TouchpadAnyWear in wearable smart devices, gaming, and AR/VR devices.

4:45 PM SB10.06.08

Fully Textile Biosensing Platforms for Real Time Monitoring of Biofluids *Beatrice Fraboni, Isacco Gualandi, Marta Tessarolo, Francesco Decataldo, Federica Mariani, Giorgio Cortelli, Domenica Tonelli, Vito Vurro and Erika Scavetta; Università di Bologna, Italy*

The development of wearable sensors, in particular fully-textile ones, is one of the most interesting open challenges in bioelectronics.
Here we present two examples of fully textile biosensing platforms based on the conducting polymer poly(3,4-thylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS), for healthcare and sport activities real-time monitoring.
The first application consists of simple threads, based on natural and synthetic fibers, coated by PEDOT:PSS and properly functionalized with either a nano-composite material or a chemical sensitive dye to obtain Cl− and pH selective sensing functionality, respectively. The single-thread sensors show excellent sensitivity, reproducibility, selectivity, long term stability and no cross interference and they can be knitted or sewed into fabrics, opening up a new vision for a textile wearable multi-sensing platform achievable in the near future[1].
The second application consists in the integration of textile sensors in a medical bandage, to directly obtain real time information on moisture status, uric acid concentration and pH level of wound exudate.
Monitoring the healing stages of hard-to-heal wounds is challenging since it can allow for better-targeted therapies and faster patient recovery, without removing the bandage and disturbing the wound bed.
The three proposed sensors are obtained by screen printing PEDOT:PSS on a medical gauze and, for all the proposed devices a key feature is the use of special medical-grade textile materials that provide a passive sampling system, thus enabling the continuous, real-time and non-invasive analysis of wound fluid.
The moisture sensor, directly integrated with an RFID chip implementing a real-time wireless monitoring, operates by detecting impedance variations that span over several orders of magnitude between dry and wet states. [2].
The pH sensor is realized by integrating a sensing layer, including the two-terminal pH sensor made of a semiconducting polymer and iridium oxide particles, and an absorbent layer ensuring the delivery of a continuous wound exudate flow across the sensor area. It exhibits a reversible response with a sensitivity of (59 ± 4) μA pH-1 in the medically relevant pH range for wound monitoring [3].
The sensor for UA is an all PEDOT:PSS OECT that can reliably and reversibly detect UA concentration in synthetic wound exudate in the biologically relevant range of 220−750 μM. Its behaviour is tested in flow conditions for better mimicking the real wound bed [4].

Continuously Monitoring Healthcare Systems Using Negatively Responsive Switching Conductive Fiber-Based Strain Sensor for Nearly Zero Standby Power

Chihyeong Won[1,2], Won Kyung Min[1], Hyun Jae Kim[1] and Taeyoon Lee[1]; [1]Yonsei University, Korea (the Republic of); [2]California Institute of Technology, United States

One of the primary challenges in the field of e-textile-based healthcare monitoring systems, particularly for patients with chronic illnesses, is the reduction of wasted power consumption. Conventional healthcare systems need to be always active to capture a broad spectrum of biochemical and physiological characteristics. In particular, wearable monitoring system based on conductive fibers exhibit a positive gauge factor (GF); the electrical resistance of conductive fibers was increased when they are stretched, so that the monitoring system consume the electrical power continuously. Herein, we developed an innovative solution; a twisted conductive fiber-based negatively responsive switch-type (NRS) strain sensor that exhibited high negative GF ~ 3.9×10^8, the conductivity changes from insulated to conductive state. The conductive fiber was coated by the encapsulation layer for induce a difference Young's modulus between the fiber and encapsulated layer through selective ultraviolet (UV)-irradiation treatment. This UV-induced modification allows the NRS fiber strain sensors to regulate mutual contact resistance effectively under tensile strain. Moreover, these sensors exhibit superior durability, capable of withstanding over 5,000 stretching cycles without performance degradation. The strain sensitivity of these sensors can also be tailored, ranging from 8% to 28% tensile strain, depending on the number of fiber twists. This adjustability makes them versatile for application across various body parts, enabling the detection of different physiological and biochemical conditions. For applications, two specific healthcare monitoring systems using these NRS fiber strain sensors were developed as smart mask and posture correction T-shirts. The smart masks can monitor respiratory patterns and other facial movements, while the posture correction T-shirts can detect and correct improper postures, thus providing comprehensive health monitoring solutions. The developed NRS strain sensor demonstrates a significant step forward in e-textile-based healthcare monitoring systems with near-zero standby power. This work holds promise for enhancing the quality of life for patients with chronic illnesses by providing continuous, reliable, and low-power health monitoring.

SB10.07.02

Tough, Stretchable and Fast Self-Healing Polymer Based Highly Sensitive Pressure Sensor

Somin Kim and Jeong Sook Ha; Korea University, Korea (the Republic of)

There have been extensive studies on self-healing materials and devices for extending the lifespan of soft electronic devices. In particular, the research on self-healing by specific stimulus such as heat, light, or moisture is in active progress.

In this work, we report on newly synthesized tough, stretchable, and fast self-healing polymer and its application to highly sensitive self-healing pressure sensor. Our thermo-responsive self-healing polymer based on oxime-carbamate bonds and disulfide bonds is synthesized via condensation polymerization of poly(tetramethylene glycol) as soft segment, isoporone diisocyanate as hard segment, dimethyl glyoxime and aminophenyl disulfide as chain extender, and 1,4-butanediol diglycidyl ether as crosslinker. The synthesized polymer exhibits the toughness of 8.1 MPa and stretchability of 1003.6 %. The toughness of the polymer is enhanced by introducing an epoxide group as a crosslinker Oxime-carbamate bonds and disulfide bonds broken by physical damages including complete bisection can be dynamically regenerated by heating at 65 °C for 1 hr, resulting in high self-healing

efficiency of 85.1 %. Self-healing properties remained even in water with varying pH levels from 1 to 10 at room temperature for 1 hr. Based on this tough and self-healing polymer, a highly sensitive pressure sensor is fabricated with a mechanical stability over 1000 repetitive cycles of pressing/releasing. Incorporation of micro pyramid structure and interdigitated Au electrodes enhances the sensitivity up-to 150 kPa^{-1} in the range of 0-1 kPa. With the fabricated sensor attached onto human skin, various bio-signals are detected Furthermore, the fabricated pressure sensor is fully self-healing from complete bisection, recovering the pristine. This work demonstrates the high potential application of our novel synthesized tough, stretchable, and fast self-healing polymer to soft skin-attachable devices with longevity.

SB10.07.03
A Fully Self-Healable Sweat Cortisol Sensor For Stress Monitoring *Mihyeon Park and Jeong Sook Ha; Korea University, Korea (the Republic of)*

Stress has been identified as one of the most critical causes of various diseases, leading to an increased interest in continuous stress management. However, most stress assessments rely on detecting and measuring physiological changes caused by stress, such as heart rate variability and changes in skin conductivity. Consequently, accurate management of stress using only bio-signals remains challenging. Cortisol, referred to as the stress hormone, directly reflects the stress response of human body so that monitoring cortisol levels in sweat allows for the evaluation of both acute and chronic stress. Due to the softness of the skin-attachable sweat sensor, it is vulnerable to damages by unintentional impacts, raising the issue of developing self-healing functionality.
In this work, we report on the fabrication of a fully self-healable sweat cortisol sensor consisting of molecularly imprinted polymer (MIP) for cortisol, laser induced graphene (LIG) electrode, microfluidic channel and bio-inspired adhesive. For the reliable detection of stress over extended periods, we synthesize self-healing cortisol MIP based on oxime-carbamate bond-based polyurethane (OC-PU). Our synthesized OC-PU can be self-healed by heating at 65 °C for 6 hours under contact of damaged interfaces. Also, graphene formed by laser irradiation on a composite of OC-PU and lignin is used as electrodes and remains conductive up to 15% strain. Such fabricated cortisol sensor exhibits a very low detection limit down to 0.1 nM and sensitivity comparable to previous works. Furthermore, various biomarkers in sweat can be also detected by simply changing the target molecules. Here, we also develop self-healing microfluidic channel for continuous collection of sweat and bio-inspired adhesive to vertically integrate with self-healing sensor layer. Owing to the oxime-carbamate bonding and hydrogen bonding between the common OC-PU layers, a fully self-healing sweat sensor system can continuously monitor the stress even after self-healing, thereby expanding their potential application to wearable electronics with longevity.

SB10.07.04
ZnO-Sputtered E-Textile for Humidity Sensing *Anupam Kumari, Ajay Agarwal and Angan Sengupta; Indian Institute of Technology Jodhpur, India*

It is crucial to manage water vapour in indoor environments due to its potential to cause issues. Effective humidity control is essential in critical areas such as medical facilities, industrial operations, household appliances, agriculture, automotive settings, community safety protocols, and precision measurement tools. Humidity sensing technology is increasingly important as it facilitates real-time monitoring and fine adjustments of humidity levels, particularly in environments where human safety and well-being are vital. Metal oxides are widely used in gas sensing applications for their high sensitivity, cost-effectiveness, and ease of fabrication. Zinc Oxide (ZnO) is especially notable for its excellent sensing capabilities, particularly in humidity detection. This research introduces a humidity sensor based on ZnO-coated fabric. ZnO was deposited on the fabric using a sputtering method, with silver yarn embroidered as electrodes. Impedance changes were measured at 1 kHz across humidity levels from

10% to 80% RH. The sensor demonstrated a sensitivity of nearly 64 kΩ/%RH and complete recovery for all measurements. Additionally, Au nanoparticles were incorporated to enhance the sensor's sensitivity further. An IoT setup has been implemented to interface the sensor for easy wireless monitoring and notification. This study illustrates the potential of ZnO-coated fabric sensors to offer reliable humidity-sensing solutions across various industries.

SB10.07.05

Laser-Induced Graphene Based Skin-Conformable Sensor for Fingers *Laura M. Ferrari[1,2,3], Sreenadh Thaikkattu Sankaran[1,2], Anna Chiara Bressi[1,2], Marina Galliani[1,2] and Francesco Greco[1,2,4]; [1]Scuola Superiore Sant'Anna, Italy; [2]Scuola Superiore Sant'Anna, Italy; [3]INRIA, France; [4]Graz University of Technology, Austria*

Conformable electronic sensors have attracted significant scientific interest in recent years due to their ability to adapt to rough and non-planar surfaces, with applications in wearable electronics spanning health, robotics, and human-machine interaction1. Unlike other wearable sensors, skin-conformable sensors are well adherent to the skin and accurately record the body movements. Though there are several techniques currently being used for the fabrication of ultra-thin and wearable electronic devices, such as chemical/physical vapor deposition, and electrospinning2, they are expensive, and often involved complex manufacturing steps.

In this study we present an alternative yet simple approach to fabricate conformable sensors, by employing Laser-Induced Graphene (LIG) technology. LIG is a three-dimensional material with very good conductivity and piezoresistive properties, produced with a single-step local pyrolysis of certain polymers by employing a commercially available laser engraver. In our study, we develop conformable strain/bending sensors for fingers, by laser scribing LIG on a polyimide (PI) tape using a hybrid IR laser (INS wavelength), and then transferring this LIG into thin elastomeric substrates made of thermoplastic medical grade polyurethane3 or silicone rubber. The LIG/elastomer sensors provide better adhesion to the skin with stretchability and maximum breathability.

Thanks to the versatility of the laser engraver, a wide variety of shapes can be scribed and tested, from simple to complex patterns. We focused our study on three sensor designs covering three knuckles of a finger for detailed investigation. Static tensile tests were carried out to analyse the piezoresistive behaviour of the LIG/elastomer sensors. The best sensor design was chosen, based on their linearity and sensitivity properties. Since the micro/nano-scale morphology of the LIG plays a role in determining its piezoresistive behaviour, we studied the LIG structure before and after transferring to elastomer, and after the mechanical testing, by using Raman spectroscopy, Optical Microscopy and Scanning Electron Microscopy.

Such novel conformable sensors open novel applications in biomonitoring and robotics. The conformable LIG/elastomer sensors have been developed with the aim of improving hand rehabilitation and teleoperation, by offering a more precise reflection of hand movements compared to traditional haptic gloves.

Free-Standing All-Polymer Ultrasound Transducer—A Wearable Solution for Medical Applications *Sofia Papa[1], Laura M. Ferrari[1], Christoph Leitner[2], Aliria Poliziani[1], Francesco Greco[1,3,4] and Luca Benini[2,5]; [1]Scuola Superiore Sant'Anna, Italy; [2]ETH Zürich, Switzerland; [3]Sant'Anna School of Advanced Studies, Italy; [4]Graz University of Technology, Austria; [5]University of Bologna, Italy*

Ultrasound (US) technology is one of the most widely used and quickly evolving diagnosis and treatment modalities, allowing real-time human body deep tissues monitoring, imaging or stimulation. Nevertheless, commercial-off-the-shelf US transducers are large, bulky, and rigid, making it challenging to cover curved surfaces like the elbow, knee, breast, and are inadequate for prolonged tissue monitoring. In addition, classical US probes are made of lead-based piezoelectric materials and are expensive to fabricate. In this context, the development of flexible/stretchable US transducers has attracted much attention as they could allow for a better mechanical match and conformable interfacing with human skin [1]. While the strategy usually adopted is to integrate rigid piezoelectric components (piezoelectric ceramic transducers) into a flexible substrate [2], our group recently proposed a fully printed, lead-free, polymer piezoelectric transducer [3]. This US transducer was fabricated by printing of Ag and P(VDF-TrFE) on a flexible polyimide substrate, showing optimal performance in the medical ultrasound range (15 MHz). The flexibility of polyimide is not enough to provide a conformal interfacing with skin, causing displacement defects risk. In addition, the use of Ag for the electrodes limits the device's stability over time because of its oxidation in humid environments and the mechanical stability because of its brittleness.

To overcome those limitations and with a view to sustainability, we made an intrinsically flexible all-polymer US transducer with a low-cost fabrication technology. We developed a US transducer based on a free-standing P(VDF-TrFE) film with top and bottom screen printed PEDOT:PSS electrodes. The P(VDF-TrFE) film was fabricated with an adjustable height film coater, making it easy to tune the film thickness (≈30 μm) and thus its resonance frequency in the medical range (≈7 MHz). PEDOT:PSS, a conductive polymer widely used in bioelectronics and in conformable skin patches, was selected thanks to its biocompatibility, transparency, flexibility . The transducer was polarized with a high voltage custom built set up at voltages equal to 1.5 times the coercive field, resulting in a piezoelectric coefficient value in the range 25-35 pC/N, coherent with PVDF state of the art. Pulse-echo and frequency responses of the device were analyzed, showing optimal performance in the frequency range 6-8 MHz, promising for biomedical applications. The all-polymer free-standing device offers an improvement both in conformability and stability when interfacing with the skin.

Moreover, it can be easily implemented in an array format, potentially enabling advanced imaging capabilities and opening new possibilities for diagnostic and therapeutic uses.

This approach is also promising for scale-up of production to large volumes, keeping material costs low.

Self-Adhesive Conformal Nanostructured Skin Resistant to Low-Motion Artifact and Sustainable Electrophysiological Monitoring

Jinyoung Kim[1], Sehyun Park[1], Jisoo Jeon[1], James B. Fitzpatrick[2], Gwendolyn Bryan[3,4], Timothy J. Broderick[3], Morley Stone[3], Yury Gogotsi[2] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Drexel University, United States; [3]Institute for Human and Machine Cognition, United States; [4]University of West Florida, United States

Conformal skin-mounted electronics involve the development of wearable electronics that adhere directly to the skin for various applications such as healthcare monitoring, fitness tracking, and human-machine interaction. Notably, Epidermal electrodes placed on the skin enable the accurate extraction of electrophysiological (EP) signals such as electrocardiogram (ECG), electromyogram (EMG), electrooculogram, and electroencephalogram. There has been growing interest in EP electrodes of ultrathin electrodes ensuring conformal contact on surfaces of *the skin for high-fidelity EP signal acquisition while minimizing motion artifacts and underwater surrounding. Herein, we introduce a self-adhesive nanostructured skin comprising conductive MXene ($Ti_3C_2T_x$), a poly-L-lysine adhesive layer, and a parylene substrate, designed for low-motion artifacts and water-resistant monitoring of EP signals such as ECG and EMG. To enhance conformability, water-assisted capillary-driven flow can be used to self-adhere the electrode to the skin, creating a highly conformal contact without air pockets between the electrode and the skin. They were characterized by a high signal-to-noise ratio, minimal motion artifacts, and the capability for underwater EP signal monitoring in real-time, as well as long-term stability.*

SB10.07.08

Design of Textile Capacitive Pressure Sensor *Fatemeh Motaghedi, Simon Rondeau Gagne and Tricia B. Carmichael; University of Windsor, Canada*

Pressure significantly influences both our external interactions and internal bodily functions. With the global population aging, there has been a heightened focus on healthcare monitoring devices, essential for enhancing longevity and quality of life. These devices are crucial for early disease detection, real-time monitoring of treatment effects, and general health tracking, leading to a surge of interest in wearable electronics. Such wearables can seamlessly integrate with the human body to monitor various health indicators like heart rate, blood pressure, and motion.

Traditional rigid and heavy pressure sensors have evolved into flexible, lightweight, and adaptable versions suitable for wearing on the human body. This innovation has resulted in sensors with excellent resolution and rapid response times, making them practical for modern applications.

Despite advancements, challenges persist in the manufacturing processes of soft pressure sensors. Researchers have recently focused on textiles for wearable electronic applications due to their softness, breathability, and flexibility. Textiles offer unique benefits, such as sensing strain, pressure, and temperature. Their three-dimensional porous structure can enhance device performance by introducing air gaps. Additionally, textiles are cost-effective and easy to produce on a large scale, making them a promising material for wearable pressure sensors.

Textile flexible pressure sensors hold significant potential in various fields, including wearable electronics, soft robotics, human-machine interfaces, sports, biomedical devices, and human motion analysis. However, typical textile-based pressure sensors often suffer from limited sensitivity and a narrow working range because they use extra chemical material as a dielectric between the fabric layers. These sensors also have limitations, such as not being washable, not being suitable for application on the skin, and losing their properties under high pressure.

In contrast, the unique structure of cut pile fabric, when left uncovered by any other material, can trap air and serve as a dielectric. This allows for better pressure distribution and an increased contact area, leading to improved sensitivity and resolution. Additionally, the flexibility and structure of the cut pile enable rapid response times, and the absence of extra material maintains the sensors' lightweight, breathable, and washable nature.

Herein, we present wearable capacitive pressure sensors fabricated entirely from cut-pile fabrics. Cut-pile fabrics consist of a knitted framework with cut piles looped through at regular intervals. We describe the selective metallization of the framework to provide the electrodes and use the cut piles as the dielectric medium. The cut piles provide a structure that effectively traps air between the cut pile fibers, which is integral to the sensor's functionality and performance, enhancing sensitivity, flexibility, breathability, mechanical response, and comfort. This makes it particularly suitable for various applications, especially in wearables.

We discuss the characterization of these new textile sensors and demonstrate their effectiveness across three different pressure ranges (0-10 kPa), (10-30 kPa), and (30-500 kPa).

Nanostructure-Filamented Fibrous Materials as Chemiresistive Sensors for VOC Detection *Guojun Shang[1,1], Dong Dinh[1], Lidia G. Gebre[1], Zeqi Li[1], Seyed Danial Mousavi[1], Alfred Obaje[1], Jin Luo[1], Susan Lu[1], Cate Wisdom[2], Zakiya Skeete[3], Tony Yuan[2] and Chuan-Jian Zhong[1,1]; [1]Binghamton University, The State University of New York, United States; [2]Uniformed Services University, United States; [3]Pacific Northwest National Laboratory, United States*

Fibrous materials have attracted increasing interest for the creation of chemically responsive electro-functionality in nonconductive or hydrophobic thin film networks. A key challenge is how to impart the 3D network structure with functional filaments to harness the structural sensitivity and selectivity for sensor applications. We have been developing electrospun polymeric fibrous substrate embedded with nano-filaments defined by size-tunable gold nanoparticles and structurally sensitive dendrons as crosslinkers. The resulting interparticle properties strongly depend on the assembly of the nano-filaments, enabling an interface with high structure sensitivity to molecular interactions. In this presentation, we will discuss recent findings of our investigations of such materials as chemiresistor arrays with nanoparticle-assembled filaments through effective electronic packaging and integration into cost-effective and flexible devices for detection of volatile organic compounds (VOCs). This platform is coupled with AI-drive data analytics and pattern recognition to enhance selectivity. The results have demonstrated promising potential applications as wearable sensors for breath and sweat VOC detection.

SB10.07.10

Flexible Heaters for Combat Boot Insoles *Adria Kajenski[1], Yudhisthira Sahoo[2], Alkim Akyurtlu[1] and Guinevere Strack[1]; [1]University of Massachusetts Lowell, United States; [2]Flexcon Holdings Trust, United States*

Wearable heaters are low-profile, portable devices that are easily integrated into clothing or footwear and used to provide protection against frostbite in harsh environments. Fabrication of flexible heaters can be accomplished using a range of techniques, including direct incorporation into the fabric itself (e-textile) or printing the heater onto a patch or directly onto the fabric. Additive manufacturing (AM) techniques enable greater versatility when transitioning to a high throughput platform. Printing enables rapid prototyping and is an effective method for the development of soft, flexible devices. This versatility is necessary when investigating wearable substrates and negates the need for the development of new fibers, yarns, and fabrics. Although printed heaters are relatively more developed than those incorporated into e-textiles, several challenges still remain. Research focused on heater design, materials, and durability testing is still needed to ensure that the technology is suitable for commercialization using domestic manufacturing processes. In our previous work, we printed flexible conductive band stop metasurface arrays directly onto fabric. The metasurface retained more than 90% rejection at the target band stop frequency after 60 wash cycles, demonstrating excellent physical integrity.

Herein, we present a printed heater suitable for a cold weather combat boot insole. Wearable heaters for footwear are expected to undergo regular mechanical stressors, and thus the design must compensate for faults including

cracks or regions with inconsistent heating. Additionally, the design must minimize voltage and the power output should remain unaffected by any mechanical deformation. This can be ensured not only by the elasticity of the materials but also assisted by a perforated design. Durability assessment such as wash cycles, and flex and abrasion testing provide important metrics for device performance. Selected inks are used to print the heater design directly onto a woven fabric. Rather than addressing defects through modifying the initial design, they may be repaired by depositing an alternative ink composite ratio, ultimately creating an anisotropic trace. This novel methodology will be enabled by prioritizing careful materials selection, given that the heater can be defined as a set design, and ink properties can be tailored to develop a resistivity with the desired value. This will produce less waste, as small traces can be printed for testing prior to heater fabrication, rather than requiring a full printed design for each iteration of the prototyping process. Understanding the available materials and processes in the printed electronics ecosystem can enable the commercialization of novel, wearable devices.

SB10.07.11

Ultra-Thin Conformal CNT Dry Electrodes for Surface Electrophysiology Monitoring *Yuhan Wen[1,2], David Fox[2], Yuting Cai[1], Ana Claudia Arias[1] and Qiang Zhang[2]; [1]University of California, Berkeley, United States; [2]Honda Research Institute USA, United States*

Epidermal electronics is a new class of non-invasive wearables with mechanical properties that match human skin or tissues, such as Young's modulus, bending stiffness, and elasticity. These characteristics enhance the coupling between the electronics and the biological tissues and allow the sensors to acquire richer information. This work uses a unique CNT synthesis process, blown aerosol chemical vapor deposition, to produce free-standing dry films roll-to-roll with high yield and controllable thickness, sheet resistance, and transmittance. The CNT films are patterned and transferred to other substrates through a laser-cut mask. The resulting ultra-thin conformal carbon nanotube (CNT) dry electrodes can be used for surface electrophysiology monitoring. We demonstrate electrocardiogram (ECG), electromyography (EMG), and forehead electroencephalogram (EEG) monitoring on the skin in a tattoo-like form, as well as multifocal electroretinography (ERG) recording on the eyes via a smart contact lens. We report the tradeoffs between CNT film thickness, conformality, and sheet resistance in reducing skin contact impedance. The CNT electrode design achieves a signal-to-noise ratio (SNR) of 67dB for ECG monitoring and a contact impedance of 100 kohm cm^2 at 10Hz which are on par with, if not better than, commercial Ag/AgCl wet electrodes, which has an SNR of 60dB. We show that the ultra-thin form factor and skin attachment reduce susceptibility to motion noises, a common downside of dry electrodes. Highly transparent (>90%) and conductive (60 ohm/square) CNT film can be readily patterned with a 200 µm resolution and transferred to the wet and curved surfaces of contact lenses. The smart contact lens can be used for multifocal ERG diagnostics of ocular diseases. We recorded simulated ERG signals on an eye mimicry phantom and showed a clear mapping between the recording from each pixel and the programmed electromagnetic field in the phantom.

SB10.07.12

Gold Nanoparticles-Coated Microneedles Based Glucose Sensor for Diabetes Diagnosis *Jihee Kim; Seoul National University of Science and Technology, Korea (the Republic of)*

Recently, the number of people with diabetes has increased due to changes in diet and lifestyle. Since diabetes is associated with many complications, such as cardiovascular disease and kidney problems, it is important to diagnose it early and treat it appropriately. However, blood glucose testing involves inserting and testing a needle four or five times a day, causing pain and discomfort to the patient. To overcome this problem, the researchers adopted a method to detect glucose using microneedles. The microneedles were fabricated using PEGDA(Polyethylene glycol diacrylate), which is highly biocompatible, and Au was coated on the surface of the needle instead of glucose enzyme to provide high conductivity and ease of measurement in various environments.

This research has the advantage that the microneedles can be easily mass-produced by photolithography, which is economical, and the microneedles can be made as long as desired, making them suitable for people of all ages and races.
This technology is expected to contribute to the medical industry as it can effectively measure glucose without pain.

SB10.07.13

Chemoresistive LIG Sensors on Colorless Polyimide with Monolithic VIA for Enhanced Chemical Stability

Jungmin Hong[1], Eunseung Hwang[1], Jinhyeong Kwon[2] and Sukjoon Hong[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Skin-interfaced wearable electronics are gaining significant attention in areas of reliable health monitoring and nondestructive therapeutics with growing interest in on-demand healthcare services that can offer precise real-time data and personalized medical descriptions against the aging society. Since those devices are directly attached to the human body, polyimide (PI) film is selected as a promising substrate with exceptional mechanical, chemical, and electrical properties in addition to its biocompatible characteristics when applied on the skin. Among the diverse utilization strategies of PI-oriented electronic devices, laser processing emerges as a one-step transformative approach to address tedious manufacturing procedures by enabling a facile fabrication of laser-induced graphene (LIG) using laser pyrolysis reaction. Recent notable results of the multifunctional uses of LIG, produced by the laser-induced pyrolytic method, include applications in electrochemical fields such as sensors, energy devices, and microheaters.
In this connection, a transparent colorless polyimide (CPI) has been newly spotlighted for the potential to comprise imperceptible skin-interface devices while retaining all the existing advantages of native PI. The superior optical transmittance of CPI is accomplished by introducing the fluorine which effectively impedes the formation of charge-transfer complexes and loosens the polymer chain density. This optical transparency of the substrate is a pivotal aspect when integrated with any other functional systems since the clear vision of the target is crucial to assess the status when employed in remote monitoring of wound healing for instance. However, transparent materials present inherent challenges in laser-driven manufacturing due to their poor absorbance of light energy. To resolve this drawback, a breakthrough technique of successive laser pyrolysis (SLP) has emerged which strategically places an initiating point to trigger a sequential reaction through an opaque layer produced after the first pyrolysis reaction. Moreover, the SLP of transparent materials not only enables in-plane patterning but also facilitates out-of-plane modification as the beam reaches the target by passing through the transparent medium. Lately, the efforts of embedding conductive interconnection channels, representatively through-silicon via (TSV) and through-glass via (TGV), between multilayered electronic circuits are of great interest for their capability in the miniaturization of the device. This vertical integration allows solid connection of electrical components without wires exposed and reduces the length of wiring resulting in mechanical and electrical advantages. This technology is essential for skin-interfaced devices where size reduction and robust reliability are vital under harsh operating environments. In this study, we fabricated a monolithic structure of LIG sensor integrated with seamless vertical interconnect access (VIA) electrode channels between the opposite CPI film surfaces by utilizing the innate optical properties of the substrate and the pyrolytic product during laser processing. The proposed LIG VIA (LIG-V) simultaneously guarantees the physical and electrical connection of electrodes while protected from external threats of disconnection as firmly embedded in the substrate. As a result, the monolithic LIG-V sensor, with all the elements composed of LIG, is successfully applied in human-machine interface applications such as responsive sensing of surrounding chemicals and mutual input/output of heat stimulations based on its chemoresistive performance.

SB10.07.14

Stretchable and Breathable Nanomesh-Based RRAM with Percolated Nanoparticle Networks *Sung Joon Cho and Taeyoon Lee; Yonsei University, Korea (the Republic of)*

Resistive random access memory (RRAM) stands out as a leading next-generation non-volatile memory, offering simplicity in operation and fabrication, thus making it suitable for wearable and skin-attachable devices. However, the insulating layer used in conventional RRAM, typically composed of inorganic materials, possesses high mechanical strength due to strong chemical bonding and crystalline structure, making it challenging to integrate into flexible components. Organic semiconductors like Musin and Pentacene have been proposed as alternatives, but their memory characteristics (endurance, chemical stability, durability, etc.) are inferior to those based on inorganic materials. Additionally, applying non-porous structures to wearable and skin-attachable devices often leads to discomfort and skin irritation due to poor breathability. Therefore, developing flexible and porous structure components based on inorganic materials is essential for applying RRAM components to wearable and skin-attachable devices. Herein, we present sliver selenide (Ag_2Se) embedded nanomesh-based RRAM devices, which possess flexibility and breathability. Silver (Ag) nanoparticles are patterned on flexible and breathable nanomesh. Furthermore, we seek to form silver selenide (Ag_2Se) inorganic semiconductor material by reacting with selenium precursor solution, followed by depositing aluminum (Al) to achieve a flexible and breathable Metal-Insulator-Metal (MIM) structure. The Ag_2Se nanoparticles embedded nanomesh-based RRAM presents outstanding switching characteristics ($I_{on}/I_{off} > 10^6$, and retention time $>10^6$ s). This study suggests the possibility of further application for memory devices of wearable and skin-attachable devices.

SB10.07.15

Robust, Washable and Stretchable Liquid-Metal-Based Electronic Textiles Enabled by Double Encapsulation

Lixi Chen[1], Yingsi Wu[1], Hong Hu[2], Xian Song[3], Fan Chen[1] and Zijian Zheng[1]; [1]The Hong Kong Polytechnic University, Hong Kong; [2]Shanghai University, China; [3]Zhejiang University, China

*Electronic textiles (e-textiles) have enabled the integration of smart devices into daily outfits for various applications, such as healthcare, human-machine interaction and fashion. Ideally, these electronics should preserve the pristine comfort, elasticity and washability of garments while achieving high functionality. In recent years, a promising strategy towards this goal is to interconnect soft and printed conductors, such as nanocomposites and room-temperature liquid metal, with rigid and miniaturized electronic components, followed by encapsulation. However, the washability of these electronics is limited by mechanical failures at the soft-rigid interfaces. Herein, we develop a double encapsulation strategy for preparing liquid-metal-based stretchable textile electronic patch (STEP) with enhanced durability and washability. This strategy involves the combination of soft encapsulation (Ecoflex) and stiff encapsulation (thermoplastic urethanes (TPU)) in the interconnects of conductors and electronic components. Our strategy enables stable soft-rigid interfaces between conductors and electronic components even against cyclic tensile test (100% strain, 10,000 cycles) and cyclic standard machine washing (100 cycles). Compared to single encapsulation with Ecoflex, the double encapsulation significantly improves the stretchability (5 folds) after cyclic stretch-wash durability test. To demonstrate the applicability of our strategy and applications of STEP, we fabricate a conformal, multifunctional, and washable electronic textile system for healthcare. This system has three distributed functional devices on a single sport shirt: one 5*9 matrix LED display on the arm, one temperature sensor on the armpit and one accelerometer at on the chest. The system can simultaneously monitor body temperature, movements, and display the information for real-time data visualization. The system could also maintain functionality after machine washing. With data fusion and artificial intelligence, the system is expected to generate energy expenditure estimation for obesity patients in the future.*

SB10.07.16

Piezoelectric Nanomesh-Empowered Skin-Attachable Capacitive Auditory Sensor *Jeng-Hun Lee, Kang Hyuk*

Cho and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Wearable auditory sensors hold vast potential in the upcoming Internet of Things (IoT) era for their use in sound-driven smart home, healthcare, and human-machine interface applications. In this work, a piezoelectric polyvinylidene fluoride (PVDF)-based nanomesh is exploited as a self-charge generating diaphragm to power a skin-attachable capacitive auditory sensor. The piezoelectric nanomesh is self-poled via a simple, scalable electrospinning fabrication process, eliminating the need for an additional cumbersome high voltage poling procedure. The deformation-induced charges in the piezoelectric nanomesh generate an electric field between two capacitive electrodes, supplying the bias voltage crucial for the operation of capacitive sensors. Importantly, this reduces the necessity of a bulky power source or environmentally susceptible electrets, which has remained a critical limitation of capacitive auditory sensors to date. Moreover, combined with its inherent porous structure and enhanced mechanical flexibility, the piezoelectric nanomesh allows the sensor to exhibit a flat frequency response (100-3000 Hz), good linearity (50-75 dB_{SPL}), and a high signal-to-noise ratio (SNR) (≥30 dB). Once attached to human skin, e.g., the neck, the auditory sensor successfully detects and decouples various acoustic information, including voice, gulping, and coughing, showing significant potential as a next-generation electronic skin for voice biometrics, human-machine interfaces, and mobile healthcare.

SB10.07.17

***Lightweight Soft Conductive Composites Embedded with Liquid Metal Fiber Networks** Jiexian Ma, Zihan Liu and Pu Zhang; Binghamton University, The State University of New York, United States*

Conductive liquid metal composites are an emerging class of super-stretchable soft conductors. Recently, liquid metal composites have been demonstrated to have promising applications in soft electronics, sensors, and soft robotics. Existing liquid metal composites usually have a relatively high filling ratio of the liquid metal phase, which not only increases the density but also the material cost. Future applications in soft electronics and robotics highly demand liquid metal composites with low density and high conductivity for large-scale, low-cost, lightweight, and more sustainable applications. This presentation will introduce our recent research progress targeting this need. Specifically, we synthesized lightweight and highly conductive composites embedded with liquid metal fiber networks. The liquid metal fiber network serves as an ultra-lightweight conductive pathway for electrons in a compliant rubber matrix. We have developed a novel manufacturing process to fabricate various liquid metal fiber networks, achieving fiber diameters as small as sub-3 microns. The microstructure, mechanical properties, and electro-mechanical behavior of the liquid metal fiber composites are thoroughly studied. Overall, our composites exhibit high electrical conductivity, low volume ratio of liquid metals, strain-insensitive resistance, excellent stretchability, and superior cyclic stability. To demonstrate the potential applications, we showcase the composites as interconnects in stretchable circuits and as electrodes in sensors and heaters. The liquid metal fiber composites we developed significantly reduce the material consumption and bulk density, which will promote the large-scale application of liquid metal composites in emerging technologies.

SB10.07.18

***A Chipless and Breathable On-Skin Sensor for Multimodel Health Monitoring** Jiayi Zhao, Wenyu Wang, Yongzhi Huang and Kaishun Wu; The Hong Kong University of Science and Technology, China*

Multimodal flexible sensors can simultaneously detect and transmit various biological signals, such as sound, sweat composition, and temperature. This facilitates long-term continuous disease monitoring and provides multi-level diagnostic information. The sensor's flexibility, breathability, stability, and power source determine its operational duration. To optimize these characteristics, we designed a novel multimodal flexible sensor based on Radio Frequency Identification (RFID) and Surface Acoustic Wave (SAW) technologies. Polyvinylidene fluoride

(PVDF), a piezoelectric material with excellent chemical resistance, high-temperature tolerance, and oxidation resistance, serves as an ideal piezoelectric component for SAW due to its stability. We used electrospinning to fabricate a PVDF film approximately 2 micrometers thick. The mesh-like nanostructure of the film ensures lightweight and breathability while enhancing its piezoelectric effect. RFID enables passive wireless communication. SAW replaces traditional RFID chips, avoiding rigid materials and converting biological signals into radio frequency signals. We applied this RFID and SAW-based multimodal flexible sensor to an artificial throat, attaching it to the neck, converting subtle throat vibrations into silent speech, while simultaneously detecting sweat composition, temperature, and strain on the neck. This sensor system can be utilized in medical and health fields such as thyroid cancer monitoring and athlete health monitoring, as well as in wearable devices for speech signal enhancement in high-noise environments.

SB10.07.19

Advanced Mental Health Monitoring with Modular Pixel Hydrogel Skin—Real-Time Emotional and Stress State Management *Yuhan Liu[1,2], Liuyang Han[1], Xing Ye[2] and Yanru Chen[1,3]; [1]Tsinghua University, China; [2]Boston University, United States; [3]UCSD, United States*

The rising prevalence of mental health disorders, such as stress and depression, have impacted on both individual well-being and global productivity, especially among young adults aged 20-24. These psychological issues cost the global economy nearly $1 trillion annually. Psychological illnesses often stem from the cumulative effect of daily mental stresses, with many individuals opting to endure silently due to the high costs of psychological services and the complicated process of meeting a doctor. Addressing this problem requires comprehensive prevention, early intervention, and real-time management strategies to increase resilience and improve mental health outcomes. We developed a polyacrylamide (PAM) based modular pixel hydrogel skin (MPHS) for real-time monitoring and assisting in the management of individual emotional and stress states. The technology divides the interface into customizable pixel regions through a patterning and layering process. Each pixel block integrates a specific functional module to realize an interactive skin interface that satisfies the resolution of skin perception. The MPHS enables actuation and multidimensional sensing, including pressure, impedance, and temperature. An ionic composite gel with an alginate-polyacrylamide (Alg-PAM) bi-network structure incorporating lithium ions (Li+) and glycerol can monitor electrodermal activity (EDA) which shows changes in the individual's sympathetic nervous system. By integrating heart rate variability (HRV) monitoring, which reflects autonomic nervous system activity, the skin interface can track an individual's stress levels in real-time. It then activates tactile feedback actuators and temperature management elements to facilitate deep breathing and meditation exercises, effectively enhancing relaxation during emotionally stressful situations.

The ionic gel sensor in our prototype features a contact impedance lower than 55% compared to that of commercial Ag/AgCl electrodes and demonstrates excellent biocompatibility. The piezoelectret pressure sensor exhibits a sensitive piezoelectric-like output of 591 pC/kPa and an excellent mechanical stability in 1.1 million cycles over 5000 s to ensure reliable detection of small pressure changes. The electret film-based tactile actuator offers a sensitivity of 0.98 mN/V and covers a frequency range from 15 to 500 Hz. It can generate programmable, independent pixel vibrations across the entire skin interface, providing users with a rich array of tactile information. Designed to be worn on the user's arm, the MPHS monitors EDA and HRV levels across different scenarios, such as watching comedy and tragedy videos or during strenuous exercise. The integration of EDA and HRV measurements in the MPHS is effective for distinguishing physiological changes caused by physical activities from those induced by emotional stress, thereby accurately identifying emotional states and differentiating them from non-psychological stress factors. This capability will enhance the precision of emotional assessments, providing a more reliable understanding of the user's emotional and physical state in real-time.

The MPHS demonstrates the potential of the interface for daily mood management and prevention of health problems caused by the accumulation of emotions and stress. This integrated and modular hydrogel skin *technology from MPHS also provides a new design direction for highly programmable, pixelated skin interfaces. We will explore denser pixel arrays on the e-skin to provide users with additional real-time interactions with their psychological and physiological states.*

SB10.07.20

Navigational and Emotional 4D Haptic Feedback Interface Based on Ultra-Low Voltage Driven Electret Actuators *Yuhan Liu[1,2], Yanru Chen[1,3], Liuyang Han[1], Siqi Lv[1] and Yuzhen Li[1]; [1]Tsinghua University, China; [2]Boston University, United States; [3]UCSD, United States*

Advanced haptic feedback interfaces represent an extremely important reality in the field of assistance for people with disabilities. People with visual and hearing impairments desire an emotional experience in reading or communicating with others, rather than being confronted with traditional Braille or mechanical sounds. Existing haptic interfaces usually rely on high voltage or current stimulation, causing safety concerns and discomfort in use.

Here, we report a thin, flexible electrostatic actuator enabling high bandwidth and programmable haptic feedback under ultra-low driving voltages. Computational studies and experimental measurements demonstrate excellent operational stability and output characteristics. By introducing multilayer variable stiffness PDMS elastomers and high-temperature charged electret films, we have achieved: 1) ultra-low voltage actuation, capable of generating perceptible haptic feedback forces at as low as 5 V actuation. 2) high gain (mN/V), with a gain of 1.06 mN/V at 200 V actuation, and 0.98 mN/V at 35 V actuation. 3) ultra-high frequency bandwidth in the range of 15-450 Hz, covering all frequency intervals of manual sensitivity. 4) electrostatic charge decay rate of less than 6% to maintain high electrostatic potential energy of the electret film for several years.

The haptic interface provides four-dimensional haptic feedback programming capabilities, including time, position, frequency, and amplitude. Through software signal design, the interface demonstrated the ability to convey Braille with four fundamental emotions. The test results by 15 users are 83 % (without learning mode) and 100 % (with a learning mode) accuracy. This demonstrates that the haptic interface can provide vivid sensations and information, and the haptic driving signals we designed can naturally induce human emotions. The interface also supports multi-command navigation based on haptic illusions. It can generate continuous signals between multiple points, simulating the sensation of real arrow-like directional flow, which efficiently meets the navigational needs of visually impaired people without requiring a complicated learning process. Potential applications of this technology extend to fields such as neuroscience and psychology, including personalized rehabilitation, disability education, and virtual reality experiences. The interface is expected to contribute to an accessible society.

SB10.07.21

Mechanically Tunable- and Photothermally Healable Photonic Structures for Shape- Reconfigurable Mechanochromic Textile Sensors *Chi Yeung Oh, Youngki Cho, Eun J. Son and Tae Soup Shim; Ajou University, Korea (the Republic of)*

Photonic crystals are nature-inspired nanostructures that exhibit structural colour due to photonic bandgaps. It has been used for permanent color expression and colorimetric sensors response to various external stimuli. To achieve stimuli-responsive structural colors using colloidal nanoparticles, colloidal photonic crystals having non-close-packed structures is required. However, these structures are particularly difficult to observe bight structural colors due to broadband light scattering. In addition, since change of structural colors is determined by the change of lattice spacing regardless of the type of material, it has been difficult to control the colorimetric performance as

a sensor.
In this study, we used the melt-shear assembly method to make colloidal photonic crystals with non-close-packed structure using core-shell nanoparticles. To achieve bright reflection colors, we designed the core-shell nanoparticles to act as light absorbers by incorporating polydopamine into the shell. The resulting particles were then dried and subjected to hot pressed to form a film. The film showed a bright structural color with high spectral purity, and it was confirmed photothermal effect by polydopamine enabled the self healing of photonic structures showing shape reconfigurability. Further, by controlling the mechanical properties of the core-shell nanoparticles, we fabricated photonic structure showing a different mechanochromic properties. This has led to the fabrication of photonic textiles, which combine multiple photonic films with different mechanochromic properties. The results showed that the photonic textile exhibited mechanically heterogeneous behaviors in 2-dimensions, enabling the development of photonic strain sensors that can visualize multidimensional deformation.

SB10.07.22

Skin-Attachable Capacitive Vibration Sensor Array with Non-Contact Piezoelectric Diaphragm and Novel Star-Shaped Structure *Kang Hyuk Cho, Jeng-Hun Lee and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)*

Skin-attachable vibration sensors have garnered significant interest due to their vast potential in noninvasive mobile continuous healthcare, advanced communication, and human-robot interactive tools. However, existing wearable vibration sensors fall short of their potential due to unsatisfactory sensing performance, such as non-flat frequency response and low signal-to-noise ratio (SNR), and their susceptibility to external environmental factors, particularly physical contact and humidity. Herein, we present a new concept of employing a piezoelectric poly(vinylidene fluoride trifluoroethylene) (PVDF-TrFE) diaphragm as a non-contact power source for a capacitive vibration sensor. Additionally, we implement a unique spacer design that simultaneously allows for (i) in-plane air ventilation and (ii) maximizing the number of sensors in an array. The piezoelectric diaphragm successfully supplies operating power by generating deformation-induced charges; this creates an electric field between the two capacitive electrodes, allowing the capacitive sensor to operate effectively with a good linear dynamic range (0.1-2 g). Furthermore, our novel star-shaped spacer design enables extremely efficient, facile in-plane air ventilation and the arrangement of 64 sensors in an array. This enhances overall sensing performance by suppressing air damping and increasing the effective capacitive area. The latter is achieved by maximizing the number of sensors in the array and eliminating the need to perforate the diaphragm or backplate for through-hole air ventilation. Overall, our vibration sensor exhibits outstanding sensitivity (380 mV g^{-1}), excellent flat frequency response (80-5000 Hz), and an exceptional SNR of 45 dBA (A-weighted). Its substantial potential as a next-generation auditory electronic skin is demonstrated by its ability to recognize important voice and physiological information when attached to human skin.

SB10.07.23

Transcranial Volumetric Imaging Using a Conformal Ultrasound Patch *Sai Zhou; University of California, San Diego, United States*

Accurate and continuous monitoring of cerebral blood flow is valuable for clinical neurocritical care and fundamental neurovascular research. Transcranial Doppler (TCD) ultrasonography is a widely used non-invasive method for evaluating cerebral blood flow, but the conventional rigid design severely limits the measurement accuracy of the complex three-dimensional (3D) vascular networks and the practicality for prolonged recording. Here we report a conformal ultrasound patch for hands-free volumetric imaging and continuous monitoring of cerebral blood flow. The 2MHz ultrasound waves reduce the attenuation and phase aberration caused by the skull, and the copper mesh shielding layer provides conformal contact to the skin while improving the signal-to-noise *ratio by 5dB. Ultrafast ultrasound imaging based on diverging waves can accurately render the circle of Willis in 3D and minimize human errors during examinations. Focused ultrasound waves allow the recording of blood flow spectra at selected locations continuously. The high accuracy of the conformal ultrasound patch was confirmed in comparison with a conventional TCD probe on 36 participants. Furthermore, we demonstrate continuous blood flow spectra during different interventions and identify cascades of intracranial B waves during drowsiness within 4h of recording.*

SB10.07.24

Soft Elastomeric Nanofibers with Coaxially Embedded Liquid Metal Particles as a Conductive Filler for Soft Bioelectronic

Joab Dorsainvil; Binghamton University, The State University of New York, United States

***Introduction**: Liquid metals (LM), like eutectic Gallium-Indium (EGaIn), are noteworthy for their liquid state at or near room temperature, offering unique properties distinct from most metals. They possess exceptional thermal and electrical conductivity, compatibility with biological systems, and the ability to undergo shape transformations with stimuli, making them ideal for flexible electronics, addressing the limitations of rigid conductors. LM finds applications in wearable technology and medical devices, including wound healing and sensors. Recent research combines LM with nonwoven nanofibers, enabling complex designs. To overcome challenges in creating LM composite fibers, we propose a solution: a non-woven fiber mat with a thermoplastic elastomeric sheath encasing an LM-based ink core. The conductive network of LM particles in the ink core allows for screen printing or coating while maintaining continuity, even under stretching. Our hypothesis is that embedding the percolation network of LM particles within the polyurethane fiber core will sustain continuity. **Materials and Methods**: Tecoflex SG-80A Thermoplastic Polyurethane (PU) was purchased from Lubrizol (Wickliffe, OH). The LM ink (ELMNT SL Ink) was obtained through collaboration with UES inc. affiliated with the Air Force Research Laboratory (Dayton, OH). Diacetoxyhexane (DHA) and Dimethylformamide (DMF) were purchased from VWR (Randor, PA) Tetrahydrofuran (THF) were purchased from ThermoFisher Scientific (Waltham, MA). PU-SL Ink fibers were created using the MSK-NFES-3 benchtop electrospinning unit. PU solutions were made at 16 wt% in a cosolvent ratio of 3:1 using THF and DMF, respectively. SL Ink solutions were created by using the SL Ink and further diluting the ink in DHA 20% by weight to reduce viscosity. PU and SL Ink solutions were placed into 15.65 mL syringes and fed through a Polytetrafluoroethylene (PTFE) tubing. To form the coaxial structure, a 21-gauge needle and 16-gauge needle were used for core and sheath respectively, with a accelerating voltage of 11 kV applied to create the fibrous network of PU-SL Ink nanofibers.*

***Results and Discussion**: Our preliminary results of coaxial electrospinning the ELMNT Ink core with the PU sheath show the fiber morphology of the LM integrated into the fibers. The percolation network from the EGaIn particles embedded into the SL Ink can be seen in the PU sheath and throughout numerous fibers, allowing for a continuous network of LM particles for conductive fibers. EDS analysis confirms the presence of the liquid metal pathway, with the mapping demonstrating the structure of randomly aligned nanofibers, indicating coaxial encapsulation into the PU sheath fibers. Furthermore, PU-SL Ink fiber mats were placed in liquid nitrogen and split to expose the cross-section of fibers through freeze fracture to observe the coaxial alignment of SL Ink particles in the PU fibers. The particles are embedded in the PU fibers; however, some fibers show the particles off-center from the PU fiber, which can be further tailored by adjusting electrospinning parameters. A crucial criterion for this conductive fiber mat to be realized for stretchable electronics is the sintering procedure responsible for fusing LM particles, creating continuity through the fiber mat. The literature discusses that most methods of sintering for particles to fuse together involve a form of mechanical strain or applied force. The PU-SL Ink fiber, after striking the surface of the fiber mat with a sharp-tipped object with enough pressure, shows mechanical sintering of the particles.*

***Conclusion:** This work aims to develop a fibrous conductive substrate as a stand-alone device for soft bioelectronics. The fibrous mat will maintain its fibrous architecture with its added conductivity while exhibiting stretchable mechanics suitable for bioelectronic applications.*

A Deep Learning-Based Wearable System for Human Hand Perception Using Strain Sensors *Suyeon Kang, Sangmin Lee and Wanjun Park; Hanyang University, Korea (the Republic of)*

We present a wearable system that emulates the perceptions of human hand by distinguishing the shapes of interacting objects and patterns of finger motion. The system was constructed by applying ten simple strain sensors, whose structures are simple carbon-elastomer composite. The strain sensor shows proper performance with moderate stretchability, durability, and repeatability characteristics, as well as immunity in the operating environment with the simplicity of the sensor architecture. In spite of the output variation of the sensor due to the inherent mechanical characteristics of polymers, the system can distinguish the shapes and sizes of objects and hand gestures with data obtained from ten sensors by applying the machine learning method. The one-dimensional convolutional neural network (1D-CNN) was used to analyze the sensor data and predict objects or motions. After proceeding through preprocessing with outlier elimination, the sensor datasets were trained by the learning algorithm. As a result, we verify that the proposed system successfully predicts shapes and sizes for testing objects and human figure motions with significant accuracy using the assembly of a single type of strain sensor.

Skin-Inspired Permeable Structure-Gradient Fiber Mats for Pressure Sensing in Rehabilitation Assistance *Jinxing Jiang and Qiyao Huang; The Hong Kong Polytechnic University, Hong Kong*

Rehabilitation devices have launched to the market, allowing patients to perform rehabilitation exercises independently without the needs for constant presence of professionals. However, they are often developed based on thin-film plastics and enclosed in bulky encapsulation cases. Such design compromises the mechanical flexibility and permeability of the devices, leading to inconvenience and discomfort for users when wearing for exercise. We herein crafted a permeable, multilayered, structure-gradient fiber mat (SGFM) using a template-assisted layer-by-layer electrospinning technique to achieve triboelectric pressure sensing textiles with high sensitivity over a wide sensing range. By regulating the materials composition and microstructure, SGFM exhibit a gradual transition from rigidity to softness as it extends from its outermost layer towards the innermost layer, possessing a multiple gradient in terms of mat structures, dielectric property, and material modulus. As a result, triboelectric pressure sensing textiles constructed using SGFM show a substantial enhancement in pressure sensing performance compared to those constructed with homogeneous fiber mat without gradient structure. Importantly, the fibrous structure of SGFM endows the pressure sensors with air and moisture permeability, ensuring a comfortable wearing experience. We showcase the pressure sensing capability of these functional textiles in rehabilitation training scenario. By simultaneously monitoring the quadricep, pulse, and plantar pressures for posture tracking and correction, SGFM-based pressure sensing textiles demonstrate high application promise in rehabilitation assistance.

Hydrogels with Improved Cohesion and Ionic Conductivity via SBMA and Acrylic Acid Copolymerization and CMC Integration for Sensor Applications *Hang Ngo Thi[1,2], Kiok Kwon[1] and Seunghan Shin[1,2]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Korea National University of Science and Technology, Korea (the Republic of)*

This study presents the synthesis of hydrogels by copolymerizing sulfobetaine methacrylate (SBMA) with acrylic acid (AA) using UV crosslinking to improve the cohesive strength and functional properties. Carboxymethyl *cellulose (CMC) was added to further improve the physical properties of the hydrogel. Metal salts were incorporated to modify the ionic conductivity. The physical and electrical properties of the hydrogels were evaluated by tensile tests, 90° peel strength tests, and ionic conductivity tests. The SBMA-AA copolymer showed significant mechanical strength and durability, while the addition of CMC reinforced the network structure, improving cohesion and overall material properties. Metal salts improved ionic conductivity, which is essential for sensor applications. Adhesion tests on pig skin showed that the hydrogels provided self-adhesion and stable sensor performance. These results highlight the potential of SBMA-AA copolymer hydrogels with CMC for use in high-performance biomaterials and various biomedical applications.*

SB10.07.28

A Highly Sensitive and Long-Term Stable Wearable Patch for Continuous Analysis of Biomarkers in Sweat

Farnaz Lorestani and Huanyu Cheng; The Pennsylvania State University, United States

Although increasing efforts have been devoted to the development of non-invasive wearable or stretchable electrochemical sweat sensors for monitoring physiological and metabolic information, most of them still suffer from poor stability and specificity over time and fluctuating temperatures. This study reports the design and fabrication of a long-term stable and highly sensitive flexible electrochemical sensor based on nanocomposite-modified porous graphene by simple and facile laser treatment for detecting biomarkers such as glucose in sweat. The laser-reduced and patterned stable conductive nanocomposite on the porous graphene electrode provides the resulting glucose sensor with an excellent sensitivity of 1317.69 $\mu AmM^{-1}cm^{-2}$ with an ultra-low limit of detection (LOD) of 0.079 μM. The sensor can also detect pH and exhibit extraordinary stability to maintain more than 91% sensitivity over 21 days in ambient conditions. Taken together with a temperature sensor based on the same material system, the dual glucose and pH sensor integrated with a flexible microfluidic sweat sampling network further results in accurate continuous on-body glucose detection calibrated by the simultaneously measured pH and temperature. The low-cost, highly sensitive, and long-term stable platform could facilitate and pave the way for the early identification and continuous monitoring of different biomarkers for non-invasive disease diagnosis and treatment evaluation.

Multimodal 5-DOF Stretchable Electromagnetic Actuators Toward Haptic Information Delivery

Si Chen[1], Li Yu[2], Weijun Shen[2], Brian Fong[1], Yizong Li[1], Penghao Dong[1], Hantang Qin[2] and Shanshan Yao[1]; [1]Stony Brook University, The State University of New York, United States; [2]University of Wisconsin–Madison, United States

The rapid advancements in artificial intelligence, particularly in the domains of robotics, prosthetics, and virtual and augmented reality (VR/AR), have driven an escalating demand for intuitive and effective human-machine interactions. Consequently, haptic devices, being electronic displays for the sense of touch, have drawn increasing attention. More efforts are in demand to develop stretchable and lightweight haptic devices that can trigger multiple mechanical cutaneous receptors using a single device. This work presents a new 3-modal 5-DOF stretchable haptic interface that is enabled by electromagnetic actuators and high-fidelity multi-layer metal printing. The haptic device renders rich haptic sensations (i.e., normal force, vibration, angular force, skin dragging) in one device, allowing for the comprehensive delivery of tactile information through the excitation of multiple cutaneous receptors. Additionally, haptic devices are designed to be compact, lightweight, and skin-compatible. The skin-like softness and stretchability enable intimate skin contact, which is crucial for efficient haptic information delivery. In addition, this feature prevents impediments to the natural movements of the skin and ensures the functional integrity of the device during daily deformations of the skin. Finally, three proof-of-concept demonstrations illustrate the potential of the reported multimodal haptic devices for advanced haptic interactions across various domains.

SB10.07.30

Variable-Stiffness Rehabilitative Hand Splints with Self-Sensing Pneumatic Inverse Artificial Muscles

Valentina Potnik, Gabriele Frediani and Federico Carpi; Università di Firenze, Italy

Dynamic hand splints are rehabilitation orthoses, usually equipped with elastic bands or springs that exert passive resistance to voluntary finger movements. In order to make the exercise dynamically controllable, it would be advantageous to replace the elastic bands/springs with soft actuators that can generate electrically variable loads. This would allow for tailoring the rehabilitation task, not only before but also during the treatment, by exercising finger movements against controllable loads, possibly enhancing the therapeutic efficacy. The ideal enabling soft actuators should produce large displacements at moderate forces, have a compact size, low specific weight, and ensure electrically safe operation. Moreover, providing the actuators with self-sensing properties would further simplify the system, for control purposes. Here, we describe a strategy to develop dynamic hand splints that embed self-sensing pneumatic actuators functioning as ‘inverse artificial muscles’. Prototype systems were manufactured by using off-the-shelf materials and cost-effective manufacturing processes. Unlike traditional pneumatic actuators that contract when pressurized, these actuators elongate. They comprise an airtight elastomeric tube encased by a nylon filament coil to prevent outward expansion. Self-sensing properties were achieved through an internal piezoresistive stretch sensor, made of a conductive elastomeric linear body arranged along the tube’s central axis. The actuators were mounted on a forearm brace, and were connected at one end to a finger via a tendon, and on the other end to an on-board load cell. The latter measured the force produced by the actuator at different driving pressures, as it was elongated when the finger was bent. This was used to control in real-time the stiffness perceived by the user.

SB10.07.31

Ag Core–Ag$_2$Se Shell Based Stretchable Thermoelectric Fiber with Nanoparticle Networks for Wearable Electronics *Chaebeen Kwon and Taeyoon Lee; Yonsei University, Korea (the Republic of)*

Amidst the swift progression in wearable technology, electronic fibers have become an indispensable element in the arena of functional textiles, demonstrating a broad spectrum of capabilities including connectivity, sensory detection, and energy generation. This breakthrough is catalyzing the development of innovative fiber-based wearable electronics, ranging from electronic skins and health sensors to sophisticated human-machine interfaces. The complexity of joining single-function fibers and the critical need for their compact integration within wearable platforms necessitate the creation of advanced multi-functional electronic fibers. Herein, we have fabricated a novel Ag core–Ag$_2$Se Shell based stretchable thermoelectric (TE) fiber, engineered through selective chemical reduction, poised to redefine the integration within wearable electronics. Ag and Ag$_2$Se nanoparticles (NPs) were embedded into a polyurethane fiber matrix, yielding a composite with extraordinary elasticity to mechanical deformation coupled with consistent electrical durability. The fiber maintains electrical even after enduring 10,000 cycles of 20% tensile strain and preserves a Seebeck coefficient of -92 μV/K up to a 100% tensile strain, with the variation in output voltage remaining under 1.752%. The successful application of selective chemical reduction facilitates the formation of efficient n-p pairs, crucial for augmenting the thermoelectric efficiency of the fiber. This technique simplifies the manufacturing process while expanding the functional potential of wearable fibers. Consequently, the Ag core–Ag$_2$Se shell-based fiber emerges as a versatile and robust component, ideal for the demands of cutting-edge wearable devices, and marks a significant stride toward seamless integration of high-performance and multi-functional wearable systems.

SB10.07.32

Liquid Bridges Mediated Crack Initiation, Propagation and Coalescence for Electronics *Shuang Zheng;*

University of Oxford, Hong Kong

Conventional flexible electronics, which integrate rigid films with excellent electrical or optical properties onto inherently deformable materials, often face circuit failures due to uncontrolled crack propagation. In this study, we present a design strategy utilizing capillary-stabilized liquid bridges (LBs) to naturally control crack initiation, propagation, and coalescence. By infusing non-volatile ionic liquids within a rigid nanowire array on polydimethylsiloxane, we observed a significant improvement in the stretchability of a platinum (Pt) film compared to its flat counterparts. In-situ observations revealed a two-stage cracking process: initially, decentralized crack initiation occurs due to LB attractions that mechanically hinder the crack front while initiating new cracks elsewhere; subsequently, crack propagation is observed with suppressed coalescence. Our findings demonstrate that fluid mechanics can be a versatile method to reprogram film cracking, enhancing the stretchability of electronic devices.

SB10.07.33

On-Skin Printable Conductive Granular Hydrogels for Human-Machine Interface *Sumin Kim[1,2], Jaepyo Jang[1,2], Donghee Son[1,2,1] and Mikyung Shin[1,2,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)*

Over the past decades, conductive hydrogels have been widely utilized as strain sensors for their tissue-like soft modulus and strain-sensitive properties. However, their poor adhesiveness and air permeability have resulted in performance issues such as delamination from skin surfaces and inflammatory responses, thereby restricting their application in wearable devices. In this study, we present a novel approach to create on-skin printable conductive granules composed of a hyaluronic acid core and a polymerized catecholamine shell. The multifunctional shell layer significantly enhances the cohesion of printed structures, improves adhesiveness to both skin surfaces and hydrophobic substrates (e.g., polystyrene) even under wet conditions, and demonstrates self-doped ionic conductivity via comproportionation reactions. Moreover, the excellent injectability of this granular hydrogel enables its use as on-tissue printable strain sensors for human-machine interfaces, including applications such as operating robotic arms and in virtual reality environments. In a virtual reality demonstration, the hydrogel strain sensors enable interactive human-machine interface (iHMI) by real-time monitoring of both large deformations, such as finger bending to control the motion of a virtual avatar, and small changes, like vibrations from a vibrator, with feedback mechanisms activating an LED and vibrator when the avatar performs a designated motion. This novel strategy for fabricating conductive granular hydrogels for strain sensors paves a new path for the design of hydrogels in wearable bioelectronics.

SB10.07.34

Development of Biocompatible Electrode with Self-Doped PEDOT *Ryota Fukuzawa, Chiaki Ushimaru, Kento Yamagishi, Tomoyuki Yokota and Takao Someya; The University of Tokyo, Japan*

Biocompatible electrodes, which are flexible, gas permeable, and self-adhesive, can be applied to long-term monitoring of biosignal on the skin. The gas permeable electrodes are less likely to cause inflammation of the skin, and self-adhesiveness is important for accurate measurements under human motion. Nanosheet electrodes are good candidates for the biocompatible electrode, and our group has developed a nanosheet electrode using polydimethylsiloxane (PDMS) and polyurethane (PU) nanofiber with Au deposition, which is referred to as Au/PU-PDMS nanosheet electrode, here [1]. In Au/PU-PDMS, PU nanofiber is used as a framework in the PDMS nanosheet, and conductivity is acquired by Au deposition. However, the self-adhesiveness is drastically decreased by Au deposition, and the conductive region is only the Au part. As a result, an electrical wire should be inserted between the skin and the Au to extract the signal, and it causes damage to the nanosheet during human motion. In *this study, we have developed a PU:S-PEDOT nanosheet electrode with an intrinsically conductive elastomer instead of PDMS, and it does not require wire insertion between the skin and electrode.*

We prepared the conductive elastomer by mixing self-doped poly (3,4-ethylene dioxythiophene) (S-PEDOT) and waterborne PUs (WBPUs), which is referred to as PU:S-PEDOT, here. S-PEDOT is a conductive polymer and is well soluble in water. Furthermore, it does not require secondary doping, unlike PEDOT: poly (styrenesulfonic acid) (PEDOT:PSS) [2]. The PU nanofiber was dipped into the PU:S-PEDOT, and it was dried in an oven.

First, we evaluated the sheet resistance of the PU:S-PEDOT nanosheet electrodes prepared with different S-PEDOT solution concentrations. As a result, the sheet resistance decreased with an increase of S-PEDOT solution concentration, and it achieved about a few kilo-ohm at 67 wt% of S-PEDOT solution concentration, which is sufficiently low to be applicable to on-skin measurements such as electrocardiogram (ECG) and skin impedance. Next, we evaluated the self-adhesiveness of the electrodes, and it has about 50 μJ/cm^2 of adhesion energy even at high S-PEDOT solution concentration. Then, gas permeability was estimated by comparing the loss of water in bottles sealed with the electrodes and in bottles not sealed, and the water loss was about 70% of that in the unsealed bottle. Finally, as a demonstration, we applied our PU:S-PEDOT electrode to ECG monitoring, and a clear signal was obtained. These results shows that our PU:S-PEDOT electrode is a biocompatible electrode for long-term monitoring.

SB10.07.35

Development of Intrinsically Stretchable Transistor Arrays Utilizing Liquid Metal for Health Monitoring Systems

Seungkyu Lee; *Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

The distribution of strain and stress inevitably deforms devices, leading to significant performance degradation. Therefore, there is increasing attention on the field of intrinsically stretchable electronics, which can overcome mechanical mismatches caused by lateral strain. In particular, with the aging population, it is essential for electronic devices to be attached to the skin and capable of quantitatively processing electrophysiological signals, which are very small values emitted from the human body, to enable professional and systematic real-time health monitoring and healthcare at home. Human sensory information such as auditory, tactile, and visual data are converted into electrophysiological signals and transmitted to the brain, which processes these complex signals simultaneously. Developing electronic devices composed of intrinsically stretchable materials that can seamlessly integrate with human skin is crucial to achieve this. The stretchable transistor array proposed in this study consists of output devices and electronic circuits based on stretchable materials, providing opportunities for human-machine interaction.

Liquid metal can exist in a liquid state at room temperature due to its low melting point and can exist as very small particles (spherical). This allows it to have inherent stretchability and high electrical conductivity due to its metallic nature (Particle size: 2-3 μm, Stretchability: 300%, Electrical conductivity: 3.4 x 10^6 S/cm). Pure liquid metal is challenging to coat as a film on hydrophobic substrates due to its high surface tension. Previous studies have mixed liquid metal with polymers or other components to form a film, which degrades the electrode performance. To address this, our study disperses liquid metal particles in two hydrophilic solvents with different boiling points and coats them on the substrate based on the Marangoni flow principle (Boiling point of DI water: 100°C, Boiling point of ethyl acetate: 77.1°C). The most critical step in liquid metal patterning through photolithography is the etching process. To break the bond between the thin (~5 nm) metal oxide layer surrounding the liquid metal particles and the hydrophobic substrate, wet etching with SC-2 (hydrochloric acid + hydrogen peroxide) solution is

necessary. This is because gallium, which constitutes most of the liquid metal, reacts with hydrogen peroxide and hydrochloric acid, enabling etching (Resolution: <5 μm).
There is a concern that the performance of stretchable transistors may degrade under high strain or repetitive stretching. Therefore, utilizing elastic stiff islands of materials with selectively variable cross-linking density significantly enhances the device's reliability and durability (PDMS modulus: 1 MPa, modulus of elastic material (SEBS): ~20 MPa). Transistors using s-CNT as the channel and SEBS H1052 as the dielectric layer are expected to show improved performance compared to previously reported stretchable transistors.
The fabricated stretchable transistor arrays are highly stretchable and attachable to the skin. These arrays can receive very small electrophysiological signals and perform complex tasks such as signal processing. This study is significant as it is the first to research electrodes and transistor arrays patterned through photolithography composed entirely of liquid metal, achieving intrinsically stretchable electronic devices.

SB10.07.37

Epidermic Tattoo Sensors Interface—An In-Depth Look at the Electrochemical Features, Biosignal Transduction Mechanism and Breathability Properties *Marina Galliani[1,1,2], Francesco Greco[1,3,4], Esma Ismailova[2] and Laura M. Ferrari[1,1,5]; [1]Scuola Superiore Sant'Anna, Italy; [2]École des Mines de Saint-Étienne, France; [3]Scuola Superiore Sant'Anna, Italy; [4]Graz University of Technology, Austria; [5]Universite Côte d'Azur, France*

Temporary tattoo sensors are emerging as flexible, soft, and ultra-thin (~ 1 μm) organic skin contact electronic devices. Tattoo electrodes establish an intimate and stable interface with the skin, and transduce signals with high quality without the need for a conductive gel, like in the case of the medical standard Ag/AgCl electrodes.[1]
Here we report a detailed and comprehensive description of the tattoo-skin interface. We detail the transduction mechanism, the factors at the basis of such high performances, and the tattoos intrinsic breathability.
By recording the tattoo-skin electrochemical impedance spectroscopy (EIS) over time, we inspected the physical characteristics and electrochemical properties. By modeling the EIS equivalent circuits of skin with tattoos and gelled Ag/AgCl, we revealed that tattoo electrodes establish a dry interface. Conversely to wet electrodes, polymeric tattoo electrodes show to transduce signals through a capacitive mechanism in which the upper skin layer acts as the dielectric. The proposed capacitive coupling explains why the tattoo EIS values at frequencies <10^2 Hz are not a limiting factor in the recording ability, despite they are higher than in other medical electrodes. Moreover, we showed that tattoo electrodes preserve a dry interface with the skin over several days of wearing, with no sign of skin occlusion.[2] These findings indirectly demonstrate that the perspiration evaporates through the electrodes, revealing tattoos as breathable devices and pushing us towards further investigations. Breathability in wearable devices is a pivotal quality to ensure physiological trans epidermal water loss (TEWL) and reduce skin inflammation and discomfort.[3] In this context, intrinsically breathable films represent an ideal material for e-skin device fabrication and to close the loop of this study, we reported on the tattoos breathability features. The internal structure of tattoo sensors plays a crucial role in the gas-liquid exchange capabilities. Therefore, SEM and AFM micrographs showed us the presence of cavities within the tattoo structure. This evidence is further confirmed by the liquid water permeance experiments that revealed tattoos function as compressible porous membranes and allow for liquid water passage. Complementarily, we experimentally calculated a water vapor transmission rate (WVTR = 70 g m^{-2} h^{-1}) remarkably higher than the physiological TEWL (=4-8 g m^{-2} h^{-1}).[4] This result confirms the sweat freely passes through and evaporates from the tattoo sensor.
Polymeric tattoo sensors transduce biosignals through a capacitive coupling with the skin, which is stable over time, thanks to their intrinsic breathability. These properties are optimal for prolonged and high-quality biosignal recordings, and their assessment is essential to design the next generation of wearable e-skin devices.

Stretchable Micro-LED Displays Based on Diffuser Superstrate for High Fill Factor in e-Skin and e-Textile Applications

Kyungjun Lee and Hyeon Ho Shin; Hanyang University, Korea (the Republic of)

Stretchable displays have been extensively studied and developed to meet the increasing demand for wearable electronic devices. One promising application of these displays is in electronic skins (e-skins) and electronic textiles (e-textiles) for visual applications such as health monitoring and smart clothing. However, the reduction in fill factor due to increased pixel spacing during stretching results in noticeable image distortion, which is particularly problematic for applications requiring high flexibility and stretchability. In this study, we developed a novel stretchable display incorporating cellulose nanocrystal (CNC) as a diffuser and superstrate to address the issue of image distortion caused by reduced fill factor during stretching. We prepared the CNC diffusers by combining them with elastomer and positioned them to cover the micro-LED pixels and a portion of the interconnects. This configuration maintained image clarity and brightness, even when stretched biaxially, by diffusing the light through the CNC-based diffuser. Consequently, our design demonstrated a relatively high fill factor and maintained luminance stability compared to conventional stretchable displays, thereby compensating for the typical resolution loss experienced during stretching. Our findings suggest that the stretchable display with the CNC-based diffuser exhibits minimal changes in fill factor and luminance stability under stretching. This advancement is particularly significant for applications in wearable technology, including e-skins and e-textiles, where maintaining display quality and functionality under mechanical deformation is crucial.

SB10.07.39

A Wearable Echomyography System Based on a Single Transducer

Xiaoxiang Gao, Xiangjun Chen, Muyang Lin, Wentong Yue and Sheng Xu; University of California, San Diego, United States

Wearable electromyography devices can be used to detect muscular activity for health monitoring and body motion tracking, but this approach is limited by weak and stochastic signals with a low spatial resolution. Alternatively, echomyography can detect muscle movement using ultrasound waves but typically relies on complex transducer arrays, which are bulky, have high power consumption, and can limit user mobility. Here, we report a fully-integrated wearable echomyography system that consists of a customized single transducer, a wireless circuit for data processing, and an onboard battery for power. The system can be attached to the skin and provides accurate long-term wireless monitoring of muscles. To illustrate its capabilities, we use this patch to detect the activity of the diaphragm, which allows the recognition of different breathing modes. We also develop a deep-learning algorithm to correlate the single-transducer radiofrequency data from forearm muscles with hand gestures to accurately and continuously track 13 hand joints with a mean error of only 7.9°.

Direct Deposited Emulsion-Templated Composites for Monitoring of Fabric Strain

Raquel I. Cano Cordero, Sean P. Ogilvie, Peter Lynch and Alan Dalton; University of Sussex, United Kingdom

The need for developing stretchable, wearable, soft-strain sensors has risen in recent decades due to their *relevance in various fields such as smart textiles, real-time monitoring, soft robotics, medical applications, and human motion detection. As is widely known, the creation of strain sensors encounters the difficulty of balancing different properties such as high sensitivity, adequate flexibility, good hysteresis and durability, and easy adaptability for incorporation into different surfaces. In this study, we are utilising liquid- exfoliated graphene nanosheets and commercially available silicones to develop the next generation of nanocomposite strain sensors. The graphene network is structured via emulsification to produce graphene-coated silicone droplets enabling high conductivity at relatively low graphene loadings. When combined with a highly elastic, flexible silicone matrix, this yields excellent electromechanical properties with a robust exponential response to applied strain. These emulsion-templated composites are robust to more than 500 cycles up to 100% strain and at a strain rate of 100%/s. The sensor exhibits good ohmic conduction, with an average conductivity of 0.8 ± 0.08 S/m. For the single, high strain rate (100%/s) strain to break measurement a well-defined (R^2= 0.96) exponential response is observed up to 160% strain, featuring an extremely high relative resistance change over $2x10^3$ and a Gauge Factor of ~60. Moreover, these composites exhibit minimal hysteresis when deposited on a fabric substrate during cyclic strain, providing a system for monitoring high-performance fabrics.*

Behaving Textiles—A Practice-Based and Design-Led Approach Towards Sustainable Shape-Changing Textiles *Aurélie F. Mosse; Ecole Nationale Supérieure des Arts Décoratifs, France*

Behaving textiles emerged in the past decades as a new family of fibre-based materials with the ability to reversibly change over time. This transformation corresponds to a change of physical property, shape or state initiated in the material's molecular structure in response to varying conditions in their surrounding environment. By introducing movement and change, therefore time, as an essential dimension of their presence, they challenge the way materials are traditionally understood by designers as passive and inert substances . However, too few designers are trained to express their ideas through temporal concept and qualities, which is all the more so concerning that global ecological challenges impose to revisit the temporality of the current textile production. Behaving textiles are nevertheless regularly discussed in the context of sustainabilityle fashion for their potential to materialise an emotionally durable fashion and for their capacity to generate renewable energy, despite the complex and extremely diversified materiality they encompass. Indeed, behaving textiles cannot be restricted to a specific material composition or shaping process. Furthermore, they are regularly questioned for the ecological impact of their production and use.

Building on the practice-based and design-led research approach developed in the Soft Matters research group of Ecole des Arts Décoratifs, this communication will address the challenges faced by textile designers when working with behaving textiles while discussing strategic eco-design approaches relevant for their conception and materialisation. First Lingxiao Luo's research into shape-changing knitted fabrics is introduced as a case study for examining the technical and poetic challenges linked to the design of garments with dynamic expressions, but also to reflect on the tension between the desire for change/novelty and the aspiration for sustainability at stake within the fashion industry. Secondly, through Reef, a self-actuated ceiling informed by dielectric elastomers and *changing shape according to wind patterns, it will be the occasion to question the nature of interactions supported by behaving textiles and how they can contribute to the design of more interconnective timescapes. Finally, a series of methods borrowed to textile and fashion design practices such as design for disassembly, biomimicry, zero-waste design or biofabrication will convoked to question how behaving textiles can become part of a more resilient culture. All in all, the aim is to underline the necessity to apprehend more holistically the conception, materialisation and consumption of smart textiles.*

9:00 AM SB10.08.02
Wearable Ionic Sensor with 3D Mesh Design for Human Finger Enclosure *Wonjeong Suh, Youngdo Jung and Bo-Yeon Lee; Korea Institute of Machinery & Materials, Korea (the Republic of)*

A wearable sensor emulating human skin has been developed, with applications in healthcare monitoring, human-machine interfaces, and robotic skin. To ensure good adherence to human skin, soft and stretchable polymer-based sensors have been created. However, these sensors can easily fall off when the skin stretches due to joint movement, necessitating additional adhesive techniques to keep them securely attached.
In this study, we propose a cylindrical mesh-type ionic sensor designed to be worn on the finger. The cylindrical shape provides a stable fit regardless of finger movement, and the mesh structure offers excellent air permeability and minimal resistance to movement. We utilized 3D printing to manufacture these sensors, overcoming the limitations of conventional methods. By configuring the printer's bed into a tubular shape, we achieved 360-degree printing of mesh-shaped ion gels that wrap snugly around the finger.
These printed ionic sensors ensure a secure fit, enabling precise monitoring of strain without any looseness between the sensor and the finger. Additionally, by adjusting the size and structure of the printer's tubular bed, we can produce sensors tailored to fit various curvatures and sizes of objects, including fingers, forearms, knees, and feet. This cylindrical mesh-type sensor holds significant potential for use in various fields where stable integration of sensors onto curved surfaces is challenging.

9:15 AM SB10.08.03
3D Printed PEDOT:PSS-Based Conducting and Patternable Eutectogel Electrodes for Machine Learning on Textiles *Ruben Ruiz-Mateos Serrano[1], Ana Aguzin[2], Eleni Mitoudi-Vagourdi[1], Xudong Tao[1], Tobias Naegele[1], Amy T. Jin[1], Naroa Lopez-Larrea[3], Matías L. Picchio[3], Marco V. Alban-Paccha[1], Roque J. Minari[2], David Mecerreyes[3], Antonio Dominguez-Alfaro[1] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]Universidad Nacional Litoral and CONICET, Argentina; [3]University of the Basque Country, Spain*

The development of medical wearables necessitates novel electrodes for cutaneous electrophysiology. Traditional hydrogel electrodes, while effective, pose limitations for long-term use due to skin irritation and the need for frequent replacement. Dry electrodes, although easier to integrate into wearable devices, often suffer from poor skin contact and high noise. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) has emerged as a leading material for bioelectronics due to its mixed ionic/electronic conductivity, mechanical flexibility, and biocompatibility. However, its poor mechanical stability limits its practical application in 3D-printed structures. This study introduces a novel approach to fabricating 3D-printed, PEDOT:PSS-based conducting eutectogel electrodes using a deep eutectic solvent (DES) and polyethylene glycol diacrylate (PEGDA). The DES, composed of choline and lactic acid, enhances the electrical conductivity and mechanical stability of the material. The PEGDA enables the use of standard stereolithographic printing of high-resolution micro-structures. The electrodes were printed in four patterns—flat, pyramidal, striped, and wavy—to assess the impact of geometry on skin conformability and mechanical contact. These electrodes were embedded in textiles and used to generate body surface potential maps (BSPMs) of the forearm during different finger movements. BSPMs for the letters B, I, and O in sign language were recorded and used to train a logistic regression classifier.

The fabricated electrodes demonstrated improved biocompatibility, mechanical stability, and electrical conductivity. When embedded in textiles, these electrodes effectively captured BSPMs, which displayed distinctive patterns corresponding to different finger movements. The logistic regression classifier trained on these BSPMs achieved an accuracy of 97%, significantly surpassing the 86% accuracy of a control array of bare silver electrodes. The performance of the classifiers was assessed by means of confusion matrices and principal component analysis, which showed reliable separation of the classes B, I, and O.
This work presents a significant advancement in the field of wearable electronics for medical applications. The novel PEDOT:PSS-based eutectogel electrodes, with their enhanced performance and stability, offer a promising solution for long-term cutaneous electrophysiology recordings. The ability to accurately classify sign language letters from forearm EMG recordings demonstrates the potential for these electrodes in developing online sign-language translation systems and other brain-machine interfaces. This methodology paves the way for affordable, scalable, and geometry-customised wearables embedded in textiles, significantly advancing machine-interface electronics.

***Stimuli-Responsive Polymer-Nanoparticle Inks for Printed Sensor Arrays** Anastasia L. Elias; University of Alberta, Canada*

Human machine interfaces rely on devices that connect humans to the virtual world, and robotics to the physical one. To provide robotic devices with real-time information about their environment, easy-to-manufacture, lightweight and customizable electronic sensors that can map physical stimuli such as temperature and pressure are required. Advances in both manufacturing techniques (such as 2D and 3D printing) and materials have enabled small, flexible, sensors to be rapidly fabricated on a variety of substrates. This presentation will focus on my research group's efforts to engineer printable, nanomaterial-polymer composites that can sense physical stimuli including temperature, humidity, and pressure, and to integrate these materials into multi-layer devices – including arrays of flexible sensors – on thin, polyimide substrates. In the first part of the presentation, I will describe the formulation of printable polymer-nanoparticle composites tailored to selectively respond to specific physical stimuli. These include temperature-response piezoresistive poly(lactic acid)-reduced graphene oxide (PLA-rGO) composites, humidity responsive hydrogel-silver microflake composites, and piezoelectric polyvinylidene fluoride (PVDF)-nanomaterial composites. These materials are formulated for patterning using direct ink writing, in which a viscous, shear-thinning ink is dispensed through a pressurized syringe onto a moving substrate. The effect of processing parameters on the crystallinity and dispersion of the resulting composites will be described. In the second part of the presentation, I will describe the use of laser-micromachining to ablate vias in polyimide substrates, allowing multilayer arrays to fabricated by printing on either side of the substrate. Data is collected from these arrays using a multiplexer to interrogate each individual sensor in the array. These materials and devices are strong candidates for integration with functional, customizable e-skins.

***Textiles for Soft Wearable Robots** Vanessa Sanchez; Rice University, United States*

Wearable robots and devices—garments with embedded elements that actuate to change shape or apply forces to the wearer, typically based on signals from integrated sensors—offer promise for assistive and augmentative applications including rehabilitative gloves, haptic devices, and dynamically thermoregulating clothing. Early iterations of wearables from the 50s and 60s primarily took the form of rigid exoskeletons; however, in the past twenty years, a growing subset of this field has transitioned to the use of soft components and materials to improve *portability, accessibility, fit, and comfort, guided in part by advances in the related field of soft robotics. Based on the unique requirements for wearables, including personalization for varied bodies and low cost for accessibility, automated and highly customizable textile-compatible manufacturing strategies must be developed to support the fabrication and integration of all the necessary components (sensors, actuators, interconnections). This seminar will explore the intersection of knowledge from the field of textile manufacturing with the needs of soft robots and devices, specifically focusing on wearable applications, including performance metrics, material and component choices, and fabrication strategies. Several integrated design and fabrication platforms will be presented in the context of their ability to manufacture constituent components for wearable robots and devices.*

11:00 AM SB10.08.06

A Flexible Electronics Platform Combining CNT Pressure Sensors and Flexible Tactors Creates a Synchronized Event-Cue Feedback Loop *Phillip D. Glass[1], Sung Hyun Park[2] and Daeha Joung[1]; [1]Virginia Commonwealth University, United States; [2]Korea Institute of Industrial Technology, Korea (the Republic of)*

Wearable devices designed for the somatosensory system aim to provide event-cue feedback electronics and therapeutic stimulation to the peripheral nervous system. The peripheral nervous system generates a neurological response that is relayed back to the central nervous system. Unlike virtual reality tools, these devices precisely target peripheral mechanoreceptors by administering specific stimuli. Given variations in mechanoreceptor density and type across different body locations, custom flexible electronics are essential for effective targeting. Here, a novel approach is employed to develop a sensing-actuation platform using advanced manufacturing techniques. This platform seamlessly integrates soft carbon nanotube (CNT)-elastomer sensors with custom flexible tactile actuators, enabling the creation of wearable electronics capable of delivering accurate and responsive feedback to. By optimizing the cantilevers of the actuators, these sensors can achieve a broad spectrum of driving frequencies. These sensing and actuating devices are fabricated onto flexible substrates through 3D printing and are attached to wearable AC generators and Bluetooth chips. Three functional event-cue feedback devices—a prosthetic, sole, and glove—are presented, demonstrating their capability to utilize CNT sensors for detecting pressure variations from weight, gait, and grip. In response to these mechanical bodily functions, devices simultaneously transmit signals to flexible tactors, eliciting programmable vibrotactile cues on healthy skin areas. The prosthetic responds to a change in pressure on the socket incident from an unsafe posture and induces actuation in the healthy innervated quadriceps. The flexible sole connects plantar sensors that monitor pressure from gait and induces vibration on the dorsum of the foot. Finally, the glove houses five pressure sensors that, upon compression, send a signal to a second glove to induce vibration. The deployment of these innovative devices holds promise for stimulating peripheral nerves, augmenting prosthetic functionality, and enhancing grip control and tactile sensation in individuals with limited nervous system function. This comprehensive investigation not only propels the advancement of wearable technology but also holds promise for diverse fields such as prosthetics, mobility aids, and assistive technology. By bridging the gap between human physiology and technological innovation, this platform can serve as a catalyst for future developments in the field of wearable devices, driving progress towards more seamless and integrated human-machine interfaces.

11:15 AM SB10.08.07

A Machine Learning-Assisted Wireless Wearable System for Stress Monitoring with Epidermal Conductive Polymer Skin Electrodes *Xiaochang Pei, Anita Ghandehari, Shingirirai Chakoma, Jorge Alfonso Tavares Negrete, Jerome Rajendran and Rahim Esfandyarpour; University of California, Irvine, United States*

Stress, triggered by a mix of environmental, social, and personal factors, can lead to severe mental and physical health impacts, including cardiovascular diseases, neuropsychiatric disorders, and increased mortality rates. In response to the urgent need for effective stress management and prevention strategies at the individual level, we *have developed a wireless, battery-free stress monitoring wearable system equipped with machine learning (ML). This system uses Ag/styrene-ethylene-butylene-styrene (SEBS)-based conductive polymer electrodes as epidermal sensors for monitoring galvanic skin response (GSR). These ultrathin, stretchable, conductive polymer electrodes are fabricated using cost-efficient screen-printing methods, ensuring low skin-contact impedance, high signal-to-noise ratio, and excellent mechanical stability for in-situ GSR signal collection on the human wrist. Unlike traditional stress assessment methods such as questionnaires and laboratory assays, which are limited by their non-quantitative nature, lack of standardization, and impracticality for continuous monitoring, our wearable GSR monitor provides real-time Skin Conductance Response (SCR). SCR is a measure of electrodermal activity that reflects increased sympathetic nervous system activity in response to stress-relevant stimuli.*

For signal collection, we employed a battery-free wireless readout system utilizing Near-Field Communication (NFC) technology for wireless power and data transmission, eliminating the need for bulky batteries and enhancing wearability and comfort. The collected GSR data is transmitted to a mobile phone for real-time processing and analysis. Machine learning models are used to accurately classify stress events, distinguishing between stress and rest states based on the GSR signals. We conducted in-situ experiments, including scenarios such as the Stroop test, to evaluate the sensor's capability to detect stressful events. The results demonstrated the system's effectiveness in providing continuous, real-time stress monitoring in everyday settings. Our device achieved an accuracy of 87.1% in distinguishing stress from rest states. This innovative wearable device represents a significant advancement in stress assessment technology, offering a practical and efficient solution for continuous health monitoring.

11:30 AM SB10.08.08

Strain-Insensitive Intrinsically Stretchable Capacitive Sensors for Tactile Applications *Geonoh Choe and Yei Hwan Jung; Hanyang University, Korea (the Republic of)*

Intrinsically stretchable electronics are promising for wearable devices and sensors due to their compatibility with human skin's elasticity. Soft pressure sensors are crucial in fields like intelligent robotics and prosthetics. However, general soft sensors have difficulty distinguishing between strain and pressure signals, necessitating additional processing for data analysis. Here, we report on a strain-insensitive pressure sensor utilizing a dielectric elastomer with tunable dielectric properties. Our group agglomerates high dielectric constant nanoparticles into spheres within a dielectric elastomer matrix. As a result, our dielectric elastomer shows a decrease in dielectric constant as the nanoparticle clusters compress into ellipsoids when stretched. This approach can produce soft sensors that are strain-insensitive and have been used to show that there is little signal variation when standing, walking, and exercising, but that a signal appears when pressure-like falls occur. This innovation represents a significant advance in the development of stretchable capacitive pressure sensors. By overcoming the inherent challenges of pressure sensors and improving their practicality, our work provides a potential solution to distinguish between pressure and strain signals. These advances pave the way for the integration of these sensors into next-generation wearable devices, intelligent robotics, and other advanced applications.

11:45 AM SB10.08.09

Scalable and Modular System of Flexible Phase Change Actuation Modules for Soft Robotics Elements and Functional Clothes *Rafal Ziembicki and Ingrid M. Graz; Johannes Kepler Universität Linz, Austria*

Soft actuators utilize many different ways of actuation that often not only require power supplies, but also devices converting its energy into different form, such as high pressure or voltage output. Therefore, many soft robotic elements remain tethered to bulky hardware, making it difficult to integrate them in wearables. One concept that offers autonomy in this field is using liquid-gas phase change actuation. This simple-in-principle technology, based *on evaporation of the working fluid in enclosed, yet elastic structures, requires only portable power supplies with no need to convert its energy, while allowing to achieve numerous and unique motion types, with programmed deformations limited only by imagination. Phase-transition actuation therefore has a potential to bridge the gap between emerging, but not yet fully developed concepts and the realistic, present needs of the functional clothes industry. To demonstrate this, we present our results on a concept of scalable and modular system of flexible elements utilizing phase change phenomena. This design was inspired by a defence mechanism utilized by puffer fish, which allows them to immensely transform their bodies by ingesting surrounding water, when they feel endangered. Similarly, our phase change actuation (PCA) modules can increase its volume approximately 20 times and are ideal for fashion and functional clothes owing to the fact of their compliance, simplicity of attachment to garments and moderate energy demand achievable by commercially available batteries. Module operation is presented in numerous setups including artificial muscle, hinge opener, mechanical instability trigger and functional clothes demonstrator, drawing inspiration from fish scales, granting both protection and smart clothing features like environment interaction or visualisation of the user state. Blocking force data and thermal imaging of a single module operating with different working liquids including ethanol, methanol, water and Novec 7000 liquid are presented. Going further we tried to implement additional color changing features into the membrane material to enrich visual signals created by the module using the mechanochromic effect of* SiO_2 *nanoparticles embedded in PDMS and creating holographic gratings on the surface of the material. Advantages and disadvantages of this design and possible steps for future improvements, encompassing choice of working liquid, size of the device and heating power are discussed. We aim to utilize mostly off the shelf components, simple manufacturing methods and conventional batteries as a power supply to develop multifunctional, scalable solution that is not only obtainable by a wide field of researchers and designers, but also easily customizable to the needs of a particular project.*

SESSION SB10.09: Devices, Systems and Applications of e-Textiles and e-Skins IV
Session Chairs: Ingrid Graz and Pooi See Lee
Thursday Afternoon, December 5, 2024
Hynes, Level 3, Room 302

1:30 PM *SB10.09.01
Smart Textiles with Soft Sensors and Actuators *Pooi See Lee; Nanyang Technological University, Singapore*

Development of e-textile or e-skin requires materials and devices that are compliant, deformable and stretchable. This talk illustrates our efforts on devising approaches to fabricate sensors and actuators using soft elastomeric nanocomposites for smart textiles. One such example is the perovskite embedded nanofibers that are electrospun into fibrous network that is breathable and washable. The nanofiber composite generates output voltage when subjected to biomechanical stimuli due to triboelectricity and piezoelectricity. In addition, incorporation of dielectric elastomeric actuator allows vibrotactile haptic performance of smart textile. We have achieved this goal through 3D printed actuator that can be mounted onto fabric and developed fiber-based artificial muscles with incorporation of 2D nanomaterials such as MXenes. Wearables for quantitative measurements of muscle stiffness for monitoring of spasticity and eventually telehealth services have been enabled through the integration of soft sensors and actuators. Further discussion will be made on sustainability considerations of these functional devices on smart textiles.

2:00 PM SB10.09.02

Streamlined Inkjet-Printing of Stiff Platforms and Organic Photodiodes on Elastomeric Substrates for Stretchable Light Sensors *Mervin Seiberlich[1,2], Christian Rainer[1,2], Leon Skarjan[1,2], Luis Arturo Ruiz-Preciado[1,2], Kai Xia[1,2], Peter Krebsbach[1,2], Stefan Schlisske[1,2], Uli Lemmer[1,2] and Gerardo Hernandez-Sosa[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany*

The swift progress in IoT, robotics, and wearable electronics has introduced new challenges and heightened the demand for advanced sensing technologies. These sensors must not only deliver customized performance but also possess properties such as stretchability and flexibility while remaining compatible with industrial manufacturing processes.

In this study, we present a streamlined approach to fabricating stretchable organic photodiodes (OPDs) arrays using exclusively inkjet printing. This is achieved by printing stiff islands and interconnects directly onto elastomeric substrates. The structures were fabricated from the UV-curable photoresist SU-8 to offer a solvent-resistant platform for creating the OPDs. Simultaneously these structures provide a mechanically stable foundation that protects the devices from mechanical stress. We thoroughly investigated and optimized the ink formulation and printing process of these structures, as well as their impact on the mechanical properties of the silicone-based elastomeric substrate. After printing the structures, we achieved elongations of up to 60% before observing any delamination or structural failure of the subtrate. Challenges encountered during the printing of Ag electrodes on the curved island surfaces were resolved through a two-step printing process and optimized annealing steps. Cyclic conductivity measurements of printed Ag layers on top of them did not observe any degradation for up to 500 cycles.

Finally, we fabricated fully-printed OPDs based on polymer: non-fullerene acceptor bulk heterojunctions (BHJ). The inkjet printing process of the multilayer architecture Ag/SnO/BHJ/PEDOT:PSS needed to be adapted to the new substrate properties and morphology. The devices exhibited state-of-the-art peak responsivities of 340 mA/W (l = 730 nm). Furthermore, they showed specific detectivity (D) of 2.8 × 10^11 Jones (at 100 Hz and -2V). The light sensors remained operational for over 600 mechanical stretching cycles at strains up to 7%. This fully inkjet-printing approach can potentially simplify the fabrication steps needed to fabricate stretchable devices and enhance compatibility with industrial printed electronics processes. Furthermore, its digital nature will enable a broader application in other types of (opto) electronic devices and emerging stretchable applications.*

2:15 PM SB10.09.03
Electronic Eco-leather—Flexible Composite from Biowaste with Laser Patterned Graphene for Sensors Application *Iuliia Steksova[1,2], Anna Chiara Bressi[1,2], Marina Galliani[1,2], Hilda Gomez Bernal[1,2] and Francesco Greco[1,3,4]; [1]The BioRobotics Institute, Italy; [2]Dept. of Excellence in Robotics & AI, Italy; [3]Interdisciplinary Center on Sustainability and Climate, Scuola Superiore Sant'Anna, Italy; [4]Institute of Solid State Physics, Graz University of Technology, Austria*

The fabrication of flexible electronics and sensors using biobased waste is one of the trends in sustainable materials science and engineering. The optimal combination of mechanical and electrical properties of materials is the leading approach to develop advanced wearable electronics, such as e-skins and e-textiles[1-3].
In this study we present a novel leather-like composite based on biowastes: almond shell powder (ASP) and chitosan, with the latter being derived from crustaceans exoskeletons. The high cellulose content (38.7%) in the ASP, measured using a modified standard for the determination of structural carbohydrates and lignin in biomass raw material, improves the mechanical properties of the composite: the material shows high tensile strength and high flexibility, with the possibility to be sewed as standard fabrics or leather. The addition of chitosan as a polymeric matrix, results in a flexible and biodegradable composite, as confirmed by the results of mechanical

tests (Young's modulus = 14 - 21 MPa, depending on the ASP content in the composite) and biodegradation tests in the soil. At the same time the high lignin concentration in shells (30.6%) improves the material thermal stability, making it also an ideal precursor for laser-induced graphene (LIG). LIG is a three-dimensional porous and conductive carbon structure, obtained by the IR or UV irradiation of substrates (i.e. synthetic and natural polymers), which undergo a laser induced pyrolysis through photo-chemical or thermal reactions. LIG synthesis and patterning is a cost-effective, one-step, fast, and digital process that meets the needs for sustainable fabrication[4,5].

The LIG obtained from ASP/chitosan composites by IR and UV laser scribing shows low sheet resistance and high specific surface area. Moreover, SEM and Raman spectroscopy characterizations reveal different micro/nano morphologies depending on laser settings and confirm the successful conversion of the composite precursors in LIG to create conducting elements.

The obtained eco-leather shows high potential for use in flexible, wearable sensors. Proof of concept applications have been tested for environmental humidity monitoring and for various electrical circuits/electrodes, opening the way to a wide range of applications.

2:30 PM SB10.09.04

Highly Stretchable and Self-Powered Triboelectric Sensor for Smart Detection of Materials *Kalyan Ghosh, Alexander Morgan and Sohini Kar-Narayan; University of Cambridge, United Kingdom*

In Industry 4.0, soft robots are creating a profound impact on human life in various applications, from industrial floor management to medical and healthcare systems. However, the soft robots cannot differentiate the type of contact materials and their environmental surface conditions. Recently, triboelectric nanogenerators (TENGs) based sensors are attracted to provide signals from mechanical actions such as motion, vibration, rubbing, and touching without needing any power pack. However, the inclusion of such a TENG sensor which is composed of a dielectric layer and conductive current collector on a soft robotic body body is difficult due to the incompatibility of materials between TENG components and a soft robotic body, and their additional circuit to integrate on the soft robot. In this research, a highly stretchable triboelectric sensor is developed and attached to a cotton glove for wearing on a prosthetic soft robotic hand. The dielectric layer of the triboelectric sensor is fabricated employing 2D MXene (V_2CT_x, T= −OF, −F) and Ecoflex-based composite film. The conductive V_2CT_x with fluoride surface termination enhances the triboelectric properties of the triboelectric sensor. The amount of MXene/Ecoflex weight ratio is optimized to obtain the highest signal output. The triboelectric sensors are assembled on the cotton glove to work as single-electrode mode TENG, and the triboelectric output signals are recorded wirelessly by integrating a microprocessor (ESP32) with the glove. The contact signals from the different household materials made of plastic (PET bottle), metal (soft-drinks can), and ceramic (tea mug) are recorded wirelessly and programmed to identify the type of contact material. Additionally, the contact signals are recorded in the wet condition of the materials. Thus, the triboelectric sensor-integrated glove can differentiate materials like metal, polymer, or ceramic and their surface condition (wettability). The smart gloves can be worn on a prosthetic soft-robotic hand for such sensing actions. In future, this research will pave the way for developing intelligent triboelectric sensors and smart gloves for the identification of any unknown materials from the family of metals, polymers and ceramics.

2:45 PM SB10.09.05

Strain-Rate Response of Self-Powered Triboelectric Tactile Sensors *Vanessa Barton[1], Vaibhav Khurana[1] and Joseph Andrews[1,2]; [1]University of Wisconsin, United States; [2]University of Wisconsin–Madison, United States*

Triboelectric transduction of applied pressures offers an attractive approach to force sensing that can enable next-generation self-powered sensors. Self-powered sensing approaches are ideal for wearable and robotic "e-skin" applications, where the form factor restricts the ability to integrate batteries or other energy storage devices. For triboelectric sensing, an applied force causes either a change in contact surface area or induces a parallel sliding between two materials. Both phenomena can induce static charge transfer which can then be measurAlsoed as an open-circuit voltage. These phenomena have been explored previously, but without direct control of the rate of the applied force. The rate of deformation in the materials within the triboelectric series, however, plays a crucial role in the measured charge transfer and should be explored directly to accurately measure forces with varied temporal characteristics.

In this work, we have designed a triboelectric sensor which consists of interdigitated copper electrodes encapsulated in polyimide. On top of that sensor, we place a lightly lubricated PDMS layer. As a load is applied to the incompressible PDMS, it induces a lateral sliding effect between the PDMS and the underlying electrodes. This sliding motion causes a differential static charge between the two materials which can be measured as an open-circuit voltage. Specifically, we apply a normal force to strain the PDMS to 75% compressive strain at two strain rates, 50% s^{-1} and 100% s^{-1}. In both scenarios, the 75% strain occurred at a stress value of approximately 5.5 – 6 MPa.

In all scenarios, during the loading phase the open-circuit voltage increases symmetrically on each electrode within the dual-electrode IDE and subsequently decreases during unloading with the maximum open-circuit voltage achieved at the peak strain. To increase the signal to noise ratio, we sum the voltages from each electrode within the IDE. While many studies then correlate the maximum open-circuit voltage directly to pressure, we find that this is highly dependent on strain-rate. For example, the maximum summed voltage at 75% strain (5.7 MPa) is 226 mV for the 50% s^{-1} strain rate, while the maximum summed voltage at 75% strain (6 MPa) is 368 mV for the 100% s^{-1} strain rate. To overcome the strain-rate dependence, one must observe the temporally resolved voltage signal. We find that through integrating the open-circuit voltage over time we are able to correlate the electrical signal directly to the applied force irrespective of strain rate. The resulting voltage-integral with respect to applied pressure results in a quadratic trend with an average sensitivity (derived from the instantaneous derivative of the fitting quadratic function) of 19.27 mV-ms kPa^{-1}.

Ultimately, our work shows that through temporal analysis of the open-circuit voltage, a triboelectric sensor that directly senses applied pressures can be derived with minimal strain-rate dependence, ultimately allowing for self-powered transduction of applied forces. The elimination of strain-rate dependence, coupled with the simple fabrication of the device, can enable fully flexible and self-powered sensors for wearable and robotic sensing applications.

3:30 PM SB10.09.06
PVDF-Muscovite Bimorph System as Flexible Transparent Thermal Sensor *Ching-Ming Su[1], Jyh-Ming Wu[2], Che-Ning Yeh[2] and Ying-Hao Chu[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Tsing Hua University, Taiwan*

With the rise of wearable devices, research on flexible materials has become more crucial. However, moderating *the connection of multiple functions and the interaction between humans and devices is essential. Thus, the actuators and sensors become significant components in this field. This study focuses on improving the sensitivity of flexible thermal sensors to follow up on the human body's condition. We propose a thermally sensitive system based on polyvinylidene difluoride (PVDF) and muscovite. Muscovite offers a platform for better thin film growth and stable mechanical flexibility in this system. The disparity in the coefficient of thermal expansion between muscovite and PVDF is enormous, leading to a considerable strain under a low-temperature variation. Further, PVDF is a piezoelectric material that exhibits electric polarization variations due to the internal generation of mechanical stress, producing an electric field. With a thickness of 20μm, this system can generate an output voltage of up to 2.21V at a 100^{O}C temperature variation. On the other hand, the transparency of PVDF /muscovite shows excellent potential for more applications, such as all-transparent wearable devices. In conclusion, considerable sensitivity can be achieved in the designed system. The subtle fluctuations of temperature can be detected daily and generate a considerable electric signal compared with a pyroelectric system. The measurement shows an effective pyroelectric coefficient of about 119.4 (10^{-4} C.　m^{-2}.　K^{-1}). Therefore, this research gives us an excellent option for integration into wearable devices.*

3:45 PM SB10.09.07

Highly Stretchable and Strain-Insensitive Liquid-Metal Based Elastic Kirigami Electrodes (LM-eKE) *Hyesu Choi[1], Carmel Majidi[2,2] and Tae-il Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Carnegie Mellon University, United States*

For stretchable electronics, there remains a critical need for electrically conductive materials that are highly deformable. Among these, gallium (Ga) based liquid metal (LM) alloys have become increasingly popular because of their high metallic conductivity and intrinsically deformable characteristics. Here, we demonstrate an LM-coated elastic kirigami electrode (LM-eKE) architecture that combines extreme mechanical deformability (up to 820% stretchable) with high electrical conductivity and relatively low electromechanical coupling. This stretchable electrode is based on a unique "Elastic Kirigami" design in which the paper-like foldable substrate typically used in kirigami is replaced with a soft and highly elastic thin film. Specifically, the LM-eKE is composed of a kirigami-patterned silicone membrane that is coated with a thin gold (Au) film and layer of eutectic gallium-indium (EGaIn) LM alloy. The biphasic Au-EGaIn film has negligible mechanical stiffness and allows the LM-eKE to maintain a low elastic modulus (kPa scale) and high degree of deformability. Moreover, the elasticity of the silicone substrate allows the LM-eKE to be stretched beyond the structural elongation of conventional kirigami since it combines folding deformation with high elastic strain. In addition, the coupling between this geometric and elastic deformation of the substrate allows the LM-eKE to maintain highly stable electrically conductive pathways along the biphasic Au-EGaIn surface. In this way, these electrodes exhibit low strain-sensitivity with only a 33% increase in electrical resistance when stretched to 820% strain and only a 1.3% ~ 1.7% increase when placed on a human knee and stretched during physical activities (walk, run, jump, bend). This low strain-sensitivity is an essential property of highly stretchable electrodes since it allows data to be transmitted without interruption from external mechanical stimuli. Moreover, as shown in this study, the high electromechanical stability of the LM-eKE electrodes allows for the avoidance of motion artifacts when collecting physiological data within wearable health monitoring applications.

4:00 PM SB10.09.08

A Multilayer Template Stripping Based Microtransfer Printing Process for Stretchable Electronics *Léo Sifringer, Daniel Laguna Cillero, Michel Sommer and Janos Vörös; ETH Zürich, Switzerland*

The development of flexible and stretchable electronics is essential for advancing wearable healthcare and biomedical devices. These technologies demand sophisticated mechanical design and integration strategies to *improve durability and form factor. Moreover, scalability is important to support the high-volume manufacturing necessary to satisfy increasing market demands [1].*

In this work, we describe a novel method for fabricating stretchable electronics utilizing a multilayer template stripping based microtransfer printing process, which builds upon published work [2]. Notably, once the master template is produced, this method does not rely on photolithography, etching, or other specialized equipment beyond metal evaporation, making it a simple process to carry out. The process involves four key steps: metal deposition, template stripping and transfer, and carrier substrate dissolution.

Initially, metal is deposited onto Si wafer etched template. The top metal layer is then stripped using a polyethylene naphthalate (PEN)-supported polyvinyl alcohol (PVA) layer. This flexible PVA sheet is gently laminated onto the template, ensuring no air is trapped, and negating the need for a vacuum chamber. The pressureless lamination ensures that the metal is only stripped from the top of the structured template, despite the adhesive sheet's flexibility. This procedure is conducted at 120°C, above the glass transition temperature of PVA, which increases its adhesive strength. Once cooled to room temperature, the two sheets are separated without applying any shearing forces. The metal pattern on the adhesive sheet is then transferred onto a stretchable substrate (PDMS). The sheet is laminated under pressure and further stabilized by applying pressure from above with a soft stamp at 120°C. The final step involves dissolving the remaining PVA in boiling water. This entire process can be repeated (using the same template or a new one) to create a multilayer structure of metallic features.

Finite Element Analysis (FEA) is conducted to optimize the structural performance of the interconnects, helping to identify design strategies that enhance device stretchability before failure. Devices can then be fabricated based on these design rules. Preliminary results indicate that our designs can achieve stretchability up to 100%, and withstand 1000 cycles at 50% strain. Ongoing research aims to further characterize devices and increase this stretchability by improving the interfacial properties between different layers.

The promising preliminary results indicate potential applications in a variety of fields, including for example strain sensors, stretchable electrodes, and cochlear implants.

Soluton Process of Low-Profile Electronics for Smart Apparel Gun-Hee Lee; Carnegie Mellon University, United States

The solution process provides significant advantages over traditional vacuum processes, particularly in integrating low-profile electronics into various substrates. While vacuum processes are often limited by material constraints, size restrictions, and design inflexibility, the solution process accommodates a wider range of materials, enables large-scale fabrication, and offers greater design versatility. This flexibility is especially beneficial for emerging functional materials like carbon nanotubes (CNTs), graphene, MXene, and EGaIn liquid metal particles, which are typically available in powder form. Dispersing these materials through colloids or suspensions using the solution process opens up innovative applications in low-profile electronics for smart apparel.

Clothing serves as a natural interface with the human body, providing a unique platform to integrate functionalities for healthcare and digital interaction. However, embedding functional materials into garments poses significant challenges in the development of smart clothing. To address these challenges, I have developed a self-assembled printing technique specifically designed for the large-scale production of sportswear incorporating low-profile electronics.

Additionally, the fabrication of electronic fibers offers a promising pathway for advancing smart clothing. By utilizing advanced solution processes, I have created stretchable and conductive fibers on a large scale, well-suited for low-profile electronic applications. Moving forward, my objective is to refine these solution processes to produce a variety of functional fibers, enhancing the capabilities of clothing and supporting the development of more seamless and natural human-machine interfaces.

4:30 PM SB10.09.10

Intrinsically Stretchable Semiconducting/Conducting Nanocomposites for AI-Aided Visual and Tactile Sensing Systems *Jiyong Yoon and Donghee Son; Sungkyunkwan University, Korea (the Republic of)*

The human sensory systems, particularly vision and tactile, play a crucial role in our daily lives. For individuals who have lost or are born without these sensory capabilities, the world can be a different and challenging place. Developing electronic devices capable of effectively perceiving and transducing these sensory modalities is an important challenge to improve the quality of life for such individuals. Especially, the need for stretchable electronic devices that can conform to the movements of the human body has driven extensive research in this area. Two representative approaches have been explored to achieve stretchable electronics. i) One method is to adopt high-performance inorganic materials together with strain-dissipative designs, which can maintain their electrical performance under mechanical deformations. However, the large area occupied by the structural designs can limit the device density. ii) The alternative method is to adopt intrinsically stretchable materials, such as elastic conductors and semiconductors using a mixture of organic/polymeric materials and elastomers, which does not require the use of special device structures. However, there are still challenges in terms of the electrical performance and durability of materials and devices under severe repetitive mechanical deformations.

In this presentation, we introduce two studies that use intrinsically stretchable semiconducting/conducting nanocomposites to overcome these challenges, mimicking the functionality of visual and tactile sensing systems. First, we report on the development of a retina-like stretchable multiplexed arrays. This new class of the intrinsically stretchable artificial retina consists of organic-inorganic hybrid semiconducting nanocomposites, crack-based gold nanomembrane electrodes, and elastomeric substrate. To enable effective light-sensing capabilities, the composite incorporates vertically phase-separated, size-tunable quantum dots that facilitate efficient charge transfers. The individual phototransistor cells can be either multiplexed or stacked in a misaligned manner using a transfer-printing method, allowing for high areal density. Additionally, a deep learning algorithm is utilized to fully compensate for optical distortions during repetitive mechanical deformations of the devices. This enables the accurate recognition of specific color patterns, such as red, green, and blue, even under harsh strain conditions, thereby mimicking the unique biological functionality of the retina.

Second, we report on the development of a skin-like intelligent wearable system, a bioinspired stretchable sensory-neuromorphic system, comprising an artificial mechanoreceptor and artificial synapse. These biomimetic functionalities correspond to a stretchable capacitive pressure sensor and a resistive random-access memory, respectively. This system features a rigid-island structure interconnected with a sinter-free printable conducting nanocomposite optimized by controlling the evaporation rate of solvent. The proposed design enhances both areal density and structural reliability while preventing the thermal degradation of heat-sensitive stretchable electronic devices. In addition, the system is able to accurately recognize different patterns of stimuli through an artificial neural network with training and inferencing functions, even in the range of skin deformation.

Biomaterials-Enabled Multiscale Drug Delivery in Plants *Benedetto Marelli; Massachusetts Institute of Technology, United States*

The infrastructure of agro-food systems is responsible for more than 25% of anthropogenic greenhouse gas emissions while facing pressure to support an increasing world population. For the first time in history, the availability of arable land has plateaued, and crop yields are threatened by stressors such as soil salinity and drought that are further exacerbated by climate change. Food security and food waste are twin crises; more than 800 million people are undernourished, and 30% of food is lost or wasted from farm to fork. As new technologies that are economically sustainable, scalable, and rapidly deployable to market are needed to address these challenges, an opportunity lies for biomaterials to lead innovation in the agro-food industry. Our laboratory strives to reinvent biopolymers as advanced materials for boosting food security. Here, we will highlight recent developments in the nanomanufacturing of biopolymers to design: (i) pollen-like biodegradable microcapsules for the precise delivery of agrochemicals via foliar spray, (ii) silk-based Pickering emulsions that target specific plant tissues such as trichomes, (iii) nanocarriers for the delivery of genetic materials in plant cells, and (iv) different solutions to enhance the deployment of biofertilizers in soil using principles of bioinspiration and biomaterials design. These examples will provide an opportunity to discuss new mechanisms of biopolymers directed assembly and nanofabrication and the production at scale of biopolymer formats that can perform at the interface with living matter to improve planetary health.

11:00 AM *SB11.01.02

***Highly Efficient 3D Templating of Microbially Induced Calcium Carbonate Precipitation** Hannah Clarkson, Sophia Jackson and Shu Yang; University of Pennsylvania, United States*

Microbially induced carbonate precipitation (MICP) of calcium carbonate ($CaCO_3$), the main ingredient of concrete or biocement, offers a carbon neutral or carbon negative route to create environmentally friendly and CO_2 capturing biocement. However, typical MICP process is slow and obtained $CaCO_3$ has different polymorphs. To enhance the growth of bacteria and its colonization and carbonation efficiency, while controlling the polymorphs of $CaCO_3$, we exploit the use of 3D printed minimal surfaces coated with biocompatible hydrogels as templates to immobilize non-pathogenic ureolytic bacteria genus S. pasteurii and photosynthetic cyanobacteria, respectively. We show that the amount of $CaCO_3$ crystals deposited on the 3D templates are an order of magnitude more than those deposited on a conventional agar gel in a petri dish. Inclusion of nanoporous materials that can capture CO_2 in bacteria growth medium further enhances bacteria growth and precipitation of $CaCO_3$.

11:30 AM *SB11.01.03

***Stronger When Wet—The Use of Metals and Water in Biological Composites** Javier Gomez Fernandez; Singapore University of Technology and Design, Singapore*

Synthetic polymers are widely used in product manufacturing due to their stability and persistence in water-based environments. This stability, however, is inversely related to their biodegradability. By enhancing their crystallinity, crosslinking density, and molecular weights, these polymers acquire the necessary water stability and mechanical properties for manufacturing. Yet, this stability in water impedes their compostability, resulting in materials that, even when bio-based, can only be biodegraded in specialized facilities, if at all, limiting their recyclability and making their end-of-life impact comparable to, if not worse than, any other persistent synthetic material.

The inability of these materials to be simultaneously resilient in the environment and integrated with ecological cycles is not a limitation of the molecules themselves but rather a consequence of the current manufacturing paradigm, where material resilience is based on their inertness to external elements and their isolation from the environment. However, biological systems evolve to utilize their environment, not isolate from it. They produce remarkable structures that develop and function in water-rich environments by making water a central element in their designs.

A prime example is the production of the chitinous cuticle of arthropods. This cuticle is secreted as a gel-like form into water, hardens to form solid exoskeletons for insects and crustaceans, and functions in humid or underwater environments throughout the animal's life. The sclerotization process, which transforms the cuticle from a soft hydrogel to a hard structure, is a complex interplay of water transport, molecular reorganizations, and mechanical forces. Recent studies have highlighted the role of transition metals in this process and the intricate relationships they share with the organic components of the cuticle. These metals are incorporated into critical areas of chitinous cuticles, such as the tips of the claws and fangs or egg shells, to exploit their mechanical properties. However, removing metals from the cuticles of some arthropods also makes them susceptible to hydration and softening when immersed in water, suggesting that they might play an essential role, beyond reinforcing, in controlling water interactions in chitinous materials.

In this talk, we will journey through our scientific exploration that began with understanding how arthropods utilize metals to control mechanical properties and their interactions with water. This understanding led to the development of a new type of metalworking at room temperature based on water exchange and the first biopolymer that gains strength in humid environments by using environmental water as part of its structure.

We will discuss how the controlled integration of water, with metal ions serving as a functional element, can create *stronger and more adaptable biological structures. This approach is based on a bioinspired manufacturing paradigm in which unmodified biological molecules are used in product manufacturing associated with their native manufacturing principles, establishing a relationship with the environment that is not isolating but bidirectional, and achieving outstanding properties while remaining fully integrated within ecological cycles.*

This talk will highlight the transformative potential of using unmodified natural molecules in manufacturing, paving the way for a future where materials are designed to integrate, rather than isolate, from the environment.

SESSION SB11.02: Bioelectronics
Session Chairs: Rossella Labarile and Junyong Park
Monday Afternoon, December 2, 2024
Hynes, Level 3, Room 313

1:30 PM *SB11.02.01
Biohybrid Photosynthetic Living Materials and Devices Eleni Stavrinidou; Linköping University, Sweden

Repurposing biology for technology is one of the pathways for a sustainable future reducing synthetic waste and carbon emissions. The integration of living components directly in materials and devices opens new possibilities for energy efficient, sustainable materials that are dynamic and responsive. Previously we leveraged the biocatalytic machinery of plants for in-vivo fabrication of functional electrochemical components. Specifically, we demonstrated that plants can polymerize conjugated oligomers in-vivo forming conductors within their structure. We showed that the polymerization is enzymatically catalyzed by endogenous peroxidases, and we developed a series of conjugated oligomers that can be enzymatically polymerized in physiological conditions. The conjugated polyelectrolytes integrate within the plant cell wall adding electronic functionality into the plant that is then explored for energy storage. We also demonstrated intact plants with electronic roots that continue to grow enabling plant-biohybrid systems that maintain fully their biological processes. The electronic roots were used to build biodegradable supercapacitors and biohybrid circuits to power low consumption electrochemical devices. Apart from augmenting plants with non-native functionality we are also interested in using synthetic materials for enhancing plant processes. Photosynthesis is the process that drives life on Earth and is vital for CO_2 capture. We developed polyethyleneimine-based nanoparticles that enhance photosynthetic biochemical reactions in-vitro while in-vivo enhance plants CO_2 capture ability. Our latest work extends these concepts to plant components combined with additive manufacturing for producing custom made sustainable photosynthetic living materials.

2:00 PM *SB11.02.02
Biopolymer-Based Mixed Ionic-Electronic Conductors for Bioelectronics Serpil Tekoglu; Johannes Kepler Universität Linz, Austria

Poly (3,4-ethylenedioxythiophene) (PEDOT):polystyrene sulfonate (PSS) is the workhorse conducting polymer (CP) for bioelectronics. Despite its outstanding performance as organic mixed ionic-electronic conductor (OMIEC), there is a growing interest for developing novel functional materials to improve its inherent limitation, e.g., biocompatibility. In this context, biomaterials are promising candidates for substitution of PSS to enhance biocompatibility.

In our group, we focus on the opportunity to endow the abundant natural biomaterials, i.e., ***deoxyribonucleic acid***

***(DNA), polysaccharides (nanocellulose, Sacran), proteins** to create mixed conductors (OMIECs). Negatively charged biopolymers are capable to serve as counterion for the first generation conductive polymers such as PEDOT, polypyyrole. The facile green synthesis is performed via oxidative chemical polymerization using mild oxidants in aqueous media. The conductive polymer chain is successfully stabilized by the negative charges on the biopolymer within various conductive composite structures. Diameter of nanoparticles are evaluated in different lengths and optimized by changing the ratio between monomer and polymer units. The CP:biopolymer hybrids possess good ionic and electronic conductivity. The findings revealed the high doping rate resulting in the electronic conductivity is recorded up to 34 S cm^{-1}. Furthermore, colloidal dispersions of the composites are successfully optimized for solution processing (spin-coating, doctor blade) to deposit thin-films for device applications. A comprehensive study is conducted with the material characterization and morphological changes of composites correlated with their micro- and nanostructure. The composites are deposited as the channel material in organic electrochemical transistors (OECTs), proving their ion-to-electron transconduction. The transconductance, g_m value is obtained up to 12 mS by adjusting the device parameters of interdigitated OECTs. Non-cytotoxicity of novel composites are highly desirable in implantable materials and devices, therefore, further evaluated in vivo. These results indicate high biocompatibility toward cell culture without any significant cytotoxicity.*

In contrast to PEDOT:PSS, the CP:biopolymer composites can be utilized through DNA and protein specific recognition properties. The proposed approach can be considered as a strategy to open up a new path for bio-functionalization of organic layers for biosensing and bioelectronics.

2:30 PM *SB11.02.03

***Leaf-Based Ultrasensitive Electronic Skins for Wearable Human Motion Monitoring** Seung Goo Lee; University of Ulsan, Korea (the Republic of)*

Nonbiodegradable components, such as synthetic polymers, have been widely used in the fabrication of flexible sensors and electronic skins (e-skins), resulting in the generation of electronic waste and toxic by-products. To overcome this issue, a wide range of biodegradable natural biopolymers and synthetic polymers have been employed to fabricate flexible sensors and wearable electronics. However, most current biodegradable e-skins demonstrate limitations such as low sensitivity, poor electrical conductivity, limited breathability, and low stability. Inspired by nature, to address these limitations, we introduce a series of highly breathable and ultrasensitive e-skin based on the coating of leaf skeletons with electrically conductive nanomaterials including, oxidized single-walled carbon nanotube (Ox-SWCNT), silver nanowire (AgNW), and carboxylated multi-walled carbon nanotubes (COOH-MWCNTs). We propose various e-skins based on different transduction strategies including capacitive and piezoresistive mechanisms. Our disposable capacitive e-skin exhibits a wide sensing range (0.01–97 kPa), high sensitivity (0.86 ± 0.16 kPa^{-1}), low limit of detection (~10 Pa), linearity for low- and high-pressure regimes, flexibility, breathability, high stability (3000 cycles), and biodegradability. In addition, the multilayered disposable e-skin based on piezoresistive transduction exhibits a remarkable performance including high sensitivity (19.75 ± 1.5 kPa^{-1}), wide sensing range (<42 kPa), ultralow limit of detection (~0.27 Pa), linearity for low- and high-pressure regimes, high flexibility, high stability (3000 cycles), low weight, ultrahigh breathability, and biodegradability. The developed leaf-based e-skins demonstrate outstanding sensing performance in human-motion monitoring by detecting various motions such as subtle and vigorous flexions, airflow, and vocal-cord vibrations. The proposed capacitive and piezoresistive e-skins are promising platforms for the development of various low-cost, biocompatible, biodegradable, and point-of-care e-skins for a wide range of subtle and vigorous pressure-monitoring applications including human–machine interfaces, robotics, prosthesis, and wearable electronics.

Surface Display Techniques for Bioelectrocatalysis *Shelley Minteer[1,2]; [1]Missouri University of Science and Technology, United States; [2]The University of Utah, United States*

Poly(hydroxybutyrate) is a biocompatible, biodegradable polyester synthesized by microbial species, which is considered a greener alternative to petroleum-based plastics, but has not become mainstream as a leading polymeric material in the plastic industry due to its high cost of production. Specifically, the extraction of this material from within bacterial cells requires lysis of cells, which takes time, uses harsh chemicals, and starts the process again with growing new living cells. Recently, surface display of enzymes on bacterial membranes has become an emerging technique for extracellular biocatalysis. In this work, a fusion protein lpp-ompA-phaC was expressed in E. coli to display the enzyme poly(hydroxyalkanoate) synthase on the cell surface. This work are the first demonstration of extracellular synthesis of poly(hydroxybutyrate), showing promise for continuous and scalable synthesis of materials using surface display and combining with bioelectrocatalysis.

4:00 PM *SB11.02.05

Bridging Living Microbes and Electrodes with Biosynthetic and Biological Polymers *Ardemis Boghossian; École Polytechnique Fédérale de Lausanne, Switzerland*

Ongoing discoveries with exoelectrogenic microbes have inspired the latest developments in whole-cell energy devices. This devicees rely on the effective interfacing of living microbes and electrodes for bioelectricity generation. A combination of materials engineering and biological engineering has thusfar contributed to record-breaking device performances in microbial fuel cells and living photovoltaics. These advancements have largely focused on the expression of protein-based electron conduits in bionengineered microbes [1], conductive polymer-based electrodes [2-3] and nanobionics [4] for enhancing device performances.

This presentation focuses on complementary approaches that exploit biosynthetic material characteristics. We explore the development of biosynthesizable electrodes based on biological polymers [5-6] as well as soluble biological mediators [7]. This presentation also examines the development andoptimization of solid-state electrode constructs with enhanced charge-extraction capabilities. Finally, we discuss recent techniques inspired by synthetic electronic laboratories. These advancements establish new benchmarking techniques fore electrobiological characterization that have been lacking in the field.

Portable and On-Demand Yeast Cells-Based Electrochemical Biosensors Enabled by Polydopamine *Matteo Grattieri[1,2], Ohiemi B. Ocheja[1], Ehthisham Wahid[3], Jefferson Honorio Franco[1], Cataldo Guaragnella[3], Enrico Marsili[4], Massimo Trotta[2] and Nicoletta Guaragnella[1]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Politecnico di Bari, Italy; [4]The University of Nottingham Ningbo China, China*

The electrical wiring of biological organisms with electrodes enables the development of sustainable, low cost, and potentially self-sustained electrochemical biosensors.(1) However, achieving such electrical communication is challenging, particularly when intact biological organisms are employed.
Yeast cells have the advantages of high stability and robustness, self-regeneration capability, and unique eukaryotic receptors. Herein, we developed a bioinspired approach for the rapid entrapment and immobilization of metabolically active yeast cells in a biocompatible polydopamine layer, which does not require a separate and time-consuming synthesis. The obtained biohybrid system allows current generation from glucose oxidation, with electrochemical performance influenced by the presence of $CuSO_4$, a widely used pesticide, in the environmentally relevant concentration range of 20 - 100 μM.(2) The effect of different substrates on current generation and biosensor sensitivity is discussed, and the enthralling possibility to utilized mutant strains with altered respiratory metabolism for biosensors with enhanced performance is presented.

Bioinspired Silicone-Based Materials for Adjustable Energy Dissipation in Soft Robotics and Electronics

Ingrid M. Graz, Rene Preuer and Ian Teasdale; Johannes Kepler Universität Linz, Austria

Nature is a clever engineer – creating living systems soft with multilayered protective structures such as bones, skin or fruit peel that can not only sustain high dynamic, but also quasi-static mechanical loads while being built-up by a small range of basic. Taking inspiration from biological tissues we present simple approaches to damping structures with adjustable stiffness based on novel silicone elastomers and their foams. Silicone elastomers as rubbers are inherently dissipative, however it is challenging to achieve graded elastic moduli within one

continuous structure. We therefore created a polyimide-polydimethylsiloxane (PI-PDMS) material mimicking the mechanical properties of the beak of the Humbold squid. The squid beak bridges a wide range of mechanical properties allowing to seamlessly connect the hard beak for cracking open mussels with the soft body of the squid. In analogy, we cover a wide range of mechanical properties by tuning the amounts of the chemical components. To demonstrate the versatility of graded structures made from PI-PDMS, we realized stretchable conductors, reducing principle strain at weak interfaces as well as simple dielectric elastomer actuators.
In aaddition, we designed open-pore silicone foams filled with carbon black mimicking the spongy structures of citrus fruit peel. Citrus fruit peel and in particular the spongy foam called albedo is a perfectly tailored biological damping structure. It protects the citrus fruit from splitting open upon its fall from the tree and thus ensures seed distribution. We created foams inspired by citrus fruit albedo and combined them with a peel-like circular pneumatic actuator to demonstrate adjustable energy dissipation as well as sensing upon impact. Material characterzation and proof-of-concept demonstrators are shown.

SESSION SB11.03: Biomaterials

8:00 AM *SB11.03.01
Programmed Sequential Degradation—Towards Eco-Friendly Morphing Interface with Biopolymers and Biohybrid Devices *Qiuyu Lu[1], Semina Yi[2], Mengtian Gan[2], Jihong Huang[2], Jihong Huang[3], Xiao Zhang[4], Yue Yang[1,5], Chenyi Shen[2] and Lining Yao[1]; [1]University of California, Berkeley, United States; [2]Carnegie Mellon University, United States; [3]University of California, Los Angeles, United States; [4]Tsinghua University, China; [5]Zhejiang University, China*

While it seems counterintuitive to think of degradation happening within an operating device as beneficial, one may argue that when rationally designed, the controlled breakdown of materials—whether physical, chemical, or biological—can be harnessed for specific functions. To apply this principle to the design of morphing interfaces, we introduce the concept of "Degrade to Upgrade" (DtU). This concept aims to create eco-friendly and self-contained morphing interfaces and devices that operate through a sequence of environmentally-triggered degradations. We explore its design considerations and implementation techniques by identifying environmental conditions and degradation types that can be exploited, evaluating potential materials capable of controlled degradation, suggesting designs for structures that can leverage degradation to achieve various transformations and functions, and developing sequential control approaches that integrate degradation triggers. To demonstrate the viability and versatility of this design strategy, we showcase five application examples across a range of environment conditions.

8:30 AM SB11.03.02
The Cribellate Nanofibrils of the Southern House Spider—Extremely Thin Natural Silks with Outstanding Extensibility *Jacob Silliman and Hannes C. Schniepp; College of William & Mary, United States*

Fibrils are fundamental building blocks of the most prevalent structural materials in the living world. This includes spider silks, featuring a strength akin to steel and extensibility reaching that of rubber. The most basic building blocks of these silks are their nanofibrils, formed from proteins in a variety of secondary structures. Despite their *importance, the mechanical properties of individual spider silk nanofibrils have not been tested before. The cribellate silk of the Kukulcania hibernalis spider features a very sophisticated structure, including the thinnest known individualized natural silk fibrils, only 5 nm thick. Here we test the nanomechanics of these thin individualized silks through three-point bending using force spectroscopy. They showed an outstanding extensibility of ~1,100%, more than double the highest extensibility, ~475%, currently achieved by any spider silk. Nanofibrils are not much larger than the protein secondary structures found in silk, yet they represent the outstanding mechanical properties of spider silk. Therefore, this research provides a unique opportunity to relate the macroscopic properties of spider silk to its molecular structure. For instance, the large extensibility may be directly related to unfolding of the protein structure.*

8:45 AM SB11.03.03

Durable Radiative Cooling Multilayer Silk Textile *Xunen Wu, Yida Wang and Yingying Zhang; Tsinghua University, China*

Passive radiative cooling, which requires no energy consumption, is gaining attention as an eco-friendly alternative to electric cooling in mitigating heat stress induced by global warming. Incorporating radiative cooling into personal thermal management has garnered widespread interest. However, existing radiative cooling textiles face challenges related to inferior solar reflectance, poor outdoor durability, or health concerns. Herein, we developed a durable multilayer silk textile (MST) that shows excellent comprehensive performance for the first time, including both ultrahigh solar reflectance and ultrahigh infrared emittance (96.5%, 97.1%, respectively, surpassing all previously reported textiles), safety, good breathability, suitable mechanical strength, washability, abrasion resistance, surface hydrophobicity, and good UV resistance. Natural silkworm silk was selected for the raw material of the cooling functional layer based on the following considerations: 1) Silkworm silk is a natural protein material with large-scale production and notable skin-friendly features, favoring its practical applications in personal cooling. 2) Silk can be regenerated into diverse morphology and structures, facilitating the construction of hierarchical structures to achieve strong solar reflection. 3) Silk has high mid-infrared emittance due to its unique molecular composition, which can reduce the external heat gain and thus promise a high heat dissipation efficiency. 4) Last but not least, compared to some synthetic polymers, apart from its biodegradability and safety, silk has higher thermomechanical stability at the nanoscale, which is beneficial for maintaining hierarchical structures during hot pressing. The obtained MST achieves a remarkable sub-ambient temperature drop of 5.1 °C under 892.4 W m^{-2} of ultra-strong solar radiation and surpasses both commercial silk and cotton textiles at noon with temperature reductions of 6.0 °C and 8.3 °C, respectively. The radiative cooling performances of the obtained MST are superior to previously reported textiles. We believe this approach to tailoring durable radiative cooling textiles with comprehensive performance can offer not only an energy-efficient method for personal thermal management but also inspire the design of other natural materials for radiative cooling.

9:00 AM SB11.03.04

Silk-Based Biomimetics Made by the Molecular Imprinting Technique—Exploiting Protein Aggregation Versus Protein Structuration to Form Target-Selective Nanotraps *Alessandra Maria Bossi[1] and Devid Maniglio[2]; [1]Università degli studi di Verona, Italy; [2]Università di Trento, Italy*

We report about tailor-made biomimetics stemmed from merging biology with polymer chemistry and material science. Aqueous-soluble nanotraps that behave as biomimetic receptors were prepared in the form of protein super-assemblies fixed by non-natural crosslinking. The starting material to form the nanotrap were biocompatible, nontoxic proteins, already in use in regenerative medicine, such as silk fibroin [1].
Molecular recognition was conveyed to the nanotraps by the unconventional exploitation of the molecularly imprinted polymers (MIPs) technique, that is a strategy to entail molecular recognition to a nanomaterial by means

of a template-assisted synthesis [2,3]. The unicity of the present approach lays in the exploitation of proteins, such as silk fibroin, as building block for the formation of the nanotraps.

Silk fibroin was methacrylated (SilMA) prior to use it as a macromolecular building block. SilMA was then placed in solution with the target analyte and the physicochemical conditions were optimized by means of surface response method to yield to discrete nucleation of SilMA nanoaggregates. The nanotraps were obtained in the form of disordered aggregation of proteins, or by the nucleation of discrete beta-structured protein superstructures.

The imprinted silk-nanotraps, called bioMIPs, were physically and functionally characterized, demonstrating high affinity binding (nM) for the targets and selectivity [4]. Enzymatic degradation of the bioMIPs was studied. The biocompatibility of the nanotraps was confirmed. The nanotraps were further labelled with fluorescent tags and tested for imaging in cell cultures [6].

The formation of the silk bioMIPs is paradigmatic of the role that protein aggregation versus protein secondary structure formation can play in the formation of functional nanobiomaterials, standing as a novel approach for the preparation of selective nanobiomaterials. The bioMIP's synthesis proved general to entail recognition towards biotargets [4,5], with perspective to sequester molecular players in vitro and in vivo, for the ultimate control of diseases, and for further translation in clinical uses.

Development of Mechanoresponsive Drug-Releasing, High Pressure Resisting Balloon Catheter via Nanostructure Control of Silk Fibroin

Heesu Cho and Jinkee Hong; Yonsei University, Korea (the Republic of)

Cardiovascular disease is one of the most highest mortality diseases worldwide and is incurring enormous social costs. Drug-eluting balloon catheters(DEBs) are used in intervention procedures by destroying atherosclerotic plaque in blood vessels through angioplasty, inserting stents to maintain vascular expansion, and eluting drugs that prevent restenosis from damaged blood vessels. DEBs can effectively treat cardiovascular diseases, but still has some problems. The two main problems are rupture at high pressure and unwanted drug release during the insertion process. To overcome these problems, we aim to create a balloon catheter using a polymer with high toughness and mechanoresponsive drug release properties.

In this study, we selected silk fibroin, which allows easy control of nanostructures and it's morphology. Silk fibroin also possesses high biocompatibility, making it suitable for various medical applications such as sutures and bone regeneration, which makes it an ideal material for balloon catheters. The beta sheet structure is the most important factor contributing to the strong mechanical properties of silk fibroin, providing crystallinity to the silk. Beta sheet crystals not only strengthen the silk fibroin networks but also generate small molecule traps by inhibiting molecular mobility. When deformation occurs in silk fibroin with trapped small molecules, the pore size of the amorphous strands increases, allowing the trapped molecules to be released as free molecules. By controlling this crystallinity, we aim to endow silk fibroin with strong mechanical properties and mechanoresponsive drug release characteristics.

To this end, we synthesized a hydrogen bond-inducing molecular template to interact with silk fibroin. Silk fibroin beta sheet crystals have numerous hydrogen bonding sites, which stack with each other and strengthen the silk fibroin network. In the denatured state of silk fibroin, the Gibbs free energy required to form beta sheet structures is too high, remaining a structure dominated by amorphous strands. With the hydrogen bonding template, silk *fibroins are induced from chaotic amorphous structures to arranged structures, which leads to lower Gibbs-free energy required for the assembly to beta sheets, inducing rapid, enormous beta sheet formation. We synthesized poly(tetrahydrofuran) (PTHF) dimer with quaternary ammonium, which we call Template, which has abundant hydrogen bonding sites to induce silk fibroin self-assembly and antibacterial properties to prevent bacterial invasion during intervention. The Template diffused into the denatured silk fibroin and controlled the nanostructure during self-assembly. Via nanostructure control of silk fibroin with Template, we trapped deoxycholic acid, the plaque digesting drug molecule, into the silk fibroin crystalline network. When this silk fibroin balloon catheter expands, the pore size increases, the drug is released from the trap, and it is released through pressure, allowing the mechanoresponsive drug releases.*

Additionally, due to the hydrogen bonding attraction between silk fibroin and the Template, silk fibroin strands gather closely and become entangled with neighboring strands. When physical force is applied, these entangled strands undergo reptation, causing friction with each other in the entangled area and dissipating the applied force. Through this viscoelastic behavior, the silk fibroin balloon catheter can effectively resist deformation and rupture from inflation pressure.

In summary, our study controlled the nanostructure of silk fibroin to enable mechanoresponsive drug release through beta sheet crystallinity, strengthen the network, and fabricate balloon catheter raw materials that resist high pressure through polymer strand entanglement. The development of the silk fibroin balloon catheter addresses the limitations of commercial DEBs, offering a promising strategy for more effective cardiovascular disease treatment.

9:30 AM *SB11.03.06

A Manufacturers Perspective of Silk Fibroin as a Functional Material for Industrial Purposes *Kenichiro Iuchi; Canon Virginia Incorporated, United States*

Canon Virginia, Inc. is a manufacturer of Canon products in the Americas, and has been exploring opportunities beyond its traditional businesses to solve social, such as the generation of more sustainable bio-based materials. In recent years one key initiative for new business development has been on developing the business and technology to manufacture and commercialize products utilizing aqueous silk fibroin at scale. In this presentation, I will share about Canon Virginia's journey of scaling up silk manufacturing for operating at industrial scale . I will also share about our efforts with silk form development for future applications including silk molding technology.

Silk Fibroin-Based Emulsions—Synthesis, Functionalization and Applications in Agritech and Food Coating

Yue Hu and Benedetto Marelli; Massachusetts Institute of Technology, United States

Biopolymers such as proteins, cellulose, and chitin are attracting increasing attention for their potential to replace synthetic materials, especially petroleum-based plastics. Silk fibroin is a biocompatible fibrous protein derived from the cocoons of Bombyx mori L. (silkworm). Its tunable secondary structure, amphiphilic property, and rich engineerable side chains have led to its investigation in multiple industries, including medicine, manufacturing, agritech, and food.

In our work, we produced silk particles at scales ranging from nano to micro sizes. We revealed their behavior at the oil-water interface, demonstrating the ability of silk particles to stabilize payloads under different conditions. Furthermore, we functionalized the surface of silk particles with polymers and antibodies to alter their surface charge, functional groups, and morphology. By using different synthetic methods and conditions, we were able to tune emulsion diameters from several microns to hundreds of microns, meeting the requirements for targeted *delivery or food coating applications, thereby helping to lower carbon emissions.*

10:45 AM SB11.03.08

Strong and Tough Tape-Based Quasi-Composites inspired by Spider Silk *Ben H. Skopic and Hannes C. Schniepp; College of William & Mary, United States*

Fibrils are a dominant archetype in biogenic and synthetic structural materials. Composites relying on unidirectional fibers are limited in penetration resistance and are anisotropic. Advanced structures like Bouligands address these problems. One remaining deficiency of fibrous systems is the weak mechanical coupling between fibers. One possible solution is to flatten fibers to ribbons, to increase contact area between filaments. We found such natural materials systems, like certain cocoons, or the recluse spider's ribbon silk. Our analysis has revealed that these materials have several other advantages, such as enhanced toughness, even at the single-filament level, or adhesive locking mechanisms. This can lead to van der Waals-based adhesive bonds surpassing the tensile strength of the tapes. Inspired by these findings, we have combined tapes with Bouligand-type approaches to make matrix-free "quasi-composites" with tunable mechanical properties and outstanding mechanical performance. We employ solvent cast printing to make such tapes and entire composites either by directly welding them together during manufacture or by stacking layer-by-layer afterward, resulting in quasi-composites with varying inter-tape adhesive strengths. Our stacked quasi-composites outperform the constituent tapes by up to 30% in strength and 290% in toughness. Our work presents the foundation to develop quasi-composites with high-performance tapes that significantly out-perform all existing fiber-reinforced composites.

11:00 AM SB11.03.09

The Hierarchical Structure of Sheep Wool and Its Impact on Physical Properties—A Comprehensive Study

Serafina R. France Tribe[1], Paloma Lee[1], Caterina Czibula[2], Reiner Bleher[1], Keith Duncan[3], Christopher Topp[3], Vinayak Dravid[1] and Cecile Chazot[1]; [1]Northwestern University, United States; [2]Graz University of Technology, Austria; [3]Donald Danforth Plant Science Center, United States

Sheep wool is the most abundant and ubiquitous α-keratinous fiber in the history of textiles, with evidence of wool fabrics dating from the fourth millennium BCE and hundreds of sheep breeds raised worldwide today. This genetic diversity provides access to a broad range of morphologies and textile-relevant properties, such as mechanical strength and hydrophilicity, offering a unique platform for the development of versatile, natural, and biodegradable fibers and fabrics. Although the science of sheep wool and other α-keratinous materials is a mature field, important hierarchical aspects of the structure and properties of wool remain unclear. We lack fundamental understanding of structure-property relationships across levels of organization, from chemical structure, to nanoscale self-assembly, and microstructural topology. Here, we leveraged the diversity of 16 different sheep wool fiber types to investigate the connections between morphological structure at various length scales and textile-relevant macroscopic properties, such as tensile strength, elastic modulus, thermal stability, and hydrophilicity. We quantified the microstructure, protein conformation, and chemical composition of the fibers, by leveraging electron microscopy, Fourier-transform infrared spectroscopy, X-ray diffraction, and thermogravimetric analysis. This comprehensive study enabled us to uncover a correlation between protein secondary structure, polymer crystallinity, and microscale topology (e.g. fiber diameter, linear density of scales, and cortical cells), bridging the gap between the different length scales of hierarchical ordering. Moreover, we investigated the hydrophilicity and mechanical properties of the wool fibers through tensiometry and uniaxial tensile testing, correlating elastic properties and water contact angle to hierarchical ordering. To the best of our knowledge, this work represents the most comprehensive study of sheep wool structure and properties to date, contributing significant insight for the development and processing of α-keratinous fibers with tailored properties.

11:15 AM SB11.03.10

Design of Experiments to Investigate the Effects of Additives on the Properties of a Poly(hydroxyalkanoate)/Poly(lactic acid) Blend *Amy M. Yousefi[1] and Gary E. Wnek[2]; [1]Miami University, United States; [2]Case Western Reserve University, United States*

Poly(hydroxyalkanoates) (PHAs) are among sustainable, bio-based polymers with desirable properties that include biodegradability, non-toxicity, and piezoelectric characteristics. The choice of feedstock used for producing PHAs could help with attaining carbon neutrality. Furthermore, PHA-based packaging materials have contributed to the ongoing efforts to reduce plastic waste and microplastics. Nevertheless, the widespread use of PHAs has been limited due to their high cost, together with the need to improve the mechanical and thermal properties of PHAs. Blending with other bio-based polymers, suitable fillers, and foaming agents has been used to manipulate the properties while reducing the overall cost of PHA-based products. This study examined the effects of calcium carbonate (CC) and boron nitride (BN), as fillers, and azodicarbonamide (AZ), as a foaming agent, on the properties of an amorphous poly(hydroxyalkanoate) (PHA) blended with poly(lactic acid) (PLA). A twin-screw micro-compounder was used to prepare formulations containing 1 - 3 wt% of CC and BN at a temperature of 185°C. Then, a design of experiments (DoE) using JMP® software enabled us to investigate the combined effects of the selected filler (BN) and the foaming agent (AZ) on the properties of the blend at a compounding temperature of 205°C (the average thermal decomposition temperature of AZ). The formulations were characterized via density measurements, tensile testing, differential scanning calorimetry (DSC), and thermogravimetric analysis (TGA). The response surface analysis was used to predict an optimal design based on the target mechanical properties (i.e., modulus, tensile strength, strain at break, and toughness). To validate the design, the proposed optimal formulation (0.25 wt% AZ and 1 wt% BN) was prepared using the micro-compounder and characterized via tensile testing, DSC, TGA, and melt flow index (MFI) measurements. This study demonstrated that the overall material cost could be reduced via density reduction (20 - 21% for the optimal formulation). Furthermore, the addition of AZ significantly influenced the mechanical properties and crystallinity of the PHA/PLA blend. Reducing the concentration of AZ via DoE (I-optimal design) could alleviate the toxicity concerns of AZ for food packaging. This study also explored the effect of cold rolling on the toughness and crystallinity of PHA/PLA. Our results indicated a 3-fold increase in toughness ($p < 0.05$) and an increase of 20% in crystallinity upon cold rolling.

11:30 AM *SB11.03.11

Silk's Contemporary Shapes and Functions Across Technology and Design *Fiorenzo Omenetto; Tufts University, United States*

Natural materials are generating unprecedented opportunities for innovation across various fields, creating a unique synergy between natural sciences and high technology. The potential for transforming naturally derived materials, such as structural proteins and, specifically, regenerated silk fibroin, is quite rich. By applying advanced material processing, prototyping, and manufacturing techniques to these widely available substances, we can envision and implement sustainable, carbon-neutral strategies that seamlessly blend the biological and technological realms.

This approach paves the way for numerous applications of biomaterials. For instance, edible and implantable electronics could revolutionize the way we interact with technology on a personal level, while new methods in food preservation could significantly reduce waste and enhance food security. Energy harvesting technologies derived from natural materials offer promising avenues for sustainable power sources. Wearable sensors, made from biodegradable materials, present a future where our devices are both high-performing and environmentally friendly.

Moreover, compostable technology could lead to a dramatic reduction in electronic waste, and distributed environmental sensing could provide more comprehensive and sustainable monitoring of ecosystems. In the

medical field, advancements in biomaterials hold the promise of creating more effective and less invasive medical devices and therapeutics. Biospecimen stabilization techniques using natural materials could improve the preservation and transport of biological samples, and advanced medical diagnostics could become more accurate and accessible.
This talk will outline these opportunities, demonstrating how the integration of natural materials with cutting-edge technology can lead to advances across multiple sectors.

SESSION SB11.04: Biopolymers
Session Chairs: Laia Mogas-Soldevila and Massimo Trotta
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 313

1:30 PM *SB11.04.01
Expanding Access to Advanced Manufacturing with Biopolymers *Neil Gershenfeld; Massachusetts Institute of Technology, United States*

Along with the versatility and sustainability of biopolymers, one of their benefits is locality. They can be locally sourced and recycled, but to complete their lifecycle they should also be locally processed, characterized, and consumed. I will explore applications and opportunities to do this in areas including hygiene, nutrition, and construction.

2:00 PM SB11.04.02
Design Principles for the Use of Sustainable Sources of Proteins for Making Protein-Based Polymers Toward Functional Materials *Nadav Amdursky[1,2]; [1]The University of Sheffield, United Kingdom; [2]Technion–Israel Institute of Technology, Israel*

In this lecture, I will discuss the use of proteins that can be derived from raw biomass for making large-scale free-standing polymers. In the first part, I will discuss several design principles for making such polymers using green chemistry principles and show how we can make polymers without using traditional crosslinkers and/or plasticizers. Due to the all-protein-based composition of the polymer, this new generation of polymers is rapidly biodegraded. And owing to the sustainable nature of the source proteins, the formed polymers are also very low cost. In terms of functionality, the immediate application for such polymers will be in the areas related to plastic replacement with biodegradable bioplastic alternatives. Nonetheless, my group's expertise also explores how well such polymers can mediate charges, specifically protons. Due to the water uptake of our protein-based polymers and the presence of oxo-amino-acids, our protein-based polymers show excellent proton conductivity. Using various post-polymerization modifications (PPM) and physical modifications is allowing us to explore the important factors and mechanisms of protonic transport. Currently, our main targeted application for our new family of proton-conductive polymers is for biological interfaces, and we show their use in biosensing applications, while other lines of applications include the use of our biopolymers for biomedical and energy applications.

2:15 PM SB11.04.03
Designing Single Polymer Chain Nanoparticles to Mimic Biomolecular Hydration Frustration *Tianyi Jin, Connor Coley and Alfredo Alexander-Katz; Massachusetts Institute of Technology, United States*

Native folded proteins rely on sculpting the local chemical environment of their active or binding sites, as well as their shapes. In particular, proteins exhibit a phenomenon known as "hydration frustration", i.e. the ability to control the dehydration of hydrophilic and the hydration of hydrophobic residues, respectively, to amplify their chemical or binding activity. Here, we uncover that single polymer chain nanoparticles formed by random heteropolymers composed of three or more components can display similar levels of hydration frustration. We categorize these nanoparticles into three types: i) fully-frustrated globules, where both types of residues display frustrated states, ii) semi-frustrated, with either hydrophobic or hydrophilic residues in a frustrated state, and iii) core-shell non-frustrated globules. Based on our results, we propose a series of physicochemical rules that determine the state of these nanoparticles. The rules have been tested in both atomistic and simplified Monte Carlo models of single polymer chain nanoparticles with different backbones and residues to show their generality. Our work provides critical insights into the design of single chain nanoparticles, an emerging polymer modality that achieves the ease and cost of fabrication of polymeric material with the functionality of biological proteins.

2:30 PM SB11.04.04
Assembly of Sequence-Defined Peptoids into Biomimetic Nanostructures Promotes Enhanced Carbon Dioxide Sequestration *Progyateg Chakma and Chun-Long Chen; Pacific Northwest National Laboratory, United States*

Artificial enzymes that mimic natural carbonic anhydrase (CA) enzymes have recently received significant attention due to their low-cost synthesis and superior stability compared to their natural counterparts for their promising applications in the promoted CO_2 sequestration. While most of these CA mimics focus on mimicking the active sites of CAs, limited efforts have been made to manipulate the arrangement and microenvironment of these active sites for high catalytic activity. Herein, we report the assembly of sequence-defined peptoids into crystalline nanomaterials with controlled microenvironment of active sites as CA mimetics for tunable catalytic ester hydrolysis to achieve promoted CO_2 precipitation. We demonstrate that the morphology, crystallinity, chemistry of hydrophilic domain, and metal-ligand coordination of peptoid assemblies are significant for catalytic activity and selectivity on hydrolysis of ester (4-nitrophenyl acetate). In addition to experimental studies, molecular dynamics (MD) simulations were carried out to understand peptoid catalysts activity based on binding energy and local microenvironment. We further demonstrate that these peptoid-based nanoenzymes are highly stable, recyclable, and highly efficient in promoting CO_2 sequestration and $CaCO_3$ mineralization Solution-state nuclear magnetic resonance (NMR) was utilized to elucidate the mechanism of CO_2 hydration and sequestration by peptoid catalysts.

2:45 PM SB11.04.05
Using Supramolecular Polymerization of DNA to Produce Tandem Repeat Proteins *Matthew Amorin, Elliot Coleman and Harry Bermudez; University of Massachusetts Amherst, United States*

Tandem repeat (TR) proteins are abundant in nature and show diverse biochemical and mechanical properties. However, these proteins can be difficult to synthesize in a precise way because of their repetitive nature. Using a supramolecular polymerization scheme known as hybridization chain reaction, we show how to generate the DNA sequences encoding such TR proteins. The polymerization mechanism allows for identical "monomers" to selectively create TR proteins of different molecular weight. We demonstrate this strategy with examples from elastin-like polypeptides (ELPs) and mussel foot proteins (mfps). Moreover, the scheme can be adapted to create protein libraries through the use of multiple DNA hairpin monomers.

3:00 PM BREAK

3:30 PM SB11.04.06

Spinning of Mechanically Tuneable Fibres from Recombinant Spider Silk Proteins *Thomas Scheibel; Universität Bayreuth, Germany*

Spider silk is a remarkable material with high mechanical properties, especially toughness, that have been the focus of research for decades. Our pilot studies have shown promise in the development of biomimetic spinning dopes using self-assembled recombinant spidroins. By varying the molecular design of spidroins, we have determined the influence of different domains on fiber mechanics and generated first artificial fibers with the toughness equaling that of natural ones.

Further investigations into the molecular and functional structure of recombinant spider silk fibers have revealed that their toughness is based on nanometer-sized crystallites. Infra-red spectral red shifts of a crystal-specific absorption bands demonstrated that macroscopically applied stress is directly transferred to the molecular scale. These features are almost indistinguishable in natural and biomimetic fibers.

Recent research on the co-production of different spidroins in Escherichia coli has shown that homo- and heterodimers could be formed. This work underlined the importance of the heterodimeric MaSp interaction at a (supra)molecular level and the contribution of this interplay to control solubility as well as self-assembly with significant impact on the mechanical performance of fibers. Moreover, the engineering of a novel two-in-one spidroin has facilitated hierarchical self-assembly into β-sheet-rich superstructures, which yielded mechanical properties at least twice as high as fibers spun from individual spidroins or blends.

In collaboration with G. Holland, we compared biomimetic dopes incorporating phosphate-induced pre-assembly and classical dopes. Solution nuclear magnetic resonance (NMR) has revealed subtle but distinct differences in the structural state of the two dopes, with more ordered states observed in the biomimetic dope. Solid-state NMR has shown that the final wet-spun fibers from the two dopes display no structural differences of the poly(Ala) stretches, but biomimetic fibers display significant differences in Tyr ring packing in non-β-sheet, disordered helical domains.

Overall, our findings provide insights into the constitution of spinning dope and the engineering of spidroins for processing of biomimetic spinning dopes and aqueous wet-spinning. The developed technology holds great potential for producing ecological green high-performance fibers.

3:45 PM SB11.04.07

Food-Grade Biomaterials-Based Microneedles for Fish Vaccination in Aquaculture *Meng Li[1], Gregory Wiens[2] and Benedetto Marelli[1]; [1]Massachusetts Institute of Technology, United States; [2]U.S. Department of Agriculture, United States*

To meet the rising seafood demand driven by rapid population growth, an expanded aquaculture industry is essential. Over the last 60 years, the consumption of aquatic food per capita has increased from 9.9kg to 20.5kg, with a projected 15% increase by 2030. Salmon and trout exports account for 18.4% of the value of all exported aquatic products in 2020, compared with 5.1% in 1976. Despite various factors that cause fish loss, such as environmental changes (e.g., temperature fluctuations, water quality, and farming density) exacerbated by climate change, disease outbreaks remain the most significant challenge. Beyond the immediate ecological impacts of fish loss caused by disease outbreaks, there are ongoing concerns about the long-term impact of antibiotic resistance and the bi-directional spread of infectious disease between farmed and wild salmonid populations. Early-stage vaccination is crucial for preventing disease outbreaks in aquaculture, ensuring food security, and reducing antibiotic overuse. Among current vaccine administration methods–oral, immersion, and injection, injection using hypodermic needles offers the highest protection with minimal vaccine usage. For fish above 25 g, injection is done for individual sedated fish with a human-operated vaccine gun. However, for juvenile fish that are

1-2 g in size, it is challenging for such a setup to operate as manual handling such small fish is difficult. Thus, for fingerlings at this size vaccination is commonly done with individual manual injections. However, the anesthesia process is costly and labor-intensive for the workers and stressful for the fish. Additionally, using fine needles on juvenile fish presents a risk of needlestick injuries to farm workers. This practice also generates needle waste which is costly and energy-intensive to process. Stakeholders are interested in innovations that can vaccinate small fish in an automated manner without needing to take them out of the water.

To address these challenges, we developed microneedles based on food-grade biomaterials. To be able to be deployed in aquatic environments, these microneedles need to be waterproofed to maintain their mechanical strength to penetrate fish skin. At the same time, the microneedles can release loaded vaccines. We demonstrate easy fabrication for hollow microneedles that can be easily loaded with vaccines and released without barriers. Inactivated bacteria and DNA vaccines are loaded and preserved. We tested injecting our microneedle using both zebra model fish and juvenile rainbow trout. After microneedle injection, the fish can swim with the microneedles attached to them to continue vaccine release. In our pilot test with 60 rainbow trout in each group, upon Yersinia ruckeri pathogen challenge 32 days after the vaccination, the microneedle-vaccinated group had a 65% mortality compared with 85% mortality in the PBS-injected negative control group. Although more optimization is needed to achieve <30% mortality for on-farm efficacy, our initial results show that immunity protection for juvenile fish can be achieved with this microneedle technology. It opens the possibility of having fish vaccination automatically deployed underwater without stressful fish anesthesia and labor-intensive manual injection.

4:00 PM SB11.04.09

From Lignin to Functional Materials via Deep Eutectic Solvent and Electrospinning *Marcin Wysokowski[1], Aleksandra J. Sikora[2], Adam Gorczynski[2], Krzysztof Nowacki[1], Patrycja Frackowiak[1] and Teofil Jesionowski[1]; [1]Poznan University of Technology, Poland; [2]Adam Mickiewicz University, Poland*

Under the triple pressure of rapid population growth, energy crisis and global warming, the development of renewable energy sources, including solar, wind, hydropower and lignocellulosic biomass, has become a hot topic worldwide in recent years [1].

Lignin is a major component of lignocellulosic biomass and an underutilized industrial raw material, with a complex and irregular structure and very low solubility in common solvents. Currently, about 95% of industrial lignin is burned as fuel in thermal power plants, as its structure makes direct industrial use difficult.

Deep eutectic solvents (DES) are multicomponent liquids that are usually formed by the combination of a hydrogen bond donor and an acceptor, leading to strong non-covalent intermolecular bonding and lowering the melting point of the system [2].

Known in the scientific community for decades, the electrospinning technique is now one of the most popular methods for producing fibers. Its success in this field is due primarily to such factors as the possibility of using a wide range of substrates, the ability to manipulate the process parameters affecting the morphology of the obtained fibers, as well as various solutions related to the apparatus, such as the use of different types of nozzles that allow the production of mixtures of fibers with different structures [3].

I will present the results of work on dissolving lignin with DES, describing the ecological and economic advantages of the process. I will then move on to discuss the electrospinning of lignin with DES. In this pioneering project [4], we proposed using urea-lactic acid (1:2) as a highly efficient medium for lignin dissolution and electrospinning. We subjected the obtained systems to numerous analyses, and the results of elemental analysis, IR and 2D NMR spectroscopy provide insight into the structural properties of the regenerated material after DES treatment. The results confirm the high degree of lignin recovery, reaching up to 96.6% for samples dissolved at 100°C. 2D NMR analysis indicates that the process leads to partial esterification of lignin with lactate ions. The ability of this DES to effectively solubilize lignin highlights its potential as an effective lignin solvent and facilitates the fabrication of lignin-based nanofibers by electrospinning. The incorporation of this DES into electrospinning processes promises *significant progress in the development of sustainable lignin-derived materials, offering a green alternative for the production of high-performance nanofibers. The attractiveness of electrospinning in terms of applications is also due to the fact that a wide range of polymers can be used to form these fibers. The results of cyclic voltammetry and galvanostatic charge/discharge measurements confirm that the prepared membrane exhibits interesting electrochemical properties, highlighting its potential for practical application in the construction of energy storage devices (specific capacitance, CSP = 95 F g-1; series resistance, RS = 2.2 Ω; charge transfer resistance, RCT = 1.6 Ω). Therefore, the DES-assisted electrospun lignin membrane can be viewed as a potential gel electrolyte matrix for practical application in the construction of sustainable energy storage devices.*

4:15 PM SB11.04.10

Co-Assembly of Cellulose Nanocrystals Through Their Click Chemistry Enabled Surface Functionalization with Single-Stranded DNA

Daria Bukharina[1], Katherine Cauffiel[1], Laura Mae Killingsworth[1], Valeriia Poliukhova[1], Minkyu Kim[1,2], Justin Brower[3], Julio Bernal-Chanchavac[3], Nicholas Stephanopoulos[3] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Dankook University, Korea (the Republic of); [3]Arizona State University, United States

Nature provides in abundance and inspires implementation of functional materials and natural polymers. Among these, cellulose can be further broken down into nanocelluloses, particularly cellulose nanocrystals (CNCs), which are promising candidates in various advanced applications due to their spontaneous self-assembly into complex multifunctional architectures. The chiral twisted assembly of CNCs results in high mechanical strength, iridescent coloration, and polarized light reflection properties, making them excellent candidates for advanced materials. However, engineering nanocomposites with tailored mechanical, thermal, and optical properties requires precise control of the assembly process, including the refinement and tuning of surface chemistry and directed assembly.

In this work, we present a synthetic route for functionalizing CNCs with complementary single-stranded DNA (ssDNA) handles to enable pre-programmed chiral complexation. We employed a three-step process that allowed for hybridization-guided self-assembly of the CNCs, where ultimately the native hydroxyl groups on CNCs were substituted with azide groups to facilitate click chemistry. By grafting functionalized oligonucleotides through copper-free click chemistry, we successfully induced the assembly of DNA-modified CNCs into chiral nanostructures through the complexation of the DNA handles on the CNCs' surface. Here, in addition to successfully grafting ssDNA onto cellulose nanocrystals to control their interparticle-interactions, we also report their assembly behavior and thus, the feasibility of leveraging CNCs as scaffolds for the assembly of DNA-based nanostructures.

The surfaces of the ssDNA-modified CNCs were studied in detail using high-resolution atomic force microscopy, revealing a moderately grafted with oligonucleotides surface. Additionally, we observed the initial complexation behavior of DNA handles during evaporation-driven formation of CNC films, demonstrating the potential for mediating chiral interactions between the DNA-modified nanocrystals and their assembly into chiral bundles as evidenced by the circular dichroism.

This study demonstrates the feasibility of using click chemistry for CNC bio-functionalization and illustrates how the complexation of individual nanocrystals affects their interactions and organization, leading to the formation of chiral nanostructures. The result is chiral DNA-decorated nanostructures with varying grafting habits and potential for optically active thin films controllably assembled from chemically grafted CNCs.

4:30 PM SB11.04.11

Bioinspired Stiffness-Controlled Protein Filaments Through Molecular Self-Assembly of Protein-Based Rod-Coil Block Copolymers *Young Hyun Noh and Minkyu Kim; The University of Arizona, United States*

Natural materials such as collagen, microtubules, and muscle fibers exhibit exceptional mechanical properties, including reversible stretchiness, toughness, and fatigue resistance. These properties stem from their complex hierarchical structures, which are formed through the self-assembly of stiffness-controlled filaments and fibrils. Achieving an understanding of this self-assembly process and the mechanisms that generate the stiffness of these filaments is essential for replicating the structural hierarchies and mechanical properties observed in natural fibers. Proteins, which provide highly controllable monomer units and diverse functionalities, can be engineered to facilitate the self-assembly of bioinspired filaments. However, a major challenge in this process is controlling the stiffness of these self-assembled protein filaments. While proteins hold great promise for forming these structures, the methods for fine-tuning their stiffness during self-assembly remain elusive.

Here, we present bioinspired stiffness-controlled protein filaments achieved through the molecular self-assembly of designed protein polymers composed of coil-like and rod-like structures. Using molecular dynamics simulations, biosynthesis, and characterization techniques, we discovered that the coil-like protein component imparts high flexibility to the filament structures, generating curvature, while the rod-like protein component enhances stiffness. This finding prompts the investigation of the fundamental relationship between the chain topology of designed protein polymers and their composition, structure, and length, as well as their interdependence. Our work provides valuable insights into the scientific principles underlying protein filaments, paving the opportunity for the development of biomimetic hierarchically structured protein fibers. These advancements have the potential to advance healthcare applications, including drug delivery, tissue engineering, and regenerative medicine.

4:45 PM SB11.04.12

Chitosan as a Versatile Biopolymer Platform for Functional Materials *Cecile Chazot[1], Eleanor Grosvenor[1], Sara Branovsky[1], Gabrielle N. Wood[1,2], Emma Sellin[1] and Malachi R. Cohen[1]; [1]Northwestern University, United States; [2]Howard University, United States*

Chitosan, a polysaccharide derived from the deacetylation of naturally abundant chitin, has emerged as a foundational biopolymer for functional materials due to its unique properties, including antibacterial activity, biocompatibility, and flame retardancy. Furthermore, chitosan can self-assemble into chiral nematic (cholesteric) liquid crystals (LCs) when suspended in strongly hydrogen-bonding acidic solvents, showcasing selective reflectivity and circular dichroism in the infrared portion of the electromagnetic spectrum. Despite these promising characteristics and their relevance to a wide range of industrial and biomedical applications, the influence of chitosan's molecular structure on its final properties remains underexplored. This hinders the deterministic design of relevant solution processing routes and final functional materials with tailored mechanical, optical, and interfacial properties. In this talk, we will discuss our recent advances in establishing structure-property relationships in chitosan solutions, elucidating its phase behavior and LC self-assembly. Combining theoretical frameworks, such as Flory-Huggins and Landau-De Gennes theories, with experimental investigation of phase *behavior and inter/intra-molecular interaction by spectroscopy methods (e.g. Fourier-transform infrared spectroscopy, X-ray diffraction), we uncovered the dependence of long-range order formation on polymer chain interactions and macromolecular mobility. Specifically, we will highlight our effort in quantifying the impact of degree of deacetylation and molecular weight on chitosan phase behavior and discuss how we have leveraged chemical modification to further tailor solubility and final optical, mechanical, and interfacial properties. Last, we will discuss how we have used these relationships in the context of designing functional chitosan-based materials for a broad range of applications, from optical coating to biodegradable food packaging and textile recycling.*

SESSION SB11.05: Poster Session I
Session Chairs: Marco Lo Presti and Laia Mogas-Soldevila
Tuesday Afternoon, December 3, 2024
8:00PM - 10:00PM
Hynes, Level 1, Hall A

SB11.05.01
Bioinspired Intelligent Adhesive Architecture with Soft Polymeric Electric Actuators for Robotics and Tactile Interfaces *Gui Won Hwang[1], Jeon Seung Hwan[1], Jihun Soon[1], Han Joo Kim[1], Minjin Kim[1], Tae-Heon Yang[2] and Changhyun Pang[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Konkuk University, Korea (the Republic of)*

Organisms often use subtle surface-transmitted vibrations to manipulate objects or communicate critical signals for survival. Inspired by this phenomenon, we present a multipixelated electroactive-actuating adhesive patch coupled with small, dense hairs possessing concave cavities. The ensuing lightweight, spatially-selective, switchable-adhesive device is demonstrated to effectively manipulate multiple objects simultaneously, thus overcoming the limitations of existing monotonous transportation devices. Complex outward texture of an object was recognized by the stretchable skin-conforming haptic interface with high breathability and repeatable attachment capability. This skin-adaptive haptic device can amplify the tiny vibrotactile feedback from the diverse surface textures of virtual creatures due to its possession of bioinspired architectures at the human–machine interface, wherein the device is integrated with machine learning-based comprehension for reproducible expression. Therefore, this technology offers promise in virtual reality and augmented reality applications.

SB11.05.02
A Reversible, Versatile Skin-Attached Haptic Interface Platform with Bioinspired Interconnection Architectures Capable of Resisting Sweat and Vibration *Jinhyung Kim[1], Gui Won Hwang[1], Minwoo Song[1], Dohyun Lim[1], Yeon Soo Lee[1], Gyun Ro Kang[1], Da Wan Kim[2], Tae-Heon Yang[3] and Changhyun Pang[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea National University of Transportation, Korea (the Republic of); [3]Konkuk University, Korea (the Republic of)*

A stable conformal interface technology for rough and sweaty complex skin is essential for a haptic interface capable of delivering sophisticated mechanical stimuli. However, conventional polymeric/hydrogel-based skin adhesives cannot maintain adequate adhesion interaction performance at the haptic interface due to repetitive vibrations or sweaty skin. This study reports a reversible, versatile skin-attached haptic interface platform, which embeds the hybrid architecture of a water-drainable hexagonal array of frog toe pads and the energy-dissipation matrix of snail pedal muscles with interconnected structures. The hybrid frog–snail-inspired adhesive patch exhibits remarkable adhesion in pulling and shear directions under both dry and sweaty conditions. Furthermore,

the microchannels between the hexagonal array can effectively drain liquid under sweaty conditions while also enhancing skin-conformal contacts. The adhesion force enhanced by energy-dissipation is analyzed considering a simple theory based on the adhesion, elastic, dissipation energies, and geometric features, resulting in the vibration-resistant characteristics against diverse dry and wet vibration environments (vibrational frequency: 1–150 Hz). Bioinspired integrated skin-attached haptic interface platform demonstrates the versatility of being reversibly applicable to various skin surfaces such as fingers, arms, and legs, yielding the feasibility of dynamic handling a basketball with multiple contacts and impacts in virtual reality (VR).

SB11.05.03

Autonomous Self-Healing 3D Micro-Suction Adhesives for Multi-Layered Amphibious Soft Skin Electronics

Dohyun Lim[1], Min Woo Jeong[2], Hyeongho Min[1], Yeon Soo Lee[1], Gui Won Hwang[1], Jeon Seung Hwan[1], Kyu Ho Jung[2], Ngoc Thanh Phuong Vo[2], Min-Seok Kim[3], Hyeonseo Cheon[1], Da Wan Kim[4], Jin Young Oh[2] and Changhyun Pang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of); [3]Korea Research Institute of Standards and Science, Korea (the Republic of); [4]Korea National University of Transportation, Korea (the Republic of)

Autonomously self-healing, reversible, and soft adhesive microarchitectures and structured electric elements could be important features in stable and versatile bioelectronic devices adhere to complex surfaces of the human body (rough, dry, wet, and vulnerable). In this study, we propose an autonomous self-healing multi-layered adhesive patch inspired by the octopus, which possess self-healing and robust adhesion properties in dry/underwater conditions. To implement autonomously self-healing octopus-inspired architectures, a dynamic polymer reflow model based on structural and material design suggests criteria for 3-dimensional patterning self-healing elastomers. In addition, self-healing multi-layered microstructures with different moduli endows efficient self-healing ability, human-friendly reversible bio-adhesion, and stable mechanical deformability. Through programmed molecular behavior of microlevel hybrid multiscale architectures, the bioinspired adhesive patch exhibited robust adhesion against rough skin surface under both dry and underwater conditions while enabling autonomous adhesion restoring performance after damaged (over 95% healing efficiency under both conditions for 24 h at 30 °C). Finally, we developed a self-healing skin-mountable adhesive electronics with repeated attachment and minimal skin irritation by laminating thin gold electrodes on octopus-like structures. Based on the robust adhesion and intimate contact with skin, we successfully obtained reliable measurements during dynamic motion under dry, wet, and damaged conditions.

SB11.05.04

Polydopamine as a Water-Soluble Photoredox Catalyst/Initiator

Hoyun Kim and Jungkyu Lee; Kyungpook National University, Korea (the Republic of)

Polydopamine (PDA), inspired by the adhesive proteins found in mussels, forms a robust coating on various surfaces and exhibits high biocompatibility and stability. Recently, PDA has been reported as a photoredox catalyst under visible light, thereby facilitating polymerization under mild conditions. However, several challenges remain for the photoredox catalysis using PDA, including an unclear mechanism, a narrow scope of monomers, and the use of organic solvent. Herein, we demonstrate the photoredox catalysis of PDA in water with various monomers under visible light. Furthermore, we aim to elucidate the mechanism of the photochemical reaction

using spectroscopic analyses such as nuclear magnetic resonance (NMR), gel permeation chromatography (GPC), and electron paramagnetic resonance (EPR). For example, PDA-based photoredox catalysis can follow either the reductive or oxidative quenching cycle depending on the co-initiator. Additionally, we propose the process the formation of semiquinone radical (SQR) species through intermolecular photoinduced electron transfer between the excited state of PDA and the co-initiator. To broaden applications, we also present the performance of near-IR-induced photoredox catalysis of PDA in water and its use in (chemo)biosensors.

SB11.05.06

Development of Peptide-Oligonucleotide Hybrid Biopolymers as Flu Type-Independent Affinity Reagents

Dain Bae, Minjong Lee and Seungsoo Oh; Pohang University of Science and Technology, Korea (the Republic of)

Influenza A virus consistently causes seasonal endemics and continuously poses a pandemic threat, recognized as a worldwide health concern and global economic burden. The frequent mutations in the viruses not only allow them to escape previously induced immunity, but also reduce the effectiveness of existing vaccines and drugs against newly evolved viruses. In this study, we demonstrate the development of novel peptide-oligonucleotide hybrid biopolymers, capable of recognizing a wide breadth of influenza viral strains. We found that regardless of genetic lineage and mutation, the influenza viruses share the common surface domains that bind to host cell receptors for infection. Since the conserved region is sterically hindered by the cave-like indented geometry, it can be accessed by relatively small molecules only. Presumably, a minimal peptide can be constructed by a computational redesign to broadly targets influenza viruses by incorporating the conserved viral epitopes into its compact size. However, it faces challenges due to its poor binding affinity and low solubility under biological conditions. To address this, through our systematic in vitro screening technology, we successfully generated a hybrid biopolymer by the conjugating minimal peptide with oligonucleotide, enhancing molecular binding affinity over 10 times compared to the original peptide. The oligonucleotide serves as a supporting scaffold structure for synergistic binding and extends the applicability of the developed hybrid biopolymers to therapeutics and diagnostics due to the its programmability. The hybrid biopolymer shows great potential for exhibiting binding tolerance to other classes of influenza, thereby overcoming current and upcoming immune escapes.

SB11.05.07

Tunicate Shell as for Animal Cellulose Candidate for Therapeutic Ultrasonic Gel Formulation

Hye Jin Hwang[1], Ji Woo Han[2], Nu Ri Han[2], Byung Man Lee[1], Sang Hyun Lee[2], Hwa Sung Shin[1] and Yun Jung Yang[1,3]; [1]Inha University, Korea (the Republic of); [2]Konkuk University, Korea (the Republic of); [3]Inha university hospital, Korea (the Republic of)

Traditionally, sea squirts have been a popular seafood in Asia, but their tough cellulose-based shells have made it difficult to repurpose them into valuable materials. In South Korea, approximately 7,000 tons of sea squirt waste are produced annually, leading to disposal costs of around one million dollars. This highlights the need to find better uses for this waste.

Cellulose, an abundant natural polysaccharide, can be converted into various forms such as gels, films, and fibers. Its excellent water absorption capacity and strong mechanical properties have expanded its applications, particularly in the medical field, where it is used for fillers, wound dressings, and ultrasonic gels, which are typically made from synthetic polymers.

This research investigated three different cellulose extraction methods and explored various gel formulations. The conductivity and viscosity of the cellulose-based ultrasound gel were compared with those of commercial gels. The formulated gel demonstrated suitable conductive and viscous properties as a therapeutic delivery gel material, comparable to commercially available gels.

SB11.05.08

Quantifying the Mechanics of Engineered Mycelium Films *Alyssa Libonati[1], Dylan Moss[2], Arjun Khakhar[2] and R. Konane Bay[1]; [1]University of Colorado Boulder, United States; [2]Colorado State University, United States*

Many of the current synthetic polymers lack features typically associated with biological systems: programmable material properties, self-regenerating capabilities, and compatibility with sustainable and scalable manufacturing practices. These qualities can be cultivated by leveraging living microbes, which is an emerging area of research known as engineered living materials (ELMs). Of interest in this field has been mycelium-based materials, which have applications in alternative packaging, construction, and medicine. Previous research on the mechanical properties of mycelium films has focused on comparing the mechanics of different fungal species, while there has been less emphasis on understanding the impacts of extracellular polymeric substance (EPS) composition, branching, and hydration. Here, we bridge this gap by investigating the uniaxial stress-strain response of Aspergillus niger fungal films engineered to act as a living template for biomineralization. We observe that the non-mineralized films of A. niger exhibit a larger elastic modulus, yield stress, and lower toughness than the biomineralized films. Our results provide fundamental insights into how biomineralization and hyphae structure impact the mechanical properties of mycelium films.

SB11.05.09

Synthesis of Multifunctional Innovative Immediate-Acting Hemostatic Patches Based on Chitosan with Enhanced Antibacterial Properties and Coagulative Additives *Dimitrios Bikiaris; Aristotle University of Thessaloniki, Greece*

Wounds resulting from various factors like trauma, surgery, diabetes, or burns, disrupt skin integrity, necessitating suitable wound dressings that are flexible, mechanically strong, and non-adherent. Effective hemostasis is a vital step in the wound healing process activated upon surgical operation or emergent injury, resulting in the control of bleeding, and forming a protective barrier. Ongoing research is focused on designing hemostatic materials with the characteristics of good biocompatibility, rapid arrest of arterial and/or venous bleeding without thermal effect, flexibility, adaptability to the wound's shape, easy to remove without leaving residues, stability in extreme temperatures and low manufacturing cost. In this context, chitosan (CS) is a naturally derived polymer that is actively involved in the development of new hemostatic products.

To achieve these goals, chitosan hemostatic powder with antimicrobial properties was created via chemical modification. Its effectiveness was enhanced by incorporating vitamin K, protamine sulfate, and iron sulfate, which accelerate clot formation. Additionally, heparin, an anticoagulant, was encapsulated in polymer nanoparticles to prevent clotting in undesired areas. The resulting hemostatic product underwent thorough characterization to confirm successful synthesis using FT-IR, and its crystallinity was assessed by XRD, revealing a decrease in crystallinity compared to chitosan alone. Additionally, swelling studies indicated that the hemostatic product has a high swelling capacity, with a maximum swelling degree of up to 4000%.

High-Throughput Analysis of Sequence-Driven Changes in Collagen Osmotic Pressure Response *James Rowe, Ulrich Hansen, Richard Abel, Nicholas Harrison and Daniele Dini; Imperial College London, United Kingdom*

Water plays a crucial role in collagen based biomaterials, including bone. Increases in osmotic pressure can *cause collagen fibril contraction, potentially toughening bone by pre-stressing the mineral phase. Recent experiments reported that collagen protein sequences respond differently to osmotic pressure, exhibiting both contraction and expansion behaviors. However, only a small number of possible collagen sequences have been explored, so it is not possible to predict the local contraction or expansion of real collagen materials. Additionally, only the osmotic pressure response of homotrimeric collagen structures have been studied, and the potential impact of heterotrimers on the osmotic pressure response remains unexplored. This work introduces a novel method using high-throughput molecular dynamics simulations of collagen-mimetic peptides to elucidate the response of different collagen sequences, including heterotrimers. Using this method we can explain, using quantitative data, why collagen sequences display different behaviors to changes in hydration. After constructing a database of sequences, we apply statistical techniques to infer from our collection of collagen-mimetic peptides to real collagen proteins present in nature. Our models advance the understanding of water's importance in controlling the mechanical behavior of collagen-based materials. Following on from this work, we plan to examine how post-translational modifications associated with aging and disease can alter the osmotic pressure response of the collagen and the implications this may have for understanding these conditions.*

Polymer Infiltrated Ceramic Network Materials as a Biomimetic Dental Restorative Material *Nannapat Siraboriphantakul, Yuwei Fan and Russell Giordano; Boston University, United States*

Human tooth tissue, comprising hard enamel and softer dentin, exhibits a graded structure with varying mechanical properties. Damage to enamel and dentin from mechanical trauma and bacterial disease (dental caries) necessitates repair using dental restorative materials. However, most existing materials do not fully replicate the mechanical characteristics of natural tooth tissues.

Polymer-infiltrated ceramics (PICs), such as Enamic (VITA Zahnfrabik), combine the strength of ceramics with the elasticity of polymers, resembling tooth dentin in strength and enamel in wear behavior. PICs typically exhibit intermediate flexural strength, elastic modulus and hardness between resin composites and glass ceramics.

This study aims to develop a biomimetic CAD/CAM hybrid ceramic material by infiltrating a feldspathic porcelain-based matrix with both glass and polymer. This approach aims to create a multilayered material where glass-infiltrated layers provide high hardness, complemented by polymer-infiltrated layers offering elasticity. Our primary objective is to enhance the material’s fracture toughness, a critical factor in determining the longevity of dental restorations, through nanoparticle reinforcement of the polymer matrix.

By integrating glass and polymer infiltrations to mimic enamel-like hardness and dentin-like resilience properties to the ceramic, this biomimetic approach holds promise for advanced restorative dentistry and educational applications. The inclusion of silica nanoparticles could enhance the flexural strength and fracture toughness, potentially improving the material’s clinical performance.

SB11.05.12
Modified Chitosan/Oxidized-Nanocellulose Hemostatic Dressings Loaded with Mesoporous Bioactive Glass Nanoparticles for Wound Healing *Rizos-Evangelos Bikiaris[1,2], Ioanna Koumentakou[2], Nikolaos-Iosif Matschek[1], Ioannis Tsamesidis[1], Faina Binder[3], Zoya Hadzhieva[3], Konstantinos Chrissafis[1], Aldo R. Boccaccini[3] and Eleana Kontonasaki[1]; [1]Aristotle University of Thessaloniki, Greece; [2]Democritus University of Thrace, Greece; [3]University of Erlangen-Nuremberg, Germany*

Hemostasis is the natural response of the body to significant wounds that result in bleeding. Hemostatic products *aim to address the initial stage of wound closure when it is compromised. In the process of hemostasis, there is a risk of wound infection, which can hinder skin healing and potentially lead to conditions such as bloodstream infection, sepsis, and dysfunction of multiple organs. Over recent decades, a variety of hemostatic agents have been created to prevent bleeding and reduce the likelihood of infection.*

Chitosan (CS) is a naturally degradable polysaccharide known for its excellent biological characteristics, including compatibility with living tissues, lack of toxicity, ability to combat microbes, and promotion of blood clotting. Cellulose, an easily obtainable biodegradable material, possesses significant capabilities to staunch bleeding and eliminate bacteria, spanning various types including Gram-positive and Gram-negative organisms. It is commonly employed in its TEMPO-oxidized nanocellulose (OCNC) form, which enables the development of hydrogels in conjunction with chitosan (CS) utilizing aldehyde groups produced during the oxidation process.

This work focused on the synthesis of hemostatic dressing using CS modified with OCNC, aiming to combine antimicrobial capabilities. Furthermore, to improve these characteristics, the dressing was loaded with mesoporous bioactive glass nanoparticles and Gelatin. Finally, the successful synthesis of the composite materials was confirmed by FT-IR, its crystallinity was evaluated with XRD and the morphology of the material was analyzed with SEM. In addition, biological studies confirmed the antibacterial properties and hemostatic activity of the chitosan dressing.

SB11.05.13

Manufacturing of Functional Films Based on Caffeic Acid Derivatives of Succinoglycan (SG) Exopolysaccharides Obtained from Sinorhizobium Meliloti with Biological Functionality and Biodegradability

Jae-pil Jeong, Kyungho Kim and Seunho Jung; Konkuk University, Korea (the Republic of)

A caffeic acid modified succinoglycan (Ca-SG) was synthesized based on SG, an exopolysaccharide extracted from soil microorganisms. The structural and physical properties of SG and Ca-SG were elucidated by structural analysis methods such as NMR, FTIR, XRD, and TGA. Additionally, enhanced or newly emerging functions investigated through various physiochemical methods. Based on those characteristics, a biodegradable, multi-functional film was fabricated by inducing film formation of SG and its caffeic acid derivative. Optimal condition of films was selected with the mechanical and rheological measurements. The results confirmed that the films based on SG and caffeic acid derivatives are multifunctional and biodegradable materials, suggesting the potential as an industrial biomaterial in various fields such as food science, cosmetics, and biotechnology using microbial polysaccharide.

SB11.05.14

Synthesis of Modified Chitosan Hydrogel—A Breakthrough Solution for the Extraction of PFAS from Environmental Samples Using High-Resolution Mass Spectrometry *Stella Petromelidou[1,2], Nina Maria Ainali[1,2], Dimitrios Bikiaris[1] and Dimitra A. Lambropoulou[1,2]; [1]Aristotle University of Thessaloniki, Greece; [2]Centre for Interdisciplinary Research and Innovation (CIRI-AUTH), Greece*

Per- and polyfluoroalkyl substances (PFAS) are a group of persistent environmental pollutants known for their resistance to degradation when found in the environment as well as their potential adverse health effects. Conventional methods for PFAS removal from water sources often fall short in efficiency and sustainability. This study explores the development and implementation of a chitosan-based hydrogel as a novel and effective solution for PFAS determination in environmental samples. Chitosan (CS), a biopolymer derived from natural chitin, offers remarkable biocompatibility, biodegradability, and adsorption properties, making it an ideal candidate for environmental applications. Chemical modification of CS is an efficient method to create new matrices that incorporate additional functional groups and exhibit enhanced characteristics, such as increased hydrophilicity and improved swelling rates. Among the different modification techniques (e.g., carboxymethylation, *thiolation, and succinylation), graft copolymerization has been the most widely used by researchers. This study aimed to ameliorate CS's adsorption capacity by grafting additional functional groups on its surface for the removal of PFAs from environmental matrices. Herein, modification of CS with 2-hydroxyethyl acrylate (2-HEA) took place applying radical polymerization (mole ratio CS/2-HEA 5/1), with potassium persulfate (KPS) as initiator and reaction conditions as 60 °C for 4 h (N_2 atmosphere). The final product (CS-g-HEA) was freeze-dried at -60°C and then the cotton-like sponge was purified using Soxhlet apparatus with methanol to eliminate any unreacted HEA moieties. The successful grafting of 2-HEA onto CS matrix was confirmed by FTIR and ^{1}H-NMR spectroscopies. X-ray diffraction (XRD) of the newly synthesized material demonstrated its amorphous nature. Additionally, TGA analysis was carried out to confirm the thermal stability, while swelling tests were performed to assess the enhanced swelling capacity of the CS-g-HEA. Our findings indicate that chitosan was effectively modified with these monomers. Following the synthesis process, the modified material was implemented as adsorbent for the development of dispersive solid phase extraction (dSPE) for the determination of PFAS in environmental water samples. The analysis was conducted using a QExactive Focus Orbitrap mass analyzer. The proposed pretreatment method was optimized and further validated in terms of recoveries, repeatability and reproducibility and limits of detection and quantification. Recovery rates were greater than 70%, method detection limits ranged between 10 and 100 ng L^{-1}, while the calculated relative standard deviations were <20%. Under the optimum conditions, the CS-g-HEA based dSPE method was employed for the determination of PFAS in challenging environmental matrices in terms of interferences and matrix. The findings of this research highlight the potential of CS hydrogel as a cost-effective, sustainable, and high-performance material for PFAS removal from water samples.*

Sustainable Fabrication of Silver Nanoparticles on Functionalized Cotton Fibers *Runjing Guo[1], Micheal Cuiffo[2] and Gary Halada[2]; [1]The Experimental High School Attached to Beijing Normal University, China; [2]Stony Brook University, The State University of New York, United States*

The synthesis of silver nanoparticles in natural fibers has become a promising green field. The antimicrobial properties of silver nanoparticles make them suitable for potential usage in wearable medical devices designed to monitor various human body conditions. For another thing, the high demand for cotton cloth results in excess of them, making the field of cotton cloth recycling important. This study researched a series of functional group modifications of cellulose aiming to make the whole process of silver nanoparticle synthesis green, safe, and effective.

In this study, cotton cloths were first treated with different chemicals for deweaving and modification of functional groups. Then the treated cotton fibers were soaked in a type of mild reducing agent made up of urea and lecithin. After that, the fibers were submerged in silver nitrate solution for silver nanoparticle synthesis.

25 pieces of 0.5cm×0.5cm square cotton cloths were treated separately with 40ml of 0.5M citric acid solution[1], 1M sodium hydroxide solution, 1M urea solution, and 1M urea, 1M sodium hydroxide mixed solution for 0.5 hours at 50 degrees Celsius with magnetic stir for 1000rpm to chemically deweave cotton cloths down to fibers. After filtration, the samples were dried in a vacuum overnight. Next, the samples were soaked in a 50ml solution with 0.25g lecithin and 0.5g urea at room temperature for 24 hours as the reduction process for nanoparticle synthesis. Then, the solutions were switched to 0.1M silver nitrate solution, and samples were fully submerged in the solution at room temperature for 18 to 24 hours to synthesize silver nanoparticles. Last, the samples were dried under a small fan at room temperature for two days, additional drying was performed in a vacuum for X-ray Photoelectron

Spectroscopy (XPS). All the solutions used were made of high-purity deionized water (18mΩ/cm).

Various methods of characterization and analysis were conducted on the samples and cotton cloth, including Optical and Digital Microscopy, Elemental Analysis, Fourier Transform Infrared Spectroscopy in DRIFT mode (DRIFT-FTIR), X-ray Photoelectron Spectroscopy (XPS), X-ray Fluorescence (XRF), Scanning Electron Microscopy (SEM), and Energy Dispersive Spectroscopy (EDS).

X-ray Fluorescence was used to check contaminants in cotton cloth, finding a relatively large amount of calcium and potassium which may come from the process of cotton cloth manufacturing. The figure obtained through the microscope indicates the most thorough deweaving process occurred in the sample treated by both sodium hydroxide and urea, which may indicate an interaction of urea and sodium hydroxide in changing the structure of cellulose. Comparing the differences of peaks in the Fourier Transform Infrared Spectroscopy, the modifications of the functional groups on cellulose were found. To be specific, the peak at $1663cm^{-1}$ *indicates the amine group attributed to urea and the peak at* $1730cm^{-1}$ *indicates C=O attributed to citric acid. It was discovered by scanning electron microscopy that silver particles scaled from nano to micro sizes, forming clusters of particles coated on the fibers and distributed uniformly. Besides, the particles were all pure silver but not compounds, tested by energy dispersive spectroscopy, suggesting a promising usage for acute care.*

Future works could focus on testing the functional properties of silver nanoparticle coated cotton fibers, including conductivity, thermal stability, cell toxicity, and encapsulation of silver nanoparticle coating.

The research was carried out based on former research of Environmentally Benign Low Temperature Degradation of Muslin Cloth with patent application number 050-9046.

In Situ Forming Ibuprofen-Grafted Hyperbranched PEG Hydrogels for Sustained Osteoarthritis Treatment

Chunyu Zhao, Rijian Song, Yinghao Li, Qiang Geng, Jing Lyu and Wenxin Wang; University College Dublin, Ireland

Osteoarthritis (OA) is a common degenerative joint disease characterized by the gradual deterioration and destruction of articular cartilage, accompanied by inflammation and pain, which severely impacts patients' quality of life. Current treatment methods primarily involve non-steroidal anti-inflammatory drugs (NSAIDs), with ibuprofen being widely used for oral administration due to its effective anti-inflammatory and analgesic properties. However, long-term oral administration of ibuprofen can lead to side effects such as gastrointestinal issues. Therefore, developing a controlled-release local drug delivery system is of significant importance.

In this study, we grafted ibuprofen onto hydroxyethyl acrylamide (HEAA) via esterification and then polymerized it with polyethylene glycol diacrylate (PEGDA) using reversible addition–fragmentation chain transfer (RAFT) polymerization, resulting in a high molecular weight polymer with ibuprofen grafts (HBPEG-IBU). Nuclear Magnetic Resonance (NMR) analysis revealed that the synthesized polymer had a high grafting efficiency. Thiolated hyaluronic acid (HA-SH), a modified natural polymer, was employed to form hydrogels with HBPEG-IBU through a Michael addition reaction, creating a hydrogel with in situ gelation capability. Rheological analysis indicated that the hydrogel exhibited favorable mechanical properties.

To evaluate the in vivo stability and drug release profile of the hydrogel, swelling and degradation experiments were conducted at different concentrations of hyaluronidase, along with in vitro release experiments. The results showed that at a hyaluronidase concentration of 1 U/mL, the degradation time of the hydrogel could reach up to 30 days, indicating a long-term sustained-release property. Additionally, the biocompatibility of the materials was confirmed through in vitro experiments, demonstrating that both HBPEG-IBU and the prepared hydrogel exhibited good cell compatibility. Furthermore, an anti-inflammatory experiment using a chondrocyte model verified the hydrogel's significant anti-inflammatory activity. In summary, the HBPEG-IBU hydrogel developed in this study *shows potential application value for the local treatment of osteoarthritis.*

SB11.05.17

Bio-Inspired Toughening Mechanisms in Densified Delignified Wood Laminates

Hajar Razi[1,2], Beatrice Ciabattoni[1], Yong Ding[1], Kunal Masania[3], Veton Beciri[1], Herwig Peterlik[4], Peter Fratzl[5] and Ingo Burgert[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Delft University of Technology, Netherlands; [4]University of Vienna, Austria; [5]Max Planck Institute of Colloids and Interfaces, Germany

Natural materials exhibit extraordinary mechanical properties, allowing them to withstand some of the most demanding environments. What sets them apart is their ability to overcome the typical trade-off between strength and toughness, thanks to their intricately designed microstructures that enable multiple energy dissipation mechanisms. In this work, we present a significant advancement in the creation of a bio-based material that not only demonstrates exceptional fracture resistance and high strength but also successfully incorporates a range of bio-inspired toughening mechanisms, mirroring nature's strategies for durability and resilience. By employing a combination of bio-inspired toughening mechanisms—including micro-scale suturing and nano-scale interlocking—our material achieves high toughness, far exceeding that of its constituent components.

We have employed a rigorous process of wood delignification and vacuum-assisted densification, which effectively reduces the porous structure of wood and enables the formation of tightly packed, unidirectional cellulose layers. This approach allows us to strategically laminate the material in both radial and tangential orientations, taking advantage of the natural interlocking of wood cells as well as native wood's material gradients. By integrating the inherent microstructures of wood into the design, we enhance the material's mechanical performance, creating a highly organized architecture that maximizes not only strength but also fracture resistance across multiple length scales. We validate the great damage-resistance performance of our modified wood using a comprehensive set of advanced techniques, including microcomputed tomography (micro-CT), scanning electron microscopy (SEM), fracture testing, and digital image correlation (DIC). These methods allow us to closely observe and quantify the material's behavior post failure, revealing insights into its toughening mechanisms. Our analysis reveals that by leveraging bio-inspired toughening mechanisms such as crack deflection, crack trapping, and fiber bridging, our densified wood laminate demonstrates fracture strengths of up to 350 MPa and fracture energy as high as 60 KJ/m^2.

When comparing our bio-based laminate to other major material classes, its damage tolerance surpasses that of native wood and virtually all technical and non-technical ceramics and polymers, as well as several pure metals and metallic alloys, including magnesium and aluminum. These comparisons highlight the outstanding mechanical properties of our material, positioning it as a remarkable alternative in fields where high-performance, lightweight, and durable materials are crucial.

The presented bio-inspired densified wood combines low density, cost-effectiveness, and recyclability. This combination of features makes our novel material highly attractive for a wide range of advanced engineering and structural applications, from aerospace to construction, where sustainability and performance are key considerations.

Viscoelastic, Antimicrobial and Recyclable Biomedical Bioplastic with Compactly Entangled Silk Structure

Woojin Choi[1] and Jinkee Hong[2]; [1]Massachusetts Institute of Technology, United States; [2]Yonsei University, Korea (the Republic of)

Global endeavors for a sustainable society have recently translated into the successful development of performance-advantaged bioplastics. Nevertheless, current healthcare service still demands considerable

advances regarding sustainability. Each hospital bed generates an average of 0.5 kg of medical plastic waste daily and a total of 6 million tons annually in the United States. Particularly in dentistry, a tremendous waste of dental care plastic has been released. For instance, every week, a dentist changes the polyethylene terephthalate-based orthodontic aligner to a new one and discards the used one. Thereby, 40-50 plastic aligner wastes are inevitably generated from one patient. Bioplastic could be a promising substitutive material of typical biomedical plastics with healthcare purposes. However, there is a big challenge resulting from the intrinsic characteristics of the human physiological system. Herein, we propose a new category of bioplastic, so-called biomedical bioplastic, that is desirable for a sustainable healthcare future.

Biomedical bioplastic should exhibit excellent durability for a prolonged period under the deformation stress from the body's essential activities. For instance, dental plastic should endure repetitive and substantial loads from tongue and tooth movements. Moreover, biomedical bioplastic should show a viscoelastic behavior to accomplish a mechanical match with human organizations. Hence, biomedical bioplastic should be flexible, tough, and viscoelastic at the same time. Biomedical bioplastic should be microbially clean regardless of the microbe, cell, and protein-abundant physiological environment. The contamination of biomedical bioplastic could damage microbiological homeostasis and cause severe complications. In summary, the desirable biomedical bioplastic should yield flexibility, toughness, viscoelasticity, and antimicrobial properties in balance.

In this study, we have developed a biomedical bioplastic composed of compactly entangled silk fibroin strands. Recent studies demonstrates that the entangled structure could cause viscoelastic behavior and reinforce the toughness. From this background, we synthesize a molecular template that can induce the compact entanglement of silk fibroin. This template also involves a quaternary ammonium group to impart antimicrobial properties to the biomedical bioplastic. The prepared biomedical bioplastic harmoniously exhibits great flexibility, toughness, and viscoelasticity. Thereby the successful dental care of misaligned rabbit incisors is demonstrated in vivo. Moreover, the biomedical bioplastic shows an intense resistance to pathogens growth, proved by ex vivo human saliva biofilm test. Remarkably, the silk fibroin and molecular templates are extracted with high selectivity through an acid-mediated disentanglement of entangled domains. This extracted silk fibroin is recycled into a new biomedical bioplastic with mechanical properties comparable to the original values. In conclusion, we anticipate that this study could be a cornerstone to establish a greener healthcare future.

A Morphology-Adaptive Janus-Adhesive Dressing with Dynamic Lubrication Overlayer for Prevention of Postoperative Infection and Adhesion

Shuangyang Li, Xu Deng and Junchang Guo; University of Electronic Science and Technology of China, China

Wound postoperative infection and adhesion is a common clinic disease induced by surgical trauma. However, integrating intraoperative repair and postoperative management into a dressing suitable for wounds with unpredictable surface shape and surroundings remains a great challenge. Slippery liquid infused porous surfaces (SLIPS) with dynamic liquid surface have universally and efficiently anti-fouling property, including repellent of biofluid and reduction of biofilm adhesion, but difficult to reflect superimpose on wound treatment. This is mainly because artificial adhesives for tissues are typically either hydrophilicity and strong interaction or hydrophobicity with limited strength, and tight fixation on the target tissue is the prerequisite for the dressing to function.

To fulfill the above requirements, we propose to integrate bioadhesive hydrogel and SLIPS into hybrid structures, named slippery-adhesive Janus gel (SAJG), and in situ gelation strategy is adopted. The hydrogel is created by spraying powders, which can quickly absorb interfacial water to construct favourable adhesion environment. The SLIPS is prepared by injecting a mixture of precured polydimethylsiloxane (PDMS) and silicon oil. Although there are related reports about the preparation of robustness of hydrogel-elastomer hybrids by chemical bonding or mechanical anchoring. Considering the implementability of in-situ preparation in vivo, these strategies are suboptimal. Here, we crosslinked the hydrogel and elastomer by mild and efficient silane coupling reaction, which *only reacted in the interface of hydrogel-elastomer. Because of the generally anti-fouling ability of SLIPS, SAJG exhibit excellent performance of liquid repellency, anti-tissue adhesion, anti- bacteria and protein adhesion. Compared to commercial bioactive dressing, SAJG without active ingredients indicated high antibacterial efficiency and anti-tissue adhesion ability. Further, rat models also showed excellent antibacterial infection and anti-tissue adhesion properties of SAJG no less than corresponding functional hydrogels. We believe that dynamic lubrication layer strategy is promising for postoperative wound management and the mechanism of preventing tissue adhesion needs to be further studied.*

SESSION SB11.06: Biomedical Applications
Session Chairs: Laia Mogas-Soldevila and Serpil Tekoglu

Living Materials Design by Synthetic Biology *Tzu-Chieh Tang; Harvard University, United States*

Synthetic biology applies genetic tools to engineer living cells and organisms analogous to the programming of machines. Engineering principles from synthetic biology and materials science are integrated to redesign living systems as dynamic and responsive materials with emerging and programmable functionalities. Here, we show that synthetic biology tools, including genetic circuits and parts from various organisms, can be applied to construct smart living materials that sense and respond to the environment. We create a suite of living functional materials, such as hydrogel devices hosting programmable cells for monitoring exposure to chemicals, engineered biofilms as smart filters, and living structural materials with genetically encoded enhancement.

8:30 AM SB11.06.02
Thioether-Functionalized Cellulose for the Fabrication of Oxidation-Responsive Biomaterial Coatings and Films *Eric M. DuBois[1], Kate Herrema[1], Matthew Simkulet[1], Laboni Hassan[1], Payton O'Connor[2,1], Riya Sen[3,1] and Timothy O'Shea[1]; [1]Boston University, United States; [2]Rensselaer Polytechnic Institute, United States; [3]Georgia Institute of Technology and Emory University, United States*

Implantable medical devices, such as subcutaneous drug delivery systems or deep brain stimulation electrodes, are powerful tools for disease treatment. However, implantation of these devices stimulates a multicellular foreign body response (FBR) leading to device encapsulation by fibrotic tissue, which attenuates device function. Biomaterial coatings, which adhere or bond to the device surface, or biomaterial films, which can be press-fit as a separate material layer onto devices, hold promise for both preventing premature failure of chronically implanted medical devices and enhancing the device functionality and performance. However, current hydrophilic polymers used in device coatings and films have significant drawbacks such as swelling and delamination. In this work, we address these limitations by developing an oxidation-responsive, bio-inspired polymer (HEC_{MTP}) which is synthesized by modifying hydroxyethyl cellulose (HEC), with 3-(methylthio)-propyl isothiocyanate (MTPI). HEC_{MTP} readily dissolves in dimethyl sulfoxide (DMSO) and blends of other green solvents. By tuning polymer solution viscosity through solvent and concentration selection, HEC_{MTP} can be controllably deposited onto substrates to create coatings between 1-30μm in thickness or drop cast to form free standing, smooth and transparent films ranging from 7-70μm in thickness. When HEC_{MTP}-coated substrates are exposed to physiologically relevant concentrations (40-80μM) of reactive oxygen species (ROS) in vitro, thioether moieties on the HEC_{MTP} are oxidized *to sulfoxide groups, resulting in a significant increase in hydrophilicity and softening of the coating interface, as well as a >92% decrease in cell biofouling in vitro. HEC_{MTP} coatings show a strong resistance to delamination, a capacity for oxidation-responsive and controlled release of small molecules and biomacromolecules, and exceptional optical transparency. Subcutaneous implantation of HEC_{MTP} resulted in a significant decrease in remodeled tissue thickness relative to similarly functionalized, non-oxidation responsive, HEC-derived materials. These results highlight the wide utility of HEC_{MTP} and support its use as a coating for implanted medical devices to enhance device efficacy and longevity.*

Anthracycline Binding and Release from the Natural Biopolymer Chondroitin Sulfate for Cancer Treatment

Jeannine Coburn, Kateryna Kushnir, Katelyn Mistretta, Isaac Levine, Tera Keang and Lyubov V. Titova; Worcester Polytechnic Institute, United States

There will be an estimated 600,000 deaths this year alone from cancer in the US. Chemotherapy, while critical to many cancer therapy regimes, has many negative side effects as it is generally non-specific and targets all proliferative cells. Local delivery has the potential to allow for higher drug concentrations at the tumor site, while minimizing systemic toxicity. Injectable photocrosslinked hydrogels may be used for local delivery. Chondroitin sulfate (CS) is a sulfated glycosaminoglycan that has many promising properties, including biocompatibility and anionic groups, allowing for binding with cationic chemotherapy drugs such as doxorubicin and sunitinib through electrostatic interactions.[1] CS can be modified with photocrosslinkable methacryloyl groups for injectable hydrogel fabrication (CSMA). These hydrogels are tunable, allowing for the manipulation of physical and mechanical properties that may be used to tune drug release kinetics. Their ability to bind and slowly release cationic drugs allows them to be an ideal system for local chemotherapeutic delivery. However, a fundamental understanding of how cationic drugs bind beyond simple electrostatic interactions and the impact on drug release is not fully understood. In this work, characterized binding and release of doxorubicin and daunorubicin, two anthracycline drugs that are structurally similar with a single difference in a hydroxyl group present in doxorubicin replaced by a hydrogen in daunorubicin. We found that the drug binding on a mole per mass of CSMA hydrogel is similar. However, the release kinetics are vastly different attributed to the hydroxyl group. Using UV/vis and ultra-fast transient absorption spectroscopy techniques, we investigated drug binding to CS polymer in solution to develop an understanding of the drug binding mechanisms and polymer or drug structural changes. By developing this fundamental understanding of drug/CS interaction, we will begin to address our long-term goal to develop intra-tumoral drug delivery systems as adjuvant therapies for cancer treatment.

Self-Assembled Collagen-Apatite Composite Biomaterial as Injectable Biomimetic Substitute for Tissue Repair

Marion Merle[1], Milena Lama[1], Camila Bussola Tovani[1], Tissiana Bortolotto[2] and Nadine Nassif[1]; [1]Sorbonne Université, France; [2]University of Geneva, Switzerland

In human biological tissue, type I collagen, the main structural protein, forms dense anisotropic structures with ordered geometries. Given that collagen exhibits liquid-crystal properties in vitro [1], it was suggested that the molecules might share such properties in vivo [2], potentially explaining these 3D arrangements. Consequently, tissue mineralization could be partly driven by collagen self-assembly and subsequent fibrillar confinement, allowing the co-alignment of collagen fibrils and apatite platelets [3].

This work aims to present a bioinspired and innovative synthesis to elaborate an injectable biomaterial. The

organic/inorganic ratio of the tissue-like composite can be adjusted to match the composition of specific natural mineralized tissues, and liquid-crystal properties of collagen molecules are leveraged to replicate its complex microstructure accurately. The organic component consists of spray-dried, non-denatured collagen microparticles. Although type I collagen is highly viscous and hardly injectable above 10 mg/mL, these dense, non-denatured particles allow the formation of highly concentrated gels by injection when mixed with an aqueous solvent and the mineral part, composed by biomimetic hydroxyapatite nanocrystals. Upon injection, the concentration required for the self-assembly of collagen molecules into liquid crystal phases is easily reached (above 40 mg/mL), a sine qua non condition to mimic the ultrastructure of biological tissues [4].
We show that our bioinspired process preserves collagen self-assembly properties and enhances fibril formation without any additional synthesis step. Moreover, the addition of biomimetic hydroxyapatite particles leads to tissue-like features with the presence of domains where collagen and apatite co-align. Furthermore, our characterizations and in vivo results demonstrate that these biomimetic materials are biocompatible and promising for various tissue repair applications.
The synthesis of a dense collagen/apatite material through a self-assembly step represents a versatile tool to form mineralized matrices with tissue-like features as well as for repairing any type of material with a minimally invasive technique. This straightforward procedure provides also a model to study the physico-chemical mechanisms involved in tissue mineralization.

9:15 AM SB11.06.05
Design Principles for Protein Polymer Networks in Biomimetic Red Blood Cells *Minkyu Kim; The University of Arizona, United States*

In light of the global blood shortage, the development of artificial blood has become crucial. Synthetic red blood cells (RBCs), a major component of artificial blood, hold the potential to transform transfusion medicine by mitigating infection risks and blood type matching issues common in allogeneic transfusions. These RBC substitutes also offer extended shelf life, making them essential for emergencies and healthcare in remote areas. However, current artificial oxygen carriers, primarily based on hemoglobin (Hb), face complications such as toxicity and non-specific interactions, underscoring the need for effective and stable Hb transport vehicles.

Existing transport vehicles face challenges due to instability and a high likelihood of being filtered out by organs such as the kidneys, spleen, and liver, likely due to their mechanical properties differing markedly from those of natural RBCs. Our research addresses these challenges by replicating the superior properties of natural RBCs, such as reversible stretchability and fatigue resistance, through the innovative design of protein polymer networks. These networks are engineered to mimic the well-organized structures and mechanical properties of the cytoskeleton, forming the core of our RBC-mimicking microparticles.

In this talk, I will discuss the principles of protein polymer design to construct networks that can replicate the mechanical properties of natural RBCs. By focusing on specific proteins that provide reversible stretchability and fatigue resistance, and employing precise protein polymer topology and crosslinking strategies, we aim to develop a well-organized protein polymer network that mimics the cytoskeletal structure of RBCs. This approach is expected to advance artificial blood technology and drive innovations in tissue engineering and drug delivery, *ultimately contributing to improved healthcare outcomes.*

9:30 AM SB11.06.06

Innovative Prolonged In Vivo Circulation Nanomicelles—Sharp-Contrast Amphiphilic Janus Star Polymers Derived from β-Cyclodextrin *Miao Zhang[1], Yuting Wen[1], Zhongxing Zhang[1], Xia Song[1], Jingling Zhu[1], Hongzhen Bai[2], Guping Tang[2], Kazushi Ogata[3], Shin-ichi Yusa[3] and Jun Li[1]; [1]National University of Singapore, Singapore; [2]Zhejiang University, China; [3]University of Hyogo, Japan*

Introduction: *Amphiphilic block polymer micelles have been widely utilized as nanocarriers for drug delivery due to their potential to reduce systemic toxicity, extend circulation time, and improve the bioavailability and biodistribution of therapeutic agents. However, their clinical application is hindered by poor stability in the bloodstream, leading to short in vivo circulation times and premature payload leakage. A promising approach to enhance micelle stability is through the design of micelles with sharp contrast in polarity, featuring a superhydrophobic lipid domain and a superhydrophilic zwitterionic polymer domain, which exhibit very low critical micellization concentrations (CMC). Despite this, designing micelles with a sufficiently dense and controllable shell to protect them in the bloodstream remains a significant challenge.*

Objective: *This study aims to develop a sharp-contrast Janus star-polymer with improved stability and extended circulation time in vivo. The polymer comprises multiple arms of superhydrophobic lipid domains and superhydrophilic poly(2-methacryloyloxyethyl phosphorylcholine) (pMPC) chains attached to a β-cyclodextrin (β-CD) core, denoted as Pal-βCD-pMPC. The goal is to form nanomicelles with a dense and controllable shell that can resist adsorption and penetration of blood proteins, thereby maintaining integrity in the bloodstream.*

Methods: *The Pal-βCD-pMPC polymer was synthesized by coupling superhydrophobic palmitoyl (Pal) groups with superhydrophilic pMPC chains, all attached to a β-CD core. The β-CD, a cone-shaped cyclic oligosaccharide composed of seven glucose units, serves as a multifunctional core that enhances the stability of the micelles. The stability and integrity of these nanomicelles were evaluated in various physiological environments, including phosphate-buffered saline (PBS), bovine serum albumin (BSA), fetal bovine serum (FBS), and blood plasma. The Förster resonance energy transfer (FRET) technique was employed to monitor micelle integrity in real-time during in vivo blood circulation.*

Results: *The sharp-contrast Janus star-polymer, Pal-βCD-pMPC, formed nanomicelles with an exceptionally dense and controllable shell, providing robust protection against blood protein adsorption and penetration. These micelles maintained their integrity for 12 hours when incubated in physiological mimicking environments, such as BSA and FBS aqueous solutions. Addiitionally, their chain exchange rate was extremely low, with negligible payload exchange among Pal-βCD-pMPC micelles over five days. Upon extremely dilution in aqueous solution, the system still assembled as micelles with negligible free polymer detected. When fluorophore-loaded Pal-βCD-pMPC micelles were administered into blood circulation, they successfully prolonged the circulation of fluorophore payloads and maintained micelle integrity for 12 hours, as detected by FRET imaging.*

Conclusion: *The sharp-contrast Janus star-polymers present a novel and effective strategy for creating ultrastable micellar nanocarriers with extended in vivo circulation times. The Pal-βCD-pMPC micelles offer significant potential for clinical therapeutic applications, overcoming the limitations of traditional linear polymer micelles. This study highlights the advantages of Janus star-polymer design in developing advanced nanocarrier systems for efficient drug delivery.*

10:15 AM SB11.06.07

Biomimetic Metallosaccharides—A New Material Class for Growing Artificial Cuticles for Biomedical and Food Safety Applications *Karina Ashurbekova[1], Kristina Ashurbekova[1] and Mato Knez[1,2]; [1]CIC nanoGUNE, Spain;*

[2]Ikerbasque, Spain

In nature, the intricate interplay between organic and inorganic components often results in materials with exceptional properties. One such example is the cuticle of arthropods, where chitin, a polysaccharide, combines with proteins and minerals to form a robust, multifunctional exoskeleton. Inspired by these natural structures, we developed an approach to creating artificial cuticles with enhanced bioactivity.

We have successfully developed and optimized a new strategy for growing coatings of artificial cuticles consisting of organic chitinoid and hybrid chitin-based films from the vapor phase using Molecular Layer Deposition (MLD). This innovative approach has led to the introduction of a new family of materials: metallochitins. These novel materials synergistically combine the properties of organic chitinoid polymers and inorganic metal oxides, exploiting a biomimetic approach to achieve unique functionalities.

The synthesis of these metallochitin based artificial cuticles was accomplished through a solvent-free vapor-phase MLD process, coupling sugar-type monomers with metalorganics. This method allows for precise control over the composition and structure of the resulting hybrid films, enabling tailored properties for specific applications.

We focused on two metallochitins: alumochitin and titanochitin. In vitro assessments of these materials against S. aureus and E. coli bacteria revealed strong antimicrobial properties, partly selective, ion dependence on the metal involved. The selectivity allows for designing specialized antimicrobial surfaces by optimizing various metal-saccharide combinations.

Beyond their antimicrobial properties, we extensively investigated the biocompatibility of our artificial cuticles using human embryonic kidney (HEK293T) cells and human fibroblasts. Both alumochitin and titanochitin demonstrated excellent biocompatibility, promoting greater cell proliferation than reference coverslips. Notably, titanochitin outperformed pure titania in promoting HEK293T cell growth, suggesting a synergistic effect between the chitin and titanium components within the hybrid film. Conversely, fibroblasts showed a preference for aluminum-based surfaces. These findings highlight the potential to selectively regulate cell proliferation by manipulating surface charge and metal composition, underscoring the versatility of metallochitins as biomaterials.

The dual functionality of our metallosaccharides - deterring bacterial adhesion while facilitating controlled cell growth - positions them as highly valuable materials for a wide range of applications. In the field of tissue engineering, these coatings could promote the growth of desirable cell types while preventing bacterial contamination, potentially revolutionizing the development of scaffolds and implants. For medical device fabrication, our metallochitins offer a promising solution to the persistent challenge of device-associated infections, potentially reducing the need for systemic antibiotics and improving patient outcomes. For food safety, these coatings could be applied to food processing equipment or packaging materials to inhibit bacterial growth and extend shelf life without compromising food quality.

Thus, by drawing inspiration from nature and combining organic and inorganic components at the molecular level, we have created a versatile platform for multifunctional materials as artificial cuticles with tunable properties.

10:30 AM SB11.06.08

Structurally Tunable Lipid Nanoparticles for Transdermal Delivery *Briana L. Simms, Sydney Dobler, Destiney Giles, Kaylyn Mitchell and Jay Lam; University of Cincinnati, United States*

Lipid nanoparticles (LNPs) have emerged in the literature as a viable vehicle for therapeutic delivery, gaining significant popularity over the last 30 years. LNPs are composed of a mixture of biocompatible lipids, which results in variance in nanoparticle properties such as size, surface charge density, or rigidity. This heterogeneity within the formulation can decrease targeting efficiency in drug delivery applications. To address these challenges, we have developed a library of structurally tunable lipid nanoparticles (stLNPs) formed by the self-assembly of a single *synthetic lipid with modifiable features. This results in uniform physical (i.e. size and morphology) and mechanical (i.e. rigidity, flexibility, and bilayer morphology) properties across the nanoparticle formulation and allows for the specific selection of LNP properties ideal for the application. With a long-term goal of advancing these materials towards clinical application for targeted transdermal delivery, we have designed and characterized synthetic lipids comprised of a poly amidoamine (PAMAM) dendron chemically linked to an acyl tail group. We have incorporated tunable features that afford nanoparticles with a range of properties. To assess the feasibility of these materials in transdermal delivery, we have treated human skin with the stLNPs and evaluated their impact on skin physiology and penetration depth. The work described herein will provide a framework for the strategic design and synthesis of LNPs for targeted drug delivery. This work will also allow us to better understand how small structural changes to materials can influence the final fate of LNPs in vivo.*

***Bioinspired Articular Cartilage Mimetic Adhesive Hydrogels** Olivia Dingus, Cesar A. Ramirez, Kathleen A. Parrish, Andrew P. Haney and Melissa Grunlan; Texas A&M University, United States*

Adhesive triple network (TN) hydrogels were developed as articular cartilage mimetic building blocks to repair chondral defects. Chondral defects occur due to arthritis, age, and wear of the joint, where the articular cartilage has a low capacity to heal. To replace the damaged tissue typical treatments, rely on grafting, hard implants, and often need biological factors. These treatments often have adverse effects such as donor site morbidity, wear debris generation and fibrocartilage formation leading to the need for a bioinspired tissue mimetic approach. Hydrogels are an excellent candidate for cartilage tissue due to the structure and high hydration akin to native cartilage (60-90%). While, they have been used for tissue engineering, hydrogels remain limited due to weak mechanical properties. Articular cartilage has discrete depth-dependent mechanical properties to allow for articulating and load bearing requiring a robust biomimetic replacement. To recapitulate the depth-dependent properties, these electrostatic TN hydrogels were developed to incorporate a polyampholyte (i.e., dual-charged [±]) 3rd network to allow for articular cartilage mimetic mechanical properties and adhesion. The inclusion of the polyampholyte 3rd network demonstrated a double in compressive strength (σ_C~13 MPa) compared to the previously developed anionic [-] TN hydrogel (σ_C ~5 MPa). The doubled mechanical strength was attributed to the increased internetwork electrostatic interactions, providing dynamic bonds to improve stress dissipation. The charge [+, -, or ±] presence in the 3rd network of these hydrogels promoted robust electrostatic adhesion characterized by shear strengths of ~100 kPa. These hydrogels are mechanically robust, adhesive, and hydrated presenting a strategy for creating biphasic articular cartilage mimetic implant achieving the necessary criteria.

11:00 AM SB11.06.10

***Function and Delivery of Antifibrotic Polysaccharides** Thomas E. Robinson, Richard Moakes, Mathieu Brunet, Iain Chapple, Adrian Heagerty, Davide Calebiro, Anthony Metcalfe and Liam Grover; University of Birmingham, United Kingdom*

Fibrotic conditions account for nearly half of all deaths in industrialised countries. Scarring in the eye can lead to blindness, and impaired healing following burns can lead to significant disfigurement and impairment. Additionally some conditions, such as epidermolysis bullosa, lead to progressive scarring of the skin and mucosa, triggered by the motions of everyday life. There is thus an urgent need for antifibrotic therapies that are not only efficacious, but also affordable, and more easily brought to market. To this end natural polysaccharides, which are abundant, low cost, and have a long history of use in food and pharmaceuticals, were studied for their antifibrotic activity. In vitro assays of epithelial fibrosis were utilised to assess the proclivity of the different polysaccharides to inhibit scarring, and understand which traits of the polymers led to increased antifibrotic action. Optical techniques were developed to probe the physicochemical mechanism of fibrosis inhibition, grafting fluorophores onto the *polysaccharides, primarily to understand their interaction with transforming growth factor beta 1. The most potent antifibrotic polysaccharide, iota carrageenan, was then formulated for improved material properties. As primarily structural polymers, the therapeutic polysaccharides themselves can be used to provide the desired mechanical properties. Ionotropic, physical cross-linking under shear was used to create discontinuous fluids consisting of high-polymer density particles within an interstitial phase. These materials were viscoelastic, yielding improved retention at the target site, but also sprayable, owing to the breaking points between the discrete particles, for ease of application. Together, these findings suggest that single-component polysaccharide formulations may represent efficacious and affordable means to inhibit fibrotic conditions, with a simplified route to market.*

11:15 AM SB11.06.11

Functionalized Hyperbranched Polymers Derived from Kinetically Controlled Polymerization for Gene Therapy *Zishan Li, Jing Lyu and Wenxin Wang; University College Dublin, Ireland*

The efficiency of drug delivery systems is of great significance in modern medicine, as it can significantly improve therapeutic outcomes and reduce side effects. Polypeptides, due to their excellent biocompatibility and diverse functional properties, have become ideal candidates for drug carriers. However, traditional polypeptide polymers still face challenges in terms of stability and delivery efficiency. To address these issues, we have developed polypeptide-functionalized cyclized/knot polymers aimed at enhancing drug delivery efficiency.

In this study, through the kinetically controlled strategy, we designed and synthesized a series of polypeptide-functionalized cyclized/knot polymers with introducing monomers with different functional groups. These polymers possess condensed conformations, multiple intramolecularly cyclized structures and well-defined three-dimensional structures. By optimizing the degree of cyclization and the design of the polypeptide chains, we can precisely control the physicochemical properties of the polymers. Experimental results demonstrate that these cyclized/knot polymers exhibit excellent stability and biocompatibility under physiological conditions, as well as low toxicity.

To improve drug delivery efficiency, we focused on the membrane-penetrating ability and endosomal escape characteristics of these polymers. In vitro experimental results show that polypeptide-functionalized cyclized/knot polymers have exceptional membrane-penetrating capabilities, efficiently crossing cell membranes and entering the interior of cells. Additionally, these polymers exhibit excellent endosomal escape ability in endosomal environments, effectively releasing the loaded drugs and thereby enhancing the therapeutic effects.

In summary, polypeptide-functionalized cyclized/knot polymers, as a new type of drug delivery carrier, show great potential in improving drug delivery efficiency. This study not only provides new strategies and methods for the development of efficient drug delivery systems but also lays a solid foundation for future clinical applications.

11:30 AM *SB11.06.12

Chiral Transfer Across Multiple Length Scales *Silvia Vignolini; Max Planck Institute of Colloids and Interfaces, Germany*

The chiral self-assembly of nanoscale building blocks is a universal phenomenon that demonstrates the emergence of large-scale structures from the properties of individual sub-units. In many self-organising colloidal systems exhibiting chiral nematic structures, such as cellulose nanocrystals (CNC), the emergence of chirality in the mesophase is correlated to the properties of the building blocks and is therefore necessarily fixed. In this talk, I will review how the chirality transfers from molecular to colloidal scale and finally the self-assembly also in the presence of different chiral additives and review some tricks that can be used to achieve CNC-colored films with circular right-polarized light reflection.

Intelligent Strategy of Bioinspired Adaptive Structural Adhesives for Soft Biomedical and Robotic Interfaces

Changhyun Pang[1,1] and Da Wan Kim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea National University of Transportation, Korea (the Republic of)

Intelligent artificial adhesive structure technology, inspired by natural living surfaces, enables reversible attachment to curved, rough, hairy, dry, wet, or soft surface, showing promise in the diverse fields of bioelectronics, medical devices, soft robots, and haptic interfaces. Recently, for a variety of future interface applications of the switchable adhesive materials, these intelligent adhesive interfaces are actively designed for purpose and function and manufactured from programmable soft materials through effective replication and 3-/4-dimensional printing methods. Controlling geometric features such as size and biphasic property of tips, as well as curvatures benefited mimicking of the adhesive phenomena and structures of natural surfaces. Polymeric small architectures have become important to address the issues of human interactions for biomedical applications such as bioelectronics interfaces and transdermal delivery. Furthermore, these technologies provide a solution for the development of soft robots with versatile grasping capabilities like those of octopuses. Here, advances in designs of biologically inspired adhesive architectures will be introduced in terms of distinct structural properties, attachment mechanisms to diverse surfaces by physical interactions, and noteworthy fabrication methods.

Bio-Inspiration to Sustainability—Making New Adhesives *Jonathan Wilker, Bradley C. McGill and Clayton R. Westerman; Purdue University, United States*

Adhesives are great for holding together many products including our electronics, furniture, cars, and packaging. This performance comes at significant environmental costs. Modern glues are petroleum-based, do not degrade, and prevent recycling, owing to bonds between substrates being permanent. With sustainability a pressing concern, new generations of bonding materials are needed. Having market impact a relevant goal, several design constraints are present when trying to replace petroleum-based glues with bio-based materials. Bonding performance must remain high while costs need to be low. Furthermore, the starting materials used must be already available on scales commensurate with ongoing adhesive production.

Soy oil is one of the most widely available sources of organics. In an effort to mimic the chemistry of industrial epoxies, we turned to epoxidized soil oil for the basis of a new adhesive system. After testing several multifunctional nucleophiles, malic acid, from apples, was a promising cross-linker (or "hardener"). Curing into viable glues, however, required incorporating a second class of cross-linking chemistry. We turned to marine *mussel adhesives, which depend upon catechol-type cross-linking. Here, tannic acid, found in all plants and containing several gallol groups, provided the analogous mussel adhesive chemistry. The end result was a high performance adhesive system with strengths similar to incumbent epoxies. Mechanical studies showed a ductile material, differing from the brittle nature of many commercial glues. Spectroscopic studies indicated that all components reacted with each other, although nucleophilic attack from the acid groups of malic acid toward epoxy groups of epoxidized soy oil was most prominent. Water resistance studies showed a middle ground between neither falling apart too quickly nor remaining bonded permanently. Costs at scale were a modest one-third premium versus commercial epoxies and urethanes. Preliminary calculations indicated this new system to be, overall, carbon negative, owing to the carbon absorbed by plant growth. We hope that bio-inspired systems can help to shift our materials economy toward the sustainability goals required for a prosperous future.*

Diatoms Microalgae with Biosilca Shells as Living Materials for Biomedicine and Nanotechnology *Gianluca Maria Farinola; Università degli Studi di Bari Aldo Moro, Italy*

Diatoms are microalgae which have their unique cell encased into a nanostructured silica shell called frustule. The silica shells can be envisioned as micro/nano structures suitable to chemical modification yielding smart functional nanomaterials [1, 2].
Differently from the chemical production of silica, the biosynthesis of natural SiO_2 occurs in mild conditions and does not require the use of toxic precursors or reagents. Biosilica from diatoms features interesting properties such as high surface area, mechanical resistance
and nanotexturization, which makes it appealing for applications in photonics, sensing, optoelectronics, biomaterial science and biomedicine. In addition, frustules' biosilica can be easily chemically modified to add new functions by simple surface functionalization, and/or in vivo by adding specific molecules to the culture medium.
We have shown applications of chemically modified frustules for bone cells growth [3] demonstrating that in vivo functionalization of diatom biosilica with sodium alendronate results in osteoactive material [4].
We have also demonstrated the production of functional structures by coating living diatoms with biomimetic organic polymers, like polydopamine [5]. The resulting living heterostructures turn out to be intriguing platforms for additional chemical modifications,
such as anchoring enzymes, affording multifunctional materials for biological applications.
Finally, we have also shown that photonic microstructures can be produced by in vivo incorporation of tailored light emitting molecules in living Thalassiosira weissflogii diatoms [6, 7]. With a similar approach, biosilica has been doped with phosphorescent Ir complexes [8].
Overall, our studies point out intriguing biotechnological routes to multifunctional nanomaterials for biomedicine and nanotechnology starting from unicellular algae.

4:00 PM SB11.08.02

A Bioinspired Polymer as Versatile Platform for the Design of Living Diatom Microrobots

Cesar Vicente-Garcia[1], Danilo Vona[1], Emiliano Altamura[1], Stefania Roberta Cicco[2], Roberta Ragni[1] and Gianluca Maria Farinola[1];
[1] Università degli Studi di Bari Aldo Moro, Italy; [2] Consiglio Nazionale delle Ricerche, Italy

Bio-based functional materials have attracted great interest due to their sustainability and versatility. The combination of extracellular, tailored matrices and living organisms (or their isolated components) has yielded functional materials with remarkable properties, and with use in a variety of applications, from sensing to catalysis [1]. Bio-inspired and biomimetic polymers hold great promise due to their chemical diversity and tuneability. Polydopamine (PDA) is a biocompatible and bio-inspired polymer, that can be easily synthetized via spontaneous oxidative polymerization of dopamine in water. Even though the structure of PDA has not been yet fully described, it exhibits interesting features like adhesive and entrapping properties and tuneable porosity [2]. PDA has been used in combination with living microorganisms, yielding biohybrids with enhanced capabilities, such as electrically conductive bacteria bioelectrodes [3], and highly resistant yeast pseudo-spores [4]. However, the coating of shelled microorganisms like diatoms, which bear biosilica exoskeletons, can afford more robust and stable biohybrids. By using their nanostructured shells as templates, a more homogeneous coating of PDA can be achieved, that can be even transmitted to a number of further generations [5]. The presence of specific chemical groups in PDA, like charged groups and aromatic rings, allows it to interact and trap specific compounds, such as polyaromatic or polychlorinated hydrocarbons [6]. This work aims to optimize the fabrication of a biocompatible PDA-based coating onto living diatoms, explore the decoration with additional functional elements (nanoparticles, enzymes, etc), and test their performance as biohybrid functional materials. The viability of diatom biohybrids coated with PDA has been evaluated through standardized tests; magnetic nanoparticles and oxidative enzymes have been incorporated into the PDA matrix (with the subsequent physico-chemical characterization); and their catalytic activity has been tested under repetitive tests of recycle and in long-term experiments, with promising results. We have designed a methodology that allows to generate PDA-embedded living diatoms with the ability to bear a heterogeneous mixture of functional elements. These biohybrid microrobots have potential applications in bioremediation and biomedicine.

Deeply Hierarchical, Multi-Functional Materials from Naturally Grown Biosilica *Aidan S. Lucas and Hannes C. Schniepp; College of William & Mary, United States*

We grow monocultures of diatoms, single-cellular algae featuring exoskeletons made from biosilica. We harvest these skeletons at gram scales to turn them into macroscopic materials via different routes. For instance, we use 3D-printing to produce structures consisting virtually completely of biosilica, featuring 6 levels of structural hierarchy from the 10-nm to the 10-mm scale. Since diatoms are photosynthetic organisms, this process sequesters carbon and has great potential for a new generation of materials that can remove greenhouse gases during their production. In great contrast to other biologically produced materials, they are inorganic, which gives rise to completely different functionalities. For instance, they can tolerate temperatures of up to 1,000 °C without damage, they show outstanding flame retardance, and they can withstand harsh chemical environments. Since diatom frustules feature outstanding specific strength, our diatom-based materials also have great potential for structural applications. Our preliminary tests have demonstrated specific strengths exceeding that of concrete. Since diatom frustules are highly porous and hollow, our materials can be made to feature densities <0.1 g/cm^3, which not only is interesting for lightweight applications, but also leads to low thermal conductivity <0.3 $W\,m^{-1}\,K^{-1}$. The combination of high temperature resistance and low thermal conductivity makes them excellent materials for thermal management.

Materials-Driven Engineering of Bacteria *Giuseppe Maria Paternò[1,2] and Giulia Simoncini[2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy*

The goal of engineering living matter is to modify biological attributes to leverage the unique capabilities of living organisms. One prevalent method involves rendering living matter responsive to specific stimuli through either synthetic biology techniques or functional materials, aiming to modulate the electrophysiology and activity of cells and organisms. This method applies to bacteria as well, despite the fact that the connections between their electrophysiology, bioelectricity, bioenergetics, and behavior have only recently started to be elucidated. Recent studies have revealed that bacterial membrane potential is a dynamic, rather than static, parameter and plays a significant signaling role. Bacteria possess a complex bioelectric signaling language that governs their metabolism, behavior, and functions within microbial communities. Given that membrane potential dynamics mediate this language, manipulating this parameter presents a promising and intriguing strategy for bacterial engineering.
Here, I show that precise optical modulation of bacterial membrane potential can be achieved through a materials-based approach. Specifically, we found that the isomerization reaction at the membrane location

induces either hyperpolarisation or depolarisation of the potential depending on the excited state deactivation pathways, within a bio-mimetic mechanism reproducing the initial fate of retinal. This can trigger neuron-like bioelectric signalling and can highlight the role of previously uncharacterized ion channels in bacteria electrophysiology. Finally, I also show recent results on the light-modulation of antibiotic uptake, as well as perspectives on the photocontrol of bacterial motion and assembly behavior in consortia and multispecies ecosystems.

4:45 PM SB11.08.05

Multifunctional Biocomposite Materials from Chlorella vulgars Microalgae *Israel Kellersztein[1], John Pederson[1], Daniel Tish[2], Martin Bechthold[2] and Chiara Daraio[1]; [1]California Institute of Technology, United States; [2]Harvard University, United States*

Extrusion 3D printing of biopolymers and natural fiber-based biocomposites enables the synthesis of multifunctional and complex structures with a diversity of mechanical properties. However, this process faces significant challenges, including reducing material viscosity through high energy consumption, i.e., by heating, and harsh treatments to enhance stress transfer within the biocomposite. In this presentation, we introduce a systematic framework for synthesizing complex shapes using natural composite materials for sustainable and scalable processing. By utilizing Chlorella vulgaris microalgae as the biocomposite matrix, we optimize bioink and processing parameters to design multifunctional, lightweight, and hierarchical biocomposite materials through extrusion 3D printing. The proposed biocomposites maintain a continuous morphology of aggregated microalgae cells, capable of withstanding high shear forces during processing. Compression and bending tests assess the impact of printing variables and reinforcement concentration on mechanical performance. We additionally explore the effects of ambient conditions on the mechanical properties of the biocomposite. The Chlorella biocomposites demonstrate isotropic heat transfer under guarded heat flow and laser heating tests, functioning as effective thermal insulators. These materials show promise as substitutes for bulk polymers and wood, particularly in applications requiring a balance between thermal insulation and structural capabilities. Our methodology can be adapted to other microalgae strains, facilitating the large-scale fabrication of complex 3D structures.

Analysis of Rheological Behavior and Antioxidant Activity of Succinoglycan Exopolysaccharides with High Succinic Acid Content Obtained Through Succinic Anhydride Esterification Reaction *Kyungho Kim, Jae-pil Jeong, Sohyun Park and Seunho Jung; Konkuk University, Korea (the Republic of)*

Highly succinylated succinoglycan (HS-SG) was obtained by reacting succinic anhydride with succinoglycan (SG) exopolysaccharide obtained from Sinorhizobium meliloti. Herein, structural analysis of HS-SG was performed through NMR, FT-IR, and GPC measurements. The rheological properties, physical properties, and antioxidant effects of HS-SG were investigated and compared with SG. HS-SG showed a tendency for the molecular weight to increase as the reaction ratio of succinic anhydride increased. HS-SG maintained the structure of SG, and the *increase ratio of the succinyl functional group was confirmed through NMR and FT-IR. Rheological property analysis showed that HS-SG had a viscosity 250% higher than SG at a shear rate of 10 s^{-1} when the reaction molar ratio of SG and succinic anhydride was 1:50. Furthermore, HS-SG exhibited higher thermal stability in rheological properties. The viscosity of SG decreased significantly to less than 10% above 70°C, but HS-SG maintained a viscosity value of over 20%. Additionally, DSC analysis showed that HS-SG exhibited a higher endothermic peak at 151 °C than SG at 93 °C, indicating improved thermal stability. In the DPPH, hydroxyl radical scavenging test, HS-SG had enhanced antioxidant activity. In these results, it was confirmed that HS-SG exhibits improved physical and rheological properties and antioxidant effects for the potential industrial use of biomaterials in various fields such as cosmetics, food, and biotechnology using microbial polysaccharides.*

SB11.09.02

Regenerated Silk Fibroin Film with a Robust Functional Surface Physically Modified by Pollen Grains *Seohan Yun[1,1], Taehoon Kim[2], Fiorenzo Omenetto[2] and Junyong Park[1,1]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]Tufts University, United States*

Silk fibroin regenerated from silkworm cocoons has provided a biocompatible and environmentally friendly platform for various technological applications. The surface of regenerated silk fibroin prepared in bulk or film form is inherently hydrophilic, so it is important to modify the surface to achieve the desired level of wettability. However, traditional chemical approaches do not guarantee robust surfaces that can withstand a variety of extreme environments. Here, we present a new strategy to physically modify the surface of silk fibroin films by imprinting the microstructure of the pollen surface. The elastomeric mold, consisting of a pollen monolayer with a spike-shaped surface, is replicated into a wafer-scale silk fibroin film through a series of imprinting processes. The resulting pollen-imprinted silk fibroin film exhibits a high contact angle of 126° without any chemical treatment. The contact angle does not decrease after repeated washing with detergent due to the physically modified surface. Additionally, the unique hierarchical topology of the pollen-derived surface allows the film to exhibit excellent optical scattering, ensuring its applicability as functional optical films. In this presentation, we will show the potential applications based on the unusual properties of silk films with robust functional surfaces.

SB11.09.03

Modified 3-Hydroxylbutanoyl Glycan/Gelatin Hydrogels for pH-Responsive Drug Delivery with Enhanced Mechanical Strength and Antioxidant Properties *Seunho Jung, Sohyun Park, Younghyun Shin, Yohan Kim and Jae-pil Jeong; Konkuk University, Korea (the Republic of)*

Rhizobial exopolysaccharide is an eco-friendly and non-toxic biopolymeric materials widely used in various industrial fields such as pharmaceutical, food and cosmetics based on its structural, rheological and physiochemical properties. Rhizobial EPS as a hydrogel biomaterial was used for a pH-responsive drug delivery system combing with gelatins. Pure gelatin (GA) hydrogels have limited practical applications due to their poor mechanical strength and poor thermal stability. We developed GA hydrogels using oxidized 3-hydroxylbutanoyl glycan (OHbG) as a polymer cross-linking agent to overcome these limitations. OHbG was synthesized from sodium periodate oxidation of 3-Hydroxylbutanoyl glycan directly isolated from Rhizobium leguminosarum bv. viciae VF39. OHbG/GA hydrogels exhibited 21-fold higher compressive stress and 4.7-fold higher storage modulus (G') than GA at the same strain. This result suggested that OHbG provided mechanical improvement. In addition, OHbG/GA hydrogels showed effective pH-controlled drug release for 5-fluorouracil and self-antioxidant capacity by uronic acids of OHbG. In vitro, cell viability tests using HEK-293 cells also showed that the OHbG/GA hydrogels were non-toxic. This suggests that rhizobial oxidized 3-hydroxylbutanoyl glycan-based GA hydrogels can be used as a potentially new biomaterial for drug delivery based on antioxidant capacity and pH-responsive drug delivery.

SB11.09.04

Reduction-Responsive Hydrogel Based on Carboxyethyl-Succinoglycan(CE-SG) for Release of 1,4-Dithiothreitol with Highly Improved Rheological, Antibacterial and Antioxidant Properties *Jae-pil Jeong, Kyungho Kim, Yohan Kim and Seunho Jung; Konkuk University, Korea (the Republic of)*

The development of exopolysaccharide-based polymers is gaining increasing attention in various industrial biotechnology fields for materials such as thickeners, texture modifiers, anti-freeze agents, antioxidants, and antibacterial agents. High-viscosity carboxyethyl-succinoglycan (CE-SG) was directly synthesized from succinoglycan (SG) isolated from Sinorhizobium meliloti Rm 1021, and its structural, rheological, and physiological properties were investigated. The viscosity of CE-SG gradually increased in proportion to the degree of carboxyethylation substitution. In particular, when the molar ratio of SG and 3-chloropropionic acid was 1:100, the viscosity was significantly improved by 21.18 times at a shear rate of 10 s^{-1}*. Increased carboxyethylation of SG also improved the thermal stability of CE-SG. Furthermore, the CE-SG solution showed 90.18 and 91.78 % antibacterial effects against Escherichia coli and Staphylococcus aureus and effective antioxidant activity against DPPH and hydroxyl radicals. In particular, CE-SG hydrogels coordinated with* Fe^{3+} *ions, which improved both viscosity and rheological properties, while also exhibiting reduction-responsive drug release through 1,4-dithiothreitol. The results of this study suggest that SG derivatives, such as CE-SG, can be used as functional biomaterials in various fields such as food, cosmetics, and pharmaceutical industries.*

SB11.09.05

Gecko-Inspired Porous Dry Adhesive Patch for Attachable Radiative Cooling *Sanga Park, Seohan Yun, Heeeun Choi and Junyong Park; Kumoh National Institute of Technology, Korea (the Republic of)*

Passive daytime radiative cooling (PDRC) is an energy-efficient technology that cools surfaces or spaces without consuming electrical power to combat global warming and achieve carbon neutrality. Highly scattering films based on heterogeneous composites or porous structures are commonly used for PDRC, but their utility is still limited. Here we demonstrate a new type of PDRC patch that can be attached and detached from any surface as needed. On one surface of the PDRC patch made of porous PDMS, mushroom-shaped, high-aspect-ratio micropillars mimicking geckos were formed, which exhibited an initial dry adhesion of ~3.42 N/cm^2 *due to collective van der Waals forces. Even after 40 cycles of repeated attachment and detachment, the dry adhesion was maintained at ~2.8* N/cm^2*. By impregnating silica nanoparticles into the pores of the porous network to form a hierarchical structure, the visible light scattering of the PDRC patch was maximized. The average solar reflectance and average infrared emittance of the resulting PDRC patch were ~87.8% and ~92.5%, respectively. In outdoor testing using a customized setup, the maximum cooling temperature of the patch during daytime was ~8.5 °C. The attachable PDRC patch developed in this study will provide a new option to selectively utilize cooling functions under various constraints.*

SB11.09.06

A Tough Physical Bond-Based Gel that is Fully Aligned to the Circular Economy *Yi Ler Eddy Pang[1,1], Xuan Zhang[1], Ian Rongde Tay[1], Pengyu Chen[1], Yuxuan Seah[1], Guijin Zou[2], Jinrun Zhou[1], Huajian Gao[2,3] and Yu Jun Tan[1,1]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research, Singapore; [3]Nanyang Technological University, Singapore*

Synthetic materials play a crucial role in many facets of modern society owing to their outstanding durability, cost-effectiveness, and adaptability allowing them to be engineered into a diverse array of applications. Despite their advantages, synthetic materials follow the take-make-dispose linear economy model which is unsustainable. The circular economy is an alternative model that seeks to reduce waste by keeping resources in a loop as long as *possible through processes such as material design, green processing, repairing, recycling, and biodegradation. However, achieving full alignment with the principles of the circular economy remains elusive and the usual problem stems from not choosing the correct starting raw material. One solution is to use bioderived raw materials that are inherently biodegradable. When biodegraded, their decomposition products can be used as building blocks for the subsequent generation of raw materials, thereby perpetuating a sustainable cycle. Nevertheless, bioderived raw materials like alginate and cellulose are often mechanically weak or stiff by themselves which limits their widespread applicability. The challenge is whether we could develop a tough yet sustainable material that is fully aligned with the circular economy.*

Herein, we developed a tough physical bond-based gel that is fully aligned with the circular economy. The material comprises a polymeric backbone with other organic compounds all of which are bioderived. We confirmed that the components interact with each other via strong physical bonds like hydrogen bonds, ionic interactions, and ion-dipole interactions. The material is tough as it can dissipate energy through the breakage of reversible physical bonds and the rearrangement of the components, delaying the rupturing of the polymer network. When contrasted against natural polymers reinforced by conventional toughening strategies such as double network and metal coordination, our gel exhibits superior toughness of at least one order of magnitude higher. Our material can achieve 100% self-healing efficiency and is close to 100% transmittance over the entire visible spectrum. Furthermore, it can biodegrade fully in soil in 5 days and is highly biocompatible and recyclable. This opens avenues to apply tough yet sustainable materials in food science, biomedical, and green robotics applications.

SB11.09.07

Synthetic Nano-Engineered Antimicrobial Polymers (SNAPs) *Sebastien Perrier; University of Warwick, United Kingdom*

Biofilms, a microbial or poly-microbial community attached to a biotic or abiotic surface that provides a suitable environment for proliferation, are considered a virulence factor, producing 65% of all human infections. The development of biofilm is categorized in a process of cell adhesion, cellular aggregation, biofilm maturation and cellular detachment. In the last stage, the biofilm community is able to release free-floating forms disseminating the infection.

Antimicrobial resistance (AMR) is partly due to the narrow range of available antibiotics which have reached their limitations in infection treatment because of their high target specificity. In such context, antimicrobial peptides (AMPs) have recently attracted interest as they were shown to target bacterial membranes instead of individual proteins.Present in the innate immune systems of various organisms, these peptides have an amphipathic structure which can adopt a facially amphiphilic arrangement with hydrophobic groups on one side and cationic moieties on the other side of the molecule. Due to the mostly non-charged surface of mammalian cells, AMPs exhibit good selectivity towards bacterial membranes. However, their isolation or production on a large scale is expensive and their peptidic nature renders them vulnerable e.g. to protease based countermeasures. In order to overcome these issues, we have developed a family of synthetic mimics based on polymers. The key structural parameters are the balance of cationic / hydrophobic moieties, the molecular weight, the nature of the charge and the structure of the polymer backbone.

This lecture will show the use of cationic polymers of various architectures in the treatment of biofilms, and address both fundamental and applied questions on understanding biofilm formation and how polymers act as new actives against microorganism living inside the biofilm.

SB11.09.08

Thermally Stable Microporous Microgels for Cell Encapsulation and Tissue Engineering *Ziqiang Guan; University System of New Hampshire, United States*

Microgel-based injectable hydrogels, which are produced by crosslinking (or annealing) the microgels, have recently received a lot of attention due to their ability to induce rapid cell adhesion and promote cell-cell interactions within the interstitial space. Although these approaches showed significantly improved cellular responses compared to the conventional nonporous injectable hydrogels, porosity of the hydrogel is limited by the interstitial pore space and the cellular growth is mostly excluded from the microgel phase. Use of microporous microgels and their assembly can increase porosity of the hydrogel and serve as better scaffolds for tissue engineering. However, most microgels are thermally unstable and the pore structures are lost during the cell encapsulation process at physiological temperature. In this research, we report a novel method of producing thermally stable microporous gelatin/alginate microgels that can be enzymatically crosslinked to form a highly porous bulk hydrogel. The porous structure of microporous microgels and of the crosslinked bulk hydrogel was characterized by scanning electron microscope (SEM) and confocal microscopy. When human dermal fibroblasts (hDFs) were encapsulated in the assembly of microporous microgels, hDFs were found to grow within the pores of microgels with high viability over 7 days.

SB11.09.09

Inkjet-Printed Humidity Sensors with Black Soldier Fly Melanin *Peter Krebsbach[1,2], Mikel Rincón Iglesias[1,3], Manuel Pietsch[1,2], Carmen Henel[1,2], Senentxu Lanceros-Mendez[3,4], Jun Wei Phua[5], Marianna Ambrico[6] and Gerardo Hernandez-Sosa[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany; [3]BCMaterials, Spain; [4]Ikerbasque, Spain; [5]Insectta, Singapore; [6]Consiglio Nazionale delle Ricerche, Italy*

With the increasing material and energy demand for the fabrication of sensors for the Internet of Things, a move towards more circular economies and the use of sustainable materials with efficient fabrication methods is necessary. Among these sensors, humidity sensors are useful tools for monitoring atmospheric conditions in fields ranging from industry and agriculture to healthcare.
In this study, the bio-sourced and biodegradable materials melanin and choline chloride were investigated for the inkjet printing of flexible humidity sensors. Specifically, an aqueous dispersion of black soldier fly melanin – a by-products of food waste management – was optimized for printing with a cosolvent and mixed with the biocompatible salt choline chloride. The composite was printed onto electrodes on different flexible substrates. Characterization by impedance spectroscopy showed that the addition of choline chloride increased the ion concentration and AC conductivity by more than three orders of magnitude, resulting in a significant improvement in sensing performance and reduced hysteresis compared to pure melanin sensors at frequencies up to 1 kHz. The devices exhibited fast detection and recovery times (~ 0.8 ± 0.3 s) with a 170 ± 40-fold decrease in impedance for relative humidity changes from 30 % to 90 %.
Overall, inkjet printing – as a material-efficient deposition method – and the use of bio-based by-products reduced the embodied energy of the sensor and enhanced its sustainability compared to conventional electronics. In addition, concepts for reusability and degradability were demonstrated that allow for the use of the sensor in wearable or agricultural applications.

SB11.09.11

Preparation and Characterization of Biohybrid Shape Memory Polymer Scaffolds *Damion Dixon, Ainsley Shields and Melissa Grunlan; Texas A&M University, United States*

“Self-fitting” shape memory polymer (SMP) scaffolds have the potential to improve healing of irregular bone defects due to their ability to fill complex geometries. After exposure to temperatures greater than their melt

transition temperature (T_m), scaffolds undergo shape recovery, expanding to the tissue perimeter for improved osseointegration and healing. SMP scaffolds were originally prepared from semi-crystalline, biodegradable linear-poly(ε-caprolactone)-diacrylate (linear-PCL-DA; M_n = 10k g mol-1; T_m = ~55 °C). However, PCL's slow degradation rate (~2 years) and lack of bioactivity is a disadvantage to neotissue formation and integration. Thus, efforts to accelerate the rate of PCL degradation and enhance its bioactivity, while maintaining both shape memory and mechanical properties is necessary. Ideally, SMP bone scaffolds should also possess intrinsic antimicrobial activities, particularly with the growing rate antimicrobial resistance and the surge in hospital-associated infections (HAIs). Chitosan (CS), a cationic polysaccharide, has been extensively used to fabricate bone scaffolds due to its biocompatibility, bioactivity, biodegradability, and broad osteoconductive and antimicrobial properties. While CS is endowed with several advantageous properties relevant to bone tissue regeneration, its use is hindered due to poor mechanical properties and limited solubility. Herein, biohybrid SMP scaffolds were prepared from linear-PCL-DA and CS-graft-PCL (for increased processibility) [90:10 and 75:25 wt% ratio], exploiting both the shape memory behavior of PCL and the biological/antimicrobial properties of CS. CS containing scaffolds displayed mechanical properties (i.e., strength, modulus, and toughness) similar to PCL-only scaffolds, in addition to their pore properties (i.e., pore size and porosity) remaining consistent. The incorporation of CS into the SMP scaffolds slightly lowered their T_m from ~55 to ~52 °C in addition to improving their degradation kinetics. Overall, these biohybrid SMP scaffolds displayed adequate mechanical properties, high porosity (> 60%), and improved degradation. The inclusion of CS is also promising as a functional component to not only improve bioactivity but also combat HAIs.

SB11.09.12

Investigation of Cure Characteristics and Tensile Properties of Rubber Composites Filled with Different Grades of Diatomaceous Earth

Bawantha J. De Costa[1], Madhubhashini Maddumaarachchi[1] and Shantha Egodage[2]; [1]University of Sri Jayewardenepura, Sri Lanka; [2]University of Moratuwa, Sri Lanka

Diatomaceous earth (DE), a bio-based material consisting of fossilized exoskeletons of diatoms, having significant porosity. DE possesses the potential to be used as a rubber filler like silica, a commodity reinforcing filler used in rubber composites. This study investigates the fundamental morphological characteristics of rubber composites with various grades of DE which includes amorphous, crystalline, a crystalline waste obtained from a brewery industry, and a ground waste to reduce the particle size alongside with silica. The objective is to analyze their rheological and tensile properties in natural rubber vulcanizates filled with these verities of DE. Using a filler with good filler-matrix interaction and a reduced particle size (preferably in nanoscale) a rubber composite with excellent tensile properties could be obtained. A thorough study about the correlation between cure characteristics and tensile properties of DE filled rubber composites has not yet been done.

The rubber compound formulation was first developed to benchmark the cure characteristics before further testing was carried out. The ground waste DE was separately prepared by ball-milling of the crystalline waste DE for 3 h at 300 rpm the fillers were first characterized using Scanning Electron Microscopy (SEM), Dynamic Light Scattering (DLS), X-Ray Diffraction (XRD), X-Ray Fluorescence Spectroscopy (XRF), and Fourier-Transform Infrared Spectroscopy (FTIR). Rubber composites were prepared with 55 phr of each filler. Furthermore, the amorphous DE and the crystalline waste DE were added as a filler blend with silica in proportions of 25%, 50%, and 75% of weight separately to prepare rubber composites. Cure characteristics were analyzed using a Moving Die Rheometer (MDR) at 150°C for 30 minutes, and tensile strength of molded rubber composites was measured at a rate of 500 mm/min, according to the ASTM D412 standard with a Universal Testing Machine.

Silica exhibited a lower scorch time (ts_2) due to the heat generation from the abrasion of filler particles and a high optimum cure time (t_{90}) due to a higher degree of cross-link formation both facilitated by the smaller particle size of silica compared to all DE forms. Meanwhile, the amorphous DE exhibited the highest ts_2 and t_{90} possibly due to the poor heat transfer throughout the matrix due to the rod shape or due to the entrapment of cross-linking agents *inside the rods which will hinder the cross-link precursor formation.*

The ball-milling process was not found to be effective to reduce the particle size of crystalline waste DE. Further, the results indicated that composites containing crystalline waste DE and ground waste DE exhibited inferior tensile properties compared to the ones filled with silica, due to the agglomeration. Composites with amorphous DE demonstrated moderate cure characteristics, while the slowest curing was observed in amorphous DE filled composites. Remarkably, composites with 25% amorphous DE loading to silica exhibited superior tensile properties compared to those with 100% silica, due to the synergism of particle size and the increased surface area of amorphous DE. Nevertheless, composites with higher amorphous DE loadings exhibited reduced tensile properties due to poor reinforcement occurring due to higher filler volumes associated with the low filler density of DE. In contrast, amorphous DE shows a positive synergism with silica as a rubber filler. The crystalline waste DE loaded composites exhibited significantly reduced tensile properties due to high agglomeration. The optimal amorphous DE filler loading for a composite was determined to be 25% amorphous DE to silica, both addressing improved tensile properties with acceptable filler reinforcement. Improved tensile properties result from faster cross-link initiation and higher cross-link density, facilitated by smaller particle size of amorphous DE.

SB11.09.13

Preparation of Polysaccharide/Synthetic Polymer Hybrids via the Polymerizable Cosolvent Method

Vladimír Raus, Ivan Kelnar, Beata Strachota and Adam Strachota; The Czech Academy of Sciences, Czechia

Polysaccharide-based synthetic-natural hybrid polymeric materials, including polymer blends, (nano)composites, and hydrogels, have attracted considerable attention as they combine the tailorable properties of synthetic polymers with the unique characteristics of natural polysaccharide macromolecules, e.g., low cost, biodegradability, non-toxicity, renewability, high functionality, and good thermal and mechanical properties. However, the application prospects of these hybrids are often limited by certain inconvenient polysaccharide properties, such the lack of good interfacial adhesion of fibers, non-meltability, water sensitivity, or poor solubility in standard solvents. These drawbacks often command the use of polysaccharide derivatives instead of the unmodified macromolecules, which removes some of the original advantages of these materials.

Ionic liquids (ILs) have emerged as powerful solvents for otherwise difficult-to-dissolve polysaccharides such as cellulose. While relatively concentrated polysaccharide solutions can be achieved by a direct dissolution in ILs, this process is often complicated by long dissolution times and high solution viscosity. The latter factor frequently precludes the efficient use of neat ILs as media for homogeneous polysaccharide modification. This drawback is routinely addressed by the addition of a suitable cosolvent (e.g. dimethyl sulfoxide or amidic solvents such as DMF) that decreases the solution viscosity without negatively influencing cellulose solubility.

In our recent work focused on the interactions in the IL-cosolvent mixtures,[1] we proposed that some common monomers could be potentially used as a reactive (polymerizable) cosolvents during cellulose dissolution. The obtained mixtures could then be, upon monomer polymerization, transformed into a (crosslinked) polymeric blend/hydrogel or a (nano)composite, depending on the dissolution state of the polysaccharide.

In the present study we investigated these options using model monomers (cellulose, chitin-glucan), different ILs (bmimCl, emimAc), and different reactive cosolvents/monomers (N-vinyl pyrrolidone, N,N-dimethylacrylamide, and 2-hydroxyethyl methacrylate). Numerous polymerization parameters were assessed and optimized, such as the IL/monomer/polysaccharide ratio, the cross-linker and photoinitiator type, the mode of IL removal, or the wavelength of the light used for photopolymerization. We found that the used monomers show a different degree of compatibility with the remaining mixture components, which can be used to fine-tune the polysaccharide dissolution state (molecular solution, aggregates of different sizes). This was exploited in the preparation of hydrogels having a character of a polymer blend or a (nano)composite. Furthermore, the same method was used *for the "compatibilization" of the cellulose-synthetic polymer interface when preparing polymeric films reinforced with cellulose non-woven textiles. The prepared materials were characterized using different techniques, including ATR FTIR, rheology, and electron microscopy. We envisage that the novel preparation protocol will afford a range of previously inaccessible polysaccharide-based hybrids and extend thus significantly the application potential of this important material class.*

Improving Water Resistance and Film Forming Ability of Cellulose Based Film with Lotus Leaf Extract and Gelatin *Behrokh Shams[1,2], Evan K. Wujcik[1,2] and Douglas Bousfield[1]; [1]University of Maine, United States; [2]Advanced structure and composite center, United States*

Cellulose is extensively employed in food packaging to enhance moisture barrier properties. However, cellulose nanofibrils face challenges such as low flexibility and high water vapor permeability. Utilizing hydrophobic materials, like lotus leaves, is a promising approach to improve water vapor transmission rates. Gelatin can help with film forming and flexibility. In this research, cellulose nanofibrils are combined with a natural hydrophobic extract and gelatin to enhance moisture resistance and film forming process.

SB11.09.16

Oregano Biomass as a Support for the Biosynthesis of Non-Precious Metal Catalysts *Yaneiska M. Ruiz and Lymari Fuentes-Claudio; Universidad Ana G. Méndez, United States*

The energy production through fossil fuels and industrial processes has led to a crisis in energy pollution, being the main cause of greenhouse gas emissions responsible for climate change. One of the alternatives to reduce the environmental consequences associated with rising temperatures, sea level rise, and ocean acidification is the reduction of fossil energy consumption. Several alternatives are being explored to address this problem. One of these options is the use of fuel cells. Fuel cells provide a solution by generating energy from chemical reactions that result in the release of water vapor. The two principal reactions in these devices are the Hydrogen Evolution Reaction (HER) and the Oxygen Reduction Reaction (ORR). Both reactions require the use of catalysts for high performance and efficiency. The most widely used and efficient catalyst known is platinum. However, platinum and other efficient precious metals required as catalysts for these reactions are costly and scarce on the planet, highlighting the urgent need to develop non-precious metal catalysts.

This project focuses on the development of non-precious metal catalysts for fuel cell fabrication using titanium dioxide as a support material for metal oxides, specifically targeting the ORR occurring at the cathode, since the HER occurring at the anode is a well-studied and understood reaction. Nevertheless, the ORR faces limitations regarding its dependency on costly catalysts and slow reaction kinetics, which impacts reaction performance.

To address this, titanium dioxide is utilized due to its high chemical and thermal stability, large surface area, abundance, and semiconductor properties, making it an alternative for supporting the development of non-precious metal catalysts. Additionally, biotemplated titanium dioxide was synthesized using oregano biomass as a template for controlled particle growth, inducing the formation of a titanium dioxide chain that protects the catalyst from degradation. Particles were synthesized through the sol-gel method and characterized based on

their size, chemical composition, and crystallinity. The analysis included data from X-ray diffraction (XRD), dynamic light scattering (DLS), Fourier-transform infrared spectroscopy (FTIR) , and X-ray photoelectron spectroscopy (XPS).
The results for the iron-doped samples were then compared with those from biotemplated and non-biotemplated controls. Preliminary results indicate that the use of biomass as a mold affects the color, particle size, and crystallinity of the synthesized materials.

SESSION SB11.10: Hybrid Devices

8:30 AM *SB11.10.01
The Sticky World of Polydopamine in Biohybrid Devices *Rossella Labarile[1], Matteo Grattieri[2], Danilo Vona[2], Paolo Stufano[1], Gianluca Maria Farinola[2] and Massimo Trotta[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Bari Aldo Moro, Italy*

In a low-carbon future, the development of solar power technologies using photosynthetic bacteria is considered one of the best options to meet the increasing future energy demand and to pioneer the cutting-edge novel strategies for environmentally safe and cost-effective energy production. Polydopamine (PDA), a covalent, biocompatible polymer obtained via self-oxidative reaction of dopamine, has been utilized to embed the photoactive reaction centre (RC) from purple non-sulphur bacteria into a thin film, while preserving its structure and therefore its activity. This RC/PDA thin film can be generated over electron surfaces, to provide photocurrent in photoelectrochemical cells [1]. The RC/PDA matrix can be further doped with specific diamine groups, rendering the composite transparent, for enhanced light transmission and photoconversion [2].
The presence of O_2 as an oxidant is crucial for the self-polymerization of dopamine and alternative routes may be of interest for the formation of adhesive PDA layers in environmental conditions where oxygen is not available. Recently, PDA polymerization was achieved exploiting the metabolism of the extremely sensitive to oxygen mutant strains R26 of Rhodobacter (R.) sphaeroides. The increase of the optical density recorded at different wavelengths, when bacteria are grown in dopamine supplemented medium, implied the contemporary biomass gain and the formation of PDA which absorbs at 588 nm [3]. Using whole, metabolically active microorganisms greatly simplifies the preparation of the biocatalyst avoiding enzyme isolation and purification and potentially enhances stability of the system thanks to their self-repairing and replication features. PDA conductive coatings were used as biotic-abiotic interfaces in biohybrid photoelectrochemical devices through the encapsulation of entire bacterial cells of R. sphaeroides [4] and R. capsulatus [5], ensuring electronic communication of the biological component with the electrodes' surfaces in photoelectrochemical cells, using one-pot or single-cells coating methods.
A biophotoelectrode was obtained with polyhydroxybutyrate (PHB), a biopolymer, which purple non-sulphur bacteria produce as an energy stock under specific environmental conditions. The composite material was modified with PDA and thermally treated to obtain a hydrophilic electrode having stable and reproducible electrochemical behavior. The bio-based electrode was tested with metabolically active cells of R. capsulatus embedded in a biohybrid matrix of PDA. The system achieved enhanced catalytic activity under illumination, with an 18-fold increase in photocurrent production compared to biophotoelectrodes based on glassy carbon [6].

This work was funded by the Fonds National Suisse de la Recherche Scientifique, project Phosbury - Photosynthetic bacteria in Self-assembled Biocompatible coatings for the transduction of energy - (Project Nr CRSII5_205925/1)

9:00 AM *SB11.10.02
Learning from Visual Ecology for Advanced Robotic Vision Systems *Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)*

The development of artificial vision systems has been inspired by unique optical features found in nature, such as aquatic-type, cuttlefish, and fiddler crab vision. These systems exhibit wide fields of view, high visual acuity, deep depth of field, and minimal optical aberrations. For example, the aquatic-type system's monocentric lens and hemispherical retina inspired a bio-inspired camera, while cuttlefish vision led to an artificial system for high-contrast imaging under uneven illumination. The fiddler crab's flat-face lenses inspired amphibious imaging with a panoramic view, and avian eyes have influenced high-resolution, compact zoom cameras. These bio-inspired systems have potential applications in advanced mobile electronics, high-performance robotic vision, and panoramic imaging for motion detection and obstacle avoidance in variable environments. In this talk, I will briefly overview recent advances in bio-inspired artificial robotic vision systems inspired by the diversity of eyes in nature, and discuss future directions and remaining challenges.

9:30 AM *SB11.10.03
Cell-Driven Supramolecular Assembly of Organic Nanofibers *Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy*

The assembly of supramolecular structures within living systems is an fascinating possibility for introducing artificial constructs and developing biomaterials capable of influencing and/or regulating the biological responses of living organisms. I will report on our study of 2,6-diphenyl-3,5-dimethyl-dithieno[3,2-b:2',3'-d]thiophene-4,4-dioxide (DTTO) molecules that self-assemble into fibers through a "biologically assisted" polymorphic form. The phenomenon, discovered more than 10 years ago by the group of Giovanna Barbarella, is still partially unknown and its potential not fully developed. A welth of characterization techniques show that cell-grown DTTO fibers present a unique set of specific morphological, optical, and electrical properties. Monitoring the process of fiber formation in cells with time-resolved photoluminescence, it is established that cellular machinery is necessary for fiber production and a non-classical nucleation mechanism for their growth is postulated. These biomaterials may have disruptive applications in the stimulation and sense of living cells, but more crucially, the study of their genesis and properties broadens the understanding of life beyond the native components of cells.

10:30 AM *SB11.10.04

Engineering Responsive Living/Non-Living Hybrid Materials *Jinhye Bae; University of California, San Diego, United States*

Active materials can respond to external stimuli, as observed in both natural and synthetic systems, from sensitive plants to temperature-responsive hydrogels. Engineering the responsiveness of living materials that incorporate both living organisms and synthetic materials enables advanced and unprecedented properties. This talk mainly presents two advancements in Engineered Living Materials (ELMs). First, we explore the concept of plant cyborgs by combining plants or plant tissues with stimuli-responsive polymeric materials. This approach allows for precise shape control in plant tissues, resulting in shape-controlled plants that offer dynamic adaptability and responsiveness to environmental threats. This innovation advances precision farming and sustainable agriculture. Next, I will discuss stimuli-responsive ELMs that react to environmental or biochemical cues, which are crucial for biosensors and actuators. We develop a novel diffusion mechanism using a temperature-responsive composite hydrogel that permits cyanobacteria to infiltrate and grow within it. These living components create non-equilibrium systems, leading to a decreasing modulus and consequently altering their shape over time.

11:00 AM SB11.10.05

Oligopeptide-Based Oscillating Devices *Gonen Ashkenasy; Ben-Gurion University of the Negev, Israel*

Living organisms are replete with rhythmic and oscillatory behavior at all levels, and accordingly oscillations have been termed as a defining attribute of life! Studies on synthetic oscillators that mimic such functions have typically shown decayed cycles in batch-mode reactions or sustained oscillatory kinetics under flow conditions. Considering the potential functionality of peptides in early chemical evolution, and furthermore their central role in current bio-nanotechnology, we have recently revealed the design and kinetic behavior of a peptide-based oscillator.[1] In this talk, we will show how oscillatory behavior can be achieved by coupling coiled-coil-peptide replication processes as positive feedback to controlled initiation and inhibition pathways in a continuously stirred tank reactor (CSTR). Our results stress that assembly into the supramolecular structure and specific interactions with the replication substrates are crucial for oscillations. When the replication-inhibition processes were first studied in batch mode, we observed a single damped oscillatory cycle. Thereafter, using combined experimental and theoretical characterization of the replication process in a CSTR under different flow and environmental (pH, redox) conditions we were able to demonstrate sustained oscillations. We argue that studies in this direction might pave the way to the design of robust oscillation networks that mimic the autonomous behavior of proteins in cells (e.g., in the cyanobacterial circadian clock) and may hence be useful to drive the production of various biomaterial-based oscillatory devices.

11:15 AM SB11.10.06

Flexible and Biodegradable Collagen-Based Organic Field-Effect Transistors *Piumi Kulatunga and Simon Rondeau Gagne; University of Windsor, Canada*

Each year, around 50 million tons of consumer electronic products are discarded worldwide [1]. This e-waste is the fastest-growing solid waste stream in the world. Since e-waste is a global environmental challenge, an emerging opportunity to address this problem is to develop biodegradable electronic devices, employing eco-friendly solvents, and recyclable materials and using, preferably, bio-sourced materials. Organic field-effect transistors (OFETs) are a promising type of organic electronics, particularly with the increasing need for new wearable, flexible, stretchable, and implantable technologies. Despite numerous important developments towards the completion of all of the above aims, designing and developing an intrinsically stretchable and biodegradable

transistor from environmentally sustainable sources remains an important challenge.
To tackle this, our work focuses on the design of flexible OFETs from selected biomaterials and finds new strategies to balance key device characteristics, including electronic properties, degradation kinetics, and mechanical compliance. Finding this balance will ultimately result in devices with enhanced compatibility with biological tissues for new applications and will contribute to reducing the bioaccumulation of used electronics.
While numerous reports have focused on key biomaterials, both natural and synthetic for the development of OFETs, such as silk, poly (lactic-co-glycolic acid), and cellulose, limited attention has been given collagen, and poly(glycerol sebacate). Notably, these two polymers can be as dielectrics and substrates respectively, opening new opportunities in organic and printed electronics due to their biodegradability and stretchability.
This presentation will highlight the results obtained from a detailed morphological, mechanical, and electrical characterization of OFETs fabricated on poly(glycerol sebacate) using collagen as bio-sourced dielectric materials. The various components of the transistor were characterized through multiple techniques including optical and atomic force microscopy, X-ray scattering, tensile stress tests, and others to unravel new structure-property relationships. This presentation will also discuss the electronic properties of the OFETs upon bending and stretching. Finally, biocompatibility, assessed through in vitro assays, will be discussed.

Thursday Afternoon, December 5, 2024
Hynes, Level 3, Room 313

1:30 PM SB11.11.01
Preserving Cholesteric Order and Structural Color in Ethyl Cellulose-Poly(Acrylic Acid) Composites *Simona G. Fine and Cecile Chazot; Northwestern University, United States*

Dyed plastics and textiles fill our world with bright colors but the toxic azo dyes, solvents, and heavy metals that endow these objects with striking hues are carcinogenic, mutagenic, and highly pollutive to the water streams near manufacturing centers. As such, there is a critical need to rethink the way colors are developed beyond absorption-based pigments. Cellulose ethers offer a promising alternative: when suspended in an appropriate solvent, these biopolymers self-assemble into cholesteric liquid crystalline mesophases that exhibit stimuli-responsive structural colors. Since cellulose-based polymers are bio-derived, biodegradable, and non-toxic, these mesophases are an attractive basis for both sustainable alternatives to traditionally-colored plastics and novel colorimetric materials. However, to realize these applications, it is imperative to morph the gel-like mesophases into solids while preserving the cholesteric order such that reflectivity is stabilized within the visible range. One method of solidification relies on suspension in a monomeric solvent followed by polymerization, resulting in a composite where cholesteric domains are trapped by an amorphous polymeric matrix. Typically, the color of the composite is blue-shifted from that of the initial mesophase, which has previously been attributed to volume shrinkage, temperature changes, or morphological reorientation. In this talk, we will clarify how balancing the self-assembly and polymerization kinetics ultimately allows for the retention of cholesteric ordering and structural color in solid-state composites based on ethyl cellulose (EC)-acrylic acid (AA) mesophases. Using reflection spectroscopy, optical goniometry, and x-ray studies, we will demonstrate that the preservation of mesophase *morphology is dependent on the EC molecular weight and photoinitiator type. Next, we will report on time-resolved studies, including differential scanning calorimetry during irradiation and photo-rheology, that we employed to assess the different curing rates associated with each photoinitator. Together, these experiments enable us to clarify what factors are ultimately responsible for the blue-shift of the photonic bandgap and final reflectivity spectrum and show that mesophases with low EC chain mobility and rapid polymerization reactions better maintain their color and structure upon composite formation due to kinetic trapping. Understanding these processing-structure-property relationships in EC-pAA will facilitate the scalable and environmentally-friendly production of structurally-colored alternatives to dyed plastics.*

1:45 PM SB11.11.02
Bioinspired Photonic Polymers Through Well-Controlled Self-Assembly of Droplet Arrays Dirven by Interfacial Tension *Dong-Po Song; Tianjin University, China*

A novel method has been developed by utilizing the self-assembly of amphiphilic brush block copolymers (BBCPs) at the water/oil (W/O) interface in an emulsion system. This approach has led to the discovery of a new mechanism called organized spontaneous emulsification (OSE), which effectively addresses a longstanding challenge in controlling the spontaneous emulsification (SE) process. As a result, a thermodynamically stable and well-ordered W/O/W multiple emulsion system has been achieved, representing a significant advancement in self-assembly systems. In comparison to bulk block copolymers with microphase segregation, the droplet self-assembly units exhibit reduced chain entanglements, resulting in accelerated self-assembly kinetics, highly organized structures, and vibrant structural colors. Notably, the construction of novel self-assembled structures, such as bridged lamellar morphology, has been successfully accomplished. The refractive index contrast has been significantly enhanced from below 0.1 to up to 0.5, leading to a substantial increase in reflectance. By manipulating the chain structure and molecular topology of the BBCPs, precise control over interfacial tension and spherical curvature has been achieved. This has enabled the tuning of photonic bandgaps across a wide range from UV to visible and near-IR regions. Importantly, the molecular weight required for generating structural color is approximately one order of magnitude lower than that of a phase separation system. Furthermore, the OSE method is universally applicable to a variety of BBCPs, without being constrained by interaction parameters, thereby expanding the diversity of structural colored materials.

2:00 PM SB11.11.03
Living Active Matter—Understanding the Self-Organisation of Bacteria in Liquid Environments for a Novel Class of Biomaterials *Marina Portoghese[1], Junwei Wang[2], Laura Catón[1], Colin Ingham[3,2] and Silvia Vignolini[1,2]; [1]University of Cambridge, United Kingdom; [2]Max Planck Institute for Colloids and Interfaces, Germany; [3]Hoekmine Besloten Vennootschap, Kenniscentrum Technologie en Innovatie, Hogeschool Utrecht, Netherlands*

Active matter is commonly defined as soft systems with built-in dispersed and local conversion of energy into forces and motions. Usually in soft matter physics, it refers to systems composed of individual units (or particles) that consume energy to produce motion or mechanical work. Here we propose to use Flavobacterium IR1, a gram-negative bacterium characterized by its rod-shaped cells and gliding motility, as a new building block to study non-equilibrium dynamics of colloidal liquid crystals. In this work, we observed that the increase of bacteria packing fraction triggers a liquid crystal-like phase transition from isotropic to nematic, then hexatic columnar phase. Microscopic changes to liquid crystal nanostructures are monitored with a variety of optical and electron microscopy techniques.

2:15 PM SB11.11.04
Color-Changing Paints Enabled by Photoresponsive Combinations of Bio-Inspired Colorants and Titanium

Dioxide Semiconductors *<u>Cassandra Martin</u>, Kaitlyn Flynn, Indya Taylor and Daniel Wilson; Northeastern University, United States*

For thousands of years, humans have incorporated natural materials into paints and coatings for decorative and protective purposes. Over time, these formulations have been further engineered to provide long lasting and a wide variety of colors, as well as optimized for modern functions ranging from fine art to extraterrestrial thermal control. Recently, there has been a push to design materials that can undergo transient visual changes in response to external stimuli without the need for advanced fabrication strategies or external power sources. In this work, we design photochromic paint formulations that utilize xanthommatin, a redox-active small molecule colorant found throughout biology, and titanium dioxide, a semiconductor and ubiquitous whitening pigment in commercial coatings. This combination of materials triggers the reversible photoreduction of xanthommatin when exposed to sunlight, shifting the coating from a yellow (oxidized) to red (reduced) color. We observe that the degree of photoreduction is dependent on the density, size, and polymorph structure of the titanium dioxide particles, as well as the type of paint matrix. These coatings can be mixed with non-photoresponsive colorants to increase the range of accessible colors and can be applied to both rigid and flexible substrates. Additionally, these coatings can be selectively irradiated using masks to create transient disappearing artwork. Overall, this work demonstrates the first step in using natural colorants for dynamic photoresponsive coatings and highlights new opportunities for consumer goods and low power optical materials.

Approval for public release pending

2:30 PM *SB11.11.05
Living Optical Networks in Orchid Leaves as Inspiration for Light Harvesting and Redistribution in Soft, Curvilinear Material Formats *<u>Giulia Guidetti</u> and Fiorenzo Omenetto; Tufts University, United States*

Plants and animals produce highly evolved, hierarchical systems that combine physicochemical material parameters with functional micro- and nanostructures to manage energy, motion, and species survival. These systems, besides providing cues on bottom-up manufacturing of technological structures, can give insight on strategies for efficient energy management. In this study, we investigate the light harvesting and redistribution capabilities of tropical orchid leaves, which employ a cell-based optical network. Unlike regular orchid leaves, the outer epidermal cells of these leaves exhibit a distinctive short-range order lattice and rounded shape, facilitating optical cross-communication. The planar redistribution of light incident on the leaf is enabled by the distinctively rounded shape of the outer epidermal cells and by their arrangement in a short-range ordered lattice. Successful replication of live leaves in a free-standing biopolymer film validates the observation and opens avenues for the exploration of non-traditional energy harvesting interfaces that are soft, conformal, and curvilinear.

SESSION SB12.01: Transport Through Single Protein
Session Chairs: Nadav Amdursky and Joshua Atkinson
Tuesday Morning, December 3, 2024
Sheraton, Third Floor, Dalton

9:00 AM *SB12.01.01
Single-Protein Electronics—Charge Transport Mechanisms and Enzymatic Junctions *Ismael D Diez Perez, Tracy Ha, Kavita Garg, Qiankun Wang, Sarah Barry and Nashili Kibria; King's College London, United Kingdom*

Bioelectronics is a rapidly evolving field moving towards designing nanoscale electronic platforms that allow in vivo sensing, fuel cell powering and chemical biosynthesis. Such devices typically require interfacing a complex biomolecular moiety as the active component to an electronic platform for signal transduction and/or electron source wiring. Inevitably, a true systematic design goes through a bottom-up understanding of the structurally related electrical signatures of such hybrid biomolecular circuits, which will ultimately lead us to tailor its electrical properties and exploit them as high performance bioelectronic devices with a wide variety of applications in organic electronics, sensing, biomanufacturing, etc.

In this contribution, we will present our latest efforts on understanding and control charge transport in a single-protein junction, with an emphasis on how to harness enzymatic activity electrically in an individual enzyme. Our approach relies on trapping individual redox proteins in an electrochemically controlled tunneling junction to characterize their main electrical signatures. The method can capture very fine details of the charge transport mechanisms across proteins in an aqueous environment [1,2].

Our studies start with a benchmark redox protein model such as a bacterial blue Cu-Azurin. We will show first the main observed electrical signatures of these systems that make them particularly efficient in transporting charge. We then bioengineer the outer protein surface using point-site mutagenesis as a mean to get a more detailed picture of possible electron pathways through the protein backbone [2,3]. Our results suggest that the protein might not use distinct physical electron pathways across its structure, but transport mechanism can be switched upon quenching of motions in the protein structure via the surface mutations.

Then, we will then switch to our very recent charge transport studies on redox enzymes. Using the above electrochemically controlled single-protein methodologies, we demonstrate that when an individual redox enzyme is trapped on a nanoscale junction, a distinct telegraphic noise can be directly correlated to the enzymatic activity of the enzyme during the active bioelectrocatalytic conditions [4]. This study open a new door for the fundamental studies of redox enzymatic catalysis and brings prospects to the high-resolution electrical detection of enzymatic *reactions.*

9:30 AM SB12.01.02
Circuit and Contact Effects on Electron Transport in Protein Junctions *Sudipta Bera; Weizmann Institute of Science, Israel*

Practical limitations of ultra-thin protein film junctions, such as reliable 4-probe measurements, hinder quantitative estimates of protein-electrode contact resistances. The total junction resistance consists of multiple components, including circuit, contact, and protein resistance. DC measurements cannot isolate the pure protein resistance component. This complexity is clarified by impedance measurements on a series of protein junctions with systematically changed electrode pairs and protein film widths (~5-50 nm). In biomolecular junctions of proteins, more resistive contacts significantly influence transport across the presumably insulating protein films. Protein resistance estimated from impedance fitting and zero-length extrapolation provides the contact resistance. The influence of electrode contributions was examined by including (challenging) metal-protein-metal permanent contacts in micro-pore devices (MpD). Results indicate unexpectedly low protein resistance. Additionally, we introduce an impedance-derived empirical parameter that characterizes the electrical properties of specific protein junctions independent of electrode configurations.

9:45 AM SB12.01.03
Understanding Electron Transport in Proteins—Insights from Poly-Ionomer Studies *David Cahen; Weizmann Institute of Science, Israel*

There are now multiple reports of puzzling efficient electron transport, ETp, across (layers of) various proteins in different experimental setups, with weak or no temperature dependence and weak length, and voltage dependence over ”too” large distances. The absence of protein energy levels within kT of the electrode Fermi level makes understanding such ETp challenging. Within a broader view, proteins are poly-ionomers, containing a high fraction (tens of percent) of ionic, i.e., charged repeating units. Thus, a clear control experiment is to measure ETp of poly-ionomers. Our current-voltage-temperature and impedance measurements on multi-layers of poly-ionomers indicate ETp across up to ~90 nm. i.e., like with protein films, ETp over widths well beyond accepted tunneling limits. In another sanity check, a junction with ~30 nm uncharged polymer, PMMA, behaves as expected, as an insulator. Thus, we should understand poly-ionomer ETp, at least as a point of reference, to identify protein-specific ETp mechanisms. Possibly, the repeating charge distribution in poly-ionomers may form a channel that enables efficient transport guided by internal electric fields. Elucidating the transport model is particularly important, as it may shed light on ETp through cable bacteria.

10:30 AM *SB12.01.04
The Role of Polarizability in Charge Transport Across (Bio)Molecular Tunneling Junctions *Christian A. Nijhuis;*

University of Twente, Singapore

The electron transport rates across biomolecular junctions can be remarkably, but the mechanisms behind this are still under debate.[1,2] Unraveling the underlying mechanisms of ET across such systems is not only interesting from a fundamental point of view, but could also lead to interesting technological applications in biomolecule-based sensors or biomolecular electronics.[3,4] We have been studying the role of polarizability in the mechanism of ET across molecular junctions and found that ET rates can increase by 4 orders of magnitude by changing the polarizability of just one atom in molecular junctions [5]. I will present our latest findings on ET rates across junctions with varying degrees of polarizability and how polarizable atoms can change the energy level alignment the junction [6] and the temperature dependency of the mechanism of ET [7] across small molecules and huge biomolecular cages with cargo (encapsuling) [8].

Electron Spin Effects in Extracellular Electron Transport Proteins Nir Sukenik[1], Christina M. Niman[1], Marko Chavez[1], Justus Nwachukwu[2], Anne K. Jones[2], Ron Naaman[3], Kakali Santra[3], Tapan K. Das[3], Yossi Paltiel[4], Lech T. Baczewski[5] and Moh El-Naggar[1]; *[1]University of Southern California, United States; [2]Arizona State University, United States; [3]Weizmann Institute of Science, Israel; [4]The Hebrew University of Jerusalem, Israel; [5]Polish Academy of Sciences, Poland*

Electron transfer through chiral molecules is characterized by a coupling between the electron velocity and its spin through the Chirality Induced Spin Selectivity (CISS) effect. Since most biomolecules are homochiral, it was recently hypothesized that CISS underlies the highly efficient electron transfer observed in biological systems by reducing the probability of electron backscattering. A remarkable example of fast, efficient, and long-distance electron transport in biology is the extracellular respiration of metal-reducing bacteria, where a pathway composed of multiheme cytochromes facilitates extracellular electron transfer (EET) from the cellular interior to external solid-state minerals and electrodes. Previous studies of the cell surface multiheme cytochromes from the EET model organism Shewanella oneidensis MR-1 confirmed their spin selective transport properties. Using conductive probe atomic force microscopy (AFM) measurements of protein monolayers adsorbed onto ferromagnetic substrates, we show that electron transport is also spin selective in two of the upstream cellular multiheme ` wire proteins' – the membrane-associated decaheme MtrA and the tetraheme periplasmic STC. Moreover, we have determined the spin polarization of MtrA to be ***~75%*** *and STC to be ~35%. These results suggest that spin-dependent interactions affect the entire extracellular respiration pathway.*
To assess the in vivo physiological impact of CISS, we also present compelling evidence that the respiration of Geobacter sulfurreducens, an EET-capable bacterium that forms thick electrochemically active biofilms, depends on the magnetization direction of the underlying ferromagnetic electrode. Electron exchange between G. sulfurreducens and the working electrode is enhanced in the same magnetization direction as the spin preference revealed from conductive AFM measurements. Taken collectively, our results demonstrate the important role of spin in biological electron transport mechanisms essential to life.

11:15 AM *SB12.01.06

Energy Transduction with Electrons—Natural and Bioinspired Electron Bifurcation *Jonathon L. Yuly; Princeton University, United States*

Life can transduce energy at the molecular level by channeling individual electrons through electron bifurcation. The electron bifurcation process oxidizes a two-electron donor species, using the two electrons to reduce one-electron acceptors. These electron transfers are coupled, allowing one of the electrons to move thermodynamically uphill, leveraging the downhill motion of the other electron. Electron bifurcation may also occur in a nearly reversible regime, allowing near 100% energy conversion. A specific free energy landscape for the electrons allows efficient and reversible electron bifurcation by suppressing short-circuiting electron transfers that uncouple the electron transfers and waste free energy. Electron bifurcation has never been accomplished in a synthetic setting, but we explore the possibility of bioinspired electron bifurcation in tailored semiconductor electrochemical cells.

SESSION SB12.02: Conductivity in Non-Protein Biological Materials

Tuesday Afternoon, December 3, 2024
Sheraton, Third Floor, Dalton

1:30 PM +SB12.02.01

Natural Molecular Materials for Optoelectronics *Clara Santato; Polytechnique Montréal, Canada*

This contribution is in the area of sustainable organic electronics, where abundant, bio-sourced organic molecular materials, potentially printable and biodegradable, are investigated for their functional properties, for applications in low-environmental impact optoelectronics.

While advancing on our sustainable organic electronics path, keeping in mind the ambitious objective to combine technical, environmental, economic and societal performance, we have gained insight on the effect of the chemical composition of the biosynthesized materials on their functional properties, e.g. electrochemical, electrical, optical and magnetic. The chemical composition dramatically affects the functional properties of the materials and permits to shed light on their bio-role in living systems, opening the opportunity for novel, bio-inspired technologies and devices.

In this contribution, we will discuss the latest developments concerning (i) the complex chemical composition of bio-sourced materials for sustainable organic electronics, as obtained by a number of different analytical chemistry techniques, and (ii) the design of experimental configurations (e.g. substrates, electrode materials, geometries), capable to reveal novel physico-chemical processes taking place in the materials, in controlled experimental conditions.

Our efforts wish to contribute to make a step ahead to bridge the fields of biology, chemistry & physics of materials, sustainability, and device & electrical engineering.

2:00 PM SB12.02.02

Nanoscale Charge Carrier Transport in Melanin Extracted from Sepia Ink *Shahid Khaleel, Alexandre Carrière, Zhaojing Gao and Clara Santato; Polytechnique Montréal, Canada*

Sepia melanin, a naturally occurring pigment found in the ink sac of cuttlefish, has garnered significant interest for its intriguing electrical properties and potential as an organic semiconductor material. Sepia melanin exhibits properties of disordered organic semiconductors as organic semiconductors display charge transport behavior attributable to a combination of band-like and hopping transport mechanisms [1]. The electrical conduction in Sepia melanin is influenced by its complex hierarchical structure, which consists of melanin nanoparticles self-assembled into granules. These nanoparticles result from variety of arrangements of pi-pi stacked molecules [2]. Sepia melanin exhibits unique characteristics, such as its moisture-dependent electrical response and broadband optical absorption [3], making it a promising material for applications in organic electronics, energy harvesting, and bioelectronics but Sepia melanin potential is limited by its insolubility in common solvents. By comprehending nanoscale charge transport phenomena, we aim to fully harness Sepia melanin's potential for these technological applications as the size of Sepia melanin granules lie in the range ~150-200 nm.

We focus our investigations on an inter-digitated planar geometry of patterns as our goal is to detect signals emitted by granules of Sepia melanin. Patterns are fabricated by Electron Beam Lithography.

Preliminary findings from our ongoing study reveal the influence of structural disorder on charge carrier transport in Sepia melanin, including charge carrier localization and trapping effects. These findings provide opportunities for tailoring charge transport characteristics in devices. A nanoscale study of Sepia melanin granules reveals their remarkable high electrical conductivity. Electrochemical Impedance Spectroscopy (EIS) response in different atmospheres complemented by current-time measurement has shed light on ionic and electronic processes featuring possible interfacial processes at Sepia melanin/metal interfaces.

Work is in progress to study Photo-induced response of melanin granules and to calculate the extinction co-efficient of Sepia melanin.

The insights gained from this research hold promise for pushing the boundaries of organic electronics and forging novel pathways in the fabrication of bioinspired electronic devices and sensors.

Sustainable Extraction of Indigo from Natural Sources and Textile for Green Electronics *Sharly Desjardins[1], Alexandre Carrière[1], Denis Rho[2] and Clara Santato[1]; [1]Polytechnique Montréal, Canada; [2]Conseil national de recherches du Canada, Canada*

The textile and electronic industries have experienced escalating concerns regarding manufacturing practices and sustainable recycling. More specifically, the extensive use of indigo dye in the denim industry presents significant challenges. For instance, the improper management of denim waste leads to serious ecological issues, because of the release of the indigo. Similarly, improper disposal of e-waste leads to the release of toxic substances, like mercury or cadmium.

Further, utilizing bio-sourced or recycled organic materials, such as indigo, for electronics could help to avoid the need for petroleum-based precursors for the synthesis of those materials. Unfortunately, the conventional extraction methods for these materials from bio-sources or waste are often harmful for the environment due to the

use of toxic chemicals and energy extensive processes.
Here, we propose to extract indigo from Persicaria tinctoria and textile waste, such as denim, using a low-energy, environmentally benign process. Because it is well-suited to the climates of Europe and North America, Persicaria tinctoria is preferred in this study over Indigofera tinctoria, a plant more commonly used because of its high yield. Collecting data on Persicaria tinctoria and recycled indigo from textiles, such as denim, could encourage the use of these sources over synthetic indigo or Indigofera imports.
Initially, analytical chemistry and spectroscopic methods have been used to obtain indigo concentration and ion determination and concentration in the bio-source. Afterwards, after indigo extraction by adoption of an optimal extraction protocol following LCA considerations, we have proceeded to study optical absorption, conductivity and photoconductivity in indigo printed films. The results of the systematic comparison between the functional properties of synthetic, bio-sourced and recycled indigo will be also included in the present contribution.

Biosourced Sepia Melanin as a Potential Donor Material for Low Environmental Footprint Solar Cells

Alexandre Carrière, Sharly Desjardins, Youssef Ben Mami and Clara Santato; Polytechnique Montréal, Canada

With the global rise in environmental awareness, countries are now transitioning to decarbonized power production while promoting economic prosperity. Sustainable energy conversion technologies must be developed to meet the increasing electricity demand: among them are solar cells.

Unfortunately, solar cell production and end-of-life have serious environmental and societal impacts. [1] For instance, there is no clear solution for the waste that silicon solar cells will generate in the years to come, after arriving at the end of their 25-year expected lifetime. [2]
To mitigate these negative impacts, new materials, processes and end-of-life scenarios should be considered. Biosourced organic, potentially solution-processable and biodegradable materials, represent a potential alternative to synthetic ones used in organic photovoltaics. [3] Even if nature "takes care" of their production, one must identify sustainable extraction protocols from the biosource.

The melanin biopigment has been studied for its electronic and optical properties as potential biosourced organic material for sustainable electronics. [4] In this work, Sepia melanin was extracted from cuttlefish ink using an environmentally benign protocol based on deionized water. [5] The absorption coefficient of the extracted Sepia melanin showed a broadband feature in the visible and ultra-violet regions of the spectrum, which is suitable for solar energy conversion. Devices were then prepared via a solution process technique using the extracted melanin powder. Atomic force microscopy images were collected to characterize the morphology, and the electric properties of the devices were measured with a semiconductor analyzer. Values of the conductivity in the range of 10^{-3} S/cm were obtained. Photoconductivity measurements show an increase in the electrical current of more than 1% upon illumination under simulated solar light.

These results demonstrate the potential for Sepia melanin to be used in organic optoelectronics, e.g. solar cells, which could lead to the design of an energy conversion device with a low environmental footprint (biodegradable, among others). Further work to probe the electronic levels of this biosourced material will be conducted by the local density of states measurement with a scanning tunnelling microscope. [6] This information will permit to identify a suitable materials like metal electrodes for contacts of acceptor for a bulk heterojunction solar cell to continue the development toward sustainable electronics.

Proton Transport Through Self-Assembled Peptide Nanochannels *Nurit Ashkenasy; Ben-Gurion University of the Negev, Israel*

In nature, protons traverse nanometer-scale distances across cellular membranes through specialized channels in membrane proteins. Over the years, considerable scientific efforts have been directed to mimic these proton channel machinery. The assimilation of such biomimetic proton nanochannels into applications necessitates scaling up the length of the nanochannels from the nanometric range to the mesoscopic and even microscopic ranges while preserving the nanometric channel cross-section and maintaining well-ordered hydrogen bond networks within them. In this talk, I will present the use of self-assembling peptides for constructing such long-range protein channel mimics.
Using three different peptide systems, I will demonstrate water-assisted proton transport, with a transport rate akin to proton transport in protein channels spanning unprecedentedly longer distances. I will reveal the critical role of titratable peptide side chains and immobile counterions incorporated in these extended biomimetic nanochannels, both as the source of protons, determining their density, and as hydration mediators that affect the

rate of proton transfer in the proton channels. Finally, unique phenomena will be presented, such as humidity-dependent channel opening and hysteresis.
The functional behavior of these inherently recyclable and biocompatible systems opens the door for their exploitation in diverse applications, including energy storage and conversion, biomedicine, and bioelectronics.

3:45 PM SB12.03.02
Self-Assembling Proteins for Bio-Electronics *Vincent Forge[1], Julien Hurtaud[1], Joffrey Champavert[1], Suhail Usmani[1], Olivier Constantin[1], Cecile Delacour[2] and Patrice Rannou[3]; [1]CEA Grenoble, France; [2]Institut Néel, France; [3]Université Grenoble Alpes, France*

Bioelectronics is a fast-growing field of research aimed at controlling the interface between biological systems and electronic devices, which requires the conversion of biological signals into electrical signals usable by conventional electronic devices. Here we demonstrate the potential of protein nanowires resulting from the self-assembly of the prion domain of a filamentous fungus protein. These nanowires are in fact functional, non-pathological amyloid fibres; they perform a biological function, namely recognition of the self and non-self of a filamentous fungus. With a diameter of 5 nm and an average length of 12 µm, these nanowires, whose structure is known on an atomic scale, have a high aspect ratio ***(1)****. What's more, hydrogels can be obtained in an easily controllable way* ***(2,3)****. Like all amyloid fibres, these nanowires have specific optical properties* ***(4)****, as well as very good intrinsic ionic/protonic conductivity* ***(2)****. Finally, the addition of a redox protein domain* ***(2)*** *or a redox chemical compound* ***(3)*** *on the prion domain gives them electronic conductivity. After self-assembly of the prion domains, these redox domains are aligned along the nanowire axes, enabling electronic conductivity by electron hopping. Measurements of ionic and electronic conductivities will be described from the macroscopic scale (film) to the nanoscopic scale (single nanowire). Applications that take advantage of the various properties of these nanowires will be illustrated. For the first application, the ability to form a hydrogel and the ionic conductivity of nanowires make it possible to produce a biocompatible electrode coating for the primary culture of neurons over very long periods and to detect neuronal electrical activity. For a second application, in the field of sensors, electronically conductive nanowires, which can transport electrons over long distances, can be used as redox mediators between enzymes and glassy carbon electrodes* ***(2,3,5)****.*
These results represent a first step towards innovative all-in-one materials for bioelectronics. Overall, we have observed that our nanowires formed by the self-assembly of a functional, non-pathological prion domain combine all the properties needed to bridge the gap between the world of biology and that of technology, particularly electronics.

The Influence of Chemistry and Microstructure on the Proton Conductivity of Natural and Synthetic Biopolymers *Marco Rolandi; University of California, Santa Cruz, United States*

Most biological systems are predominantly made of water. Given that water is not a good electronic conductor, electrical currents in biology often involve fluxes of ions such as H+, K+, Na+, Cl-. H+, as the lightest ion,involves a transport mechanism that has more aspects in common with the transport of electrons and holes in conjugated systems than the transport of the heavier ions. This mechanism- known as the Grotthus mechanism- involves the exchange of hydrogen bonds with covalent bonds in water molecules and the hydrophilic residues of the hydrated biomaterials. Thus, hydrated proton conductors often comprise a network of hydrogen bonds referred to proton wires.

In this presentation, I will discuss fundamental aspects of proton conductivity in hydrated natural and synthetic polymers and how materials chemistry and microstructure affect this conductivity. To this end, I will present three biomaterials: 1) The biopolymer found in the Ampullae of Lorenzini of sharks and rays, 2) Sulfated polysaccharides, and 3) A synthetic hydrogel with a tunable microstructure and porosity. I will compare data from impedance measurements, DC measurements with proton-conducting PdHx contacts, and solution-based measurements. I will draw trends in this data as a function of biomaterial chemistry and microstructure. With these trends, I will provide insights on how proton conductivity can be used to predict the conductivity of other ions and discuss simple design rules for maximizing proton conductivity while maintaining the stability of the materials.

4:30 PM *SB12.03.04

***Assembly of Tyrosine Based Peptide and Proton-Enabled Activation for Biological Bimodal Memory** Ki Tae Nam; Seoul National University, Korea (the Republic of)*

The process of memory and learning in biological systems is multimodal, as several kinds of input signals cooperatively determine the weight of information transfer and storage. I will describe a peptide-based platform of materials and devices that can control the coupled conduction of protons and electrons and thus create distinct regions of synapse-like performance depending on the proton activity. In two-dimensional interfacial assemblies, there is an interplay between molecular ordering and interface geometry, which determines the final morphology and order of entire systems. I will present the interfacial phenomenon of spontaneous facet formation in a water droplet driven by designed peptide assembly. We utilized tyrosine-rich peptide-based films and generalized our principles by demonstrating both memristor and synaptic devices. Interestingly, even memristive behavior can be controlled by both voltage and humidity inputs, learning and forgetting process in the device can be initiated and terminated by protons alone in peptide films. We believe that this work can help to understand the mechanism of biological memory and lay a foundation to realize a brain-like device based on ions and electrons.

***Elucidation of Ionic and Electronic Charge Transport for Sensitive Electronic Characterization in Phage Films** Daniel Modafferi, Kingsley Wong, Xinxin Hao, Juliana Ferraro and Noemie-Manuelle Dorval Courchesne; McGill University, Canada*

Long range electron transport is a rare trait in nature. Using rational design on naturally non-conductive proteins, we can apply our current mechanistic understanding of this not fully understood process and learn more about it in a bottom-up approach. However, several difficulties occur in measuring very low conductive proteins, often orders of magnitude lower than natively conductive protein nanowires. More complex analyses are needed to sensitively track performance changes, and to better understand the diversity of charge transfer mechanisms involved in these heterogeneous environments.
We selected M13 bacteriophages as models for detailed electronic characterization in natively non-conductive proteins, for their dual potential of tolerating mutagenesis and structural organization into nanotubes for potential

charge transport. Phages insert their genetic code into bacteria, messaging the host to create multiple copies of its parasite. In the case of M13 bacteriophage, the E. coli host creates virus particles self-assembled into protein-based nanotubes 800 nm long and 5 nm in diameter. Along its coat, up to 2700 copies of pVIII alpha helical proteins form the majority of the rod.

The multiple repeats of pVIII protein, their self-assembly into a nanorod, and the phage's liquid crystal properties allowing it to reach high ordered supramolecular structures make the phage an intriguing candidate for inferring conductivity. This follows multiple efforts to genetically engineer more conductive protein-based self-assembling materials.

Using M13 bacteriophage films as a model, we cast them on interdigitated micro electrodes to study their electrical properties. The micro features and multiple digits of the electrodes lead to enhanced geometry to amplify the current read from low conductive material. In addition, to better distinguish between and understand different electric circuit parameters, we developed a simplified Randles circuit model based on IV sweeps and transient current we observed. To then deconvolute ionic from electronic charge transport, we adapted transient current measurements with humidity control.

These techniques allow us to study ionic and electronic charge transfer separately. At low relative humidity (10%) and after the current reaches steady state, few ions are mobile enough to migrate, and they reach equilibrium with the electric field. At this point, only electrons are moving through the material. Additionally, with our simplified Randles circuit model, the transient current at such a low humidity could be principally attributed to electronic parallel plate capacitance. We were able to mathematically derive different parameters from the model, such as film and contact resistance, and capacitance. As humidity increases, the transient current decay becomes dominated by ionic migration (double-layer capacitance-like). The dependence of the amplitude of the decay was used to identify the extent of ionic charge transport present in the material.

This method could be potentially applied to diverse proteins. We can compare between different proteins with different conductivity enhancement strategies, or between mutants obtained from the same origin through different design approaches. This allows us to get a better mechanistic understanding of complex bioprocessed protein environments, containing salts from growth and purification, and diverse amino acid chemistry. In addition, this technique, which uses microfabricated interdigitated electrodes, has high enough sensitivity to discriminate between materials with less than two-fold differences in conductivity. Therefore, it would allow the identification of small improvements in conductivity and guide towards the evolution of more conductive proteins with potentially unexplored charge transport mechanisms.

5:15 PM SB12.03.06

Enhancing the Conductivity of Curli Fibers Using Dyes and Plasticizers for Soft Electronic Applications *Mario Arenas Garcia, Julia M. de Medeiros Dantas, Xinxin Hao and Noemie-Manuelle Dorval Courchesne; McGill University, Canada*

Biologically derived polymers have several advantages over conventional polymers for their use in wearable electronics or medical applications, which include biodegradability, bioavailability and cell proliferation. However, their use has been limited due to their unsuitable mechanical properties, inconsistent production quality and risks of an immune response. A biological scaffold that can offset these problems is curli fibers, an amyloid protein produced by Enterobacteriaceae. Curli fibers have been shown to have robust stability, as evidenced through their ability to withstand incubation in detergents, harsh solvents and proteolysis. Similarly, it can be characterized as hard tissue due to their high Young's modulus, which is between 3 – 20 GPa. In contrast to other protein-based materials, it can be produced through a scalable vacuum filtration protocol. The production of curli fibers can be assessed through Congo Red (CR) assay, which relies on the use CR dye and its ease of binding to amyloid structures.

Biopolymers are generally known to have poor mechanical properties for wearable applications and tend to be mixed with plasticizers to improve this. Some considerations for their use include miscibility, resistance to leaching and cost. While many plasticizers are petroleum-derived and have raised concerns with regards to their toxicity and degradability, bio-based plasticizers have gained prominence. Common bio-plasticizers used for this purpose include glycerol and polyethylene glycol (PEG).

Given the use of dyes to identify the presence of proteins as well as the use of plasticizers to enhance their mechanical properties, we sought to evaluate the conductivity impact of incorporating dyes and select plasticizers on curli fibers and evaluate their feasibility as a conductive bio-based materials.

We mixed curli fibers with CR and other similarly structured dyes, such as Tartrazine, Indigo Carmine and Phenol Red. The blends were cast on silver ink printed electrodes to measure their electrical properties through IV sweeps. Overall, we observed a pattern where the dyes reached a peak increase in conductivity upon reaching an ideal concentration before dropping after adding more dye to curli fibers, where this peak varied according to the dye. Additionally, we observed different responses to the behavior of the dyes when mixed with different proteins. Pili, bovine serum albumin and gelatin were used for their different structures to assess changes in the conductivity response.

On the other hand, we observed a similar trend with the blends of glycerol and PEG with curli fibers, where a peak conductivity was achieved at a particular concentration and subsequently dropped. We also saw with PEG that there is a notable difference on the conductivity impact depending on its molecular weight, where the smallest molecular weight gave the largest increase in conductivity. Lastly, we evaluated the conductivity of a mixture of the best performing dye and plasticizer to determine if there was an additive effect.

Furthermore, we generated a curli-tartrazine-glycerol composite and assessed its suitability for use as a bioink and as thin films. In hydrogel form, the composite exhibited shear thinning behavior and was deemed suitable for extrusion printing applications. On the other hand, thin films were fabricated by casting in a silicon mold, which showed stretchable capabilities between 80 – 150%, far greater than regular curli thin films which are brittle.

The use of dyes and plasticizers to enhance the conductivity of biomaterials contrasts with conventional inorganic conductive fillers, with the advantage that they are sourced in an easier and inexpensive manner. Further exploration could lead to an insight on the binding and organization of the presented dyes and plasticizers to further enhance the conductivity of biological scaffolds.

Conductive Microtubule-Templated Gold Nanowires *Brenda Palestina Romero[1], Borja Rodriguez-Barea[2], Foram M. Joshi[1], Artur Erbe[2] and Stefan Diez[1,3,4]; [1]B CUBE-Center for Molecular Bioengineering, Germany; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]Max Planck Institute for Molecular Cell Biology and Genetics, Germany;*

[4]Cluster of Excellence Physics of Life, TUD Dresden University of Technology, Germany

Metallic nanowires (NWs) are considered good connectors in electronic circuits due to their lateral electron confinement [1]. Various methods exist for synthesizing NWs, and bio-templating has emerged as a promising approach to grow nanowires under mild conditions, such as low temperature, neutral pH, and without the need for clean room facilities. Specifically, metallic NWs have been successfully synthesized using high aspect ratio templates like DNA origami nanotubes [2], tobacco mosaic viruses [3], and microtubules [4].

Microtubules (MTs) are cytoskeletal filaments composed of self-assembled alpha- and beta-tubulin proteins, which can be easily polymerized in vitro from porcine brain tubulin. The resulting structure is a hollow cylinder with outer and inner diameters of 25 nm and 15 nm, respectively, and lengths extending up to tens of microns. Their geometry makes MTs ideal templates for casting gold nanowires (AuNWs). The process begins with the attachment of functionalized gold nanoparticles (1.4 nm in diameter) to the MT lumen [4]. These nanoparticles act as seeds and grow upon the addition of a gold precursor (chloroauric acid) and a reducing agent (hydroxylamine), ultimately forming AuNWs shaped by the MT lumen [4]. Using this method, smooth-appearing AuNWs with lengths of a few hundred nanometers were achieved [4]. However, to accurately characterize their electrical properties, such as conductivity and charge transport, the length of the AuNWs needs to exceed 500 nm.

In this study, we report the electrical characterization of AuNWs templated by MTs. We optimized the synthesis process to produce longer nanowires, reaching lengths of up to 900 nm, by fine-tuning the concentrations of the gold precursor and the reducing agent relative to the seed concentration. Subsequently, we characterized the electrical properties of the AuNWs by measuring the changes in electric current in response to varying applied voltages at both room and low temperatures. At room temperature, we observed both linear and non-linear behaviors in the I-V curves, along with an increase in conductivity over multiple measurements, likely due to sintering. Low-temperature measurements provided further insights into the electronic transport properties of these AuNWs.

Our results indicate that MT-templated AuNWs have diverse electrical properties, potentially attributed to grain boundaries and the broad distribution of morphologies in each sample. In future studies, we will aim to reduce the length distribution of the AuNWs and explore different surfactants to increase their uniformity. Potential applications of MT-templated AuNWs include (i) connectors for DNA-origami electronic devices and (ii) novel biosensors capitalizing on their high surface-to-volume ratio.

Optogenetics for Control of Biofilm Deposition and Extracellular Electron Transfer in Shewanella Oneidensis MR-1

Fengjie Zhao[1], Marko Chavez[1], Christina M. Niman[1], Kyle Naughton[1], Joshua Atkinson[2], Jeffrey A. Gralnick[3], Moh El-Naggar[1] and James Q. Boedicker[1]; [1]University of Southern California, United States; [2]Princeton University,

United States; [3]University of Minnesota Twin Cities, United States

Shewanella oneidensis MR-1 is a model electroactive bacterium, whose extracellular electron transfer (EET) pathway includes a network of multiheme c-type cytochromes to route electrons from the cellular interior to external, solid electron acceptors. S. oneidensis MR-1 is able to form living conductive biofilms on electrode surfaces for long-distance electron transport. Optogenetics circuits combine the light-sensitive proteins and transcription factors for spatiotemporal control of gene expression within living organisms as a response to illumination with light. Here, we introduced optogenetic circuits into S. oneidensis to control the electron transfer with different scales. We first developed a lithographic strategy to pattern conductive biofilms of S. oneidensis by controlling expression of the aggregation protein CdrAB with the blue light-induced genetic circuit pDawn. This controlled deposition enabled S. oneidensis biofilm patterning on transparent electrode surfaces and electrochemical measurements allowed us to demonstrate tunable conduction of living biofilms dependent on pattern geometry. Next, we developed a red light-induced genetic circuit in S. oneidensis based on a reported iLight system. This red light-induced genetic circuit was used to control the cytochromes expression in S. oneidensis which allowed us to adjust the extracellular electron transfer activity of S. oneidensis with light. Overall, these two new genetic tools enabled the control of biofilm conduction and EET activity by light which could have implications for both studying and harnessing bioelectronics.

SB12.04.03

Thermoelectricity in Conductive DNA Systems *Vicenta Sanchez Morales and Chumin Wang; Universidad Nacional Autónoma de México, Mexico*

Biological materials can transport heat and charge over macroscopic length scale, while the molecular electronics inspired by nature may exhibit unique quantum behaviors even at room temperature [1]. The self-assembled deoxyribonucleic acid (DNA) molecules, made by either cytosine-guanine (CG) or adenine-thymine (AT) stacked pairs coupled via hydrogen bonds and attached to the double-helix structure through sugar-phosphate backbones, behave as low-dimensional conductors or insulators depending on the system length and base-pair sequence [2]. In this work, the transport of electron and phonon in macroscopic DNA double chains connected to two reservoirs at their ends is studied by means of a real-space renormalization method within the Boltzmann formalism, where the poly(G)-poly(C) base-pair segments arranged following periodic and Fibonacci sequences are comparatively analyzed. We start from a widely used coarse-grained fishbone model for electrons, in which each base pair (CG or AT) is considered as a single site with a hopping integral of p-electrons between nearest-neighbor sites, while the backbone sugar-phosphates are represented as Fano impurities [3], whose self-energies depend on environmental conditions. In the corresponding vibrational coarse-grained model, the pair bases and backbones are grouped in grains with representative masses, while the interaction between grains is modeled via the Born potential including central and non-central restoring forces. Analytical solutions of the electric conductance have been found for periodically arranged infinite poly(G)-poly(C) double chains. The results show the appearance of gaps in phononic transmittance spectra of segmented poly(G)-poly(C) double chains, which leads to a remarkable enhancement of the thermoelectric figure of merit (ZT) when the periodic interfaces between poly(G) and poly(C) segments are introduced. Such ZT can be further improved by a quasiperiodic rearrangement of the segments, because the long-range quasiperiodicity avoids the presence of low-frequency vibrational modes that are insensitive to local defects or impurities. Finally, the influence of reservoirs on ZT is also investigated [4].

This work has been partially supported by projects UNAM-IN112522, UNAM-IN110823, and CONAHCYT-CF-2023-I-830. The computations were performed at Miztli of DGTIC-UNAM.

SB12.04.04
A Nanoscale Study on The Morphology and Conductivity of Biosourced Chlorophyll

Rebeca-Esmeralda Retezan, Shahid Khaleel and Clara Santato; Polytechnique Montréal, Canada

The increasing demand for electronics causes increasingly worrying environmental issues. For instance, only about 20% of e-waste is formally collected and recycled in an environmentally sound manner, at the global level [1]. Further, the growth of the electronics industry causes the shortage of certain chemical elements (critical and strategic) [2]. This brings us to look for alternatives, e.g. based on abundant bio-sourced and biodegradable organic electronic materials.

As the pigments most used in nature for light absorption, as well as energy and electron transfer [3], chlorophylls are ideal candidates for organic optoelectronic devices. In this work, we initially performed morphological and structural studies on chlorophyll extracted from spinach, deposited on substrates of technological interest. Our extraction protocol is an Ultrasound-Assisted Extraction (UAE), consisting of sonication, centrifugation, filtration, and evaporation steps to obtain a powder that can be then suspended in green solvents (DI water, ethanol, acetone, methanol) [4]. The suspensions were both spin-coated and drop-casted onto SiO_2/Si, to compare the deposition method's impact on coverage and supramolecular aggregation, keeping in mind structures reported in the literature, such as tubular or stacked aggregates [5]. We performed preliminary electrical response studies using e-beam lithography-patterned interdigitated Au electrodes with 400 nm inter-electrode distance. Downsizing the inter-electrode distance is meant to advance the discovery of charge carrier transport mechanisms within individual aggregates, a piece of knowledge required to rationally design biodegradable electronic devices utilizing chlorophyll’s (photo)conductive properties [4].

Peptoid Nanostructure Deposition Using Plasma Enhanced Chemical Vapor Deposition *Parthiv Ravikumar[1], Thi Kim Hoang Trinh[2], Jordan E. Pagliuca[1], Chun-Long Chen[2] and Milana Vasudev[1]; [1]University of Massachusetts Dartmouth, United States; [2]Pacific Northwest National Laboratory, United States*

Biomimetic materials are fabricated to imitate the behavior of certain biological molecules and the ability to manipulate these programmable materials to form diverse types of structures with a distinct function presents it as a promising alternative material that could be utilized for coating applications in bioengineering and biomedical engineering. Peptoids, a class of biomimetic materials, are N-substituted glycine oligomers that can mimic naturally occurring peptides/proteins and are currently being investigated for their advantages including increased stability, enhanced programmability of the sequence, biocompatibility, and a less complex structure. With these advantages, amphiphilic peptoids can serve as building blocks for assembling more complex nanostructures due to the interactions among hydrophobic side chains and the different patterns formed through their distinct chemical composition. In this study, we demonstrate the ability to manipulate these amphiphilic peptoids for the formation of distinct biomimetic nanostructures on various substrates through deposition via plasma enhanced chemical vapor deposition (PECVD). The use of plasma ionization allows the use of sequence-defined synthetic polymers such as peptoids for the formation of stable, and high-information content nanostructures which makes it an attractive for surface agnostic coating. Varying the deposition conditions for peptoid-based material synthesis allows for the formation of various nanostructures. The simplicity, low cost of synthesis and room temperature deposition associated with PECVD allows a broad range of precursors as well as unconventional substrates such as polymers (silicone), and fabrics (such as cotton) to be used. The peptoids used in this study include the Npm4Dig which has been demonstrated to form helical ribbon structures and NBrPE5C2 which has been demonstrated to form nanomembranes. Following deposition of the desired peptoid oligomer on the desired substrate, numerous qualitative and quantitative analysis methods contribute to the visualization of the nanostructures on different substrates and characterization of the chemical composition of the peptoid after the deposition process. The structural and morphological characteristics of the fabricated nanostructures will be studied using scanning and transmission electron microscope (SEM and TEM). The microscopic structure (length, diameter and spacing between nanostructures) as well as FTIR and Raman spectroscopy.

SESSION SB12.05: Conductivity in Native Protein Wires

Mechanistic Understanding of Electronic Conductivity in Biological Structures via High Performance Computing *Jochen Blumberger[1], Andras Petho[1], Xiaojing Wu[2] and Zdenek Futera[3]; [1]University College London, United Kingdom; [2]ENS, France; [3]University of South Bohemia, Czechia*

Multi-heme cytochromes (MHCs) have attracted much interest for use in nanobioelectronic junctions due to their high electronic conductances. Their charge transport mechanism has puzzled the community for many years, though experiment and computation now seem to have converged on a consistent picture.

Up-to-date as of November 14, 2024

An often overlooked aspect is that the transport mechanism in MHCs depends strongly on how the transport is induced: in the native biological environment electrons are injected in and ejected from the heme chain by molecular donors and acceptors that have a redox potential similar to the heme groups. Here, ultrafast pump-probe transient absorption spectroscopy and molecular simulation have shown that transport is via heme-to-heme electron hopping[1]. By contrast,in a junction the electron injection and ejection is facilitated by metallic electrodes with Fermi-levels that can differ substantially from the redox potentials of the heme groups, here by 1 eV [2]. Recent measurements on dry and aqueous MHC junctions as well as high performance computing suggested that a off-resonant coherent tunneling mechanism, not hopping, is operative over surprisingly long distances, up to about 7 nm [3]. We explain the long coherent tunneling distances by (i) a low exponential distance decay constant for coherent conduction (\beta = 0.2 Å−1), much lower than for biological electron transfer (\beta = 1.2-1.4 Å−1) (ii) a large density of protein electronic states that electronically couple to the electrodes, a factor of 10 higher than for typical molecular wires made of small molecules, prolonging the coherent tunneling regime to distances that exceed those in molecular wires [4].

In my talk I will consolidate this view by presenting new conductance calculations on MHC junctions where the number of hemes is systematically varied from 1 to 2 to 3 and 4 hemes and multiples of 4-heme protein chains approaching lengths of several 10 nanometers. I will also compare MHCs with cable bacteria which exhibit electronic conductances 3-4 orders of magnitudes higher than MHCs [5]. The transport scenario in cable bacteria is likely to be very different from the one in MHCs and potentially more similar to the one in highly conductive organic semiconductors or metal-organic frameworks.[6]

Long Distance Interprotein Electron Transport in Redox Proteins and Photosynthetic Complexes *Pau Gorostiza; ICREA-IBEC-CIBER, Spain*

Interprotein electron transport is an essential process in cell respiration and photosynthesis. It takes place between redox proteins and complexes, and it displays an outstanding efficiency and environmental adaptability. Although the biochemistry of electron transport processes is well characterized, nanoscale experimental methods are needed to understand electronic pathways in these redox protein structures, both for fundamental and for technological purposes. Electrochemical scanning tunneling microscopy (ECSTM) is a unique tool to study electronic materials and redox molecules including proteins. It offers single molecule resolution and allows working in aqueous solution, in nearly physiological conditions in the case of proteins, and under full electrochemical control (López-Martínez et al., 2017). ECSTM also allows performing conductance measurements by current-potential and current-distance tunneling spectroscopy (Artés et al., 2012), notably between cognate redox partner proteins. An overview of these methods will be presented together with recent results of the laboratory in the respiratory (Lagunas et al., 2018; Gomila et al., 2022) and photosynthetic chains (López-Martínez et al., 2019; Zamora et al., 2022; López-Ortiz et al., 2022 and 2023). The mechanism of interaction between donor and acceptor proteins and the role of charges in these measurements will be discussed, for example in cytochrome phosphorylation (Gomila et al., 2022) and in the interaction between plastocyanin and photosystem I complexes (Zamora et al., 2022, López-Ortiz et al., 2023).

How Do Electric Bacteria Breathe Without Oxygen or Soluble Electron Acceptors? Protein Nanowires—Structures, Functions and Ultrafast Electron Transfer Mechanisms *Nikhil S. Malvankar; Yale University, United States*

*Deep in the ocean or underground, where there is no oxygen, Geobacter "breathes" by projecting tiny hair-like protein filaments called "nanowires" into the soil to dispose of excess electrons resulting from converting nutrients to energy and cleaning up radioactive sites. Although it is long known that Geobacter uses filaments for electron transfer (**Nature 2002, 2005)**, it is unclear what they are actually made of and why they are conductive.*

Our studies have revealed a surprise: the nanowires have a core of hemes lining up to create a continuous path along which electrons travel.
*Nanowires can be engineered with atomic precision using recombinant DNA technology, making for remarkably versatile electronic components **(Cell'19, Nature Chem. Bio.'20, Nature Micro.'23)***

*We have further found that Geobacter pili remain hidden inside the cell and serve as a piston to secrete nanowire-forming cytochromes **(Nature 2021)** rather than functioning as a nanowire themselves as previously thought **(Current Opinion 2020)**.*

*These studies solve a longstanding mystery to explain our previous findings that these bacteria transport electrons via nanowires **(Nature Nano. 2014)** over 100 times their size to electron acceptors **(Nature Nano. 2011)** and partner cells **(Science 2010)** and store electrons when acceptors are absent, akin to how humans use their lungs **(ChemPhysChem 2012)**.*

*Our contact-free measurements of intrinsic electron conductivity in individual protein nanowires reveal how energetics and proximity of proton acceptors modulate conductivity by 100-fold **(PNAS 2021, Biochem. Journal 2021)**. Using non-natural click-chemistry functionality, we have also developed synthetic protein nanowires with tunable conductivity and programmable self-assembly **(Nature Comm. 2022)**.*

*In this talk, I will present our efforts to identify the physical and molecular mechanisms of the high conductivity of microbial cytochrome nanowires. Our conducting-probe AFM measurements show one of the highest electronic conductivity ever reported in proteins (> 100 S/cm) **(Nature Chem.Bio.'20)**. Femtosecond transient absorption spectroscopy and quantum dynamics simulations reveal ultrafast (<200 fs) electron transfer between nanowire hemes upon photoexcitation, enhancing carrier density and mobility. Photoconductive atomic force microscopy shows a 100-fold increase in photocurrent in purified individual nanowires. Photocurrents respond rapidly (<100 ms) to the excitation and persist reversibly for hours **(Nature Comm.'22)**. Furthermore, nanowires and biofilms show the non-classical temperature dependence of conductivity with cooling accelerating electron transport by 300-fold **(Science Adv.)**.*

*Computations yielded up to a billion-fold lower conductivity than experiments (JPCB'21, JPCB'22), illustrating that the hopping assumption fails to capture electron transfer in biological nanowires. This raises the possibility that biological nanowires employ a fundamentally different, currently unknown mechanism. Thus, existing models predict the same conductivity for all nanowires with computed timescales for heme-to-heme electron transfers (100 ns), million-fold lower than that measured using transient absorption in excited-state **(Nature Comm.'22)** and conductivity in ground-state for fully hydrated (Nature & Cell) or air-dried nanowires **(Science Adv.)**.*

Notably, multiple computational studies have predicted that invoking quantum effects could account for the high conductivity of these nanowires (Nanotechology'20, IEEE'21, ACS Nano'23). I will present our efforts to *experimentally assess these computational predictions using multiple probes such as light, temperature, and electric and magnetic fields. I will also show how our recent spectroelectrochemical studies are helping to understand, predict, & control extracellular electron transfer by nanowires used by diverse environmentally important microbes and their giant extrachromosomal elements to capture, convert and store energy (**Nature Comm.’24 #1** & **#2**).*

10:30 AM *SB12.05.04
Understanding the Microscopic Mechanisms Associated with Conductivity in Cytochrome Wires from First-Principles Modeling *L. Nambi Mohanam[1], Rafael Umeda[2], Allon Hochbaum[2], Ruqian Wu[2] and Sahar Sharifzadeh[1]; [1]Boston University, United States; [2]University of California, Irvine, United States*

To develop new biologically-inspired materials for electronics, we need to understand the microscopic mechanisms associated with carrier conductivity. Such an understanding is hindered by the structural and chemical complexity of these systems. Here, we present theoretical studies of conductivity within microbial cytochrome wires, which exhibit carrier conduction over microns. We introduce an approach to extract charge carrier site information directly from Kohn-Sham density functional theory (DFT), providing input to a quantum charge carrier model that includes both coherent charge transport and the impact of decoherence. We demonstrate that molecular fluctuations strongly impact electron carrier diffusion lengths; specifically, both non-instantaneous decoherence and non-perturbative dynamic disorder allow the system to more easily overcome static site energy barriers, improving conductivity within certain parameter regimes. These studies provide insights into molecular and electronic determinants of long-range electronic conductivity in microbial cytochrome wires and highlight design principles for bioinspired, heme-based conductive materials.

This research was primarily supported by the National Science Foundation Materials Research Science and Engineering Center program through the UC Irvine Center for Complex and Active Materials (DMR-2011967).

11:00 AM *SB12.05.05
New Insights into the Mechanism of Centimeter-Scale Electron Transport in Cable Bacteria *Filip Meysman; University of Antwerp, Belgium*

Electron transport in biological systems is classically thought to occur over nanometre to micrometre distances. Yet, recent studies on filamentous cable bacteria suggest that electrical currents can also run over centimeter distances, thus giving a whole new meaning to the term long-range biological transport. These electrical currents are channeled through protein fibers embedded in the cell envelope, which display extraordinary electrical properties for a biological material, and hence could form the basis of radically new green technologies. Here we present the latest insights into the mechanism of long-range conduction in cable bacteria. New data reveal that the conductive protein fibers in cable bacteria contains a nickel-cofactor. This observation is highly remarkable from a biochemical point of view, as all known metalloproteins involved in biological electron transport rely on Fe or Cu cofactors, but never Ni-centers. Additionally, cryogenic electrical characterization reveals that the conductivity remains anomalously high at extremely low temperatures. This conductivity behavior has not been seen before in a biological structure and challenges our understanding of protein biophysics. Together, these recent data suggest that the conduction mechanism in cable bacteria could be different from all other known biological electron transport mechanisms. Our findings reveal a novel biological structure with an unprecedented conductivity that could enable new bio-electronic applications.

11:30 AM SB12.05.06
Genetically Tailoring Pilin-Based Nanowires Expressed with E. Coli for Enhanced Electronic Functions *Derek*

Lovley[1], Jayesh Sonawane[1], Eric Chia[1], Toshiyuki Ueki[1], Jesse Greener[2], Stephen Nonnenmann[1] and Jun Yao[1];
[1]University of Massachusetts Amherst, United States; [2]Université Laval, Canada

Pilin-based electrically conductive protein nanowires (e-PNs) are sustainably produced 'green' electronic materials that have served as the functional components of novel electronic devices for sensing, neuromorphic memory, and the generation of electricity from atmospheric humidity. An E. coli chassis for the expression of e-PNs, grown on the biodiesel waste-product glycerol, enables sustainable e-PN mass production. It is a simple matter to genetically tailor e-PN properties, such as conductivity, and their sensitivity and selectivity for sensing analytes of biomedical and/or environmental interest. Thus, the possibility of incorporating e-PNs in a water-stable polymer while maintaining e-PN function was evaluated to further expand fabrication and applications options.

Mixing e-PNs and polyvinylbutryal (PVB) yielded transparent, electrically conductive composites. e-PNs were evenly distributed throughout the composite. Composite conductivity increased with increasing weight percent e-PNs in a manner consistent with percolation theory. The conductivity of the e-PNs was tuned by modifying the abundance of aromatic amino acids encoded in the pilin genes. Incorporating e-PNs with different conductivities resulted in the changes in the conductivities of the e-PN/PVB composites that were consistent with the changes made in pilin aromatic amino acid composition.

Electronic sensors with e-PN/PVB composites as the sensing unit were incorporated into a microfluidic system that continuously passed water over the sensor, enabling high throughput analysis of different analyte concentrations. Flexible wearable sensors for detecting ammonia in sweat or other bodily fluids are of interest because ammonia concentrations are diagnostic of certain aspects of the body's physiological state and the presence of several diseases. The conductivity of the e-PN/PVB composites changed in direct response to the concentration of ammonia dissolved in the water, consistent with previous demonstrations that the conductivity of thin films of e-PNs differently responded to gaseous ammonia concentrations.

Previous studies demonstrated that modifying pilin genes to encode specific sequences of six-to-nine amino acids at the carboxyl end of the pilin protein yielded e-PNs with the added amino acids displayed on the e-PN outer surface. Pilin genes were modified to determine whether displaying amino acid sequences known to specifically bind analytes of interest would enhance the e-PN/PVB sensor response to the target dissolved analytes. Sensor response was dramatically improved. For example, displaying a peptide known to bind ammonia increased sensor sensitivity 10-fold. There was negligible sensor response to other common sweat components. Modifying pilin genes to display different amino acid sequences on the e-PN outer surface specifically increased sensitivity to other target analytes.

Conductive composites for effective sensing were also made by mixing whole cells of E. coli, with e-PNs still attached, with PVB. This method eliminates the need for e-PN harvesting and purification, the most labor-intensive step in producing e-PN-based electronics.

These results demonstrate for the first time the fabrication of electrically conductive, water-stable e-PN/polymer composites and show that it is possible to tune the conductivity and sensing capabilities of these composites with simple modifications of the pilin gene sequence. It is well-known that it is possible to design short amino acid sequences to specifically bind a diversity of biomedical and environmentally relevant analytes. Therefore, our findings demonstrate the ability to exquisitely genetically tailor e-PN properties to inexpensively and sustainably fabricate a broad array of flexible e-PN/polymer composites, each with the potential to specifically sense in real-time one of a broad diversity of medically and/or environmentally relevant analytes.

11:45 AM SB12.05.07

Microbial Syntrophy Within Electroactive Biohybrids *Ramya Veerubhotla[1], Shaofeng Zhou[2,3], Yonggang Yang[4], Meiying Xu[2,3] and Ugo Marzocchi[1,1]; [1]Aarhus University, Denmark; [2]Guangzhou Academy of Sciences, China; [3]Guangdong Academy of Sciences, China; [4]Foshan University, China*

Electroactive microbes are capable of wiring themselves to electrodes, driving biochemical reactions by shuttling electrons to and from electrodes. Embedding these microbes in biocompatible polymers accelerates their attachment to electrodes and enhances biofilm stability. In this study, we use a synthetic co-culture of Lysinibacillus varians GY32 (a filamentous Gram-positive bacterium isolated from freshwater sediment) and Shewanella oneidensis and embed them to agar to form an electroactive biohybrid onto a graphite electrode. At equal bacterial cell density, the co-culture yielded higher maximum current (4 $\mu A/cm^2$) as compared to the axenic cultures (2.8 $\mu A/cm^2$), possibly due to more effective substrate (lactate) utilization.

Given that Lysinibacillus varians GY32 has electrically conductive nanowires, we hypothesize that Shewanella might utilize it as an electron conduit to channel the electrons produced from lactate oxidation to the electrode, thereby establishing long-distance electron transport (LDET) to the anode. We use an Electric Potential microsensor to measure electric fields as a proxy for LDET within the biohybrid matrix. We observe that maximum electric fields up to 33 V/m are generated by the co-culture as compared to the 26 V/m and 4.99 V/m by Lysinibacillus varians GY32 and Shewanella oneidensis biohybrids, respectively. Moreover, confocal microscopy images reveals Shewanella cells tightly bound to Lysinibacillus varians GY32 filaments at multiple locations, supporting the idea of an interaction between the two microbes. Our results contribute to better understanding of interaction between electroactive microbes, potentially leading to more effective bioelectrochemical systems.

1:30 PM *SB12.06.01

Bioinspired Heme Binding Peptide Assemblies—Synthetic Analogs of Electronically Conductive Multiheme Proteins *Christopher Fry; Argonne National Laboratory, United States*

Anaerobic bacteria cast long, one dimensional, cytochrome rich, nanoscale fibers to transfer electrons over long ranges as part of their respiratory pathway. These fibers were found to be electronically conductive due to the organized network of overlapping heme molecules. Inspired by this phenomenon, a library of synthetic one-dimensional heme binding peptide assemblies has been synthesized and characterized. Although these materials are reminiscent of the naturally occurring multiheme cytochromes, they currently do not possess the same electronically conductive properties. However, due to the synthetic ease of these libraries, the molecular structure of the peptide can be modified to facilitate variations in amino acid and secondary structure content that impact the function of the resulting assemblies. Consequently, the self-assembled peptide product can be tuned to accommodate a multitude of fabrication processes for incorporation into materials and devices. The presentation will highlight the molecular assemblies and the motivation behind their design and briefly introduce our use of machine learning to predict new sequences of heme binding peptide assemblies.

2:00 PM ^SB12.06.02

Fabrication of Metalloprotein Nanowires for Bioelectronics and Biointerfacing *Dominic J. Glover; University of New South Wales, Australia*

The transfer of electrons and protons through protein assemblies is a fundamental process of life for the production and use of energy, such as photosynthesis that converts solar energy into chemical energy. Harnessing the ability of proteins to transfer charge carriers may enable the creation of ultralow power bioelectronic devices from sustainable and nontoxic materials. This presentation will describe several engineering approaches to create electron and proton conductive protein-based materials that can be used to regulate energy transfer between living cells, enzymes, or the environment. In the first approach, a variety of different metalloproteins, such as cytochrome c3 or azurin were aligned in proximity along a protein filament. The resulting individual nanowires were capable of efficient long-range electron transfer, with a conductivity of up to 6 S/cm. In addition, the nanowires were shown to be conductive to protons, which is attributed to a high concentration of carboxylic acid-containing residues in the protein filament that provide proton transfer pathways. As an alternative to attaching metalloproteins to filaments, we also demonstrated that protein assemblies can be rendered electronically conductive through the direct incorporation of heme molecules. The binding of heme in the coiled-coil domains of a filamentous protein was shown to create micrometer length conductive nanowires. Photoexcitable porphyrin molecules such as chlorophyll b or zinc protoporphyrin IX can be incorporated into the filaments using a similar strategy, which enabled the creation of nano-antennas for solar energy harvesting. The presentation will also highlight recent applications of conductive protein nanowires, such as mediating energy transfer in microbial fuel cells and energy harvesting from light or ambient humidity to power enzymatic catalysis. Ultimately, the creation of metalloprotein nanowires with tailorable conductive properties will serve as a foundation for building bioelectronic devices that bridge the biotic-abiotic divide.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

3:30 PM *SB12.06.03

Engineered Electroactive Microbes as Building Blocks for Living Electronics *Marko Chavez[1], Joshua Atkinson[2], Fengjie Zhao[3], Christina M. Niman[3], Magdalene MacLean[3], Nir Sukenik[3], Sukrampal Yadav[3], Carolyn Marks[3], Jeffrey A. Gralnick[4], Moh El-Naggar[3] and James Q. Boedicker[3]; [1]Rice University, United States; [2]Princeton University, United States; [3]University of Southern California, United States; [4]University of Minnesota Twin Cities, United States*

Electroactive bacteria, such as Shewanella oneidensis and Geobacter sulfurreducens, can couple the oxidation of organic electron donors to the reduction of external solid surfaces, including minerals and electrodes. To carry charge from within the cell to external surfaces, these electroactive bacteria utilize outer membrane multiheme cytochromes. These multiheme cytochromes can (1) facilitate long-distance (micrometer-scale) redox conduction along the outer membrane and (2) reduce metal ions in solution for the biogenic synthesis of technologically relevant nanomaterials. By exerting control over these bioelectronic properties with synthetic biology and electrochemistry, the foundation can be laid for developing living electronics, devices that combined the properties of both biology and solid-state electronics. To this end, we implemented an optogenetic biofilm patterning gene circuit and a small molecule sensor in S. oneidensis to control cytochrome expression in response to added concentrations of vanillic acid. This allowed us to pattern cells on electrode surfaces with light and to tune the electrochemical activity, conduction, and the intrinsic conductivity of living biofilms as a function of cytochrome expression. Additionally, using G. sulfurreducens, we allowed a biofilm to form on electrodes ahead of Pd nanoparticle biomineralization for biofilm-localized synthesis of biogenic nanomaterials. This allowed us to create a hybrid nanoparticle-cell film. Here, we have used different combinations of synthetic biology, electromicrobiology, and biomineralization to develop methods for controlling biofilm geometry, conductivity, and *nanomaterial synthesis. Thus, just as photolithography, ion implantation, and metal deposition form the building blocks of solid-state device fabrication, perhaps similar capabilities for patterning, tuning electrical properties, and material synthesis demonstrated here in electroactive microbes can become the building blocks for the fabrication of living electronics.*

SESSION SB12.07: Fabrication and Technologies

Session Chairs: Nadav Amdursky and Noemie-Manuelle Dorval Courchesne

4:00 PM *SB12.07.01

Design Rules for Polymers to Improve Microbial Electrochemical Technologies *Ariel L. Furst; Massachusetts Institute of Technology, United States*

Electroactive microbes (EAMs) are those that can transfer electrons across their membranes. Exporting electrons from the cell occurs through a process known as extracellular electron transfer (EET). Though many microbes perform EET, two of the best-studied genera are Shewanella and Geobacter. These EAMs employ their electron transfer capabilities for respiration, among other fundamental cellular processes. Critically, these processes can also be harnessed for sustainable technologies. However, these strategies have yet to be implemented outside of the lab due to their low current generation.

In engineered systems, EAMs can perform EET to or from an electrode. However, these microbes behave very differently on electrodes than they do in native ecosystems. At electrodes, EAMs show sluggish electron transfer, and materials developed to boost electron transfer are not biocompatible, sacrificing either membrane integrity or nutrient transport. A less destructive strategy is to incorporate biocompatible conductive polymers onto a carbon electrode. Though these materials improve cell attachment, they rarely boost the current per cell. Thus, these systems bear little resemblance to behavior in ecological niches, and observed improvements do not translate to utility in engineered systems.

We have looked beyond established biocompatible polymers to materials used in abiotic systems, such as photovoltaics and batteries. Many polymers contain conductive backbones as well as pendant groups capable of ion transfer. One popular moiety for this is imidazolium, which resembles a histidine residue prevalent in enzyme active sites. Thus, we expected these ion- and electron-conductive polymers to serve as effective bio-inspired materials to achieve relevant electron transfer.

Shewanella oneidensis has high rates of EET, oxygen tolerance, and ability to consume diverse organic substrates and has been shown to directly transfer electrons extracellularly through both membrane-associated cytochromes and secreted mediators, mainly flavin mononucleotide (FMN). These mediators also increase the distance over which electrons can be transferred and the diversity of substrates that can be used, ranging from solid metal oxides to sulfate-reducing bacteria. Though direct electron transfer is well-studied, mediated processes have not been due to limitations in recapitulating EAM native behavior in the lab. Specifically, the reaction kinetics of mediators with the electrode are slower than most electron transfer in bio-logical systems. We observe unprecedented behavior of Shewanella on ion- and electron-conductive polymers, where bio-relevant, concerted two-electron transfer between flavins and these polymers, the prevalent mechanism in flavoenzymes. These plastics have evolved over billions of years to accelerate electron transfer by confining substrates within a controlled chemical environment. In contrast, extracellular flavins participate in successive one-electron transfers due to the relative stability of the semiquinone in the absence of an active site. We show *that the key characteristics of enzyme active sites can be recapitulated in an abiotic material by controlling material design. Specifically, our polymers reproduce the local flavoenzyme environment electrode. This biosimilar mechanism greatly improves the rate of Shewanella electron transfer, resulting in the greatest enhancement of per-cell current reported to date.*

4:30 PM SB12.07.02
Mechanical and Electrical Tuning of Polydimethylsiloxane (PDMS) with Microbially Produced Protein Nanowires *Eric Chia, Jayesh Sonawane, Derek Lovley and Stephen Nonnenmann; University of Massachusetts Amherst, United States*

Electrically conductive protein nanowires (e-PNs) synthesized via expression of the Geobacter sulfurreducens pilin gene in aerobically grown Escherichia coli strain show great promise in applications including sensors, bio-memristors, and electrical power generation. Most studies have focused on the electrical properties and performance of e-PNs, whereas the mechanical properties of e-PNs have been largely unexplored. Therefore, the elastic properties of individual e-PNs and their effects as nanocomposite fillers was measured with atomic force microscopy (AFM) nanoindentation. Fast force mapping (FFM) revealed that individual e-PNs exhibited an elastic modulus of 2.13±1.61 GPa, in reasonable agreement with previous theoretical calculations for microbial type IV pilus filaments. When e-PNs were integrated into a polydimethylsiloxane (PDMS) elastomer matrix the elastic modulus of e-PNs/PDMS nanocomposites displayed filler loaded-dependent trends similar to other polymer-based composites with nanowire fillers. Amplitude modulation, frequency modulation (AM-FM) bimodal imaging yielded an elastic modulus for pristine PDMS of 159.87±7.13 MPa. The elastic modulus of the e-PN/PDMS composites were highly tunable over a range of 1 – 10 wt% e-PNs, highlighted by a ~ 51% increase at 10 wt% (241.70±11.91 MPa). The correlation between e-PN weight percentage and the Young's modulus of e-PN/PDMS composites aligns with percolation theory. Evaluation of the electrical properties of the e-PN/PDMS composites revealed a threshold behavior at approximately 5 wt% e-PNs. This study demonstrates concentration-dependent elastic and electrical properties of e-PN/PDMS nanocomposites, making them a strong candidate for conductive elastomers in a variety of functional devices.

4:45 PM SB12.07.03
A Protein-Based Free-Standing Transparent Elastomer for Large-Scale Sensing Applications *Ramesh Nandi[1], Yuval Agam[2] and Nadav Amdursky[2]; [1]Heidelberg University, Germany; [2]Technion-Israel Institute of Technology, Israel*

A crucial aspect of modern materials research is the ongoing transition to environmentally friendly and sustainable green materials. Natural resources are one of the attractive building blocks for making environmentally friendly materials. In most cases, however, the performance of nature–derived materials is inferior to the performance of carefully designed synthetic materials. This performance issue is especially true for conductive polymers. Conductive polymers are a special class of materials that have the potential for a wide range of applications (such as solar cells and bioelectronics). Like many common polymers, conductive polymers are derived from petrochemicals and are not biodegradable, hence producing tons of waste over time. However, conductive polymers derived from natural building blocks often do not possess all the attractive properties together (such as one–pot easy synthesis, bio– degradability, non–cytotoxicity, transparency, stretchability, and scalability). Here, we have used bovine serum albumin (BSA) to make a free-standing transparent polymer with a highly elastic nature and proton conductivity comparable to that of synthetic polymers. The polymerization process is spontaneous and relies on the reshuffling of natural protein crosslinkers; moreover, it's an energy–efficient one-pot synthesis. The protein used in this process is one of the most affordable proteins, resulting in the ability to create large–scale materials at a low cost. Due to the inherent biodegradability and biocompatibility of the *elastomer, it is promising for various potential applications. Here, we have focused on its utilization as a solid–state electrode for recording electrophysiological signals from the human body.*

5:00 PM SB12.07.04
Electrical Characterization of the Alleged Bio-Memristor Physarum Polycephalum *Markus Schmidt[1], Günter Seyfried[1], Uliana Reutina[1], Zeki Seskir[2] and Eduardo R. Miranda[3]; [1]Biofaction KG, Austria; [2]Institut für Technikfolgenabschätzung und Systemanalyse, Germany; [3]University of Plymouth, United Kingdom*

Quantum circuits can be simulated using classical computers and various physical systems, including memristors. Reports in the literature suggest that the slime mold Physarum polycephalum exhibits memristive properties. In this study, we aimed to simulate a quantum CNOT gate using memristors based on P. polycephalum.
We cultivated 25 slime molds in a setup comprising two chambers connected by electrically conductive rings and a transparent tube. After the slime molds traversed the tube, we conducted 187 electrical measurements using the conductive rings. Surprisingly, the resulting I-V curves provided minimal evidence of memristive behavior in the slime molds.
We developed equivalent circuit models and determined that most slime molds could be approximated primarily by resistors and capacitors. A more detailed equivalent circuit must account for the slight resistance (impedance) changes induced by internal plasma flow at a frequency of approximately 1/60 to 1/120 Hz and a voltage source of about 20-40 mV. Although our findings do not support the initial objective of simulating a quantum CNOT gate with slime molds, we will discuss the potential for organisms like P. polycephalum to serve as components in bioelectronic circuits (e.g. biosensors, microbial fuel cells).

SESSION SB13.01: Metal-Halide Perovskites under Harsh Environments
Session Chairs: Ahmad Kirmani and Felix Lang
Monday Afternoon, December 2, 2024
Hynes, Level 3, Room 308

1:30 PM *SB13.01.01
Radiation Tolerance and Defects Activity in Metal Halide Perovskite Single Crystals *Beatrice Fraboni; Università di Bologna, Italy*

Metal halide perovskites (MHPs) are low-temperature processable hybrid semiconductor materials with exceptional performances that are revolutionizing the field of optoelectronic devices. Despite their great potential, commercial deployment is hindered by MHPs lack of stability and durability, mainly attributed to ions migration and chemical interactions with the device electrodes.

The presence of electronic trap states has been a tough challenge in terms of characterization and thus mitigation. Many attempts based on electronic spectroscopies have been tested, but due to the mixed electronic-ionic nature of MHPs conductivity, many experimental results retain a large ambiguity in resolving electronic and ionic charge contributions. Here we adapt a method, previously used in highly resistive inorganic semiconductors, called photo-induced current transient spectroscopy (PICTS) on lead bromide 2D-like ((PEA)2PbBr4) and standard "3D" (MAPbBr3) MHPs single crystals. We present two conceptually different outcomes of the PICTS measurements, distinguishing the different electronic and ionic contributions to the photocurrents, based on the different ion drift of the two materials. Our experiments unveil deep levels trap states on the 2D, "ion-frozen" (PEA)2PbBr4 and set new boundaries for the applicability of PICTS on 3D MHPs [1].

We focus our attention on 2D layered MHPs, recently reported as very promising candidate for the direct detection of X-rays, with superior radiation resilience if compared to standard "3D" perovskites [2]. The physical mechanisms responsible for such improvement are still not fully understood, possibly associated the peculiar charge transport process in PEA2PbBr4 crystals

We demonstrate that PICTS can detect three distinct trap states (T1, T2, and T3) with different activation energies, and that the trap states evolution upon X-ray exposure can explain PEA2PbBr4 superior radiation tolerance and reduced aging effects [3]. Overall, our results provide essential insights into the stability and electrical characteristics of Metal Halide perovskites and on the great potential of 2D perovskites in applications where reliable and highly radiation tolerant active materials are needed.

Laser-Printed Perovskites for Stable Optoelectronic Devices under Radiation, Thermal and Humidity Stress

Oana D. Jurchescu; Wake Forest University, United States

Metal halide perovskites offer a unique combination of optoelectronic properties which could transform the landscape of modern optoelectronics, but their instability and reliance on hazardous solvents hinder their widespread use. We introduce a solvent-free laser printing technique for depositing perovskite films with exceptional stability under harsh conditions, including radiation exceeding 200 Gy, blue laser illumination, 90% relative humidity, and thermal stress up to 80°C for over 300 minutes in air. The laser-printed films outperform conventionally processed films in terms of stability, which we attributed to the unique film formation mechanism and defect-tolerant microstructure of the laser printing process. The exceptional resilience of these films under harsh conditions, particularly high radiation doses, suggests their potential for applications in space exploration and satellite technology. Additionally, the elimination of hazardous solvents makes laser printing an eco-conscious fabrication method suitable for scalable production and widespread adoption of perovskite technologies.

3:00 PM *SB13.01.03

Threshold Displacement Energies in Halide Perovskites from Ab Initio Molecular Dynamics Simulations

Mario F. Borunda[1], Rosty Martinez[1], Ahmad Kirmani[2] and Ian R. Sellers[3]; [1]Oklahoma State University, United States; [2]Rochester Institute of Technology, United States; [3]University at Buffalo, The State University of New York, United States

Predicting radiation damage to materials requires estimating the threshold displacement energy (E_d). We calculated E_d using ab initio molecular dynamics for halide perovskites. The E_d values we have obtained, which are considerably lower than those commonly assumed in the literature for several species, hold significant implications for predicting radiation damage to materials. We performed Monte Carlo simulations with the AIMD-obtained E_d and compared them to those obtained using the default E_d. Our results show an increase in specific vacancies in halide perovskites that were not captured in simulations using the default E_d values. This suggests that the default E_d values may not accurately predict the radiation damage in these materials.

3:30 PM SB13.01.04

Critical Role of Low-Energy Protons in Radiation Testing of Perovskite Space Solar Cells *Buh Kum Tatchen and Ahmad Kirmani; Rochester Institute of Technology, United States*

While perovskite solar cells (PSCs) appear attractive for space power applications, a true radiation tolerance assessment requires development of proper radiation testing protocols. A basic criterion is that protons normally incident on a PSC during ground-based testing should create a uniform damage profile, mimicking the profile that the omnidirectional and polyenergetic proton spectrum in a space orbit would create in the PSC. However, given the low thicknesses of PSCs, proton energies above 0.05 MeV can meet this criterion, leading to ambiguity regarding the precise energy needed for testing. Here, we address this ambiguity by highlighting another major criterion: the optimal proton energy should also closely mimic the elemental vacancy distribution created in the perovskite layer by space protons. To arrive at this conclusion, we use Monte-Carlo ion-solid simulations to first calculate the elemental vacancies in a PSC resulting from low-Earth orbit (LEO) protons. We then show that only

~0.07 MeV protons normally-incident on a PSC result in a similar elemental vacancy distribution. Higher energies (~1 MeV) lead to 25% more iodine vacancies, 33% more lead vacancies, and 50% less hydrogen vacancies, and therefore do not represent the space radiation environment. Our study offers more precise guidelines for PSC radiation testing, paving the way for more accurate, reliable, and comparable radiation tolerance assessments.

3:45 PM SB13.01.05

Stability and Degradation of Metal Halide Perovskite Solar Cells Under Multiple Space Relevant Stressors

Megh Khanal[1], Mritunjaya Parashar[2], Tamara Merckx[3], Vincent R. Whiteside[1], Giles E. Eperon[4], Melissa Davis[5], Kelly Schutt[5], Joseph Luther[5], Mohin Sharma[2], Bibhudutta Rout[2], Yinghuan Kuang[3], Bert Vermang[3] and Ian R. Sellers[1]; [1]University at Buffalo, The State University of New York, United States; [2]University of North Texas, United States; [3]imec, Belgium; [4]Swift Solar, United States; [5]National Renewable Energy Laboratory, United States

The operational stability of metal halide perovskite (MHPs) solar cells in space is influenced by various factors including launch-induced degradation, radiation exposure, high intensity photoexcitation under large temperature swings, as well as charge accumulation effects (amongst others). Here, we present a study that focuses on employing combinations of space relevant stressors to mimic the operational conditions that MHP solar cells may experience in space and under pre-launch conditions. [1] A series of MHP solar cells are assessed in terms of their stability and performance while implementing various encapsulation protocols, as well as in unencapsulated devices which are used to accelerate environmental degradation. Consistent with previous studies, the MHP devices assessed here show high radiation stability, but are much more sensitive to environmental conditions that might be experienced under the high temperature high humidity prelaunch conditions expected in the United States. Degradation is also evident under constant solar illumination at fixed biases particularly when the devices are exposed to high temperature thermal cycling implemented to mimic charge build up in MHPs in space. Additionally, initial assessments of polymer based encapsulants indicate these systems suffer decomposition due to excessive heating under high energy proton exposure. [2] While the use of space grade glass prevents parasitic low energy radiation from directly impacting the structure, there is also a loss of device performance in these architectures when exposed to high fluence proton irradiation. This is attributed to the low thermal conductivity of the glass and the generation of excessive local heat in the cover glass that negatively affects the device layers.

Hole Transporter Reinforcement for Deployable Perovskite Solar Cells *Ahmad R. Kirmani; Rochester Institute of Technology, United States*

Perovskite solar cells are now beginning to achieve relevant real-world fielding data; however, long-term durability remains elusive. I will present our latest results on reinforcing the commonly used hole transport layer, PTAA, using a carbazole-based phosphonic acid overlayer, leading to more columnar growth of perovskite grains, a 40 mV V_{OC} enhancement, and improved proton radiation and thermal tolerances. The reinforcement strategy results in the most durable perovskites devices reported to date, with T_{90} exceeding 2,500 h at 65°C under 1.2 AM1.5G illumination (T_{80} >5,000 h). Deployed on a CubeSat, this device maintains T_{80} for the complete mission duration of >95 days in Low Earth Orbit.

4:15 PM *SB13.01.07

Radiation Tolerance and Ion Beam Microscopy of Photovoltaic Materials and Devices *Bibhudutta Rout; University of North Texas, United States*

Energetic ion beams have been used for materials analysis, modifications, and synthesis in various fields involving semiconductors, photovoltaics, and biomaterials. At the University of North Texas, Ion Beam Laboratory, we have several dedicated ion accelerator facilities providing proton and other heavy ion beams of energies from a few tens of kilo electron-volts (keV) to several Mega electron-volts (MeV) enabling targeted irradiation of various layers of the materials and device structures. We also have a novel and powerful scanning ion microprobe (~400 nm probing spot sizes) for elemental concentration, composition, and charge collection efficiency characterization in various stacks of devices. In this presentation, we will highlight our ability to carry out quantitative micro-analysis of a wide range of elements in PV devices and electronic materials utilizing several complementary ion beam analysis techniques. These characterization techniques are relatively non-destructive and require minimal sample preparations providing quantitative information about elemental diffusion due to the aging of the PV devices. A review of some of our works on ion irradiation-induced effects in various photovoltaic materials and devices will be described.

4:45 PM SB13.01.08

Stress Engineering for Mitigating Thermal Cycling Fatigue in Perovskite Photovoltaics *Joseph Luther; National Renewable Energy Laboratory, United States*

Mechanical residual stresses within multilayer thin-film device stacks become problematic during thermal changes because of differing thermal expansion and contraction of the various layers. Thin-film photovoltaic (PV) devices are a prime example where this is a concern during temperature fluctuations that occur over long deployment lifetimes. Here, we show control of the residual stress within halide perovskite thin-film device stacks by the use of an alkyl-ammonium additive. This additive approach reduces the residual stress and strain to near-zero at room temperature and prevents cracking and delamination during intense and rapid thermal cycling. We demonstrate this concept in both n-i-p (regular) and p-i-n (inverted) unencapsulated perovskite solar cells and minimodules with both types of solar cells retaining over 80% of their initial power conversion efficiency (PCE) after 2500 thermal cycles in the temperature range of −40 to 85 °C. The mechanism by which stress engineering mitigates thermal cycling fatigue in these perovskite PVs is discussed.

SESSION SB13.02: Metal-Halide Perovskites for Radiation Detection
Session Chairs: Joseph Luther and Ian Sellers

Advance in Photon Counting Detectors Using Perovskites *Jinsong Huang; University of North Carolina at Chapel Hill, United States*

Detection of ionization photons are increasingly important to construct better medical and other types of imaging devices. Perovskites are known for their strong stopping power to ionization radiation, tolerance (self-healing) to defects, and large mobility-lifetime products. However detection of single photon X-ray using perovskite materials is still challenging due to multiple factors. In this talk, I will present our progress in solving multiple issues in materials, devices, and data collection using perovskite single crystals or polycrystalline films. High energy resolution detectors (<1% for Cs137 source) will be reported.

9:30 AM *SB13.02.02

Stabilize the Interface of Perovskite Electronics for Sensing *Wanyi Nie; University at Buffalo, The State University of New York, United States*

Metal halide perovskite semiconductors are emerging low-cost materials for photovoltaics, light emitting devices and detectors. Because of the inclusion of high atomic numbered elements, perovskites are demonstrated for high efficiency X-ray sensing surpassing the performance of the detectors made with classical semiconductors. However, among all these applications, the operational stability has been a major challenge. One key cause is the interface degradation between the perovskite material and the electrode. In this talk, I will discuss two alternative interface materials to stabilize the perovskite detectors' performances. Firstly, we investigate graphene as an electrode for perovskite X-ray detector. We found that building perovskite on monolayer graphene form a charge injection interface that exhibited high sensitivities. Interestingly, The full device can be recycled by removing perovskite with solution method, and the graphene layer is fully recovered for the next fabrication. Secondly, we employed GaN as an n-type electrode for perovskite diode. It can efficiently collect the generated electron from the perovskite absorbing layer. And the GaN is a chemically robust interface for perovskite, device made over GaN remained stable over 200 cycles of X-ray irradiation without sign of degradation. In summary, finding robust electrode and interface material is the key to stabilize the perovskite devices.

10:00 AM BREAK

10:30 AM *SB13.02.03

Towards Extremely Low-Dose Photon Counting Perovskite X-Ray Detectors *Samuel D. Stranks; University of Cambridge, United Kingdom*

Halide perovskites are generating enormous excitement for optoelectronic applications. Over recent years, they have been demonstrated to be excellent candidates for direct detectors of X-ray and other high-energy radiation, with hints of photon counting ability. This demonstrates their promise for low-dose medical imaging with low cost detectors, which could revolutionise CT scanning.

Here, I will give an overview of our recent work towards photon counting detectors based on halide perovskites. I will discuss the importance of passivation and interface control, as well as the quality of the single crystal. 2-photon optical imaging allows us to identify buried defects in crystals that otherwise lead to enhanced dark currents, leading to a requirement for extremely high quality crystals. The mode of operation also strongly effects the performance and stability of the device. By combining high quality crystal growth and interface control, we demonstrate photon counting from single pixel devices, and operation from multi-pixel arrays. This work shows promise for future detectors for medical imaging and other applications.

11:00 AM *SB13.02.04

Fundamental and Applied Aspects of Lead Halide Perovskite Nanocrystals in Future Scintillator Technology *Sergio Brovelli; University of Milano-Bicocca, Italy*

The utilization of scintillators for detecting ionizing radiation is pivotal across various domains, such as medicine, nuclear monitoring, homeland security, and space exploration. Lead halide perovskite nanocrystals (LHP-NCs) embedded within plastic matrices have surfaced as promising scintillator materials, addressing the limitations of traditional scintillators like inorganic crystals and plastic scintillators while enhancing their strengths. Specifically, LHP-NCs as nanoscintillators in polymer waveguides offer scalable solutions and potentially superior scintillation performance. This enhancement stems from the unique photophysics of quantum-confined materials, providing *size-tunable emission spectra that align with the spectral sensitivity of light detectors and ultrafast sub-nanosecond scintillation kinetics due to the recombination of multi-excitons generated by ionizing radiation. Recent findings on the radiation hardness of lead halide perovskites underscore their suitability for use in harsh environments, further boosting their appeal for applications where traditional materials may fail. However, substantial challenges persist, starting from properly understanding the very mechanism of scintillation in nanoscale materials, rationally design and realize LHP NCs for scintillation possibly via cost-effective scalable routes as well as embedding LHP-NCs in optical-grade nanocomposites without compromising their optical properties. This talk will present our latest advancements in the fundamental and applied aspects of scintillation based on LHP-NCs. We will explore the basics of the process and several methods for effective integration into plastic waveguides, including nanocrystal functionalization strategies, defect passivation, and advanced polymerization techniques.*

SESSION SB13.03: Radiation-Induced Defect Generation, Manipulation and Healing in Electronic Materials
Session Chairs: Ahmad Kirmani and Wanyi Nie
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 308

1:30 PM *SB13.03.01
Defect-Mediated Degradation of Microelectronics in Radiation Environments *Sokrates T. Pantelides, Haardik Pandey, Grant M. Mayberry, Dennis R. Ball, Daniel M. Fleetwood and Ronald D. Schrimpf; Vanderbilt University, United States*

X-rays, gamma rays, and beams of energetic charged particles (electrons, protons, and heavy ions) can cause microelectronic devices to degrade or fail in space and terrestrial environments. All these forms of radiation generate electron-hole pairs, whose total accumulation in a device, known as total ionizing dose (TID), cause gradual alteration of device parameters such as threshold voltage and transconductance in metal-oxide-semiconductor field-effect transistors (MOSFETs) and high-electron-mobility transistors (HEMTs). In lab experiments, X-rays are often used, which do not carry sufficient momentum to displace atoms. Parametric changes are caused by the trapping of holes at pre-existing defects or by the activation of pre-existing hydrogen-passivated defects at the insulator/semiconductor interface via hole-mediated hydrogen release, hydrogen transport, and reaction processes. Measured threshold voltage shifts, transconductance degradation, and low-frequency 1/f noise, combined with density-functional-theory (DFT)-based quantum calculations have provided extensive understanding of these defect-mediated processes in Si-based MOSFETs, GaN-based HEMTs, and in devices based on graphene and other 2D materials that may lead to flexible electronics.

Energetic charged particles with sufficient energy and momentum may also cause displacement damage. In particular, single heavy ions striking a device can cause degradation or instant failure. Examples of destructive single-event (SE) effects are SE gate rupture and SE burnout. In both cases, the device failure is attributed to the generation of large concentrations of electron-hole pairs and the concomitant formation of a highly conducting "electron-plasma wire" along the path of an ion strike in a region of high electric field. In power devices, degradation or failure is aided by the stored energy due to the high voltage and Joule heating due to the large current pulse. A role for lattice defects generated by the energetic ions (displacement damage) is not usually invoked to channel or enable this plasma wire, but experiments show that defects generated by the ion strike can sometimes play important roles in device degradation and/or failure. We have pursued extensive DFT calculations *that enable us to make the case for the formation of a "vacancy nanowire" along the single ion-strike path that channels a persisting current (degradation) and ultimately a catastrophic current or exploding void growth (failure). Among prominent candidate materials for power devices, we find that the energetics of these processes make SiC the most resistant and b-Ga_2O_3 the least resistant to such degradation, while GaN and AlN are intermediate cases.*

2:00 PM *SB13.03.02

Degradation and Self-Healing of Halide Perovskites Under X-Ray Irradiation *Stefania Cacovich; Centre National de la Recherche Scientifique, France*

Halide perovskites have emerged as a highly promising class of materials across various optoelectronic applications, encompassing solar cell technology, light-emitting diodes (LEDs), lasers, and X-ray detection. However, the advancement of perovskite X-ray detector technology remains in its early stages, necessitating further research to comprehensively elucidate the properties of these materials and their responses to external stimuli. Furthermore, given the prevalent utilization of X-rays in fundamental chemical surface analysis techniques like X-ray photoelectron spectroscopy (XPS), a thorough understanding of the effects of X-ray exposure on halide perovskites is imperative for the accurate interpretation of surface characterizations via XPS and related methodologies. This imperative is accentuated in the context of operando experiments, wherein materials endure prolonged exposure to high doses of X-rays.

We propose a comprehensive, multi-scale, and multi-technique approach by integrating X-ray photoelectron spectroscopy with steady-state photoluminescence imaging to investigate the detrimental effects and subsequent self-healing of Formamidinium Lead Bromide ($FAPbBr_3$) under ion bombardment and X-ray irradiation[1]. We observed that short and low flux irradiation with synchrotron light causes local decomposition of $FAPbBr_3$ into $PbBr_2$. Concomitantly, metallic lead clusters are created in the decomposed sites by further decomposition of $PbBr_2$, causing pinning of the Fermi level close to the conduction band. Conversely, prolonged exposure to higher-flux irradiation triggers local self-healing mechanims, which aid in restoring optoelectronic properties. Ion migration is key to "heal" the surface as the lost Br atoms on the surface are replenished by Br atoms coming from the underlying material.

Subsequently, our investigation extends to triple-cation double-halide $Cs_{0.05}(MA_{0.14}, FA_{0.86})_{0.95} Pb(I_{0.84}, Br_{0.16})_3$ perovskite thin films, employing a comparable experimental framework[2]. Employing an array of optical imaging techniques, including spectrally and temporally resolved methodologies such as hyperspectral imaging and time-resolved fluorescence imaging (TR-FLIM), in combination with surface chemistry analysis via XPS, we delineate two principal degradation pathways within the perovskite layer. At lower X-ray fluences, we observe minor alterations in surface chemistry composition alongside the emergence of electronic defects. A second degradation pathway, occurring at higher fluence, involves the evaporation of organic cations and results in the formation of an iodine-deficient perovskite, which exhibits a faster carrier decay time. Leveraging insights derived from localized variations in optoelectronic properties, we propose a kinetic model elucidating the underlying mechanisms governing these degradation phenomena.

Defect Control with the Electron Wind Force *Md Hafijur Rahman, Nahid Sultan Al-Mamun, Luke Warner, Sarah Todaro, Daudi Waryoba and Aman Haque; The Pennsylvania State University, United States*

The flow of current generates Joule heating as electrons are scattered by the lattice or ordered atoms. However, when they are scattered by defects, such as grain boundaries, they transfer all their momentum to the defects. This momentum transfer gives rise to the so-called electron wind force (EWF), which is purely mechanical in nature. The well-known damage phenomenon of electromigration results from the combined influences of EWF and Joule heating. However, this study focuses on exploiting the EWF constructively. We hypothesize that if we can suppress the temperature rise, the EWF can impart significant mobility to defects and anneal them in a very short amount of time. This is because temperature-driven diffusion is mostly random, whereas EWF-driven diffusion follows the direction of electron flow, exhibiting convection-diffusion behavior.

We performed experiments on a diverse set of materials to investigate our hypothesis. The first set involved atomic layer deposited tin disulfide and tin oxide in thin film and electronic device forms. The EWF was observed to cause a remarkable increase in current-voltage characteristics. Since the slope of this curve represents defect density (via electrical resistance), the results indicate appreciable annealing at room temperature in less than a minute. Similar results achieved via thermal annealing require several hours at 350°C. The second set involved metals and alloys. We present evidence of unique grain reconfiguration through controllable rotation, which is not possible with conventional heat treatment. At room temperature, we observed up to 18 degrees of grain rotation, which could be reversed by varying the current flow direction. The ability to control Joule heating provides a unique tool to manipulate microstructure: at low temperatures, we can induce grain refinement while maintaining low-angle grain boundary (LAGB) density, and at moderate temperatures, we can increase grain size and eliminate LAGBs.

The findings of this study highlight the potential of 'convective diffusion' of defects that are specifically targeted by electrical current-based materials processing for microstructural control at room temperature.

3:30 PM *SB13.03.04
Radiation Effects in Quantum Well Enhanced Solar Cells *Seth Hubbard; Rochester Institute of Technology, United States*

The space III-V photovoltaic industry relies on multijunction solar cell technology meeting high-efficiency, low weight, and radiation tolerance metrics. Incorporation of nanostructures in the current- limiting subcell of the III-V multijunction solar cells has been shown to be an efficient way to achieve current matching between the subcells. Adding QWs to the intrinsic region of the limiting GaAs subcell of a standard triple junction InGaP/GaAs/Ge solar cell, on the one hand, enables absorption of the sub- band edge photons, effectively lowering the bandgap of the middle cell, and at the same time can allow for efficient carrier extraction. In this talk, I will demonstrate development of both single-junction GaAs and tandem InGaP/GaAs solar cells incorporating InxGa1-xAs strain balanced quantum wells. Up to 50 layers of strain balanced QWs have been added to a single junction device with minimal degradation in Voc and monotonic increase in Jsc. A distributed Bragg reflector (DBR) was added below the structure centered at the collection energy of the QWs to increase the optical path length of the QW region and further *increase subgap current collection. Finally, these components were assembled into dual-junction device comprised of an InGaP homojunction and InGaP/GaAs heterojunction optimized with and without the incorporation of 50x QWs and a DBR for AM0 and AM1.5G spectra. These developments have resulted in radiation tolerant 2-junction solar cells incorporating QWs, with a 27.5% AM0 (>30% AM1.5G) efficiency, representing a 2.5% absolute efficiency increase over a control 2-jucntion solar cell without QWs. Radiation testing has shown over 92% of remaining factor in short-circuit current at an end-of-life condition near 1×1015 e-/cm2. Impact of device design and background doping on the open-circuit voltage remaining factor will be discussed in detail.*

4:00 PM *SB13.03.05

Coupled Effects of Electronic and Nuclear Energy Loss on Radiation Response of Oxide Perovskites *William J. Weber; The University of Tennessee, Knoxville, United States*

Oxide perovskites (ABO$_3$) exhibit fascinating properties that identify them as key materials for the next generation of multifunctional devices, and their response to electron and ion beam irradiation can provide insights into the behavior expected in hybrid perovskites. It is well-established that atomic-level defects are created by elastic energy transfer (nuclear energy loss), S_n, from charged particles to atomic nuclei; however, the effects of inelastic electronic energy loss, S_e, to target electrons are more complicated. At low to medium energies, the response of many oxide perovskites to charged particles is dependent on the ratio of S_e/S_n. At low values of S_e/S_n, radiation damage by elastic collision processes dominates, often leading to phase transformations, such as amorphization. When S_e is comparable to S_n, the coupling of electronic and nuclear processes along the ion trajectory can lead to ionization-induced dynamic recovery, reducing the rate of damage production and accumulation. For high-energy ions with high values of S_e/S_n (>100), the dissipation of electronic energy loss via electron-phonon coupling dominates, and amorphous nanotracks due to melt-quenching along the ion trajectory can form for S_e values above a threshold. In the presence of pre-existing defects, amorphous tracks are formed at much lower values of S_e, and track sizes increase with defect concentration and values of S_e. For charged particles with high S_e/S_n values (>100), but with S_e values below the threshold for amorphous track formation, ionization-induced annealing of defects is observed. Experimental data on SrTiO$_3$, KTaO$_3$ and LiTaO$_3$ will be presented to demonstrate these phenomena. Molecular dynamics simulations combined with the inelastic thermal spike model in these materials confirm the formation of the amorphous tracks due to melt-quenching along the ion trajectory at high values of S_e, while at intermediate values of S_e, defect recovery is demonstrated. Two distinct regimes of ionization-induced recovery are observed in SrTiO$_3$, and only a single recovery regime is observed in KTaO$_3$.

4:30 PM SB13.03.06

A & X Ions Govern APbX$_3$ Halide Perovskite Self-Healing in Crystals & Films *David Cahen, Gary Hodes, Dan Oron and Pallavi Singh; Weizmann Institute of Science, Israel*

Self-healing (SH) materials can become game changers in developing sustainable “stuff”, especially in (opto)electronics. In terms of sustainable use, APbX$_3$ Halide (=X) Perovskite (HaP) semiconductors have a strong advantage over most others, as they can self-heal (SH) damage. We show SH, using "fluorescence recovery after photobleaching" (FRAP), also in (encapsulated) polycrystalline films, as used in most devices. There, SH from photodamage is faster for γ-CsPbI$_3$ and α-FAPbI$_3$ than for MAPbI$_3$ and substituting ≧15 at.% MA$^+$ with guanidinium (Gua$^+$) or acetamidinium (AA$^+$) enhances SH. However, substituting dimethyl ammonium (DMA$^+$), about the size of Gua$^+$ and AA$^+$, for MA$^+$ does not change the SH rate. Thus, while the A cation is considered electronically relatively inactive, it affects both SH kinetics (and photodamage thresholds). Based on the time scale of SH, we infer that the rate-determining step of SH involves short-range diffusion of A$^+$ and/or Pb^{2+} cations, complementing earlier findings, and implicating halides (X$^-$) in SH. The SH rate correlates with the material’s strain, the A$^+$ dipole moment, *and $A^+ \cdots I^-$ hydrogen bonding, offering clues to the roles of ion, electron, and energy migration in the SH mechanism, which will help guide the design of SH materials.*

4:45 PM SB13.03.07

Simulating Proton Radiation Effects in Indium Oxide Using Cascade Molecular Dynamics Simulations *Sogol Karami[1], Buh Kum Tatchen[2], Ahmad Kirmani[2] and Niaz Abdolrahim[1,1]; [1]University of Rochester, United States; [2]Rochester Institute of Technology, United States*

Metal oxide (MO) materials, such as Indium Oxide (In_2O_3), are transparent semiconductors with significant potential in catalysis, energy storage, and optoelectronics. In this study, we employed molecular dynamics (MD) simulations to study the effect of ion beam modification on the electrical, structural, and mechanical properties of In_2O_3 under dual-dose irradiation conditions. A custom potential was tabulated by combining the Ziegler-Biersack-Littmark (ZBL) potential for short-range atomic interactions with Buckingham and Coulombic potentials for long-range forces, to enable accurate atomic-scale simulations in a high-energy irradiation environment. The dual-dose irradiation was then simulated by applying two-step Primary Knock-on Atom (PKA) cascade irradiation simulations. First, low-energy irradiation was applied to create displacements and primary defects in the system, followed by a second high-energy simulation, mimicking the experimental energy inputs. Experiments have shown improvement in electrical properties, i.e., conductivity, potentially due to recovery of defects. Our MD simulations revealed the mechanisms behind defect recovery, specifically by tracking the evolution of oxygen vacancies which plays a key role in increasing the concentration of charge carriers and enhancing electrical conductivity. This work provides fundamental insights into the defect dynamics of ion beam modification of MO materials and offers potential pathways to improve the mechanical and electrical properties of such materials, particularly in radiation-intensive environments.

Facile Spinning of Tough and Conductive Eutectogel Fibers via Li^+-Induced Dense Hydrogen-Bond Networks
Lingtao Fang and Qiyao Huang; The Hong Kong Polytechnic University, Hong Kong

Tough conductive eutectogel fibers synthesized based on deep eutectic solvents (DESs) have attracted increasing attention in fields of flexible/stretchable electronics, due to their promising thermal stability, stretchability, mechanical strength, conductivity, and relatively inexpensive cost. However, it is still challenging to fabricate such high-performance eutectogel fibers in a simple and versatile strategy. Here, we report a facile spinning of tough conductive eutectogel fibers based on one-pot photopolymerization and Li^+-induced toughening effect. This photopolymerization allows the formation of eutectogel into a long fiber format within seconds. The introduction of Li salt into the DESs can regulate the hydrogen bonding interactions, which can significantly promote the *construction of a dense interchain hydrogen-bonding network in the eutectogel. Consequently, the spun eutectogel fibers exhibit outstanding Young's modulus (103.8 MPa), high toughness (38 MJ/m^3), promising stretchability (>300 %), conductivity (6×10^{-3} S/m), and good thermal stability at high temperature. The mechanical properties of the resultant eutectogel fibers can also be modulated by varying the DESs constituents. We demonstrate the multifunction of the fibers in shape-memory behavior, strain sensing at high temperatures, and recyclability. This facile spinning strategy offers a promising way to develop super-strong and conductive gel fibers as smart materials for diverse flexible and wearable device applications.*

SB13.04.02

Pressure-Sensitive Adhesive Materials Under Human-Centric Extreme Environments *Jisoo Jeon[1], Jinyoung Kim[1], Sehyun Park[1], Gwendolyn Bryan[2,3], Timothy J. Broderick[2], Morley Stone[2] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Florida Institute for Human and Machine Cognition, United States; [3]University of South Florida, United States*

Maintaining the adhesion strength of flexible pressure-sensitive adhesives (PSAs) is crucial for advanced applications such as health monitoring with mounting wearable sensor devices especially under challenging surroundings. However, these polymer adhesives must also perform in harsh conditions. Herein, we consider adhesive, mechanical, and optical properties of common medical-grade double-sided PSAs by simulating extreme human-centric environments. Diverse temperature conditions, water and humidity exposure, and cyclical loads were selected and tested such as very low and high temperatures (e.g., polar regions or deserts), underwater and sweat environments (intense physical activity), and cyclical shear complex stresses. Additionally, we demonstrated that variable adhesive performance and optical transparency of pressure-sensitive materials can be directly related to changes in their morphologies, surface roughness, swelling state, and alternation of the mechanical contact area helping to establish the broader rules of design for wearable human health monitoring sensors for long-term mounting and protection of wearable devices, sensors, and electrodes.

SB13.04.03

Small Molecules Transport Across Grafted Polymer Layers and Its Role for Contamination and Decontamination of Surfaces *Laura J. Frink[1], Frank van Swol[1], Arianna Serrano[1], Anthony Malanoski[2] and Dimiter Petsev[1]; [1]The University of New Mexico, United States; [2]U.S. Naval Research Laboratory, United States*

The transport of small molecules across grated polymer layers presents interesting fundamental challenges and is of great practical importance. Such layers can be designed to protect surfaces against various chemical and biological contaminants. The diffusion of low molecular species towards the surface is identified as contamination, while the diffusion away from the surface corresponds to decontamination.

We offer a theoretical analysis of the contamination and decontamination process using classical Density Functional Theory (cDFT) in combination with a Smoluchowski type of equation describing the diffusion in an external field. The cDFT approach is based on defining a grand thermodynamic potential for an open system, which is then minimized by solving the resulting Euler-Lagrange equation. The output of the computation are the density profiles of all species (polymer segments, solvent, and solute). These profiles are used to calculate the potential of mean force (PMF) that a contaminant molecule is subjected to in a grafted polymer layer. The PMF is then introduced into the transport Smoluchowski equation as an external field, which is then solved to obtain the density profiles in time and space. Hence, we can assess both the structure and the transport dynamics in the grafted layers.

Grafted polymer layers in contact with solution present a rather complex system because the overall structure, *and consequently the transport, depend on the sizes and specific interactions between all participants. Even the simplest example includes a substrate, polymer chains, solvent and a contaminant species. Hence, the resulting parameter field is 18-dimensional, which is presents an overwhelming explorative task from an experimental perspective. We offer reduction of the space by designing suitable variables that combine the various interaction energies, similarly to the Flory energy parameter. Next, we explore the contaminant transport in the two limiting cases of dry (solvent free) and swollen polymer layers. The analysis provides useful guidelines for the experimentalists and offer prediction for the protective quality of polymer layers that follow from the molecular interactions.*

SB13.04.04

Effect of Hydrated Structure of Zwitterionic Polymer Network on Ice and Frost Formation from the Chilled Surfaces

Joonbum Lee, Eunji Lee and Jihun Seo; Korea University, Korea (the Republic of)

Frost refers to an ice layer formed by the condensation of water vapor from air on a chilled surface. Frosting occurs at temperatures below the dew point, which causes water vapor to solidify onto chilled surfaces. After the initial formation of the ice phase, the adjacent water vapor is sufficiently saturated and cooled owing to the reduction in temperature below the dew point. Consequently, water vapor directly undergoes desublimation to form frost on chilled ice or material surfaces, contributing to the growth of frost in the atmosphere. Therefore, unlike ice, whose entire structure features densely packed crystallized water molecules, frost exhibits a porous dendritic configuration of ice crystals and air spaces. However, the porous frost layer on the surfaces of chilled materials diminishes their thermal conductivity, thereby deteriorating the energy efficiency of infrastructural facilities. For example, in transportation vehicles, such as airplanes, ships, and automobiles, the surface-frost-induced increase in air resistance or body weight can reduce fuel efficiency. Moreover, the heat exchangers typically used in heating, ventilation, and air conditioning (HVAC) systems can experience reduced heat-transfer and fluid-flow rates owing to frost on their surfaces, leading to a significant decrease in energy efficiency. Therefore, anti-icing/frosting technologies have been actively researched in recent years, with emphasis on achieving sustainability.
Various surface treatment technologies have been developed, such as superhydrophobic surface to repel water droplets or hydrophilic polymer surface as a slippery surface for ice, to design anti-icing/frosting materials; however, few have been able to fully satisfy the fundamental requirements of an ideal anti-icing/frosting material. Recently, hydrogel materials have opened up new possibilities in the industrially important field of anti-icing/frosting material design because they exert anti-icing/frosting effects via intermolecular interactions between water and the material (that is, hydration). Therefore, comprehensive explorations of these intermolecular interactions are imperative to fully understanding and harnessing the potential of hydrogels as anti-icing/frosting materials. However, theoretical and fundamental approaches for inducing and tweaking the anti-icing/frosting effects based on the hydration states have rarely been reported. Therefore, the present study was aimed at elucidating the manner in which the state of water of hydration within the hydrogels affected their anti-icing/frosting properties. To that end, hydrogels comprising four different hydrophilic polymers showing different electrically charged nature, i.e. cationic, anionic, neutral, and zwitterionic, were prepared, and their hydration states and anti-icing/frosting performances were investigated. The results showed that the zwitterionic hydrogel exhibited a significantly low freezing temperature (−33 °C) and the highest activation energies for ice formation within the hydrogels and frost growth on the surfaces (9.44 and 4.32 kJ/mol, respectively). Furthermore, they demonstrate that the thermodynamic analysis of hydrogel materials based on an understanding of hydration states can aid significantly in addressing icing/frosting-related problems.

SB13.04.05

Transmission Electron Microscopy Simulation of Van Allen Belt Electrons for Hardening Electronic Polymers

Robert Waelder[1,2], Cheri Hampton[1,2], Vigneshwar Dhavamani[3], Parag Deotare[3] and Lawrence Drummy[2]; [1]UES, Inc,

United States; [2]Air Force Research Laboratory, United States; [3]University of Michigan–Ann Arbor, United States

Polymeric materials properties relative to their mass make them ideally suited for space applications, where reduced weight pays dividends in cost and service life, since less fuel is needed to maneuver the object. Materials in space are subject to myriad environmental hazards not present on Earth. Among these hazards are the Van Allen belts, which surround the planet in two bands of energetic charged particles, primarily electrons and protons, which affect all object beyond low Earth orbit, and extend beyond geostationary orbit. The electrons trapped in these belts range in energies from 10s to 100s of keV, and approach energies as high as 10 MeV in the outer belt. These energies can be achieved on the ground in dedicated electron chambers as well as in variable energy transmission electron microscopes (TEMs), enabling characterization of the response of polymeric materials to ionizing radiation. In particular, structural changes as a function of electron dose can be tracked in TEM by quantifying changes in mass loss, electron energy loss spectroscopy, and diffraction intensity in a series of scans at increasing dose. This procedure has enabled us to determine the critical dose of several semiconducting organic materials, and explore methods of hardening by incorporating low-dimensional materials such as graphene. In the case of graphene interfaced directly with a semiconducting polymer, PBTTT, we observed an orientation-based effect, indicating that the graphene was able to mitigate charge buildup due to secondary damage processes, suggesting an increase in polymer stability is possible using this approach. Raman and photoluminescence as a function of radiation dose also demonstates changes to the polymer chemistry resulting from damage. Additionally, high spatial and time resolution HREM images were captured from pentacene and copper pthalocyanine demonstrating defect-mediated response to ionizing radiation damage. We have shown this method can be used to determine mechanisms of improving the electron radiation hardness of polymeric materials as well as determine the specific structural features that change leading up to failure.

SB13.04.06
High Deformability and High Thermal Conductivity Film Using Polymer Nanosheets and Liquid Metal

Daisuke Kuse[1], Tamami Takano[1], Yutaka Isoda[1], Tatsuhiro Horii[2], Ryohei Fujita[3], Toshinori Fujie[2], Housei Nagano[3] and Hiroki Ota[1]; [1]Yokohama National University, Japan; [2]Tokyo Institute of Technology, Japan; [3]Nagoya University, Japan

The development of highly deformable electronic devices is advancing rapidly, and thermal management within these devices become a significant challenge. Traditional thermal dissipation materials, such as copper or graphite sheets, are rigid and incompatible with flexible device architectures. Alternative materials, like stretchable polymers, offer poor thermal conductivity, thereby limiting their heat dissipation capacity. Attempts to enhance polymer performance by incorporating rigid materials, such as metals or graphene, generally result in compromised deformability despite improved thermal conductivity.

Gallium-based liquid metals, including GaInSn and EGaIn, represent a novel class of thermal management materials that combine high thermal conductivity with excellent deformability and biocompatibility. However, their corrosive nature towards some metals poses additional challenges. To address this, there is a need for heat-dissipating materials that simultaneously offer high thermal conductivity, deformability, electrical insulation, and corrosion resistance. One approach involves the development of composite materials by embedding liquid metal in polymer matrices. Nevertheless, this technique significantly reduces thermal conductivity, achieving less than one-third that of the pure liquid metal due to the high polymer content.

In this study, we developed a heat-dissipating material that encapsulates liquid metal within a nanoscale polymer film, enhancing both thermal conductivity and material deformability. This encapsulation prevents corrosion and maintains high deformability and insulation. The thickness of the liquid metal layer is 200 μm, surrounded by a polymer film with a thickness of less than 500 nm. The thermal conductivity of the resulting heat transfer sheet in the in-plane direction is 28.6 W/mK, approximately six times higher than that of conventional materials.

To demonstrate its effectiveness, the heat-dissipating sheet was integrated into a stretchable electronic device, *positioned between an LED and a stretchable substrate. The device's thermal performance was evaluated by powering the LEDs under mechanical deformation. It was observed that the temperature of the LEDs with the heat-dissipating sheet was approximately 20°C lower compared to the control setup without the sheet. This finding underscores the capability of the liquid metal sheet to enhance thermal diffusion under both static and dynamic conditions.*

SB13.04.07

Understanding Process-Property-Structure for Elastoplastic Behaviour of Polymer Nanocomposites with Agglomeration Anomalies and Interfacial Property Gradients *Prajakta V. Prabhune[1,2], Anlan Chen[1], Yigitcan Comlek[3,4], Wei Chen[3] and Catherine Brinson[1]; [1]Duke University, United States; [2]Los Alamos National Laboratory, United States; [3]Northwestern University, United States; [4]GE Global Research, United States*

Polymer nanocomposites are inherently tailorable materials and capable of providing higher strength to weight ratio than traditional hard metals. However, their disordered microstructural nature makes processing control and hence tailoring properties to desired values a challenge. Additionally, interfacial region, also called interphase, is a key material phase in these heterogeneous materials and its extent depends on variety of microstructural features like dispersion.
Understanding process-structure-property (PSP) relation can provide guidelines for process and constituents' design. Our work explores nuances of PSP relation for polymer nanocomposites with attractive pairing between particles and polymer bulk. Past works have shown that particle functionalization can help tweak these interactions in attractive or repulsive directions and can produce slow or fast decay of stiffness properties in polymer nanocomposites. In absence of any nano or micro-scale local property measurement, we develop a material model that can represent decay for small strain elastoplastic(Young's modulus and yield strength) properties in interfacial regions and simulate representative or statistical volume element behavior. The interfacial elastoplastic material model is devised by combining local stiffness and glass transition measurements that were obtained by previous researchers by atomic force microscopy and fluorescence microscopy.
This is further combined with a microstructural design of experiments for agglomerated nanocomposite systems. Agglomerations are particle aggregations that are processing artefacts that result from lack of processing control. Twin screw extrusion process can reduce extent of aggregation in hot pressed samples via erosion or rupture depending on screw rpms and toque. We connect this process-structure relation to structure-property relation that emerges from our study. We discover that balancing between local stress concentration zones(SCZ) and interfacial property decay governs how fast yield stress can improve if we break down agglomeration via erosion. Rupture is relatively less effective in helping improve nanocomposite yield strength. We also observe an inflexion point where incremental increase brought on by rupture is slowed down due to increasing SCZ vs saturated interfacial fortification.

SB13.04.08

Donor Defect Mobilization in Transparent Oxides Via High Energy Proton Irradiation—Implications for Space Applications *Buh Kum Tatchen[1], Sogol Karami[2], Mohin Sharma[3], Mritunjaya Parashar[3], Bibhudutta Rout[3], Niaz Abdolrahim[2] and Ahmad R. Kirmani[1,1]; [1]Rochester Institute of Technology, United States; [2]University of Rochester, United States; [3]University of North Texas, United States*

Tin-doped indium oxide (ITO) is a versatile transparent conductive material widely used in electronics, photonics, and optoelectronics, necessitating a comprehensive understanding of its behavior under extreme environments. Here we study proton radiation effects in ITO and reveal the subtle interplay between displacement defect formation and electronic ionization upon irradiation. Guided by Monte Carlo simulations, we irradiate 100 nm thick ITO films with 20 keV and 1 MeV protons that fully penetrate the films mimicking polyenergetic and omnidirectional *radiation in space orbits. We find that while both proton energies activate donor defects via atomic displacements, electronic ionization associated with 1 MeV protons further mobilizes these defects resulting in a ~7% improvement in electronic conductivity at 10^{14} cm^{-2} fluence. X-ray diffraction experiments suggest a ~15% increase in nanocrystalline size, while reflectance enhancement observed at 600 – 800 nm points toward an increased free-carrier concentration. The interaction is simulated via a cascade irradiation molecular dynamics model explaining the role inelastic thermal spikes play in activating displacement defects. Our findings have implications for space applications of transparent oxides and suggest that electronic ionization can improve these materials.*

SB13.04.09

Electrospun Silica Nanofibers as Passive Thermal Control Materials for the Extreme Environment of Low Earth Orbit *Chieloka D. Ibekwe[1], Xuanjie Wang[1], Adam Swanger[2], Jason Hartwig[3] and Shankar Narayan[1]; [1]Rensselaer Polytechnic Institute, United States; [2]NASA Kennedy Space Center, United States; [3]NASA Glenn Research Center, United States*

Effective thermal management is crucial for maintaining spacecraft and onboard systems at optimal temperatures, ensuring their longevity in space missions. Passive thermal management is particularly promising due to its lower power consumption compared to active systems. This study focuses on developing materials with low solar absorptance and large thermal emittance to facilitate self-cooling under the harsh thermal conditions of space. We employ electrospinning, a nano/micro-manufacturing technique, to create a lightweight, fibrous thermal control material from silica (SiO2). Using scanning electron microscopy (SEM), we examine the nanoporous structure of the electrospun material. Its optical properties, including reflectance, transmittance, and absorptance across ultraviolet, visible, and infrared wavelengths, are assessed using spectrometers interfaced with integrating spheres. To test durability in space, we conduct high-temperature endurance, atomic oxygen and ultraviolet resistance tests to observe changes in optical properties of the materials and evaluate their performance in low Earth orbit (LEO). Calorimetric tests performed at NASA's Kennedy Space Center on the material in a deep space environment simulator at cryogenic temperatures and using a solar simulator which closely matches the sun's radiation, reveals the material's thermal performance as a passive thermal control material.
We also compare the material's solar reflectance and thermal emittance to existing spacecraft materials. The findings suggest that electrospun silica nanofibers presents a new paradigm for passive thermal control in space applications.

SESSION SB13.05: Mechanical and Thermal Effects in Next-Generation Materials for Extremes

Addressing Mechanical Instabilities in Metal Halide Perovskites *Adam Printz, Anton Samoylov, Patrick Lohr, Matthew Dailey, Sean Raglow and Yanan Li; The University of Arizona, United States*

Metal halide perovskites ("perovskites") are promising materials for next-generation optoelectronic applications, but chemical and mechanical instabilities remain barriers to widespread usage. Recent efforts in my research group have focused on understanding and addressing these instabilities through multiple complementary *pathways. First, I will discuss the use of extrinsic approaches to improving the mechanical stability of perovskite thin films. I will highlight the strategy developed by my group to nanocomposite the perovskite layer with polymeric nanofibers, which can increase the cohesive fracture energy by at least 5-fold with minimal reduction in device performance. I will also discuss our recent observation from multibeam optical stress sensor (MOSS) measurements that inelastic deformation occurs in metal halide perovskites during thermal cycling. Importantly, stress hysteresis during thermal cycling occurs, which is correlated with film quality degradation. This stress hysteresis can be mitigated with the inclusion of additives which improves film stability to thermal cycling, but the overall film stress increases. This observation suggests that minimization of the stress hysteresis—not the magnitude of the residual stress—may be the most appropriate target for enhancing perovskite film stability to thermal cycling.*

9:00 AM SB13.05.02
High-Rate Fracture Dynamics of Polymer Glasses through Laser Ablation *Jonathan Raybin, Katherine Evans and Edwin Chan; National Institute of Standards and Technology, United States*

Understanding the failure mechanisms of polymer materials under extreme conditions is crucial for applications ranging from impact mitigation to advanced manufacturing. However, the fracture behavior of glassy polymers is highly rate-dependent, and traditional quasistatic testing does not necessarily translate to the high-strain-rate conditions (10^6 to 10^{10} s^{-1}) most relevant to ballistic impact events. In this work, we apply pulsed laser ablation to investigate the high-rate fracture of glassy poly(methyl-methacrylate) (PMMA) membranes. Laser ablation of the gold substrate generates inertial stress waves at the impact site that propagate through the PMMA film, resulting in the formation of a characteristic pattern of radial and circular cracks. Within the deformation zone, these cracks develop to accommodate the rapid membrane expansion and serve as a record of the internal stress state. With increasing strain rate, we observe a ductile-to-brittle transition signified by an abrupt decrease in film fracture toughness, a significant reduction in the number of radial cracks, and the ejection of fragmented material. We find that the transition point strongly depends on the molecular mass, indicating the importance of chain entanglements in determining the polymer response rate and mechanism. This measurement approach offers a new platform for characterizing the fracture mechanics of polymers at high-strain rates, aiding in the design of polymer materials for various impact-related applications.

9:15 AM SB13.05.03
An Experimental Technique for Probing Cavitation Pressure in Soft Matter Under Azimuthal Shear *Alexandria Trevino, Yuan Ji, Vladimir Coon, Christopher Karber and Justin Wilkerson; Texas A&M University, United States*

Many biological tissues experience a variety of complex, quasi-static and dynamic loading conditions that lead to diverse material deformation and failure modes. The highly tailorable, biomimetic properties of gels make them favorable materials for systematically probing the mechanical behavior of biological tissue. Cavitation is one common tissue failure phenomena that can be reproduced in a laboratory setting using gels. Cavitation in gels, however, has only been investigated under hydrostatic loading conditions, largely due to limited experimental capabilities. This lack of data under multi-stress states significantly restricts the development and validation of generalized cavitation theories. Yet, such theories could provide deeper insights into the primary damage mechanisms behind key physical injuries, such as traumatic brain injury (TBI). Previous studies have even suggested that the physics governing gel cavitation could be leveraged for targeted medical treatments. This study introduces a superimposed shear cavitation (SSC) apparatus that enables an examination of the role shear stress plays in cavity nucleation, expansion, and collapse. The SSC test expands on the established needle-induced cavitation (NIC) experiment by using a Taylor-Couette cell instead of a beaker to contain the sample. Gel samples can be subjected to torsional loading prior to the insertion of a hollow needle. The needled is then pressurized to *generate and grow a cavity until a critical pressure (P_c) is reached, beyond which cavity expansion becomes unstable. This pressure can be used to estimate material mechanical properties. To demonstrate its capability, the SSC apparatus was used to determine P_c for an ultra-soft, tri-block copolymer (PMMA-PnBA-PMMA) subjected to various degrees of torsion. Similar NIC experiments were conducted for comparison. The SSC critical pressure at no degree of torsion was found to be similar to that of NIC and nominally increased with applied shear stress. Cavity morphology and growth dynamics appeared similar between the two methods, regardless of the applied shear stress. Data was also compared to analytical calculations to show that the SSC approach can better test generalized cavitation models.*

10:00 AM *SB13.05.04
Soft, Pressure-Tolerant Ocean Sensors for Oceanographic Measurements and Exploration *Xueju (Sophie) Wang; University of Connecticut, United States*

The ability to monitor and record various environmental and population parameters using ocean sensors enables significant understanding of changes in marine systems including geographical position and animal behaviors. Current ocean sensors including conductivity, temperature, and depth (CTD) sensors require high-pressure chambers and seals in the oceanographic environment, which entails a large power supply and footprint of the sensor system. The emerging soft matter electronics, with stretchable electronic sensors embedded in incompressible soft elastomers, can potentially eliminate the need for high-pressure chambers due to their capability of potentially withstanding large hydrostatic pressure, and therefore may substantially reduce the power requirements and the size of electronic ocean sensors. Therefore, they are a promising candidate for sensing in the ocean environment. In addition, these power-efficient, small, and non-invasive electronics are suitable for integration with many platforms including animal tags, profiling floats, diving equipment, and physiological monitoring.

In this talk, I will introduce soft, pressure-tolerant, flexible electronic sensors that can operate under large hydrostatic pressure and salinity environments, thereby eliminating the need for pressure chambers and reducing the power consumption and sensor size. By using resistive temperature, pressure and conductivity (salinity) sensors as an example for demonstration, the soft sensors are made of lithographically patterned metal thin films (100 nm) encapsulated with soft oil-infused elastomers and tested in a customized pressure vessel with well-controlled pressure and temperature conditions. The resistance of the temperature and pressure sensors increases linearly with a temperature range of 5 °C-38 °C and salinity levels of 30-40 Practical Salinity Unit (PSU), respectively, relevant for this application. Pressure (up to 15 MPa) has shown a negligible effect on the performance of the temperature and salinity sensors, demonstrating their large pressure-tolerance capability. In addition, temperature, pressure and salinity sensors have exhibited excellent cyclic loading behaviors with negligible hysteresis. Encapsulated with our developed soft oil-infused rough polydimethylsiloxane (PDMS), the sensor has shown excellent performance under 35 PSU salinity water environment for more than 7 months. The soft ocean CTD sensors are further integrated with acoustic transducers for underwater data transmission. The soft, pressure-tolerant, and non-invasive electronic sensors reported here are suitable for integration with many platforms including animal tags, profiling floats, diving equipment, and physiological monitoring.

10:30 AM SB13.05.05
Annihilating Foam Using an Applied Voltage *Saurabh Nath[1], Maxime Costalonga[1], Valentina Negri[2], Sreedath Panat[1] and Kripa K. Varanasi[1]; [1]Massachusetts Institute of Technology, United States; [2]ETH Zürich, Switzerland*

Here we discuss a voltage-driven mechanism of foam breakage - a method free from chemicals and mechanical components, that could be pivotal in settings like bioreactors. We provide direct experimental evidence of the origin of the foam rupture: hydrogen evolution at the cathode, where a proton deficit reduces surface tension, triggering localized Marangoni flows leading to cascade of bubble ruptures. Two operational regimes are identified: one where foam breakage conforms to natural evaporation rates and another where it accelerates (at least) eightfold beyond a critical electrolysis voltage. The latter regime reveals constant breakage rates, a feature that underscores a lack of electrokinetic effects. Finally, building on our mechanistic findings, we engineer a bench-scale foam mitigator designed for continuous foam suppression using electrolysis.

10:45 AM *SB13.05.06

Atomistic Simulations of the Strengthening Effect of High-Density Bubble Formation in Helium-Irradiated Single Crystalline Copper *Niaz Abdolrahim; University of Rochester, United States*

We conducted atomistic simulations to examine the strengthening effect of He bubbles with varying He atom concentrations in a single crystal copper matrix. Uniaxial tensile tests showed mechanical strengthening and enhanced ductility in copper with high-density He bubbles. The yield strength and failure strain increased up to a vacancy/He ratio of 1:3, but sharply decreased at a ratio of 1:4. High-density He bubbles formed 3D regions with distinct crystallographic orientations. Sessile dislocations formed at the boundaries of these regions for samples with vacancy/He ratios of 1:2 and 1:3, contributing to mechanical strengthening along with Cu/He interfacial energetics. Higher He concentrations also increased total dislocation density and reduced dislocation mobility, promoting homogeneous plastic deformation. During plastic flow, He bubbles underwent significant decrystallization, detwinning, and formation of Shockley partials, while copper exhibited typical dislocation-mediated plasticity. The growth rate of He bubbles significantly influenced plastic deformation and led to sample failure through bubble coalescence.

Dynamic Epoxy Concrete Composites for Lunar Habitats *Broderick Lewis[1], Cheol Park[2], Joseph Dennis[3] and Kenneth Shull[1]; [1]Northwestern University, United States; [2]NASA Langley Research Center, United States; [3]U.S. Army Research Laboratory, United States*

Thermoset polymer glasses are promising material candidates for use in the harsh environmental conditions relevant to aerospace and space applications because of their robust thermomechanical properties, chemical resistance, and low mass density; however, these polymeric materials can suffer from brittleness and sensitivity to some forms of radiation due to their highly crosslinked structure and chemical constituents. Thermoset polymers and their composites also tend to be unrecyclable because of the covalent crosslinks present in these network materials. In recent years, the incorporation of dynamic covalent bonds into thermosets has been utilized to improve their recyclability, leading to the development of a class of polymers known as vitrimers or covalent adaptable networks (CANs). Recent work has shown that the inclusion of dynamic, aromatic disulfide bonds in high-performance epoxy glasses not only endows these materials with reprocessability (improving sustainability and material lifetime), but also can be used to improve material toughness without sacrificing strength [1-3]. This work investigates the use of these healable and mechanically robust polymers as matrices in highly filled composites for use as structural materials for lunar habitats via in situ regolith utilization (ISRU). Specifically, a series of dynamic, disulfide-containing epoxies and composite concretes with 80-90 wt% lunar regolith simulant have been fabricated to study their fracture and mechanical properties over the broad temperature range relevant to the lunar surface. Additional multi-functional fillers being used to improve the composite resistance to various forms of radiation and demonstrations of the reprocessability of the materials will also be discussed. The structure-property relationships developed will be used to optimize materials for structural integrity, radiation *resistance, and reprocessability, while minimizing the weight of polymer matrix needed to save costs for lunar missions.*

Self-Healing Polyimide Containing Dynamic Covalent Bonds and Aliphatic Diamine *Haeun Shin[1,2], Dukkyu Park[2], Heung Cho Ko[2] and Nam-Ho You[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)*

Polyimide is an engineering plastic that has excellent thermal and mechanical properties and is widely used in various applications with electronic devices, and aerospace. Once converted from the precursor to an imidized structure with an imide ring through thermal or solution process, it is insoluble, infusible, and chemical resistant, allowing it to have advantages for a variety of applications as it can be used in high temperatures and hazardous environments. Most polyimides are processed in the form of thin films and used for electronic materials such as flexible devices, the importance of durability is increasing. If the flexible polyimide film is damaged by scratches or impacts, it is harmful to the mechanical strength of the polyimide, and device performance may deteriorate. Including soft and flexible segments in the polyimide chain lowers the glass transition temperature and increases chain mobility, making it easier to recover from damage to the film, but mechanical strength could be reduced. Therefore, efforts have been made to impart self-healing performance to polyimide while maintaining thermal and mechanical stability, and the introduction of dynamic covalent bonds (DCB) with various structures in the network has received attention.

Dynamic covalent bonds include disulfide, imine, and boronate ester, and these are covalent bonds that allow reversible exchange reactions by external stimuli such as temperature, light, or catalysts. When an external stimulus is applied to the network, original bonds at exchangeable dynamic covalent bonds dissociate and new bonds are formed nearby. This process enables the material to have reprocessability and self-healing properties. Polyimide with dynamic covalent bonds exchange bonds by external stimulation but can exhibit close to the original value of thermal and mechanical properties. Therefore, when the materials are damaged or fatigued, self-healing and recovery are possible in a simple method, thereby increasing the sustainability of the material.

In this study, diamine monomers with disulfide bonds and siloxane groups were incorporated into polyimide networks. the thermal, mechanical, and optical properties of polyimide can be adjusted by selecting the ratio of two types of diamine. In particular, the self-healing properties of polyimide film are related to the amount of disulfide bonds contained in the polymer network, and aliphatic diamine changes the glass transition temperature of polyimide, making dynamic covalent bond exchange reactions possible at lower temperatures. In addition, the mechanical strength of polyimide increases by the rigid aromatic segments with disulfide bonds, it is possible to prepare a self-healing polyimide film with desired thermal and mechanical properties. Polyimides with dynamic disulfide bonds can recover from mechanical damage through short-time processing at temperatures near T_g. By performing a stress-relaxation test on polyimide, the activation energy was calculated from the relaxation time during which the network was reorganized. By setting self-healing conditions of the polyimide film, and compared with the properties of the original film after process under those conditions. We confirmed the application of self-healing polyimide for use in electronic devices. Electrodes were deposited using polyimide as a substrate, and the effects of damage and recovery through self-healing to the substrate on device operation were confirmed. Self-healing polyimide can have controlled thermal and mechanical properties by disulfide-containing and aliphatic diamine monomer content, and is expected to be used in various applications using rapid self-healing through an *easy process.*

11:45 AM SB13.05.09
***Stability Assessment of Perovskite Solar Cells via In-Situ Characterization** Monica Lira-Cantu; Catalan Institute of Nanoscience and Nanotechnology, Spain*

With record efficiencies above 26 % for single junction and above 34 % for Silicon-Perovskite tandem, Perovskite solar cells (PSCs) have demonstrated to be a superb player for the energy supply of our future. However, soon after the emergence of this technology back in 2009-2012, the research community recognized the need for the understanding and management of degradation mechanisms to boost cell device stability, module reliability and, in general, device lifetime. Additive engineering has become one of the most attractive pathways to enhance PSC stability. The interaction of their functional groups with the halide perovskite (HP) absorber, as well as with the transport layers, results in defect passivation and ion immobilization improving device performance and stability. In this talk, we will briefly summarize the different types of strategies recently applied in PSC to enhance not only efficiency but also long-term operational stability. My talk includes the application of organic additives which can passivate exclusively shallow defects and thus immobilize ion, or the application of additives and 2D materials, such as MXenes, working as transport layers in PSC. Special emphasis is given to their effect on the stability of PSCs under special environmental conditions such as humidity, atmosphere, light irradiation (UV, visible) or heat, considering the recently reported ISOS protocols, especially outdoor testing. Finally, I will also show our most recent results on in-situ characterization of PSCs under accelerated tests or our results in Machin Learning.

SESSION SB13.06: Radiation Effects in Organic and Biological Materials

***First-Principles Modeling of Electronic Excitation Response of DNA to Ion Radiation in Water** Yosuke Kanai; University of North Carolina at Chapel Hill, United States*

The momentum transfer from highly-energetic charged particles to electrons in condensed matter is often referred to as electronic stopping. The quantum-mechanical response of electrons to perturbating time-dependent external potential is at the heart of the electronic stopping processes. Understanding this phenomenon under ion irradiation has great implications in various modern technologies, ranging from nuclear fusion reactors to semiconductor devices for space missions, to cancer therapy based on proton beam radiation. The lack of molecular-level understanding of the electronic excitation response of DNA to charged particle radiation, such as high-energy protons, represents a fundamental knowledge void for advancing proton and other ion beam cancer therapies. We developed and employed first-principles real-time time-dependent density functional theory simulation, using a massively parallel supercomputer, to unravel the quantum-mechanical details of the energy transfer from high-energy protons and other ions to DNA in water. The calculations reveal that the irradiating ions deposit significantly more energy onto the DNA sugar-phosphate side chains than onto the nucleobases, and greater energy transfer is expected onto the DNA side chains than onto water. As a result of this electronic stopping process, highly energetic holes are generated on the DNA side chains as a source of oxidative damage.

2:15 PM SB13.06.02

Characterization of Channel Structures Observed in the Radiation-Induced Dielectric Breakdown of Polymethyl Methacrylate for Space Applications *Raphael I. Rose, Bryson Clifford, Karen Wiratan, Noah Hoppis, Kathryn Sturge, Holly Wilson, Carolyn Chun, John Cumings and Timothy Koeth; University of Maryland, United States*

Dielectric breakdown due to solar radiation poses a significant problem for polymers in space. This type of component failure can be modeled in bulk dielectric materials, such as polymethyl methacrylate (PMMA). We irradiate the PMMA with an electron accelerator to accumulate space charge within the bulk, this we discharge by mechanical insult to force an electrical breakdown. This process forms permanent dendritic breakdown patterns, colloquially known as electrical trees. Here we study and categorize these trees using optical and electron microscopy by computer vision, and X-ray computed tomography.

We investigate the various types of discharge. Other authors [1,2] have categorized the discharge channel structures into branch and bush types by their morphology. However, our analysis provides the first characterization of novel discharge channel types only observed in radiation-based dielectric breakdown [3]. We provide a structural description including a heuristic analysis and channel diameter measurements.

We confirm the presence of branch and bush discharge structures and characterize a novel discharge structure and transition channel type, both of which suggest gaps in the present understanding of the physical processes at play.

Using Irradiated Polymers to Forensically Reconstruct Uranium Enrichment *Avery Nguyen, Rachel C. Connick, Charles A. Hirst, Daniel Reinfurt, Julie V. Logan, Kevin B. Woller, R. S. Kemp and Michael P. Short; Massachusetts Institute of Technology, United States*

"Trust, but verify" is the operative phrase when it comes to verifying nuclear non-proliferation treaties (NPTs). Trust is easier accomplished than verification. Fortunately, polymers are ubiquitous in uranium enrichment systems, finding use as gaskets, containers, and resins and epoxies to name a few, and they are particularly sensitive to ionizing radiation damage. While the majority of research about radiation effects concerns metals and ceramics, the ubiquity and sensitivity of polymers renders them both useful and under-utilized to act as retrospective dosimeters in any process involving ionizing radiation.

Here we show that multiple polymers, ranging from PTFE [1] to PCTFE [2] to fluorinated epoxy and beyond, exhibit sufficient sensitivity to function as retrospective dosimeters in forensically reconstructing uranium enrichment activities. Differential scanning calorimetry (DSC) is used to establish the relationship between a polymer's irradiation dose and changes to its material properties. Nanoscale flash scanning calorimetry (nano-FSC) further extends this ability to nanoscopically sized specimens, rendering the technique effectively non-destructive and adding additional elements of isotopic selectivity and spoof-proofing. Raman spectroscopy and synchrotron-based small-angle x-ray spectroscopy help to confirm the physical nature of the radiation damage resulting in DSC/FSC-measurable property changes. These reveal a core-shell damage geometry which explains how parts per billion direct radiation damage leads to far higher signal to noise ratios than would be expected. Finally, machine learning is used to improve upon physics-first signal feature identification to help separate nearby dose-response curves, significantly improving the ability to discern between closer levels of radiation damage.

Challenges to facile exploitation of this technique outside of the laboratory remain, including mapping which polymers require which measurement statistics to establish confidence intervals for NPT verification activities, accounting for the uranium-bearing corrosion deposits which form on the insides of enrichment equipment, and further linking the precise structural changes from radiation damage to changes in material properties as measured. The idea of in situ ion irradiation flash scanning calorimetry (I^3FSC) will be presented here for the first time, which should allow researchers to improve the data throughput of this technique by a thousand fold, analogous to our group's 1000-fold data throughput enhancement using in situ ion irradiation transient grating spectroscopy (I^3TGS) [2].

4:00 PM *SB13.06.04
Sustainable & Scalable Heavy Metal Removal from Water Using Yeast Christos E. Athanasiou; *Georgia Institute of Technology, United States*

Traces of heavy metals in water resources, resulting from mining activities and e-waste discharge, pose a significant global threat, with lead being one of the most abundant and toxic contaminants. Incidents of lead-contaminated drinking water have prompted revisions of water regulations, as the US Environmental Protection Agency considers no level of lead in drinking water to be safe. Conventional treatment processes struggle to remove trace lead from drinking water in a resource efficient manner.

In this talk, I will demonstrate how the yeast Saccharomyces cerevisiae can facilitate the effective removal of trace lead from water through a rapid mass transfer process known as biosorption. I will also showcase the role of nanomechanical testing in deciphering the biosorption mechanism in yeast cells, alongside micromechanical testing allowing for scaling up the approach through yeast-laden hydrogel capsules. Finally, I will discuss how, yeast, a model organism in biology, has been tested in space for its radiation resistance, indicating its potential for applications in space missions. This research not only paves the way for a new generation of environmentally friendly, highly effective, and sustainable biosorbents targeting emerging contaminants but also opens up *promising implications for water purification technologies in space exploration.*

4:30 PM SB13.06.05

Electronic Traps Induced by Radiation in Organic Field-Effect Transistors *Derek Dremann[1], Evan J. Kumar[1], Karl Thorley[2], Edgar Gutiérrez Fernández[3,4], James Ververs[1], John D. Bourland[1,1], John Anthony[2], Ajay Ram S. Kandada[1] and Oana D. Jurchescu[1]; [1]Wake Forest University, United States; [2]University of Kentucky, United States; [3]University of Warwick, United Kingdom; [4]XMas/BM28-ESRF, France*

Organic field-effect transistors (OFETs) have a range of attractive properties that make them a compelling and advantageous solution in the field of electronics. These properties include the ability to solution process the constituent layers, tune molecular structure to adjust their electronic characteristics, and make flexible, biocompatible devices, all at a competitive cost. One possible application of OFETs is in radiation dosimetry, since radiation dosimeters based on OFETs (RAD-OFETs) offer the possibility of creating inexpensive, flexible devices to accurately measure radiation doses with a response similar to that of human tissue. This can enable better patient care in medical applications such as cancer treatments and improved safety in environments with increased levels of radiation.

Here we present our findings on the nature of electronic traps induced within the organic semiconductor when integrated in RAD-OFETs. These devices were exposed to 6 MeV X-ray radiation. produced by a clinical linear accelerator, with dosages ranging from 0 Gy to 5 Gy. RAD-OFETs based 2,8-difluoro-5,11-bis(triethylsilylethynyl)anthradithiophene (dif-TES-ADT) were fabricated and characterized via IV measurements, photoluminescence spectroscopy, and grazing-incidence wide-angle X-ray scattering (GIWAXS). Compared to control devices, the samples exposed to a 5 Gy dose of radiation exhibited a large shift in threshold voltage and change in subthreshold slope indicating a difference of interfacial trap density of 9×12 eV^{-1} cm^{-2}. A spectral analysis of the trap density of states was also performed utilizing the Grünewald method. We observed that devices exposed to radiation had an increase in the density of trap states by 3×10^{17} cm^{-3}, while no change was detected for the control devices. Photoluminescence spectroscopy measurements of the ratio of intensities for the 0-0 and 0-1 transitions demonstrated a change in activation energy from 56 meV to 71 meV, evidence that radiation exposure increases local structural disorder within the aggregates. GIWAXS analysis also confirmed structural disorder as a cause for the increase in trap states with the growth of a second peak in the main reflection for samples exposed to radiation. Our results provide a deeper understanding of radiation-induced defects in organic semiconductors, which can inform the creation of more efficient and reliable radiation dosimeters.

4:45 PM SB13.06.06

Radiation Hardness of Organic Solar Cells *Yongxi Li, Karthik Kamaraj, Haonan Zhao, Claire Arneson, Bin Liu, Yogita Silori, Jennifer Ogilvie and Stephen R. Forrest; University of Michigan, United States*

Organic photovoltaics (OPVs) have long shown promise for application as solar power generation panels for space application due to their outstanding specific power (power generated per weight), compatibility with flexible substrates, ability to integrate devices on virtually any large area and the potentially low cost of fabrication processes. And while OPVs are now demonstrating efficiencies at or even exceeding 20%, and an extrapolated intrinsic lifetime ranging from decades to centuries under AM 1.5G illumination, their ability to withstand use in harsh space environments with high energy incident radiation is yet to be clarified. In this study, we investigate the radiation hardness of organic photovoltaics. Contrary to the common belief that organic semiconductor devices are vulnerable to rapid degradation when exposed to high energy radiation, we find that small-molecule OPVs grown by vacuum thermal evaporation are resistant to degradation by 30 keV proton irradiation, in contrast to polymer-based OPVs that suffer a 50% efficiency loss under similar conditions. Thermal annealing at low

temperatures significantly restores the polymer-based OPV power conversion efficiency. The loss of efficiency is attributed to cleavage of pendant alkyl groups on the polymers, resulting in cross-linking and the subsequent formation of deep electronic traps. This result offers a proof-of-concept demonstration that OPVs possess radiation hardness required for successful use in extended space missions.

SESSION SB13.07: Novel Experimental and Theoretical Tools for Defect Investigation

Formation of Two-Dimensional Covalent Organic Frameworks and the Impact of Defects *Haoyuan Li[1] and Jean-Luc Bredas[2]; [1]Shanghai University, China; [2]The University of Arizona, United States*

Two-dimensional (2D) covalent organic frameworks (COFs) are a class of crystalline and porous polymers being explored in electronic and energy storage devices. So far, these materials are prone to defects, which have restricted their usage. Utilizing kinetic Monte Carlo and molecular dynamics simulations, we modeled the formation of 2D COFs at the atomic and molecular levels. Our results revealed the factors impacting the nucleation and growth of these 2D crystals. In particular, we established a quantitative model describing their non-classical crystallization processes, providing insights into growing high-quality 2D COF crystals. Our atomistic simulations showed that monomer addition and island coalescence contribute to forming 2D COF crystals. We also studied the mechanisms underlying the formation of vacancy and dislocation defects during polymerization. Additionally, using the density functional-based tight binding method and molecular dynamics simulations, we investigated the impact of defects on the electronic band structures and mechanical properties of 2D COFs. These results inform the design and fabrication of 2D COFs for various applications.

9:00 AM SB13.07.02
On-the-Fly SAXS/WAXS Analysis for Soft Materials Processing *Siyu Wu; Brookhaven National Laboratory, United States*

In-situ characterization of polymers under processing conditions is critical for developing materials that can withstand extreme conditions; however, it poses significant challenges due to the dynamic and often unpredictable nature of these environments. The characterization of these processes, along with the corresponding on-the-fly analysis and visualization, are crucial for understanding material dynamics and optimizing the efficiency of photon usage in synchrotrons. This talk will present the transformative capabilities of in-situ SAXS/WAXS experiments at the CMS beamline of NSLS-II in studying soft materials, such as polymers, under various processing conditions, including heating, stretching, pressing, poling, and exposure to humidity, even extreme conditions like high pressure. . We will present case studies of in-situ SAXS/WAXS experiments conducted on polymers, which reveal important insights into the materials' structural dynamics and stability. Additionally, the talk will cover advanced data analysis methods enabled by artificial intelligence and machine learning, which enhance the interpretation of complex data sets and contribute to a more accurate and efficient analysis of structural changes. These studies are expected to contribute significantly to the development of next-generation soft, reconfigurable materials designed for applications in challenging conditions.

9:15 AM SB13.07.03

Impact of Space Like Temperature Conditions on Metal Halide Perovskite Solar Cells *Simon A. Wegener[1], Altantulga Buyan-Arivjikh[1], Zerui Li[1], Kun Sun[1], Xiongzhuo Jiang[1], Matthias Schwarzkopf[2] and Peter Muller-Buschbaum[1]; [1]Technische Universität München, Germany; [2]Deutsches Elektronen Synchrotron DESY, Germany*

Perovskite solar cells offer significant potential as a power source in space due to their exceptional properties. Their high absorbance in the visible spectrum allows the active layer thickness to be reduced to just a few hundred nanometers. Combined with efficiencies comparable to state-of-the-art silicon devices, this results in an outstanding power-to-weight ratio. Additionally, their solution processability significantly reduces both launch and manufacturing costs, making them an attractive, cost-effective alternative to current multi-junction gallium arsenide cells. However, numerous challenges must be addressed to make perovskite solar cells viable in the harsh space conditions, including high vacuum, extreme temperatures, and radiation. Our study focuses on the extreme temperature fluctuations experienced in low Earth orbit, between the illuminated and eclipse phases, and their impact on solar cell performance. Operando grazing-incidence wide-angle X-ray scattering (GIWAXS) allows for insights into the crystal structure of perovskite active layers while the solar cell is simultaneously illuminated and subjected to extreme temperature changes. Synchrotron radiation sources, with their high beam intensities, provide the necessary high time resolution for these observations. The experiments aim to understand the complex system of the entire solar cell assembly, which consists of multiple layers and interfaces with varying thicknesses, elastic moduli, and thermal expansion coefficients. Additionally, I-V curve measurements and optical absorption spectrum tracing of the perovskite solar cells provide further information on their electrical and optical properties. This comprehensive investigation of the mechanical, optical, and electrical properties of the solar cell under extreme temperature changes from -100°C to +100°C achieves a thorough understanding of the interplay within the device. This understanding is crucial for the targeted optimization of the devices for the harsh space environment. The results of the experiments show a significant dependence of temperature on device efficiency. Additionally, the degradation of the cells is not primarily driven by the active layer but is dependent on other layers in the device and their interfaces. Based on these results, our research aims to enhance the durability and performance of perovskite solar cells in harsh space conditions, ultimately making them a more viable option for space applications.

10:00 AM *SB13.07.04

Nonradiative Energy Loss in Organic Solar Cells—Linking ΔV_{nr} to Morphology and Photostability *Aram Amassian; North Carolina State University, United States*

Bulk heterojunction (BHJ) organic solar cells have made remarkable inroads towards 20% power conversion efficiency, yet nonradiative voltage losses (ΔV_{nr}) remain the highest as compared to silicon and perovskite photovoltaics. Recent work has revealed nonradiative voltage losses are primarily due to back charge transfer (BCT) through the charge transfer (CT) state resulting in the formation of triplets within acceptor domains. Other work have revealed the CT state disorder and CT-S1 offset both influence nonradiative voltage losses (ΔV_{nr}). However, the CT manifold associated with interfaces buried within the BHJ blend, holds the key to these recombination losses and insights into the energetic landscape underpinning CT states and their disorder remain elusive. In this talk, we reveal the energetic landscape and CT state manifold of modern BHJs with both spatial and energetic resolutions and link the offset between singlet (S1) and CT energy (S1-CT) and interfacial energetic disorder with ΔV_{nr}. We do so by locally mapping the energy distributions of modern PM6-based BHJs with IT4F, Y6 and $PC_{71}BM$ acceptors and combine it, for the first time, with sensitive EQE measurements, to visualize and quantify donor (D) and acceptor (A) energetics at interfaces and associated them with CT states within a modified

Marcus framework. We quantify energy levels and electronic disorders directly at these and other interfaces and connect these contributions to the energy losses. We delineate the influences of S_1 to CT offset and interfacial energetic disorder on the ΔV_{nr} across multiple morphologically varied BHJs. Our results clearly show both factors influencing energy losses and that changing the interfacial disorder affects non-radiative voltage losses in systems with comparable S_1 to CT offset. We go on to connect these observations of interfacial energetics with ΔV_{nr} as well as with expected changes in the triplet quantum yield using complementary optical spectroscopies. Finally, we go on to demonstrate how modulating the triplet population in the BHJ through the CT state manifold influences photobleaching rate of the BHJ.

10:30 AM *SB13.07.05
Engineering the Structure and Properties of 2D Materials by Ion Irradiation, Strain and Intercalation *Arkady Krasheninnikov; Helmholtz-Zentrum Dresden-Rossendorf, Germany*

As 2D materials have a high surface-to-volume ration, nearly all of them contain defects and impurities, which may have appeared due to the effects of the environment or exfoliation, or in case of synthetic materials, during the growth. The defects can govern the electronic and optical properties of 2D systems. Moreover, defects can intentionally be introduced using beams of energetic particles – ions and electrons. Formation of defects may also give rise to phase transformations in these materials and/or tune their properties. Mechanical strain and intercalation by, e.g., alkali metal atoms, can further be used to tailor the materials characteristics. All of these calls upon the studies on defects and their role upon intercalation, response of materials to strain and irradiation. In my talk, I will present the results of our recent theoretical studies of point and line defects in 2D materials [1-5] obtained in close collaboration with several experimental groups. I will further discuss how strain can affect the characteristics of defective 2D materials [6] and how new 2D phases of materials can be created upon atom intercalation between graphene sheets and address the role of defects in this process [7].

Driving and Observing Defect Formation and Healing at the Atomic Scale Using Electron Microscopy *Stephen Jesse, Ondrej Dyck, Mina Yoon and Andrew Lupini; Oak Ridge National Laboratory, United States*

The scanning transmission electron microscope (STEM), a workhorse instrument in materials characterization, can not only be used to observe dynamic processes with atomic resolution, but also drive and control synthesis with atomic precision. Through custom control of the electron beam position that actively feeds back on image, spectroscopy, and other data streams from electron detectors, it is possible to use focused beam energy to precisely initiate, direct, and terminate material transformations. This high degree spatial and temporal control can be used to generate point defects, drill holes that are a single or few atoms in size, and mill thin lines or other patterns in materials, change phase, modify bond coordination, and reposition dopants.
Control over the local environment in the vicinity where the beam meets the sample provides additional and critical capabilities to control and observe reactions. Custom MEMS devices for heating and biasing, in situ evaporators, and laser irradiation provide the means to dose the sample with thermal energy, optical excitation, and reactant or dopant materials to provide the conditions for reactions and targeted synthesis and transformation

of atomic scale structures to occur. Finally, to close the loop, the STEM can then be used in its more traditional characterization modes to image transformation processes as they occur and assess if new functional properties emerge.

Presented here are recent results highlighting advancements towards such a "synthescope"[1] including new insights gained by studying the generation and temperature dependent diffusion of beam-generated single vacancies in suspended 2D materials [4,5], strategies to restrict vacancy diffusion so they can serve as sites for dopant insertion, demonstration of patterning of arrays of dopants [3,6], and in situ delivery of dopant atoms to the sample [2,6]. Furthermore, results of in-depth modeling and analysis of the often-counterintuitive behavior of material transformations where the exceedingly small reaction area/volume is defined by the beam are discussed. The development of this combination of experimental methods with theory and modelling (both operating at the atomic level) provides a window into the dynamic processes at fundamental length scales and a path towards fabricating materials and devices with atomically precise components.

Degradation of Printed Organic Solar Cells at Extreme Temperatures *Christoph G. Lindenmeir[1], Manuel A. Reus[1], Simon A. Wegener[1], Christopher R. Everett[1], Julian E. Heger[1], Sigrid Bernstroff[2] and Peter Muller-Buschbaum[1]; [1]Technische Universität München, Germany; [2]Elettra Sincrotrone Trieste, Italy*

In research, organic solar cells (OSCs) have received a lot of attention in recent years because of their non-toxicity, short energy payback times, and high efficiencies reached within only a couple of years of research. Additionally, OSCs are also particularly intriguing because of their easy solution-based manufacturing technique and high absorbance, which allows for thin and flexible solar cells. Especially, slot-die printing is a very promising fabrication approach because it is fast, causes low waste, and is easily upscalable, making OSCs even more viable for future applications like being used in space. Being thin, lightweight, and having a significantly higher power-to-weight ratio compared to commercially used gallium arsenide solar cells, makes them very promising for space applications, reducing production and rocket launch costs. However, the conditions in space are very harsh and these conditions in terms of extreme temperatures, high vacuum, and radiation are supposed to lead to a fast degradation of the OSCs.

Therefore, in this work, we investigate the influence of extreme temperature changes from 0 up to 100 °C on printed OSCs. We optimize the printing process of OSCs and study their degradation process with the help of in-operando grazing incidence small-angle X-ray scattering (GISAXS). GISAXS is a nondestructive technique to examine the morphology and buried structures of thin films. Compared to other scattering techniques, GISAXS measured at a synchrotron benefit from its large probing area and high beam intensity to provide the required time resolution for these investigations. At the same time, we track the performance of the OSCs in vacuum to simulate space conditions. In addition to the electrical characterization and GISAXS measurements, we used techniques *such as spectroscopy and real-space imaging to gain further valuable information about the degradation of printed solar cells. The goal of this experimental setup is to gain a deeper understanding of the behavior of OSCs during high-temperature variations. By addressing these issues, we expect to increase the OSCs' longevity and performance and learn more about the upscaling procedure, which will make them a more practical choice for space applications.*

11:45 AM SB13.07.08

Analysis of Charge Collection Efficiency in Photovoltaic Materials and Devices Using Ion Beam Induced Charge Microscopy *Mohin Sharma[1], Mritunjaya Parashar[1], Todd Byers[1], Darshpreet Kaur Saini[1], Charles Bowen[1], Gary A. Glass[1], Ian R. Sellers[2] and Bibhudutta Rout[1]; [1]University of North Texas, United States; [2]University at Buffalo, The State University of New York, United States*

Ion Beam Induced Charge (IBIC) microscopy is a powerful ion beam technique for studying semiconducting materials and devices. This scanning ion microprobe technique mainly utilizing 1-3 MeV energetic hydrogen or helium ions provides a detailed analysis of the electronic characteristics of various semiconducting materials and devices by allowing us to investigate how efficiently they collect charge, at a sub-micro-meter spatial resolution. By measuring the charge pulse heights produced by individual probing ions, IBIC helps in understand how well these devices perform and how reliable they are. The local charge collection efficiency (CCE) fluctuates mainly due to the interplay between how charge carriers diffuse and the surface morphology of the sample. This relationship is crucial for pinpointing the areas within a solar cell that are most vulnerable to radiation-induced damage. In our study, we used IBIC to map out the spatial distribution of CCE to locate electrically active defects in solar cells.

We also looked at how the IBIC signal changes with increasing ion fluence to evaluate the radiation hardness of solar cells. This part of the study is especially important for solar modules used in space, where high levels of radiation can significantly affect their performance and longevity. Our findings show how radiation exposure impacts charge collection efficiency and, in turn, the overall efficiency and durability of the solar cells.

In summary, our research highlights the value of ion beam analysis techniques such as IBIC along with Rutherford Backscattering Spectrometry (RBS) in providing detailed and spatially resolved information about electronic defects, charge collection properties, and elemental migrations in solar cell materials [1,2]. These insights are critical for improving the design and manufacturing of solar cells, especially for applications that need high radiation tolerance, like those used in space.

SESSION SB13.08: Lightweight Barriers for Harsh Environments
Session Chairs: Bibhudutta Rout and Ian Sellers
Thursday Afternoon, December 5, 2024
Hynes, Level 3, Room 308

1:45 PM *SB13.08.01
Flexible Inorganic Substrates for Electronic Device Integration *Sean Garner; Corning, United States*

Emerging electronic and optical device applications with integrated flexible substrates are attracting increasing interest. These applications include photovoltaics, displays, sensors, and antennas as examples. In many of these, a high-quality substrate/superstrate is required for device processing as well as a durable encapsulation approach. Applications specifically targeting harsh environments require substrate and encapsulation materials with optical & surface quality, dimensional & thermal stability and hermeticity which can be difficult for polymer and metal materials.

This presentation overviews flexible glass and ultra-thin ceramic materials ≤100um thick that can address these device packaging challenges. These thin, lightweight, and flexible inorganic substrates are compatible with both sheet and high-throughput roll-to-roll manufacturing processes. By providing thermo-mechanical and environmental durability, they can protect the more susceptible device functional materials and enable new device designs, applications, and performance levels.

2:15 PM SB13.08.02
Understanding Performance and Stability of Perovskite-Based Tandems for Space Applications *Felix Lang[1], Biruk A. Seid[1], Etienne Beier[1], Julian Steele[2], Kai O. Brinkmann[3], Dieter Neher[1], Thomas Riedl[3] and Martin Stolterfoht[1]; [1]University of Potsdam, Germany; [2]The University of Queensland, Australia; [3]Universität Wuppertal, Germany*

All-perovskite tandem solar cells (2J-PSCs) combine two complementary band gaps to reduce thermalization losses and thus promise high power conversion efficiency (PCE). If fabricated on ultrathin substrates, they offer power-weight values beyond traditional space PV solutions. Yet there are still questions regarding their long-term stability outside Earth's protective atmosphere where Atomic-Oxygen (AtOx), high-energetic radiation as well as extreme temperature cycles and low-intensity low-temperature (LILT) pose unconventional challenges.

In this presentation, I will discuss the extraordinary radiation tolerance of all-perovskite tandem solar cells and then move on to Atomic Oxygen degradation and their low-temperature, low-intensity behaviour. [1–4] Atomic oxygen, unfortunately, corrodes unencapsulated PSCs swiftly, which in future has to be mitigated with ultralight barriers. Despite that, micrometeorites may cause an encapsulation failure, and therefore, we set out to understand the AtOx-induced degradation mechanisms of phenethylammonium iodide (PEAI)-2D passivated and non-passivated devices. Surprisingly, degradation is more severe in 2D passivated PSCs. Combining injection-current-dependent electroluminescence (EL), EL imaging and intensity-dependent photoluminescence quantum yield measurements (IPLQY) with resistance photovoltage transient measurements as well as grazing incidence wide angle X-Ray scattering (GIWAX) we find that 2D passivation layers are severely prone to accelerated degradation because of lateral diffusion of AtOx though the 2D surface owing to the large interplanar distance of 2D perovskites. This renders widely used 2D passivation's problematic for space applications.[5]

We then tested un-passivated all-perovskite tandem solar cells for their performance under low-intensity low temperatures. This is interesting for outer planetary missions, e.g., to the vicinity of Saturn, where conditions feature a stark light intensity of 0.01AM0 with spacecraft temperatures hovering around ~120K. At these conditions, the tandem device drops to around $50\%_{rel}$ of its initial performance, while control 1.5eV single junction solar cells retain their initial PCE without any loss. To enable a deeper understanding of the mechanisms behind these PCE losses, we then investigated the PCE, EL and PL of tandem solar cells and corresponding single junctions as a function of temperature. [8]

Liquid-Based Encapsulation for Implantable Bioelectronics Across Broad pH Environments *Xiaoting Xue, ChangHee Son, Xincheng Zhang and Yi Zhang; University of Connecticut, United States*

Implantable bioelectronics designed for interfacing with highly mobile organs across a broad pH range (1.5-7.4) has a wide range of applications in basic biomedical research and clinical medicine. The encapsulation of these systems represents a key challenge as they require encapsulation materials not only to have superior barrier performance in diverse pH environments but also to maintain stretchability. However, the existing encapsulation materials for implantable bioelectronics typically possess superior barrier performance or high stretchability, but not both. Here, we present a waterproof yet stretchable liquid-based encapsulation material, named oil-infused elastomer, by infusing a thin oil layer on a rough elastomer, which not only maintains the transparent and stretchable properties of the elastomer but also offers additional waterproof properties of the oil layer. Importantly, the oil-infused elastomer demonstrates outstanding waterproof properties over 550 days across various pH environments (pH = 1.5, 4.5, and 7.4) in a set of implantable wireless bioelectronics, including near-field communication antennas and wireless optoelectronic devices. Additionally, in vivo immunohistochemistry reveals the biocompatibility of oil encapsulation. Finally, the wireless optoelectronics encapsulated with an oil-infused elastomer show robust operation over the duration of testing (three months) in vivo in freely moving mice. Overall, this new class of encapsulation layer offers the desired mechanical stretchability and softness, optical transparency, biocompatibility, and waterproof properties in diverse biological environments (pH = 1.5 to 7.4). All these properties suggest potential applications in implantable bioelectronics for emerging applications ranging from gastrointestinal monitoring to bioelectronic medicine.

Synthesis, Optical Performance Characterization and Durability of Electrospun PTFE−PEO for Space Applications *Chieloka D. Ibekwe[1], Xuanjie Wang[1], Adam Swanger[2], Jason Hartwig[3] and Shankar Narayan[1]; [1]Rensselaer Polytechnic Institute, United States; [2]NASA Kennedy Space Center, United States; [3]NASA Glenn Research Center, United States*

Passive heat management is crucial in space, especially for extended missions involving protection from sunlight. Thermal coatings with desirable optical properties can drastically reduce the power consumed by active cooling *systems, thereby reserving more resources for other critical systems onboard. Specifically, materials with wavelength-dependent reflectance and emittance are desirable for managing incident sunlight and self-cooling by thermal emission. This study demonstrates the use of polymer nanofibers, specifically poly(tetrafluoroethylene) (PTFE), for passive temperature control in space applications. This study describes the electrospinning fabrication process to create nanofibers and how process parameters can be varied to control the fiber geometry. We combine poly(tetrafluoroethylene) (PTFE) and poly(ethylene oxide) (PEO) polymers to fabricate highly reflective thermal control materials by electrospinning. To understand the role of material and fiber geometry, we measure spectral reflectance, absorptance, and transmittance using spectrophotometers interfaced with integrating spheres. We control the materials' fiber geometry and solar reflectance by modifying the solution properties, flow rate, rotating collector speed, and fabrication time. With 220−1560 μm thick electrospun nanofiber materials, we demonstrate an average solar reflectance of 94.73−99.75%, with values approaching 99.9% for thicker samples, which is among the highest for space applications. Meanwhile, a thermal emittance of 81.4% was observed at 300 K for a 3360 μm thick sample. The durability of these samples was also tested under ultraviolet light and atomic oxygen. Compared to the state-of-the-art materials, the electrospun PTFE−PEO fibers present a new paradigm for passive thermal management in space applications.*

Mathematical Modeling and Optimization of Poly (Ethylene Vinyl Alcohol) Film Thickness and Ethylene Composition Based on I-Optimal Design *Kowsar Rezvanian and Vijaya Rangari; Tuskegee University, United States*

Understanding the factors and processes that influence the mechanical properties of plastic films is essential for numerous scientific and technological applications. Film thickness significantly affects these mechanical properties. EVOH (ethylene vinyl alcohol) is extensively used in the food packaging industry because of its exceptional air and moisture barrier properties. However, the mechanical properties of EVOH films are dependent on the thickness of the EVOH layer in multilayer films, which also affects the preservation capabilities of the food packages. In this research, mathematical models have been formulated to develop a functional relationship between the effect of EVOH films thickness and ethylene content, as independent variables, on mechanical properties including ultimate tensile strength, elongation at break, and elastic modulus, as dependent variables, using a Response Surface Methodology (RSM) through I-optimal design. The optimum conditions accrued with the EVOH films thickness of 0.03 and ethylene content of 48 mol%. Under the optimal conditions, the values of 25.178% for Elongation at Break, 3077.86 MPa for Elastic Modulus, and 97.44 MPa for tensile Strength were predicted. Analysis of variance (ANOVA) technique was employed to check the adequacy and significance of mathematical models and the model's regression coefficients were significant. The extruded EVOH films were further characterized using several characterization techniques such as scanning electron microscopy (SEM), FTIR, and mechanical testing.

Crystal Nucleation from a Hard-Sphere Liquid—The Discrepancy Between Experiments and Simulations

Frans Spaepen, Zizhao Will Wang, Alp M. Sunol and David Weitz; Harvard University, United States

Understanding crystal nucleation from the melt is central to the study of glass formation. The hard-sphere system has been particularly useful here, because it allows direct experimental observation of the nucleation events in colloidal suspensions. On the theoretical side, there are detailed determinations of the equations of state of the two phases, calculations of the interfacial energies, as well direct simulations of the nucleation events. At high liquid densities, there is fair agreement between the nucleation frequencies measured in experiments and simulations. At lower liquid densities, however, abundant nucleation is observed where simulations predicts there should be none.

This talk will be a critical review of the possible origins of this discrepancy: (i) Establishing homogeneous nucleation conditions by suppressing heterogeneous nucleation at the sample cell walls; (ii) Determining the (small) degree of softness and the size dispersion of the polymeric spheres; (iii) Determining the effects of (ii) on the equations of state and the phase diagram; (iv) Evaluating and comparing the different crystal identification algorithms, especially for the small crystal sizes; and (v) Evaluating the methods for extracting crystal nucleation rates.

Central to this study is the concept of the crystal-liquid interfacial energy. Some experimental values can be extracted from the equilibrium size distribution of crystalline fluctuations in the liquid. Under non-equilibrium conditions, we determine the critical nucleus size, at which a crystal is equally likely to grow as to shrink. Classical nucleation theory, combined with the appropriate equations of state, then also gives values for the interfacial energy. These will be compared with earlier determinations on macroscopic interfaces.

11:00 AM SF01.01.02

The Formation of Amorphous Si Induced by Eutectic Reaction and Ag-Nodule Mediated Bonding *Koji S. Nakayama[1], Masahiko Nishijima[1], Yicheng Zhang[1], Chuantong Chen[1], Minoru Ueshima[2] and Katsuaki Suganuma[1]; [1]Osaka University, Japan; [2]Daicel Corporation, Japan*

Metastable phases such as supersaturated solid solutions, supercooling, and amorphous phases are well-known in metallurgy. They are often composed in non-equilibrium states and can be transformed into a stable phase by overcoming an energy barrier with driving forces. Particularly, it has been widely used for material strengthening and heterogeneous nucleation of precipitates in solids is mainly induced by heat treatments for supersaturated solid solutions. However, little is known about the metastable phases of the Ag-Si alloy, although it is a well-known simple binary eutectic alloy. We show that the metastable phases composed of amorphous Si and supersaturated Ag solid solution are induced by the eutectic reaction under rapid cooling of Ag-Si. Conventionally, the underlying concept of amorphous alloys has been considered as the mixing of multi-atomic compositions, which leads to the stabilization of the liquids due to the negative values of heat mixing. Here, we present a new concept of amorphization that induced by the significant supercooling due to the deep eutectic depression of the liquidus temperature near the eutectic composition of Ag-Si. The similar amorphization was recently found in the Al-Si eutectic system, but the amorphous phases were expected to appear in the hypereutectic region of 25-45 at % Si in Al-Si. Furthermore, the solute Si in the Ag matrix reacts with oxygen to precipitate Ag by-products, which grow as nodules. The Ag nodules have high crystallinity and robust interfacial structures, and the nodule growth leads to the formation of cross-links between the Ag-Si particles. We also demonstrate the Ag nodule-mediated bonding where the rapidly cooled Ag-Si ribbon is directly used as a bonding medium, indicating the possibility of using it as a high-temperature bonding material with low-temperature processes.

11:15 AM *SF01.01.03

Atomic Cooperativity in Metallic Glasses and Liquids *Takeshi Egami[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States*

Liquids and glasses are condensed matter with density comparable to those of crystalline solids. Thus, atoms are not free to move, and they are strongly correlated with each other in space and time. In the glassy state atoms are confined and caged by neighbors. Understanding and specifying the nature of dynamic heterogeneity and cooperativity in terms of such correlations has long been the focus of glass physics. In this talk I review the scales of dynamic cooperativity in space and time and present a new view of the phenomena based on the density wave theory. Starting with Adam and Gibbs, historically cooperative motions were thought to occur around low-density areas, such as free-volume. But that thinking reflects a bias toward the hard-sphere models, whereas atoms are not hard spheres. Local density can deviate from the average both in positive and negative directions. Then, a better way to characterize the state of liquid and glass is through density fluctuations, decomposed into density waves. I show when atomic interactions are introduced to a gas, density waves are created in all directions. But density waves are unstable against local thermal and quantum fluctuations and become spatially limited to form the medium-range order (MRO). Many phenomena, including mechanical deformation, viscosity and relaxation, can be described in terms of the interplay among density waves, local topology of atomic connectivity and local *elasticity.*

11:45 AM SF01.01.04

Experimental Measurement of Configurational and Vibrational Entropy in Metallic Glasses *Hillary Smith, Wuqian Zhang and Grady M. Savage; Swarthmore College, United States*

Liquid fragility characterizes how quickly viscosity decreases above the glass transition in glass-forming liquids. This property is fundamental to glass physics and of critical importance for engineering applications. Competing theories have suggested that vibrational properties may play a role in describing fragility by contributing vibrational entropy to the large excess entropy of the undercooled liquid over the crystal above the glass transition [1]. We have developed in situ inelastic neutron scattering methods to assess the phonon density of states in glasses as they traverse the glass transition, capturing real-time changes to the phonon vibrational modes in the amorphous, crystalline, and supercooled liquid states. Results on bulk metallic glasses with a range of fragilities have been reported [2, 3], indicating that vibrational entropy provides a minor contribution to the entropy of the glass transition. This talk will discuss the correlation between excess vibrational entropy in the undercooled liquid and liquid fragility. These new results will be considered in the context of a universal understanding of vibrational contributions to the thermodynamics of the glass transition, and in comparison with additional glass systems.

SESSION SF01.02: Atomic Structure and Its Relationship with Properties
Session Chairs: Takeshi Egami, Mo Li and Shuai Wei
Monday Afternoon, December 2, 2024
Hynes, Level 3, Room 310

1:30 PM *SF01.02.01

Elastic Microstructures in Bulk Metallic Glasses—Are They Real? *Birte Riechers[1], Reza Rashidi[1] and Robert Maass[1,2,3]; [1]Bundesanstalt für Materialforschung und –prüfung, Germany; [2]University of Illinois at Urbana-Champaign, United States; [3]Technical University of Munich, Germany*

In the past decades, numerous experimental reports have revealed signatures of an elastic microstructure in metallic glasses, some of which with length scales much beyond the expected short- or medium-range order inferred from atomistic simulations. In the latter, extended network formation of interconnected clusters has been reported that give insights into potentially larger emerging structural length scales (JALCOM 821, 153209, 2020). Experimentally, a compatible signature of spatially resolved elastic properties can indeed be revealed for metallic glasses (Phys. Rev. Lett. 106, 12, 2011), directly highlighting structural heterogeneities at the nanometer scale. This reflects the strong interplay of topology and modulus, which may further be affected by internal stresses or density fluctuations occurring during the glass formation. When extending the probed sample area, surprisingly, fluctuations of the elastic modulus are revealed that persist on much larger length scales of the order of 100 nm (Adv. Func. Mat. 28, 1800388, 2018), but their origin continues to remain unclear.

In this talk we discuss the possible origins of such large length-scale heterogeneities. Based on our recent work, *we are able to exclude chemical fluctuations as for example caused by chemical spinodal decomposition as the origin of this length scale (Materials & Design 229, 111929, 2023). We consequently hypothesized that either geometrical cooling constraints during casting may induce internal stress fluctuations at the revealed length scale, or that extended density fluctuations are the origin of the elastic microstructure. We now test this hypothesis via a detailed analysis of how thermal treatment and thus physical aging affects the spatially resolved elastic fluctuations and by leveraging nano-beam diffraction to interrogate the structural fluctuations across the elastic microstructure. Clear signatures of systematic annealing-induced fluctuation changes across different metallic glass casts substantiate the existence of a hierarchical elastic microstructure in metallic glasses and therefore the notion of length scales much beyond short- and medium range order distances.*

2:00 PM *SF01.02.02

Structure and Atomic Motion in Metallic Glasses at High Pressure *Beatrice Ruta, Antoine Cornet, Alberto Ronca and Jie Shen; Université Grenoble Alpes, France*

Despite metallic glasses are among the most studied metallic materials, still very little is known on the evolution of their unique structural, dynamical and elastic properties under hydrostatic compression, owing to the difficulty to perform in-situ high pressure experiments.
By combining fast scanning calorimetry with synchrotron high energy X-ray diffraction and X-ray Photon Correlation Spectroscopy measurements, we performed a detailed study of the relation between thermal properties, structure and collective atomic motion in metallic glasses under different in situ and ex-situ high pressure treatments [1-3]. Our results provide new insights on the effect of hydrostatic compression in non-ergodic materials and on the surprising rejuvenation and strain hardening reported in previous studies [4].
In this talk, I will present recent advances in this field and show how hot compressions can be used to irreversible modify the structure of metallic glasses and tune at wish the relaxation state of the material.

Cluster Dynamics and Anomalous Transport in Metallic Glasses *Birte Riechers[1], Amlan Das[2], Zengquan Wang[1], Eric Dufresne[3], Peter M. Derlet[4] and Robert Maass[1,5,6]; [1]Bundesanstalt für Materialforschung und –prüfung, Germany; [2]Cornell University, United States; [3]Advanced Photon Source, United States; [4]Paul Scherrer Institute, Switzerland; [5]University of Illinois at Urbana-Champaign, United States; [6]Technical University of Munich, Germany*

Quenching a metallic liquid sufficiently fast can give rise to an amorphous solid, typically referred to as a metallic glass. This out-of-equilibrium material has a long suite of remarkable mechanical and physical properties but suffers from property deterioration via structural relaxation, also known as physical aging. In search for a structural understanding of aging of metallic glasses, we exploit here the ability to track atomic-scale dynamics via x-ray photon correlation spectroscopy (XPCS). Conducted across temperatures and under the application of stress, the results reveal strong signatures of intermittent aging and structural dynamics (Nature Communications 10 (2019) 5006). Non-monotonically evolving and fluctuating relaxation times persist throughout isothermal conditions over several hundred thousands of seconds, demonstrating heterogeneous dynamics at the atomic scale. In concert with microsecond molecular dynamic simulations, we identify possible mechanisms of correlated atomic-scale dynamics that can underly the temporal fluctuations and structural decorrelations. Through simulated XPCS, we find strong evidence of atomic-scale cluster dynamics that underly the intermittent structural decorrelations seen in experiments (Acta Materialia 267 (2024) 119730). Furthermore, a transition from classical stretched exponential *to power-law decorrelations emerges at sufficiently long waiting times, which we interpret as a signature of anomalous transport (Nature Communications (2024) in press). We discuss these findings in the context of an emerging microstructure in metallic glasses.*

3:30 PM *SF01.02.04

Complex Behavior of Supercooled Metallic Liquids—Composition-Dependent Dynamics and Two-Stage, Non-Classical Crystal Nucleation *Carter Francis, Shuoyuan Huang and Paul M. Voyles; University of Wisconsin, United States*

Supercooled metallic liquids exhibit complex behavior both in equilibrium and as nucleate and grow crystals. In equilibrium, we have used momentum-resolved electron correlation microscopy to measure the structural relaxation time as a function of composition for two noble metal / transition metal / metalloid alloys, $Pt_{57.5}Cu_{14.7}Ni_{5.3}P_{22.5}$ *and* $Pd_{43}Cu_{27}Ni_{10}P_{20}$*. The experimental results point to a strong role for chemical bonding and composition in determining local spatially heterogeneous dynamics and a weak role for topological structure including high symmetry structures like icosahedra. During isothermal annealing of* $Pd_{77.7}Cu_4Si_{16.3}$ *in the supercooled liquid state, we observe two-stage, non-classical nucleation using in situ 4D STEM. Instead of a crystal embryo forming directly from the liquid, creating a liquid-crystal boundary, we observe first the formation of a nanometer-diameter object with long persistence time but disordered structure as observed in nanodiffraction. A crystal then forms inside this disordered precursor, consumes it, then grows larger by consuming the liquid. This behavior is similar to previous reports of amorphous precursor particles in crystal nucleation from aqueous solution, but we believe this may be the first experimental observation of non-classical nucleation of a metal crystal from a liquid of the same composition.*

4:00 PM SF01.02.05

Liquid-Like Versus Stress-Driven Dynamics in a Metallic Glass Former Observed by Temperature Scanning XPCS *Maximilian Frey[1], Ralf Busch[1], Beatrice Ruta[2] and Eloi Pineda[3]; [1]Universität des Saarlandes, Germany; [2]Université Grenoble Alpes, Centre National de la Recherche Scientifique, France; [3]Universitat Politècnica de Catalunya, Spain*

X-ray photon correlation spectroscopy (XPCS) under temperature scan conditions can only be sporadically found in literature. In terms of metallic glass formers, all hitherto existing XPCS studies have been measured isothermally. In the present work, we use state of the art detector technology and the high flux of a fourth-generation synchrotron source (ESRF, ID10) to study metallic glass formers upon heating and cooling with 1 K/min through the glass, glass transition and supercooled liquid (SCL). The obtained intensity autocorrelation functions, g_2*, are fitted using the Kohlrausch-William-Watts (KWW) model. High fit quality is obtained in the SCL state, allowing to precisely define the temperature-dependent relaxation time* τ*, and therefore the fragility. In the glass and especially the glass transition region, the conventional KWW approach fails to model the* g_2 *decay. Instead, we demonstrate that a multiplication of two KWW functions allows to describe the complex shape. Within the glass transition region, the fit parameters of the two separate KWW fits decouple massively. While one fit reflects non-equilibrium dynamics, showing a compressed decay and Arrhenius-like temperature dependence of the relaxation time, the other fit features liquid-like characteristics, being stretched and following a VFT-like relaxation time behaviour.*

We present an approach that interprets these findings as the superposition of heterogeneous liquid-like and stress-driven ballistic-like atomic motions. This work not only extends the dynamical range probed by standard isothermal XPCS, but also clarifies the fate of the α-relaxation across the glass transition and provides a new

perception on the anomalous, compressed temporal decay of the density-density correlation functions observed in metallic glasses and many out-of-equilibrium soft materials.
Overall, temperature scanning XPCS appears to be a highly potent method to observe rate-sensitive effects like glass transitions, phase separations, or liquid-liquid transitions, which are otherwise difficult to characterize isothermally.

4:15 PM *SF01.02.06
Structural Heterogeneity in Metallic Glasses—Dependence on Various Parameters and Effect on Plastic Flow *Udo Schwarz; Yale University, United States*

The ability to modify the atomic-scale structure of metallic glasses by processing allows to tailor their mechanical properties. To fully use this ability, it is important to understand local ordering and density fluctuations, both of which manifest as structural heterogeneity. For example, deformation mechanisms are strongly affected by the details of the structure, transforming from homogeneous deformation for small deformation volumes to inhomogeneous deformation with stress localization when larger deformation volumes are in play. This transformation is mainly driven by the ability of the material to localize stress, which is affected by both the degree of structural heterogeneity as well as by the free volume available to release externally applied stress. In this talk, we first study heterogeneity on the nanometer and micron scale in samples made from $Pt_{57.5}Cu_{14.7}Ni_{5.3}P_{22.5}$ *by thermoplastic forming followed by an annealing procedure that sets their fictive temperatures* T_f*. Atomic force microscopy imaging revealed both topography as well as the sample's stiffness, modulations of which reflect structural inhomogeneity. The results show that samples featuring* T_f*'s close to the material's glass transition temperature* T_g *of 235 °C are more homogeneous than samples with* T_f*'s that are lower or higher, a trend that is markedly different from the one found for the absolute values of the average stiffness, which monotonically increases for lower* T_f*'s. The experimental results are then being discussed in the light of recent molecular dynamic simulations.*

Multi-Component Microalloying as a Strategy to Mitigate Relaxation-Induced Embrittlement in Metallic Glasses *Miguel B. Costa, Owain S. Houghton and Alan Lindsay Greer; University of Cambridge, United Kingdom*

The embrittlement of metallic glasses (MGs) due to structural relaxation is a concern for their practical use. Single- or dual-element microalloying have been explored as effective strategies to improve the mechanical and functional properties in MGs. This work considers how multi-component microalloying affects the properties of as-cast and thermally-annealed states. It is found that multi-component microalloying can mitigate relaxation-induced embrittlement and improve the plasticity in annealed states. Changes in glassy states are explored using XRD and DSC, and the mechanical properties in different states are characterized by mechanical testing, microindentation, and nanoindentation. HR-TEM suggests the improvements are due to structural features of the glassy state. The microalloyed relaxed states are more plastic due to a larger number of shear events with lower propagation velocities. It is proposed that multicomponent microalloying is translatable to other systems, and an effective method to achieve properties critical for the adoption of MGs in industry.

SESSION SF01.03: Glass Forming Ability
Session Chairs: Michael Ferry, Isabella Gallino, Naijia Liu and Beatrice Ruta

8:00 AM SF01.03.01

Density Dependence of the Dynamics in Supercooled Liquids and Glasses—Insights from High-Pressure X-Ray Photon Correlation Spectroscopy *Antoine Cornet[1,2], Alberto Ronca[1,2], Jie Shen[1,2] and Beatrice Ruta[1,2];*
[1]Institut Néel, France; [2]European Synchrotron Radiation Facility, France

Glasses form during the tremendous, highly non-linear increase of the viscosity of supercooled liquids upon cooling, when the relaxation time becomes larger than the typical observation time [1]. As such, they are defined dynamically, and their properties up to the macroscopic scale depend heavily on the relaxation processes taking place at the microscale [2]. A consequence is that the complete description of a glass state and properties passes by a combinatory dynamical and structural approach. In metallic glasses, the dynamical information can often be obtained from X-Ray Photon Correlation Spectroscopy (XPCS), an experimental technic that takes advantage of the coherent nature of x-ray beams at 3rd and 4th generation synchrotron sources to monitor the timescale and nature of the relaxation processes at the atomic level [3].
The past fifteen years have seen many successes from atomic scale XPCS, leading to a deeper understanding of the dynamical behavior of glasses across the full temperature range, from the deep glassy state at room temperature to the supercooled liquid state above the glass transition [4]. However, the effect of density on this dynamical description of the glassy/liquid state remains scarce at best, mostly due to the experimental difficulty of coupling high pressure environments to XPCS. Taking advantage of the exceptional coherence properties of 4th generation synchrotron sources, our recent development of high-pressure XPCS (HP-XPCS) waived these limitations, and allowed for the monitoring of the internal dynamics of glasses in-situ under extreme conditions of pressure [5].
In this talk, I will discuss the pressure effect on the atomic scale relaxation phenomena of a prototypical bulk metallic glass system, $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$, as observed from HP-XPCS. At room temperature, a dichotomy appears between structure, which only reveals a monotonous densification, and dynamics, which initially reveals a surprising acceleration of the dynamics by a factor 30, challenging a pure free volume approach. A second step at higher pressure consists in a slow-down of the relaxation processes, following the typical physical aging observed at atmospheric pressure. In the supercooled liquid state, HP-XPCS shows that pressure changes the liquid's fragility and shifts the glass transition temperature by 8 K/GPa, a factor twice higher than that obtained from ex-situ measurements on the recovered high pressure quenched glasses, showing the necessity of performing in-situ measurement for the determination of the liquid dynamics under pressure.

Breaking the Vitrification Limitation of Monatomic Metals *Hai Yang Bai; Chinese Academy of Sciences, China*

The question of whether all materials can be put into the glass form proposed by Turnbull half a century ago remains unsolved yet. Some of the simplest systems of monatomic metals have not been vitrified, especially for the close-packed face centred cubic (fcc) metals. Here, we report on the vitrification of gold, which is notoriously difficult to be vitrified, and several similar close-packed fcc and hexagonal metals, using a method of picosecond pulse laser ablation in liquid medium. The vitrification occurs through the rapid cooling during laser ablation and the inhibition of nucleation by the liquid agent. Through this method, a large number of atomic configurations including glassy configurations can be generated simultaneously, from which a stable glass state can be sampled. Simulation results demonstrate that the favourable stability of monatomic metals stems from the strong topological frustration of icosahedra-like clusters. Our work breaks the limitation of glass-forming ability of matter, indicating that vitrification is an intrinsic property of matter and providing a strategy for the preparation and design of metallic glasses from an atomic configuration perspective.

8:30 AM *SF01.03.03
Ultrafast Calorimetry on Bulk Metallic Glasses *Jorg F. Loffler; ETH Zürich, Switzerland*

Although calorimetry is an established method in materials science, it has only become recently possible to run it at ultrafast time scales and at temperatures beyond the melting temperature of metallic materials. Therefore, it is now possible to study the details of phase transformations and metastable phase formation in metallic systems, despite their rapid nucleation and growth kinetics.

Applying fast differential scanning calorimetry (FDSC) at heating and cooling rates of several 10,000 K/s to slowly transforming bulk metallic glasses (BMGs), we are able to explore novel glass states [1], determine their stochastics of nucleation, and investigate the pathways of solid-solid phase transformations, which we found to often occur via metastable melting. Furthermore, while classical calorimetry cannot sufficiently characterize metastable phases owing to their structural changes upon slow heating, FDSC can suppress such transitions and allow for their detailed measurements of thermophysical properties, such as heat capacity and melting temperatures [2]. Combining in situ FDSC with synchrotron X-ray measurements [3], we can also study simultaneously the structure and thermophysical properties of metallic materials and organic compounds. The talk reviews the wealth of physicochemical information, we have gathered in recent years with the method of FDSC and its combination with other analysis methods such as electron microscopy and synchrotron X-ray diffraction.

Metalloid Glasses vs. Metallic Glasses *Shuai Wei; Aarhus University, Denmark*

While metallic glasses are extensively studied as structural materials in the past several decades, “metalloid glasses”, composed of metalloid elements such as Ge, As, Sb, Te, are investigated as electronic and optical functional materials. Despite being separate research fields, metallic and metalloid glasses share a considerable portion of properties, but also exhibit distinct behaviors. Here, I will show a comparison of thermodynamics, kinetics, and structures between the two types of glasses. While metallic glasses are tailored to show bulk glass forming abilities (critical cooling rate down to ~ 1 K/s), metalloid glasses are usually designed to be poor glass formers (critical cooling rate ~ 10^9 K/s) for their functionalities in devices. During calorimetric scans, many *metalloid glasses do not even show a glass transition before crystallization sets in. The kinetic fragilities of metalloid glasses are much higher than those of bulk metallic glasses. However, both types of glasses may exhibit beta-relaxations relaxations below glass transition temperatures, which may facilitate crystallization processes in both cases. Pronounced Boson peaks are observed in both types of glasses, although their correlation with glass transition behaviors depends on their bonding types. In contrast to metallic glasses with metallic bonding, metalloid glasses, being covalently bonded, show a range of complex bonding natures with different extent of covalency or metallicity. Upon heating, metalloid glasses may transform into a metallic state at high temperatures through a semiconductor-to-metal transition. The latter is also accompanied with a strong-to-fragile transition in liquid viscosity. A comprehensive comparison between metalloid and metallic glasses may help advance the understanding of both types of glasses.*

10:00 AM *SF01.03.05

The Fragile-to-Strong Transition and Relaxation Mechanisms in Glass-Forming Supercooled Liquids *Lina Hu; Shandong University, China*

*This report first introduces the understanding and exploration of the fragile-to-strong transition phenomenon in supercooled liquids. The fragile-to-strong transition is crucial for elucidating the nature of glass transition and controlling the properties of solid glasses. It has been found that the extent of the fragile-to-strong transition not only relates to the glass-forming ability but also determines the plasticity of amorphous alloys. The fragile-to-strong transition are prevalent in various amorphous materials such as oxide glasses, metallic glasses, and polymers, exhibiting common characteristics. For instance, the temperature at which the fragile-to-strong transition occurs is about 1.36*T_g*, and the degree of the fragile-to-strong transition (f) shows a negative exponential relationship with the ratio between the activation energies for the α and the β relaxations. Using amorphous alloys as model systems, it is found that the fragile-to-strong transition arises from the dissociation and recombination of icosahedral clusters. Additionally, using the* $Au_{50}Ag_{7.5}Cu_{17.5}Si_{25}$ *system as a model, this report discusses the evolution of α and β relaxations observed through nanocalorimetry during the glass to supercooled liquid transition, providing a systematic description of the evolution of relaxation behavior in supercooled liquid regions. The study reveals that all β relaxations in Au-based metallic glasses participate in α relaxation upon heating. Two typical α and β relaxation coupling modes are identified, dependent on the degree of coupling between α and β relaxations in the glass. During isothermal annealing, as the potential energy of the glass state decreases, the coupling degree increases. Above a critical coupling level, the decoupling mode shifts from 'β decoupling from α' to 'α decoupling from β.' Investigation of metallic glasses, polymer glasses, and oxide glasses indicates a critical coupling degree commonly exists in glasses. Molecular dynamics simulations analyzing atomic non-affine displacements elucidate differences in local structural features of glasses with varying coupling degrees between α and β relaxations. Theses findings further demonstrate that modulating the coupling behavior between α and β relaxations can effectively adjust the plasticity of metallic glasses.*

10:30 AM *SF01.03.06

The Effect of Composition on the Thermodynamics, Structure, Mechanical Properties and Atomic Motion of (Pd-Pt)$_{42.5}$***Cu***$_{27}$***Ni***$_{9.5}$***P***$_{21}$ ***Alloys*** *Ralf Busch; Universität des Saarlandes, Germany*

The $Pd_{42.5}Cu_{27}Ni_{9.5}P_{21}$ *alloy is one of the best metallic glass formers that has been discovered so far, reaching critical casting thicknesses of up to 80 mm. According to basic hard sphere models Pt should be able to replace Pd in this alloy. In fact,* $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$ *shows significant structural differences compared to the Pd based counterpart[1] with a reduced critical thickness of only 20 mm, despite both alloys behave very similarly if it comes* *to the temperature dependence of the overall kinetics (fragility), which is expressed by the viscosity or a-relaxation time of the supercooled liquid.*

To study the differences, a series of (Pd-Pt)$_{42.5}$Cu$_{27}$Ni$_{9.5}$P$_{21}$ alloys is prepared, in which Pd is gradually replaced by Pt[2]. For these alloys the thermodynamic functions are assessed namely specific heat capacity, enthalpy, entropy and Gibbs free energy revealing that the driving force for crystallization increases with the increase of the Pt content, which is in line with the decreasing critical casting thickness when the amount of Pt increases and the amount of Pd decreases in the alloy. In addition, the Pt-richer alloys are thermodynamically more fragile than the Pd-rich alloys, which is revealed by a larger specific heat capacity and a faster drop of the configurational entropy in the Pt-richer alloys. This together with structural investigations using high energy x-ray diffraction (HEXRD) leads to the conclusion that the structure of the Pt rich alloys is dominated by its change in medium range order whereas the Pd-rich alloy is dominated and constricted by its extraordinary short range order that is already pronounced at high temperatures in the equilibrium liquid[2]. The mechanical properties change drastically from a ductile behavior on the Pt-rich side to an embrittlement with increasing Pd content and decreasing Pt concentration.

Nanoindentation investigations together with the HEXRD studies reveal that the embrittlement with increasing Pd-content can be connected to the structural changes. The increase in brittleness is quantitatively related to an increase of rigid 3-atom connections of adjacent icosahedral clusters[3].

Since the two alloys show similar kinetic fragilities but different thermodynamic and structural fragilities we extensively used XPCS to study the atomic dynamics of the two extreme cases of the series, namely the alloy $Pd_{42.5}Cu_{27}Ni_{9.5}P_{21}$ and the alloy $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$ not only as a function of temperature but also as a function of the wave vector. The structural fragilities correlate with the temperature dependence of the stretching parameter describing the decay of the density fluctuations. This implies that the evolution of dynamical heterogeneities in supercooled alloys is determined by the rigidity of the melt structure. We find also that the atomic motion not only reflects the topological order but also the chemical short-range order, which can lead to a surprising slowdown of the α-process at the mesoscopic length scale. These results will contribute to the understanding of the glass transition, which is still missing[4].

***What Does the Structure of Metallic Liquids Tell Us About Glass Forming Ability?** W. Porter Weeks, Suzanne LoTempio and Katharine Flores; Washington University in St. Louis, United States*

While the structures of metallic liquids have been heavily investigated, relating that structure to lower temperature phenomena has proven challenging due to difficulty with elucidating the role of subtle variations among local atomic arrangements. We have adopted a machine learning-based approach to compare the geometry of nearest-neighbor atomic structures in simulated binary and ternary metallic liquids, resulting in a surprisingly small number of fundamental "building-block" atomic cluster motifs that persist across a wide range of alloy *compositions and temperatures. Quantitative evaluations of the population distribution of these motifs and their geometric similarity to “embryos” of intermetallic phases, in combination with Miracle’s Efficient Cluster Packing model based on critical combinations of atomic radii, yields a highly effective a priori indicator of experimentally observed glass formation from the liquid. Based on these observations, we propose three necessary and sufficient conditions required to achieve high glass forming ability from metallic liquids: (1) the liquid structure should be highly disordered, with many competing nearest-neighbor structures; (2) the nearest-neighbor structures in the liquid should have low similarity to crystalline phases; and (3) the liquid structure should be efficiently packed to limit diffusion. While these criteria have been discussed in the literature previously, to our knowledge, the present work is the first demonstration that the simulated high temperature liquid structure and simple elemental features (i.e. atomic radii) can be combined as a sufficient a priori predictor of glass formation, without needing to simulate the structure of the undercooled material. Furthermore, the observation of fundamental building block motifs in the disordered structure opens the door to unambiguously defining atomic-scale structural defects, which may determine other material properties.*

11:30 AM *SF01.03.08
Size-dependent Deformation Behavior In Nanosized Amorphous Metals Suggesting Transition from Collective to Individual Atomic Transport *Naijia Liu; Northwestern University, United States*

The underlying atomistic mechanism of deformation is a central problem in mechanics and materials science. Plastic deformation in crystalline materials typically utilizes dislocations which slide in slip planes. For amorphous metals, the plastic deformation mechanism is generally recognized as viscous flow. At low temperature and high strain rates, deformation is highly localized in narrow shear bands. At high temperature and low strain rates, deformation is essentially homogenous.

We study the size-dependency of the deformation mechanism in amorphous metals. Thermomechanical nanomolding (TMNM) allows us to deform bulk metallic glasses under well-defined size confinement and temperatures. By applying compression deformation across a temperature range from Tg – 50 K to Tg + 10 K, and a size range from 10 nm to 250 nm, we found that the underlying deformation mechanism of amorphous metals changes at small scales, typically below 100 nm, from collective atomic transport through viscous flow to an individual atomic transport based on atomic diffusion. Scaling experiments further reveal that the critical length scale of the transition between diffusion- and viscous-based flow is temperature dependent. This critical length scale increases and then decreases with temperature, exhibiting a maximum at the glass transition. While deformation based on viscous flow does not discriminate among alloy constituents, diffusion does and the constituent element with the highest diffusivity deforms fastest. Hence, composition changes during deformation.

In this presentation, I will discuss the size-dependency of deformation mechanism under nano-scale confinements, including a dislocation-diffusion transition in crystalline and a viscous flow-diffusion in amorphous metals. I will discuss the theoretical framework behind the mechanism transitions with size based on a maximization of energy release rate. Discussion on nano-mechanics and physics of amorphous materials will also be covered, including but not limited to the bulk and surface glass transition, breakdown of the Stokes-Einstein relation, and glass structures.

SESSION SF01.04: Mechanical Properties and Mechanisms of Plastic Deformation and Failure

Simulation-Informed Models for Amorphous Metal Mechanical Property Prediction *Bin Xu[1], Zhao Wu[2], Jiayin Lu[3,4], Michael Shields[1], Chris H. Rycroft[3], Franz Bamer[2] and Michael L. Falk[1]; [1]Johns Hopkins University, United States; [2]RWTH Aachen University, Germany; [3]University of Wisconsin–Madison, United States; [4]Harvard University, United States*

To enable design of additively manufactured amorphous metal parts with desired mechanical properties, including strength and toughness, we are pursuing simulation-informed modeling as an integral component of a simultaneous design approach. Through the interrogation of an 3D atomistic representative volume element of a binary glass, we harvest simulation data that quantifies plastic constitutive response. The resulting data quantifies the stress drops characteristic of metallic glass mechanical response in terms of state variables related to the stress and the structural state of the glass. This data informs a stochastic finite state automata model that can reproduce aspects of the mechanical response and the associated evolution of the material's structural state. This serves as a lower-scale constitutive model for a continuum model capable of achieving predictions of mechanical response on significantly larger length scales. Validation of the continuum model is undertaken in comparison with large scale atomistic simulations. This work is supported by NSF under Grant Nos. DMR-2323718/DMR-2323719/DMR-2323720.

2:00 PM SF01.04.02

Effect of Cooling Rate and Composition in the Mechanical Properties and Avalanche Dynamics of CuZrAl Metallic Glasses—Insights from Hybrid Simulations and Machine Learning Potentials *Silvia Bonfanti[1,2], Anshul D. S. Parmar[2], Antoni Wadowski[2], Tero Mäkinen[3] and MIkko Alava[3,2]; [1]Università degli Studi di Milano, Italy; [2]NOMATEN, National Center for Nuclear Research, Poland; [3]Aalto University, Finland*

This study investigates the role of cooling rate and composition in the mechanical properties and avalanche dynamics of CuZrAl metallic glasses using advanced computational techniques.
We employ a hybrid simulation approach combining Monte Carlo and Molecular Dynamics (MD) methods to generate equilibrated samples at temperatures below the conventional glass transition. This enables us to achieve a stable glassy regime, facilitating a detailed examination of the kinetics, thermodynamics, and rheology of CuZrAl glasses.

Our findings reveal an enhanced understanding of the stability and behavior of the CuZrAl system, and we observe abrupt stress drops corresponding to shear band precursors and dynamics. We further utilize machine learning interatomic potentials specifically developed for the Zr-Cu-Al system, trained on a comprehensive Density Functional Theory database. This model allows for large-scale MD simulations with near ab initio accuracy, validating the MLIP model's accuracy through comparison with other computational techniques and providing a comparative analysis showcasing the prediction of elastic properties.

Additionally, we explore avalanche dynamics and local structural arrangements in Zr-Cu-Al metallic glasses under shear. By systematically varying the ratio of the elements, we examine the relation between composition and local configurations in shear transformation zones. Our findings on avalanche dynamics reveal that avalanches are universal in the steady state, and unlike Lennard-Jones systems, CuZrAl shows avalanches approaching the peak stress. The gap distribution is flat in the steady state with a power-law exponent in the small strain regime.

Overall, we propose an integrated approach to advance our understanding of complex metallic glasses and *provides comparisons with experimental data.*

2:15 PM *SF01.04.03

***Capturing Shear Bands and Explaining Plasticity of Metallic Glasses with Continuum Mechanics** Jurgen H. Eckert[1,2], Oleksandr Glushko[2], Reinhard Pippan[1], Daniel Sopu[1] and Christian Mitterer[2]; [1]Austrian Academy of Sciences, Austria; [2]Montanuniversität Leoben, Austria*

Capturing a shear band in a metallic glass during its propagation experimentally is very challenging. Shear bands are very narrow but extend rapidly over macroscopic distances, therefore, characterization of large areas at high magnification and high speed is required. Here we show how to control the shear bands in a pre-structured thin film metallic glass in order to directly measure local strains during initiation, propagation, or arrest events. In-situ scanning electron microscopy with digital image correlation was utilized to measure local strain fields within, and in the vicinity of propagating shear bands in PdSi thin film metallic glasses. Dynamic stages of shear band propagation as well as multiple shear band arrest events are documented and quantified in terms of local von Mises strain fields. Quantification of local conditions for shear band propagation and arrest allowed to formulate a consistent model of shear banding purely within the framework of continuum mechanics. We claim that, at the nanoscale, metallic glasses always exhibit an elastic limit of about 5% which must be exceeded either at a stress concentrator to initiate a shear band, or at the tip of a shear band to support its propagation. At the same time, the "universal" elastic limit of about 2%, reported for various metallic glasses, reflects the violation of the shear band arrest condition within a large enough sample volume so that generated shear bands can escape from the sample and form surface steps. The presented continuum mechanics model of shear banding does not imply the existence of atomic-scale phenomena that are specific to metallic glasses, such as structural rejuvenation or collective activation of shear transformation zones. The model can successfully connect micro- and macroscopic plasticity of metallic glasses and suggests an alternative interpretation of controversial experimental observations.

2:45 PM SF01.04.04

***Microscopic Mechanisms of Plastic Deformation in Colloidal Glass** Aidan J. Duncan[1,2], Frans Spaepen[2] and Katharine Jensen[1]; [1]Williams College, United States; [2]Harvard University, United States*

Although defect-mediated plasticity in crystals has been well understood for decades, understanding equivalent processes in glasses remains an area of active research. In particular, global plastic deformation in crystals can be accounted for by adding up the local contribution of each individual dislocation to the bulk strain; this quantitative connection between local and global deformation is known as the "Orowan Relation." Theory and simulation predict, and experiments support, the existence of "shear defects" or "shear transformation zones" (STZs) in glasses that play an analogous role to dislocations in crystals, but direct observations of individual STZs and measurements of their contribution to the bulk strain remain challenging. Colloidal glasses provide a unique experimental system in which we can directly study structures, defects, and dynamics of amorphous materials. In this work, we analyze particle-level trajectories and local strain fields obtained from confocal microscopy experiments on 1.55-μm-diameter, hard-sphere colloidal glasses under conditions of uniform shear deformation. We develop quantitative methods to identify individual shear defects in the glass during deformation and characterize their location, size, and individual contribution to the global strain. We find that these STZs account for the entire applied strain, thus demonstrating an Orowan Relation for glass.

***Using Crackling Noise for Materials Testing** Karin Dahmen[1], Jordan Sickle[1], Wesley Higgins[2], Wendelin Wright[3]* *and George Phharr[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Texas A&M University, United States; [3]Bucknell University, United States*

Recent methods allow novel amorphous alloy compositions to be rapidly manufactured at small scale; however, obtaining materials properties such as compressive ductility from these smaller specimens has remained a challenge. Here, we suggest a potential high-throughput method that may be able to rapidly characterize the relative compressive ductility between these alloys based on their serration characteristics. The properties of emergent serrations, when interpreted in a simple micromechanical stress relaxation model, may order these materials by their compressive plastic strain to failure. These results are consistent with the ordering obtained from compressed specimens as well as with model simulations, suggesting that this model may be broadly useful for interpreting compressive ductility from serrations. After it is validated on more materials, this new method will match the rapid pace of amorphous alloy development, thus allowing metallic glass properties to be fine-tuned for each application prior to scale prototyping.

4:00 PM SF01.04.06
Shear Band Stability in Bending—Tension-Compression Asymmetry in Metallic Glass *Ethen Lund[1], Sungwoo Sohn[1], Axel van de Walle[2], Stefano Curtarolo[3], Douglas Hofmann[4] and Jan Schroers[1]; [1]Yale University, United States; [2]Brown University, United States; [3]Duke University, United States; [4]NASA Jet Propulsion Laboratory, United States*

Shear band stability is measured for a Zr-based bulk metallic glass in tensile and compressive bending. Different failure modes in bending are realized via beam geometry, using either rectangular or trapezoidal prisms. These characterizations are done at multiple fictive temperatures, revealing a compression-tension asymmetry in shear banding stability. Stability is higher in compression than tension at all measured fictive temperatures. This asymmetry suggests that shear band propagation is different in tension and compression, and possible mechanisms underlying this difference are suggested. Additionally, shear band stability, quantified in a critical stress gradient, is explored as a means of predicting plasticity in other testing geometries. The critical stress gradient measured in bending is shown to be consistent in uniaxial compression testing, demonstrating its potential for predicting a brittle vs. ductile response in different loading modes of bulk metallic glasses. Overall, our findings indicate that shear bands are more stable in compression than tension and offer a route towards predictive modeling of BMG deformation behavior.

4:15 PM SF01.04.07
Are Metallic Glasses Brittle or Ductile? *Jan Schroers, Sungwoo Sohn and Ethen Lund; Yale University, United States*

Crystalline metals generally exhibit ductility which is enabled by dislocation sliding. We show here that metallic glasses, which carry ductility through shear banding as opposed to dislocation sliding, exhibit ductility only in certain stress fields and such ability is an intrinsic property. Such ability, only depending on chemistry and fictive temperature of the metallic glass, manifests in the ability to form stable shear bands that carry plasticity. We measured this quantity, $\nabla\sigma_{DB}$ for a range of metallic glasses to represent the material class of metallic glasses. If a metallic glass behaves ductile or brittle in a given application is determined by the comparison between $\nabla\sigma_{DB}$ and the applied stress field, $\nabla\sigma_{app}$; if $\nabla\sigma_{DB} > \nabla\sigma_{app}$ the metallic glass will behaves brittle, if $\nabla\sigma_{DB} < \nabla\sigma_{app}$ the metallic glass will behaves ductile, and $| \nabla\sigma_{app} | - \nabla_{DB}$ indicates how ductile.
Measured $\nabla\sigma_{DB}$, and the concept of comparing it with $\nabla\sigma_{app}$ can explain the mechanical properties of metallic glasses and their apparent contradicting brittle and ductile characteristics. Proposed concept allows to determine the behavior of a metallic glass in an application and lays the foundation of using metallic glasses as structural

materials.

SF01.05.01
Thermodynamic Properties of Pt-Cu-P Bulk Metallic Glasses *Wuqian Zhang, Grady M. Savage and Hillary Smith; Swarthmore College, United States*

Ultra-fragile Pt-Cu-P metallic glasses and their thermodynamic properties have been systematically investigated using differential scanning calorimetry. The thermodynamic functions of excess enthalpy, entropy, and Gibbs free energy between the liquid and crystal phases were calculated as a function of Cu content from the isobaric specific heat capacity measurements of the glass, crystal and liquid phase. The glass transition, crystallization, and liquidus temperatures, and the enthalpies of crystallization and melting were also assessed. New calorimetry results, coupled with statistical analysis, suggest a high likelihood of insufficiency of the Kubaschewski equation in accommodating heat capacity in the supercooled liquid phase for some metallic glasses. These results will be discussed in the context of previous work on these glasses which introduced a more general empirical form for the liquid configurational enthalpy [1].

Structural Transformations and Localized Amorphization in Al/Ni Nano-lamellar Composite Under Microballistic Indentation *Iremnur Ceylan and Jae-Hwang Lee; University of Massachusetts Amherst, United States*

Al/Ni nano-lamellar composites (NLCs) are nanomaterials with unique properties, including high-energy density, tunable reaction rates, large interfacial density, and substantial mechanical contrast. Exhibiting self-propagating exothermic reactions upon initiation, these NLCs are known for their applications in joining, welding, energetic systems, and microelectromechanical devices. This study investigates the high-strain rate (HSR) dynamic behavior and impact-induced amorphization of Al/Ni NLCs using the Laser-Induced Projectile Impact Test (LIPIT) method as microballistic indentation. In the LIPIT, an 8 ns infrared laser pulse ablated a gold layer on a launch pad, propelling an alumina microsphere (20 µm diameter) toward a Ni/Al NLC. The collision kinetics are recorded from ultrafast stroboscopic imaging, capturing the entire trajectory in one frame. This technique enabled the calculation of impact dynamics, including impact and rebound velocities (Vi and Vr) and the coefficient of restitution (CoR), defined as the ratio of the residual momentum of the µP, based on inter-µP distances and time intervals. Al/Ni NLCs undergo microballistic impacts at Vi ranging from 200 to 800 m/s, inducing HSR from 10^5 to 10^8 s^{-1}. Under HSR microscopic deformation, adiabatic heating models, incorporating deformation-induced and exothermic Al/Ni reaction heat, predicted temperature spikes in impacted regions. These extreme physical conditions facilitate a complex, multi-stage structural transformation in the Al/Ni nanolamellar composite system. This transformation encompasses several processes, such as the amorphization of fcc-Al, exothermic dissolution of Ni *into the amorphous Al, temperature elevation to Al's melting point, amorphization of fcc-Ni, formation of intermetallic compounds, localized metallic glass formation in regions of severe deformation. The structural transformation is driven by multiple synergistic mechanisms involving strain-induced crystalline phase instabilities, thermal effects resulting from adiabatic dynamic nonlinearity, structural disordering by the self-propagating exothermic reaction, and high mixing enthalpy of the Al-Ni system. In the post-impact analysis, these alterations are examined using scanning electron microscopy. Impact crater profiles are measured using laser profilometry, and the relationship between hardness-Vi for Al/Ni NLCs is determined to characterize the plastic deformation response during the ballistic loading. Nanostructural changes and phase transitions under the impact craters resulting from the collision are analyzed through cross-sectional electron images after focused ion beam milling. These comprehensive analyses provided detailed insights into its mechanical response under extreme strain and impact-induced localized metallic glass formation. The research elucidates the intricate interplay between HSR adiabatic deformation, high mixing enthalpy, and amorphization in driving structural transitions in Al/Ni NLCs, with significant implications for a new path in metallic glass formation.*

Fe-Cr-B, a Case Study—The Amorphous Phase as a Bulk Metallic Glass *David Hinojosa, Renela M. Valladares, Alexander Valladares, Isaías Rodríguez, Enrique Geffroy and Ariel A. Valladares; Universidad Nacional Autónoma de México, Mexico*

Bulk Metallic Glasses (BMG) have been heralded as a promising technological breakthrough due to their remarkable mechanical properties. However, the fabrication of large samples presents several experimental limitations, inhibiting their industrial application at large. From a theoretical standpoint, ab initio simulation methods are valuable resources that can relate macroscopic properties to the intrinsic disordered atomic arrangement in BMG, but quantum-mechanical calculations that include their different atomic species make these simulations a challenge. In this work we amorphize a 264-atom supercell of a Fe-based BMG, namely $Fe_{74}Cr_8B_{18}$*, using the undermelt-quench computational procedure developed in our group that consists of ab initio molecular dynamics (MD) thermal processes of heating and quenching below its melting point. After the MD process, the resulting structure was relaxed. The disordered structure obtained was characterized using several atomic correlation functions. Also, we study its entropy, in order to identify features of this ternary system as a possible Fe-based High Entropy Alloy. Results will be presented.*

SF01.05.04

Thermodynamic, Kinetic and Structural Study of $Pt_{42.5}Cu_xNi_{36.5-x}P_{21}$ ***Alloy Variations*** *Ziyu Ling[1], Maryam Rahimi Chegeni[1], Nico Neuber[1], Amirhossein Ghavimi[1], Ralf Busch[1] and Isabella Gallino[2]; [1] Universität des Saarlandes, Germany; [2] Technische Universität Berlin, Germany*

Pt-P based alloy is one of the best glass-forming systems, in recent years, Pt-Cu-Ni-P alloys have drawn much attention due to its industrial potential. Their high glass forming ability (GFA) and remarkable thermal stability also predestinates them for thermophysical characterization. In a study by Neuber et.al, $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$ *was developed from the well-known glass former composition* $Pd_{43}Cu_{27}Ni_{10}P_{21}$ *and was shown that despite the topological similarities between Pt and Pd, the supercooled liquids of these two alloys are stabilized by different mechanisms. Compared to the low driving force of Pd-P system, in Pt-P system, large interfacial energy is considered to compensate the high driving force for crystallization. Moreover, an interesting pre-peak at low-Q value was observed in structural data of* $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$ *during synchrotron measurement, which is argued to be a signature of medium range order (MRO) and arise from Pt-Pt or Pt-Cu correlations.*
In this work, four alloy variations based on the composition $Pt_{42.5}Cu_{27}Ni_{9.5}P_{21}$ *with fixed atomic contents of Pt and P (42.5 and 21) were developed and studied via different methodologies in differential scanning calorimetry (DSC)*

and flash DSC (FDSC) and by high-energy synchrotron X-ray diffraction. Focus is laid on the influence of compositional changes on thermodynamic and crystallization behavior of the alloy liquids. In addition, an attempt is made to build connections between thermodynamic fragility and structural signature.
Firstly, the thermophysical properties were obtained by standard scan in DSC, then Tg shift method and step method were applied to attain the relaxation time and specific heat capacity (Cp) evolution with Cu substituted by Ni, from which fragility parameters are calculated. By measuring the critical cooling rates and TTT-diagrams of the selected compositions in FDSC, the GFA and interfacial free energy of each alloy liquid is evaluated. Furthermore, the structural data during heating from room temperature to crystallization of amorphous alloys were investigated via high-energy synchrotron diffraction experiments (HEXRD) at DESY.
Due to the dominant Pt-Pt partial scattering function, the respective role of Cu and Ni in the formation of the medium range order is still not fully revealed. In the next step efforts will be made to trace the single element behavior in the alloy, to achieve a deeper understanding of the influence of compositional change on the atomic packing scheme within the supercooled liquid.

SF01.05.05
Structural and Thermal Properties of a $Pd_{40}Cu_{30}Ni_{10}P_{20}$ BMG by Ab Initio Simulations *Isaías Rodríguez, Renela M. Valladares, Alexander Valladares, David Hinojosa, Enrique Geffroy and Ariel A. Valladares; Universidad Nacional Autónoma de México, Mexico*

Bulk metallic glasses (BMGs) such as the $Pd_{40}Cu_{30}Ni_{10}P_{20}$ alloy have been invoked as a promising technological breakthrough due to their unique mechanical and thermal properties. These materials combine high strength, elasticity, and resistance to wear with a lack of long-range atomic order. The formation of BMGs requires rapid cooling from the liquid state to bypass crystallization and achieve an amorphous structure. In this work, we undertook the task of simulating the $Pd_{40}Cu_{30}Ni_{10}P_{20}$ alloy using the undermelt-quench computational process developed in our group, on a 216-atom supercell that was subjected to an ab initio molecular dynamics (MD) thermal process of heating and quenching below its melting point. After the MD process, the resulting structure was relaxed. The disordered structure obtained was characterized by several atomic correlation functions like the Pair Distribution Function (PDF) and the partial PDFs. The electronic structure was studied using the Electronic Density of States (eDoS). Also, we study some of its thermodynamic properties, particularly its entropy, in order to identify features of this system as a Pd-based High Entropy Alloy. Results will be presented.

SF01.05.06
Unveiling the Formation of Shear Bands in Metallic Glass—A Hypothesis on the Influence of Low-Density Regions and Density Fluctuations *Siya Zhu[1] and Axel van de Walle[2]; [1]Texas A&M University, United States; [2]Brown University, United States*

Localized shear phenomena play a crucial role in the deformation of bulk metallic glasses (BMGs), leading to the formation of shear bands. Molecular dynamics (MD) simulations serve as a powerful tool for replicating and analyzing this shear banding process. Typically, MD simulations require high strains or pre-existing voids to induce shear bands. In this study, we introduce low-density areas by creating a vacancy density of ~1% within a narrow band to facilitate shear band formation. In addition, we quantitatively define the shear band width and critical strain, and analyze the impact of these low-density areas on shear band development.

SF01.05.07
Comprehensive Atomistic Analysis of the Thermal Conductivity and Stability in Advanced Metallics Glass-Ceramic Composite Materials *Sungwook (Leo) Hong; Loyola Marymount University, United States*

Research on various metallic glass-ceramics has garnered significant attention in nanotechnology and materials science. Notably, lithium disilicate, aluminum silicates, and lithium aluminum silicate glass-ceramics have proven successful in numerous industrial applications due to their superior mechanical properties, such as high flexural strength and fracture toughness. Therefore, it is crucial to gain a fundamental understanding of the thermal properties of these glass-ceramic materials to extend their use to other commercial applications, such as display glasses and window shields. However, this remains challenging due to the lack of computational efforts to model such complex systems. In this study, we conduct reactive molecular dynamics (RMD) simulations to determine the thermal conductivities of various glass-ceramic materials. Additionally, we examine the thermal behaviors of glass-ceramic composites containing crystal grains to better understand the impact of these grains on the thermal properties. Consequently, our research aims to significantly advance the field of glass-ceramic-based composites, paving the way for enhanced applications across various industries.

SESSION SF01.06: Manipulation Strategies of Properties Through Atomic Structure, Including Rejuvenation and Relaxation

8:30 AM *SF01.06.01
Pursuit of Improved Properties of Bulk Metallic Glasses by Post-Solidification Treatments *Alan Lindsay Greer; University of Cambridge, United Kingdom*

It is now widely accepted that treatments after casting a bulk metallic glass (BMG) can greatly extend its range of properties. Useful effects can be achieved both by relaxation (lowering the enthalpy) and by rejuvenation (raising the enthalpy). The most widely applied treatments are thermomechanical, and these can be relatively easily applied to BMGs. This talk will focus on our recent work that explores:
- *how the state of a BMG affects its crystallization kinetics*
- *how BMGs may be tuned to avoid or reverse annealing-induced embrittlement*
- *how energy is stored in BMGs via anelastic processes.*

We will also consider new approaches to the optimization of BMG compositions for particular applications, where the required properties range from toughness to tarnish resistance.

9:00 AM SF01.06.02
Unraveling the Role of Relaxation and Rejuvenation on the Structure and Deformation Behavior of the Zr-Based Bulk Metallic Glass Vit105 *Lucas M. Ruschel[1], Sergej Jakovlev[1], Oliver Gross[2], Nico Neuber[1], Bastian Adam[1], Maximilian Frey[1], Benedikt Schmidt[1], Benedikt Bochtler[2] and Ralf Busch[1]; [1]Universität des Saarlandes, Germany; [2]Amorphous Metal Solutions GmbH, Germany*

The influence of relaxation and rejuvenation on the deformation behavior of the Zr-based bulk metallic glass Vit105 ($Zr_{52.5}Cu_{17.9}Ni_{14.6}Al_{10}Ti_5$) was investigated, where a well-defined thermal history was systematically introduced by thermal treatments. Various annealing states were characterized, covering a broad range that has not been systematically studied so far. Samples with a progressively lower fictive temperature exhibit a lower enthalpic state, coupled with a reduced degree of free volume, which is responsible for the continuous embrittlement observed in three-point beam bending tests. Additionally, it could be shown that complex BMG parts exhibit highly *inhomogeneous relaxation states distributed throughout the entire component, allowing the assessment of the mechanical behavior based on the generated database by simple calorimetric measurements and the determination of the fictive temperature. These findings can be transferred to any component made of Vit105, which cannot be easily evaluated in mechanical tests. Diffraction experiments with high energy synchrotron X-ray radiation revealed that the structure is dominated by icosahedral motifs that are forming an icosahedral short-range order. Furthermore, annealing results not only in an ordering on the short- but also the medium-range order. Specifically, the increasing trend in the reduced pair distribution function on the length scale of rigid 3-atom cluster connections were found to be decisive for the reduction in the total strain, as a measure of ductility, indicating a strong correlation with the thermal history. The current findings provide fundamental insights into the role of thermal history in metallic glass forming alloy systems and how it can be used to manipulate the structure and tailor their mechanical properties specifically to the needs of each application.*

9:15 AM *SF01.06.03
Structural Rejuvenation in Micro- and Nano-Scale Metallic Glasses *Golden Kumar; The University of Texas at Dallas, United States*

Metallic glass samples with diameters ranging from sub-100 nm to 100 μm were subjected to cryogenic cycling, mechanical rejuvenation, and annealing before tensile loading at room temperature. Shear-localized failure with no ductility is observed in large samples whereas the smaller diameter specimens show ductile necking irrespective of the structural state of metallic glass. With decreasing sample diameter, the fracture surface changes from vein pattern to featureless in the shear-localized samples and the ductility increases in the necked samples. Despite similar size-dependent trends, the changes in deformation mode and fracture morphology occur at different diameters in as-cast, cycled, deformed, and annealed samples. The critical diameters for transitions from shear localization to necking and from vein pattern to smooth fracture surface shift to larger values in cryogenically and mechanically rejuvenated samples whereas annealing has the opposite effect. The role of structure and sample size in preventing catastrophic failure in metallic glasses will be discussed.

9:45 AM SF01.06.04
Multi-Scale Defects Activation in $Gd_{18.33}Tb_{18.33}Dy_{18.34}Co_{17.5}Al_{27.5}$ High-Entropy Metallic Glasses Revealed by Nanoindentation *Wei Li[1,2], Xiaofei Zuo[1,2], Rui Liu[1,2], Changmeng Pang[1,2], Fan Jin[1,2], Weiwei Zhu[1,2] and Chenchen Yuan[1,2]; [1]Southeast University, China; [2]Jiangsu Key Laboratory for Advanced Metallic Materials, China*

Metallic glasses (MGs) exhibit high strength, hardness, elastic limit, and excellent corrosion resistance due to their atomic characteristic of long-range disorder. Nevertheless, the lack of ductility of MGs resulting from the local shear band extremely restricts their further practical application as a structural material. It is studied that the defect activation is of fundamental importance for plastic deformation. However, its mechanism is not yet fully disclosed in MGs, especially for those with high configurational entropy that demonstrate outstanding physical or chemical properties, more particularly, mechanical characteristics.
In this work, multi-scale defects activation of three rare-earth-based MGs with low-, medium-, and high-entropy (LE, ME, and HE) were systematically investigated by tracing their room-temperature nanoindentation behaviors. Among the three alloys, the $Gd_{18.33}Tb_{18.33}Dy_{18.34}Co_{17.5}Al_{27.5}$ HE MG exhibits the highest hardness and elastic modulus. Unlike the poor deformability of the LE MG, the pronounced nanoindentation displacements under a constant load were observed in HE and ME MGs, especially at high loading rates. To reveal the plastic origin of HE MGs, a generalized physical model (so-called Maxwell-Voigt) was utilized to describe the nanoindentation deformation on the mesoscale. The characteristic relaxation spectra show that the activated defects with longer relaxation time are mainly responsible for the large nanoindentation displacement at high strain rates. Based on the cooperative shearing model, the shear transformation zone (STZ) volume is determined to be around 0.45-2.98

nm^3. The statistics of the short-range order indicate that the HE MG possesses a highly ordered configuration, which results in the difficulty of STZ activation for requiring overcoming a high energy barrier, and a high elastic modulus of the HE MG. Our work might provide insight into the underlying plastic deformation mechanism of HE MGs from the characteristics of activated defects as well as their entropy effect.

10:30 AM *SF01.06.05

Gradient Effects on Mechanical Properties of Metallic Glasses *Mo Li; Georgia Institute of Technology, United States*

Inhomogeneity exists in metallic glasses that naturally introduces variations of structural, chemical or property changes in different regions. The spatial variations lead to gradient of these quantities that in turn affects properties. In this presentation, I will examine in quantitative way how these gradients affect mechanical properties, in particular strength and toughness of metallic glasses. We show that in a sample with a continuously varying density, or density gradient, or free volume gradient, the internal stresses are affected through redistribution. This causes the local shear and later, shear band formation to be distributive. The larger the gradient, the more effective to prevent the local shear from concentrating in a single location, and thus, high toughness can be achieved. The principles we learned from these theoretical studies point to new use of gradient in design of metallic glasses and their composites. We show, in an example, that the thickness gradient of the regions with the network structure in a metallic glass composite can indeed help us to improve the toughness as well as strength. Lastly, we examine the length scales associated with the gradients and how they influence the mechanical behaviors of metallic glass and its composites.

11:00 AM SF01.06.06

Distinct Relaxation Mechanism at Room Temperature in Metallic Glass *Yi-Tao Sun; Institute of Physics, China*

How glasses relax at room temperature is still a great challenge for both experimental and simulation studies due to the extremely long relaxation time-scale. Here, by employing a modified molecular dynamics simulation technique, we extend the quantitative measurement of relaxation process of metallic glasses to room temperature. Both energy relaxation and dynamics, at low temperatures, follow a stretched exponential decay with a characteristic stretching exponent $\beta=3/7$, which is distinct from that of supercooled liquid. Such aging dynamics originates from the release of energy, an intrinsic nature of out-of-equilibrium system, and manifests itself as the elimination of defects through localized atomic strains. This finding is also supported by long time stress-relaxation experiments of various metallic glasses, confirming its validity and universality[1]. The distinct relaxation mechanism can be regarded as a direct indicator of glass transition from a dynamic perspective.

11:15 AM SF01.06.07

Introduction of Sulfur into the (Zr_3Ti)(NiCu) System—Characterization of a New Group of Zr Based BMG Containing Sulfur *Bastian Adam, Oliver Kruse, Lucas M. Ruschel, Maximilian Frey, Nico Neuber and Ralf Busch; Universität des Saarlandes, Germany*

The usage of the element sulfur in Bulk Metallic Glass (BMG) synthesis was recently introduced by Kuball et al. and lead to increased research interest into these new family of BMG [1]. Here we report on the influence of sulfur on the A_2B type intermetallic composition ($Zr_{50}Ti_{16.6}Ni_{18.3}Cu_{15}$) that was characterized by synchrotron diffraction of copper mold cast specimen to determine crystalline phases around the induced primary crystallization change. The addition enables the bulk glass forming ability (GFA) of up to 6 mm 2 at % to 3 at% sulfur. The structure of *amorphous solid and liquid as well as the devitrification behavior and the melting behavior was also studied by heating and melting of the samples in an in-situ synchrotron wide angle scattering experiment (WAXS) experiment utilizing a LINKAM THMS 600 furnace and a high temperature LINKAM TS1500 furnace. The study is accompanied by investigations of primary phase and nucleation mechanism by electron back scattering diffraction and scanning transmission electron microscopy where the nucleation behavior and phase sequence upon initial crystallization is explored in-depth.*

For the best glass former of the system the mechanical properties were investigated in terms of three-point beam bending determining the offset yield strength and breaking elongation of the alloy.

Hynes, Level 3, Room 310

1:30 PM *SF01.07.01

Magnetic Properties of Fe-based Amorphous Alloys Produced by Melt-spinning and Selective Laser Melting

Gabriele Barrera[1], Enzo Ferrara[1], Purbasha Sharangi[1], Isabella Gallino[2], Amirhossein Ghavimi[3], Ralf Busch[3], Marcos Rodriguez[4], Maria Teresa Perez Prado[4], Saumya Sadanand[4], Lena Thorsson[5], Hans Juergen Wachter[5] and Paola Tiberto[1]; [1]Istituto Nazionale di Ricerca Metrologica, Italy; [2]Technische Universität Berlin, Germany; [3]Universität des Saarlandes, Germany; [4]IMDEA Materials Institute, Spain; [5]Hereaus AMLOY Technologies GmbH, Germany

Amorphous soft-magnetic materials play an important role as core constituents in improving the energy transformation efficiency of electrical machines and passive electrical components [1]. Although the melt-spinning process remains the main technique for obtaining amorphous soft-magnetic ribbons with remarkable soft magnetic properties, new and efficient production methods based on additive manufacturing have been developed in recent years, enabling the direct synthesis of larger elements. Metal manufacturing techniques allow shaping the material into the desired geometry while simultaneously engineering its microstructure and properties. Ribbons were obtained by a conventional melt-spinning process, where the pre-alloy was first inductively melted in a quartz tube equipped with a nozzle under vacuum and then injected onto a rotating copper wheel by insufflating high-purity Ar. The 3D-printed samples were produced by additive manufacturing via Selective Laser Melting (SLM), using powder of the same alloy as a precursor. In this study, we investigate the hysteresis properties of amorphous Fe-Si-B-based alloys in ribbon shape and 3D-printed bulk samples produced by different casting techniques. A digital wattmeter was used to measure the hysteresis loss behavior of ribbons and massive elements as a function of frequency (range 1 Hz to 1 kHz) at a fixed peak induction ($J = 0.5$ T). Room temperature quasi-static hysteresis loops of all printed samples and as-cast ribbons were measured using VSM magnetometry [2,3].

The SLM processing conditions have been observed to play a crucial role in the microstructure of the printed parts and, therefore, in their magnetic properties, due to their dependence on morphology (i.e., surface roughness, porosity, density). The effect of different printing parameters on magnetic properties, such as laser power (20-60 W) and scan speed (350-900 mm/s), has been studied. The tuning of these parameters to maximize the amorphous fraction, control the formation of crystalline phases, and consequently optimize soft magnetic properties is *discussed in detail. This study highlights the critical link between microstructure engineering through manufacturing techniques and the resulting magnetic performance, offering insights into optimizing both for enhanced energy efficiency in electrical applications.*

2:00 PM SF01.07.02

Advancements in Developing Fe-Based Metallic Glasses for Additive Manufacturing of Soft Magnetic Components *Amirhossein Ghavimi[1], Maryam Rahimi Chegeni[1], Lucas M. Ruschel[1], Bastian Adam[1], Purbasha Sharangi[2], Gabriele Barrera[2], Enzo Ferrara[2], Paola Tiberto[2], Isabella Gallino[3] and Ralf Busch[1]; [1]Universität des Saarlandes, Germany; [2]Istituto Nazionale di Ricerca Metrologica, Italy; [3]Technische Universität Berlin, Germany*

This research aims to create suitable Fe-based soft magnetic amorphous alloys for the 3D printing of motor components, concerning the iron-silicon-boron (Fe-Si-B) ternary system [1]. Since a fully amorphous structure of the 3D-printed parts is expected to improve motor efficiency, i.e. increased magnetic softness and decreased energy losses, the glass forming ability (GFA) is enhanced through the judicious change of the alloy chemical composition yet maintaining competitive soft magnetic properties. A higher GFA of the alloys enhances the possibility of achieving a fully amorphous structure of the printed parts.
The GFA of the compositions was studied by evaluating the critical casting thickness (d_c) of the samples, which were produced in the form of ribbons and plates in the thickness range of 35 to 800 micrometers by melt spinning and suction casting. Subsequently, conventional X-ray diffraction (XRD) and high-intensity X-ray diffraction (wide-angle X-ray scattering by synchrotron), differential scanning calorimetry (DSC), and differential thermal analysis (DTA) were used to characterize the structure and thermal behavior of the samples of new alloys. The magnetic properties including saturation polarization (J_s) coercivity (H_c), and magnetic susceptibility (χ) were determined under quasi-static conditions by a vibrating sample magnetometer (VSM). Furthermore, hysteresis loops were measured in a low and medium frequency range up to 1 kHz using a digital wattmeter.
Evaluation of quaternary and quinary component alloys involved studying the effects of promising elements such as niobium and nickel on GFA and magnetic properties. Finally, optimal compositions were identified with a critical casting (d_c) of 1.5 mm for the rods, supercooled liquid region (ΔX) of 45 to 50 degrees, saturation polarization J_s ranging from 1.1 to 1.3 T, and coercivity H_c between 3 and 5 A/m (ribbons, J = 0.5 T).

2:15 PM SF01.07.03

Additive Manufacturing of Soft Magnetic Bulk Metallic Glasses—A Promising Approach for High-Efficiency Electric Motors *Anna Langham[1], Georgia Leigh[1], Olaf van't Erve[2], Sebastian Lech[1], Luis Delfin[3], Li Ma[1], Wendy Gu[3] and Mitra L. Taheri[1,4]; [1]Johns Hopkins University, United States; [2]U.S. Naval Research Laboratory, United States; [3]Stanford University, United States; [4]Pacific Northwest National Laboratory, United States*

Electric motors play a vital role in various industries ranging from automotive to aerospace to the energy and manufacturing sectors. Directed Energy Deposition (DED) additive manufacturing has emerged as a promising technique to produce geometrically complex components with enhanced functionalities, including inductor cores. Iron-based bulk metallic glasses (BMGs) have garnered attention due to their unique magnetic properties that make them ideal for inductor cores: high magnetic permeability, low coercivity, and reduced hysteresis losses. The lack of long range order and the absence of grain boundaries in BMGs, which is responsible for domain wall pinning, leads to the significantly reduced energy losses. This work utilized DED to optimize processing of an Fe/glass system toward fully dense, net shaped magnetic cores.

Amorphous Fe-based flake (Metglas) was used as DED feedstock. Amorphous content of the resulting builds was assessed via XRD and dominant phases via electron microscopy (BSE,EDS,EBSD). In all cases, the Metglas recrystallized in the printing process due to insufficient cooling rates. Vibrating Sample Magnetometry (VSM) and Magneto Optical Kerr Effect (MOKE) Magnetometry were used to assess bulk and spatially variant magnetic properties of each build. Magnetic saturation of the builds was incredibly high, hovering around 200 emu/g and coercivities varied based on parameters.

Bypassing crystallization is a challenging kinetics problem and requires both novel materials that are compositionally optimized for glass formability and an ideal thermodynamic environment of the cooling process. The DED system is uniquely situated to tackle this challenge by virtue of its fast cooling rates and graded composition functionality.

Enhancing the Mechanical Properties of a Zr-Based Bulk Metallic Glass via Laser Powder Bed Fusion Process Control *Jamie J. Kruzic[1], Bosong Li[1], Vladislav Yakubov[2], Keita Nomoto[2], Simon Ringer[2], Bernd Gludovatz[1] and Xiaopeng Li[1]; [1]University of New South Wales Sydney, Australia; [2]The University of Sydney, Australia*

Laser powder bed fusion (LPBF) enables the fabrication of large-dimensioned bulk metallic glass (BMG) components; however, we are only just learning how to control the LPBF process to obtain specific mechanical properties. LPBF was used to produce dense and fully amorphous $Zr_{59.3}Cu_{28.8}Nb_{1.5}Al_{10.4}$ *BMG samples from two different starting powders. One powder had a relatively finer particle size range of 10-45 μm and the other had a relatively coarser particle size range of 25-63 μm. Fully amorphous samples were achieved for both powders within a large processing window of laser power and scanning speed combinations. When the LPBF volumetric energy density was raised above ~30-33 J/mm*^{3}*, high relative density (> 99%) was maintained along with devitrification and embrittlement. Low LPBF energy densities below ~20 J/mm*^{3} *produced low relative density (< 99%) and fully amorphous samples. Strength and hardness generally increased with increasing LPBF energy density while the relaxation enthalpy, ductility, and fracture toughness decreased. Furthermore, the coarser powder had four times lower oxygen content and gave better glass forming ability, compression ductility up to 6% plastic strain, and fracture toughness up to ~38 MPa√m. These findings demonstrate that it is possible to tailor the structure and mechanical properties of BMGs by tuning the LPBF process parameters within a wide processing window and by controlling the feedstock powder oxygen content.*

3:45 PM SF01.08.02

Improving Plasticity and Toughness of Additive Manufactured Zr-Based Bulk Metallic Glass Composites by Martensite Phase Transformation *Lin Liu; Huazhong University of Science & Technology, China*

Additive manufacturing based on laser powder bed fusion (LPBF) technique offers a novel approach for fabricating bulk metallic glass (BMG) products without restriction in size and geometry. Nevertheless, the BMGs prepared by LPBF usually suffered from less plasticity and poorer fracture toughness as compared to their cast counterparts due to partial crystallization in heat-affected zones (HAZs). Since crystallization in HAZs is hard to avoid completely in LPBF BMGs, it is desirable to design a suitable alloy system, in which only ductile crystalline phase, instead of brittle intermetallics, is formed in HAZs. This unique structure could effectively improve the toughness/plasticity of the LPBF BMGs. To achieve this goal, a BMG system with a composition of $Zr_{47.5}Cu_{45.5}Al_5Co_2$ *is adopted and subjected to LPBF. It is observed that ductile B2-ZrCu phase precipitates in HAZs, while a fully amorphous phase formes in molten pools (MPs), which alternatively distribute in the whole LPBF samples. This B2 phase reinforced BMG composite exhibits excellent mechanical properties with enhanced plasticity and toughness. Importantly, it is easy to modulate the mechanical properties by altering the amount of the B2 phase via adjusting the laser energy input. Finally, the best combination of strength, plasticity, and notch toughness is obtained in the BMG composite containing 27.4% B2 phase and 72.6% amorphous phase, which exhibits yield strength* (σ_s) *of 1423 MPa, plastic strain* (ε_p) *of 4.65%, and notch toughness* (K_q) *of 53.9 MPa* $m^{1/2}$*. The detailed microstructural investigations reveals that the improvement of plasticity/toughness are mainly due to the martensite phase transformation from the B2 phase to the Cm phase during plastic deformation (i.e.,TRIP effect). The current work provides a guide for making advanced BMGs and BMG composites by additive manufacturing.*

4:00 PM *SF01.08.03

Strategy for Tailoring Thermoplastic Forming Process in Bulk Metallic Glasses *Wook Ha Ryu[1], Min Kyung Kwak[1], Myeong Jun Lee[1], Chae Woo Ryu[2], Hyunseok Oh[3] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Hongik University, Korea (the Republic of); [3]University of Wisconsin–Madison, United States*

The technical interest in bulk metallic glasses (BMGs) has grown over the past few decades due to their potential for new applications based on thermoplastic forming (TPF), previously unattainable with conventional crystalline alloys. However, the difficulty in controlling the TPF process due to the metastability of the amorphous phase has posed a barrier to widespread commercial use. This study provides practical guidelines for tailoring the TPF process, incorporating the influence of process variables in BMGs.
Firstly, a practical indicator of the ideal thermoplastic forming ability (TPFA) of metallic glasses ($\Delta T_F = T_l - T_x$) *is proposed by comprehensively considering flow instability and phase stability. Using this indicator, it is possible to select superior glass-forming alloy systems with excellent TPFA easily.*
Secondly, we accurately identify the TPF window and TPFA according to the heating rate, in a wide range from 10^{-1} *to* 10^4 *K/s, by constructing the continuous heating transform (CHT) diagram with iso-viscosity contours. These approaches enable the selection of customized TPF processes for each amorphous alloy, providing guidelines for tailored TPF processes.*
Finally, as an example of a TPF process, we demonstrated excellent thermoplastic formability (TPFA) in Be-free Zr-based MGs with T_g *below 350 °C and a wide TPF window over 70 K, which is comparable to advanced engineering plastics like Polyimide, expanding the TPF process to MGs. The findings indicate that even marginal MGs have an advantage in manufacturing micro-to-nano scale products at ultra-fast heating rates, akin to advanced engineering plastics. This work inspires further exploration of MGs as practical materials for industrial applications.*

In Situ Rheological Characterization During Thermoplastic Joining of Novel Zr-based Bulk Metallic Glasses
Michal Bialy, Mariusz Hasiak and Amadeusz Laszcz; Wroclaw University of Science and Technology, Poland

Bulk Metallic Glasses (BMGs) are a captivating class of advanced materials that exhibit exceptional mechanical *properties, such as high strength, large elastic limits, and excellent wear resistance, coupled with superior corrosion resistance. Unlike traditional crystalline alloys, BMGs lack long-range atomic order, and are characterized by an amorphous atomic structure. However, their broader engineering applications are restricted, largely due to limitations in the production process. The fabrication of these materials necessitates a specific chemical composition and high cooling rates. Rapid heat dissipation kinetically suppresses the nucleation and growth of crystalline phases. As a result, a metastable amorphous structure is formed. However, these production requirements lead to limitations in the critical sizes of as-cast objects that can be manufactured.*

A practical approach to obtain larger, ready-to-use objects out of BMGs and overcome the casting size limitation is to join the as-cast intermediates. One of the ways of joining is to utilize the distinguishing characteristics of amorphous BMGs – the presence of the glass transition temperature (T_g). This temperature signifies the shift from a supercooled liquid state to a glassy structure upon cooling, with reversibility observed upon heating. Therefore, in controlled heating, BMGs feature a supercooled liquid region (SCLR) below the actual melting point, specifically between T_g and the initial crystallization temperature (T_x). Within the SCLR, homogeneous deformation of material via viscous flow is possible, allowing for thermoplastic processing of BMGs. Thermoplastic joining method of BMGs in the SCLR targets the attainment of metallic bonding during superplastic flow and large deformation at the interface between the elements. However, this method has only been applied and verified for a small group of alloys.

The success of the joining process is intrinsically linked to the rheology of the flow. The viscosity directly impacts the BMG's ability to flow, break up surface oxide layers and achieve bonding as well as determines the timescale of the process. Therefore, investigating and controlling viscosity is crucial for achieving strong, defect-free joints.

Here we demonstrate the thermoplastic joining of novel highly stable BMGs from the ZrCuAgAlBe group with continuous viscosity measurement. Studied BMGs were manufactured by arc melting and conventional suction casting into 5 mm diameter copper molds. Two cylinders, each 4 mm in height, were used for joining by uniaxial compression at different temperatures within the SCLR under constant force. Microstructural and nanomechanical characterizations of the joining site cross-section revealed no distinctive bonding line for the compression strains above 50 % indicating proper bonding. In-process displacement measurement allowed for the estimation of viscosity over the entire procedure, which was found to be in the range 10^9–10^6 Pas. Continuous measurement provides valuable insights into the evolution of the process.

Precise control over viscosity is essential for optimizing thermoplastic joining processes for BMGs. The viscosity should be low enough for sufficient flow and bonding at the interface, but high enough to prevent excessive deformation or crystallization. A comprehensive understanding of thermoplastic joining considering viscosity is then crucial for further, wider applications of this method and consequently the increasing industrial adoption of BMGs.

Amorphous Semiconductors from Amorphous Alloys *Shipeng Sun, Tiantian Chai, Kefu Yao, Zhengjun Zhang and Na Chen; Tsinghua University, China*

Both n-type and p-type amorphous semiconductors are essential for realizing new functions in emerging optoelectronic and magnetoelectronic devices. Their conduction types are determined primarily by their local atomic configurations. However, their disordered amorphous structures pose significant challenges to the design of local atomic arrangements and thus hinder the development of amorphous oxide semiconductors with predetermined conduction types. To address this long-standing issue, we developed a new class of amorphous oxide semiconductors by adding oxygen into different amorphous alloy systems. These amorphous oxide semiconductors showed different conduction types mainly depending on the compositions of the selected amorphous alloy systems. Integrated with the mainstream semiconductor Si, these amorphous oxide semiconductors showed the potential for developing useful full-color filters and spintronic devices. These findings may pave a way to create novel amorphous oxide semiconductors with promising optoelectronic and magnetoelectronic properties for applications in thin film diodes, transistors and solar cells.

Properties and Potential Applications of (Fe,Co) and (Fe,Mo)-Based Bulk Metallic Glasses *Mihai Stoica and Jorg F. Loffler; ETH Zürich, Switzerland*

Since their discovery, ferromagnetic metallic glasses and their subsequent nanocrystalline counterparts were intensively investigated. They possess superior soft-magnetic properties, characterized by a high saturation polarization (J_s) and high relative permeability (μ_r), as well as low coercive force (H_c) and core loss (W). These materials show great industrial relevance, and products based on these materials are widely used as anti-theft labels, high-efficient magnetic transformers, power inductors, or sheets for magnetic shielding. Currently, foils, consolidated powder particles or micrometric irregularly shaped flakes are used for such applications. The field may be substantially enhanced by using such materials in bulk form. The amorphous nature of bulk metallic glasses (BMGs) allows them to be cast in shapes ready to be used, without the shrinkage inherent to crystalline materials, with no or just minimal post-processing necessary.
The current work will present two BMG-forming alloys for comparison: $(Fe_{36}Co_{36}B_{19.2}Si_{4.8}Nb_4)_{99.5}Cu_{0.5}$ and $Fe_{74}Mo_4P_{10}C_{7.5}B_{2.5}Si_2$ BMGs. The (Fe,Co)-based glassy samples possess moderate glass-forming ability, enabling the direct casting of samples with reduced bulk geometry (i.e. rods with diameters up to 2 mm or parts having volumes of 10-20 cubic millimeters). Upon annealing such samples show tailorable DC soft-magnetic properties (J_s = 1.2 T, H_c = 3 A/m), which can be easily controlled by tuning the annealing parameters. The (Fe,Mo)-based BMGs reveal better glass-forming ability and excellent mechanical properties, which makes possible the direct casting in ring shape. In their as-cast state, these samples show not only very good DC magnetic properties (J_s = 1 T, H_c = 3 A/m, μ_r = 110,000), but also satisfactory AC properties up to 1 MHz and only 10 W/kg total loss at 1 kHz. The present work will discuss the manufacturing routes and magnetic properties of these two BMGs, and present in detail the structural evolution upon heating.

9:30 AM SF01.09.03

Exploring the Biomedical and Therapeutic Potential of Metallic Glasses *Mariana Calin[1], Jurgen H. Eckert[2] and Annett Gebert[1]; [1]Leibniz Institute for Solid State and Materials Research Dresden, Germany; [2]Austrian Academy of Sciences, Austria*

In recent years, a significant surge in interest around biomaterials has been raised due to their diverse array of types and considerable potential for future biomedical and bioengineering applications. Metallic glasses are newcomers in the biomedical fields. They offer a unique combination of properties not found in conventional

biomaterials: high strength and wear resistance combined with outstanding elastic properties, corrosion resistance and isotropic behavior. Moreover, due to their amorphous structure, the bulk metallic glasses (BMGs) exhibit an unusual temperature-dependent mechanical behavior that enables plastics-like processability and offers new shape/surface design opportunities, which do not exist for crystalline metals [1,2].
By fine-tuning the alloy composition and the processing routes/parameters, bio-mechanical and bio-chemical characteristics can be appropriately adjusted for specific biomedical applications [3]. BMGs have a great potential for small medical devices useful in dentistry (e.g. dental implants and suprastructures), orthopaedics and trauma surgery (e.g fracture fixation systems) and occlusive vascular diseases (e.g stents and aneurysm clips) [3-5,7].
Ti-, Zr- and precious metal-based BMGs have been widely investigated as potential biomaterials especially for bone-related implant applications [4,5]. However, the major problem still facing the development of biomedical metallic glasses is the one of inducing amorphization without using any harmful alloying additions. We recently reviewed the biological safety and glass forming tendency in Ti of a series of alloying elements [3].
In the present paper we discuss the underlying processes for amorphous phase formation, mechanical and biochemical behaviour as well as the biocompatibility of various Ni-free Ti- and Zr-based BMGs with potential for biomedicine [6]. For miniaturized implants like stents or aneurysm clips, besides the conventional biomedical properties, the magnetic resonance imaging (MRI) compatibility is required for the follow-up post-operative inspection and control. This talk will also include our recent results on MRI- compatible glassy Ti-Zr-Nb-Hf-Si alloys designed based on a high entropy alloys (HEAs) approach, by exploring the central region of multi-component alloy phase space [7].

Surface Nanostructuring of $Ti_{40}Cu_{40}Zr_{11}Fe_3Sn_3Ag_3$ Amorphous Alloy by Chemical Dealloying for Potential Use as a Biocompatible Material *K. Tiwari[1], F. Scaglione[1], Nora Fernandez-Navas[2], Cristina Pavan[1], Annett Gebert[2], Francesco Turci[1] and Paola Rizzi[1]; [1]Università di Turino, Italy; [2]Leibniz Institute for Solid State and Materials Research Dresden, Germany*

Amorphous alloys show potential as implant materials due to their superior mechanical properties and good corrosion resistance. However, the presence of toxic elements in the alloy composition can pose challenges, as they can react with the surrounding tissue, leading to inflammation and cell death. This study focuses on the design of a new Ti based multicomponent amorphous alloy for the development of biocompatible implant materials with enhanced hemocompatibility. Ti40Cu40Zr11Fe3Sn3Ag3 at% amorphous alloy was developed, with composition comprising biocompatible elements (Ti, Zr, and Sn) and antimicrobial elements (Ag, Fe, and Cu). While this class of amorphous alloys has shown its potential for biomedical implant applications, there are major concerns due to the presence of elements such as copper which can lead to cytotoxicity in the human body during long term implantation. Nevertheless, copper is indispensable in the development of an amorphous alloy. Thus, *the objective of this work is to selectively remove copper from the surface of the Ti40Cu40Zr11Fe3Sn3Ag3 (at%) amorphous alloy using the dealloying technique using a solution of ammonium hydroxide and hydrogen peroxide and produce a patterned protective passivated surface rich in Ti and Zr oxides. The surface of the samples was analyzed using atomic force microscopy, scanning electron microscopy, and X-ray photoelectron spectroscopy. The modified surfaces show titanium oxide-rich nanostructured topography with depleted amounts of copper from the surface. The kinetics of the selective removal of copper, and the influence of parameters such as electrolyte concentration, immersion time, and stirring velocity on the evolution of morphology were investigated. Our findings elucidate the mechanism of pseudo-dealloying using an ammonia based solution and demonstrate its efficacy in enhancing the biocompatibility of the alloy. This study underscores the significance of our approach in tailoring the surface properties of amorphous alloys for biomedical applications, paving the way for their utilization in implant materials with improved biocompatibility.*

***Observation of an Isothermal Glass Transition in Metallic Glasses** Maozhi Li[1], Yi-Tao Sun[2], Yanhui Liu[2] and Weihua Wang[2]; [1]Renmin University of China, China; [2]Chinese Academy of Sciences, China*

Glass transition, commonly manifested upon cooling a liquid, is continuous and cooling rate dependent. For decades, the thermodynamic basis in liquid–glass transition has been at the center of debate. Here, long-time isothermal annealing was conducted via molecular dynamics simulations for metallic glasses to explore the connection of physical aging in supercooled liquid and glassy states. An anomalous two-step aging is observed in various metallic glasses, exhibiting features of supercooled liquid dynamics in the first step and glassy dynamics in the second step, respectively. Furthermore, the transition potential energy is independent of initial states, proving that it is intrinsic for a metallic glass at a given temperature. We propose that the observed dynamic transition from supercooled liquid dynamics to glassy dynamics could be glass transition manifested isothermally. On this basis, glass transition is no longer cooling rate dependent, but is shown as a clear phase boundary in the temperature-energy phase diagram. Hence, a modified out-of-equilibrium phase diagram is proposed, providing new insights into the nature of glass transition.

11:00 AM SF01.10.02
***Measurements of Surface Diffusion on Metallic Glasses** Zijian Wang, Chengrong Cao, Lian Yu and John H. Perepezko; University of Wisconsin-Madison, United States*

The surface mobility of glasses plays a crucial role in various applications, including friction, sintering, heterogeneous catalysis, and thin-film deposition. This area has garnered significant attention over the past decades, predominantly focusing on organic glasses. Metallic glasses (MGs), characterized by their relatively simple atomic arrangement and a range of unique properties, are considered ideal model systems for studying the fundamental properties and behaviors of glassy materials. However, the surface diffusion on MGs has remained *largely unexplored due to their multicomponent, highly reactive chemical nature. Building on the pioneering work of long-term surface dynamics measurement on a $Pd_{40}Ni_{10}Cu_{30}P_{20}$ MG in 2015, we investigated the surface diffusion on $Au_{60}Cu_{15.5}Ag_{7.5}Si_{17}$ and $Pd_{77.5}Cu_6Si_{16.5}$ MGs at temperatures well below their glass transition temperatures (T_gs) using surface grating decay and surface scratch decay methods, respectively. The decay of these surface nanostructures with increasing annealing time was analyzed using the Mullins model, enabling the derivation of temperature-dependent surface diffusion coefficients. Specifically, surface diffusivities were evaluated to range from $(9.0 \pm 2.1) \times 10^{-20}$ m^2 s^{-1} and $(2.6 \pm 0.5) \times 10^{-18}$ m^2 s^{-1} in the temperature range from $0.83T_g$ to $0.94T_g$ for the Au-based MG, and from $(8.66 \pm 0.80) \times 10^{-19}$ m^2 s^{-1} and $(5.90 \pm 0.60) \times 10^{-18}$ m^2 s^{-1} within $0.83T_g$ to $0.91T_g$ for the Pd-based MG. By fitting the temperature dependence of surface diffusivities with the Arrhenius equation, the average activation energies for surface diffusion were determined to be approximately 0.67 eV for the Au-based MG and 0.92 eV for the Pd-based MG. Notably, the activation energy for the Pd-based MG is about half the value for bulk diffusion, aligning with theoretical predictions. Furthermore, our experimental results support the correlation between enhanced surface diffusion and liquid fragility. These findings not only pave the way for measuring surface diffusion on other MGs but also contribute to a broader understanding of surface mobility in glassy materials.*

11:15 AM SF01.10.03

Studies of the Glass Transition in Metallic Glasses via Fast Scanning Calorimetry *Isabella Gallino; Technische Universität Berlin, Germany*

Only recently, the development of fast differential scanning calorimetry (or chip-calorimetry) has allowed us to characterise in situ the glass transition response of metallic glasses during cooling from the liquid over a wider range of time scales employing scanning rates from 100 K/s up to 50,000 K/s. The generally accepted description is that the vitrification kinetics should exhibit the same temperature dependence as the realxation time for the alpha-process. However, we have recently observed that vitrification at deep undercooling may occur with a milder temperature dependence than the alpha-relaxation [1, 2]. The slower the system is cooled the more pronounced is the decoupling between these vitrification kinetics and the atomic mobility. As a consequence, vitrification can occur at fictive temperatures lower than those which would be obtained only accounting for the alpha-process. This apparent decoupling of the time scales for the vitrification kinetics from the time scales for the alpha-relaxation process is more pronounced at deep undercooling [1] and for small sample sizes[2]. This is of most importance because, it advocates a heterogeneity of cooperative atomic rearrangements, where faster mechanisms for atomic mobility that apparently are not contributing to the alpha-relaxation process, are maintaining the undercooled liquid system in (metastable) equilibrium and delay vitrification to lower temperatures.

Predicting the Glass Forming Ability of Binary Alloys *Corey O'Hern[1], Weiwei Jin[1], Jan Schroers[1] and Mark Shattuck[2]; [1]Yale University, United States; [2]The City College of New York, United States*

Metallic glasses represent a promising materials class because they possess larger values of the strength and elastic limit compared to conventional crystalline alloys. However, there are an exponentially large number of possible glass-forming alloys, but it is currently extremely difficult to predict those that will form glasses at experimentally accessible cooling rates. Recently, combinatorial sputtering techniques have been developed that enable the experimental characterization of the glass-forming ability (GFA) of thousands of alloys simultaneously. In this work, we classify the atomic structure as amorphous or crystalline for all binary alloys formed from Cu, Al, Mg, and Ni obtained from sputtering experiments. We compare the experimental results to those from molecular dynamics simulations aimed at calculating the GFA of these binary alloys using inter-atomic energy functions that span a wide range of resolutions, including the pairwise Lennard-Jones and patchy particle potentials and many-body embedded atom method (EAM) and modified EAM potentials. We show that the GFA for all of the the binary alloys that we consider can be accurately modeled using the pairwise patchy particle potential.

2:00 PM SF01.11.02
Glass Formation in Binary Alloys Studied Through Combinatorial Sputtering *Salena Huang[1], Sebastian A. Kube[2], Nathan Johnson[3], Sungwoo Sohn[1], Apurva Mehta[3] and Jan Schroers[1]; [1]Yale University, United States; [2]University of Wisconsin–Madison, United States; [3]SLAC National Accelerator Laboratory, United States*

Glass formation is a complex phenomenon including thermodynamic and kinetic aspects that are often controlled by extrinsic contributions. While bulk metallic glasses are typically fabricated through multicomponent alloys, binary alloys offer a simpler alternative for studying glass formation. In this study, we fabricated 57 binary alloy systems through combinatorial sputtering, with 66 alloys per alloy system. We developed an automated analysis to determine structure and composition through x-ray diffraction and energy-dispersive x-ray spectroscopy respectively. We found that 17% of the alloys form glasses under a cooling rate of ~10^8 K/s. Interestingly, commonly used factors like size ratio, heat of mixing, and full-width-half-maximum of a diffraction peak are ineffective in predicting glass formation. However, crystal structure mismatch of the alloys' elements emerged as the strongest indicator of glass formation under sputtering conditions of binary alloys. The differences in glass formation under slow cooling rates used for bulk glass formation and the here observed glass formation under rapid cooling rates is discussed.

2:15 PM SF01.11.03
Mechanisms of Metallic Glass Formation—Insights from High-Throughput Methods *Mingxing Li and Yanhui Liu; Chinese Academy of Sciences, China*

Despite the importance of glass forming ability as a major alloy characteristic, it is poorly understood and its quantification has been experimentally laborious and computationally challenging. Here, we uncover that the glass forming ability of an alloy is represented in its amorphous structure far away from equilibrium, which can be exposed by conventional X-ray diffraction. Specifically, we fabricated roughly 5,700 alloys from 12 alloy systems and characterized the full-width at half-maximum, Δq, of the first diffraction peak in the X-ray diffraction pattern. A strong correlation between high glass forming ability and a large Δq was found. This correlation indicates that a *large dispersion of structural units comprising the amorphous structure is the universal indicator for high metallic glass formation.*

2:30 PM SF01.11.04

Combinatorial Investigation on the Properties of Metallic Glasses *Yanhui Liu; Chinese Academy of Sciences, China*

Metallic glasses are typical multicomponent alloys. The identification of metallic glasses of desired properties out of a vast compositional space is a daunting task. In the past, metallic glasses were predominantly developed through a sequential and time-consuming trial-and-error approach. In this presentation, we introduce the combinatorial methods developed for the characterization of glass properties as a function of alloy composition. The developed methods enabled us to identify metallic glasses of diamond-like wear and confirm the respective roles of chemical composition and amorphous structure on corrosion resistance.

Classification of Amorphous Versus Crystalline Phases of Alloys Using Electrical Resistivity *Daegun You, Haechan Jo and Dongwoo Lee; Sungkyunkwan University, Korea (the Republic of)*

Efficient identification of amorphous versus crystalline phases in multi-component alloys is crucial for the high-throughput development of new metallic glasses, yet it is often limited by the reliance on slow or expensive techniques like table-top or synchrotron-based X-ray diffraction (XRD). This study investigates electrical resistivity as a predictive descriptor for alloy phases due to its sensitivity to atomic arrangements and rapid measurability. Using a combinatorial magnetron sputtering process, hundreds of multi-component alloys with both amorphous and crystalline phases were synthesized, followed by XRD measurements. High-throughput electrical resistivity measurements of the combinatorial alloy thin films were performed using a custom-built robotic stage equipped with a 4-point probe. Artificial neural networks were then developed to correlate electrical resistivity data with X-ray diffractograms across a wide range of the combinatorially synthesized alloys. These machine learning models accurately classified amorphous and crystalline phases in both thin-film libraries and bulk alloys, offering a promising alternative to traditional phase identification methods.

3:45 PM *SF01.11.06

High-Temperature Mo-Based Bulk Metallic Glasses *Wen Chen; University of Massachusetts Amherst, United States*

Among bulk metallic glass (BMG) alloys, molybdenum-based BMGs are lacking due to the weak glass forming ability (GFA) of existing Mo-based alloys. In this talk, I will introduce a novel family of low-cost refractory Mo-Co-B BMGs with enhanced GFA and high thermal stability. These Mo-based BMGs exhibit ultra-high glass transition temperatures up to ~1050 K, paired with exceptional nano-hardness and Young's modulus up to 17.1 GPa and 260 GPa, respectively. The excellent thermal stability and mechanical properties are closely related to the prominent covalent metal-metalloid bonds in the Mo-Co-B BMGs. I will discuss the physical origin of the superior GFA underlying these Mo-based BMGs and the broad implications of our work for the development of other refractory BMGs. Our finding expands the palette of BMG alloys and opens a new arena for the exploration of low-cost refractory BMGs for applications at high temperatures and extreme environments.

4:15 PM SF01.11.07

Oxidation of Metallic Glasses Detected via Optical Characterizations *Chao Wang; Chinese Academy of Sciences, China*

Oxidation of metallic glasses has been shown to be different from crystalline alloys due to the disordered atomic structures and far-from-equilibrium state, and quick characterization is required to reveal their early stage oxidation. In this talk, the oxidation behavior of bulk metallic glass by measuring the changes of optical constants via spectroscopic ellipsometry will be presented. Characterizations with X-ray diffraction, scanning electron microscopy, and thermogravimetric analyzer confirmed that the changes of pseudo-optical constants reflected not only the onset temperature at which the alloys underwent obvious oxidation, but also the subtle oxidation which was tedious to characterize. This study suggests a more efficient and accurate approach to understand the oxidation of metallic glasses, which can be extended as a high-throughput characterization method to mapping oxidation of crystallization of metallic glasses within a vast compositional space.

10:30 AM *SF02.01.01
Functional High Entropy Alloys *Dierk R. Raabe; Max Planck Institute for Sustainable Materials, Germany*

This presentation reports about recent progress in the field of high-entropy alloys that have interesting functional properties, at maintained good mechanical properties, for which some of these materials are known. Five specific topics are discussed, namely, mechanically strong and ductile high- and medium entropy alloys with good magnetic, invar, electrocatalytic, and hydrogen tolerant properties. Although these features are in part also *available from other alloy systems, their combination with good mechanical properties makes them particularly attractive for future applications in fields related to sustainable energy conversion, electrification and longevity.*

11:00 AM *SF02.01.02

Tailoring A2/B2 Microstructures of Refractory Compositionally Complex Alloys (RCCA) for Assessing Creep Properties *Martin Heilmaier, Stephan Laube, Liu Yang, Daniel Schliephake, Sandipan Sen, Raja J. Vikram and Alexander Kauffmann; Karlsruhe Institute of Technology, Germany*

Refractory compositionally complex alloys (RCCA) are promising candidates for high-temperature structural applications. Many of the reported alloys consist of A2 or B2 phases with additional intermetallic phases, often located at grain boundaries. However, to achieve good mechanical performance at elevated temperatures as well as sufficient plastic deformability at room temperature, the proper formation of a strengthening phase is crucial. We report here on the current status of our investigations within the Ta-Mo-Ti-Cr-Al system which exhibits a promising combination of strength and oxidation resistance at elevated temperatures [1]. The objective is to attain a suitable multi-phase microstructure of A2 matrix and B2 precipitates without significant grain boundary decoration. Thermodynamic calculations were employed to predict specific transformation sequences of ordering and diffusion-controlled phase separation within this system. These predictions were experimentally verified. The microstructure of alloys with high Al concentration exhibited a B2 matrix with A2 precipitates; in contrast, an A2 matrix with B2 precipitates was determined in Al-lean alloys [2]. Additionally, it maintains a stable ultrafine particle microstructure even after prolonged exposure to elevated temperatures (1000°C) [3]. The phase separation into an A2+B2 two-phase microstructure in RCCA has been speculated as being spinodal in nature with continuous chemical distribution during the separation. However, phase separation in the system Ta-Mo-Ti-Cr-Al, occurs via interface motion-controlled precipitation as verified by atom probe tomography and electron microscopy techniques. Thus, the requirements for controlled strengthening by superalloy-like microstructures are verified in a certain compositional range, e.g. in 82(Ta-Mo-Ti)-8Cr-10Al (in at.%). We therefore present the current status of investigations into the creep behavior of this B2 precipitation strengthened A2 alloy: Compression creep tests were conducted at elevated temperatures close to the solvus temperature and above, with varying constant true stresses to unveil the creep deformation behavior and underlying mechanisms. Subsequently, SEM/TEM were employed to examine the deformed microstructures at different creep strains. The discussion will encompass the impact of the coherent interface between the matrix and precipitates.

Computationally Guided Development of High Entropy Alloys *John Sharon, Ryan Deacon, Anthony Ventura, Ken Smith, Soumalya Sarkar and Jenna Krynicki; RTX Technology Research Center, United States*

High Entropy Alloys (HEAs), which contain multiple principal elements, can exhibit unique property combinations that are not necessarily observed in conventional alloy systems. HEAs are typically comprised of four or more elements present from five to thirty-five atomic percent, resulting in a vast composition space that can be daunting to material designers. Computational tools are vital to sorting through the billions of potential HEA compositions to identify the most promising candidates. This talk will describe a machine learning framework that leverages physics-based models, hand-book data, and other information to rapidly home in on alloy candidates. Subsequent *experimental characterization of identified alloys will also be presented. Industry perspective in terms of predictive modeling gaps and experimental challenges key to HEA maturation and adoption will also be provided.*

11:45 AM SF02.01.04

Deformation Mechanisms and Activation Parameters in RMPEA Micropillars Across the Temperature Spectrum—From Cryogenic to High Temperature *Nicolo Maria della Ventura[1], Carolina Frey[1], Julia Puerstl[1], Morgan Jones[1], Leah Mills[1], Ravit Silverstein[1], Chunhua Tian[2], Christian Minnert[2], Thomas Edwards[2], W. Refractory multi-principal element (RMPE) alloys possess remarkable strength retention at elevated temperatures, making them attractive for extreme structural environments. Several promising single-phase alloys demonstrate an intermediate temperature strength regime that is quasi-athermal, motivating studies that aim to link the temperature-dependent mechanical behavior to dislocation behavior in these concentrated BCC alloys. To elucidate the relationships between strength, dislocation plasticity, and thermal activation, in situ single crystal micropillar compression experiments are conducted in the SEM on a newly developed RMPE alloy (Hf-Mo-Nb-Ta-Ti) deformed along two different crystallographic directions at both cryogenic and elevated temperatures. At each testing temperature, the specimens are subjected to various strain rates allowing for the extraction of activation parameters, with post-mortem TEM used to evaluate resulting dislocation structures. The obtained results, supported by phase-field dislocation dynamics (PFDD) simulations, are analyzed within the framework of thermally activated deformation mechanisms and the origins of the quasi-athermal strength observed at intermediate temperatures, bolstering the understanding of defect dynamics in high temperature multi-component alloys.

SESSION SF02.02: Next-Generation Structural Materials for Extreme Environments—Fundamentals, Design and Discovery I

Strength, Ductility and Toughness in bcc vs. fcc High-Entropy Alloys *Robert O. Ritchie, Punit Kumar, David H. Cook, Madelyn I. Payne, Wenqing Wang, Pedro P. Borges, Andrew M. Minor and Mark Asta; University of California, Berkeley, United States*

Face-centered cubic (fcc) medium- and high-entropy alloys (HEAs) can display exceptional combinations of strength, tensile ductility and fracture toughness, properties that can be further enhanced at cryogenic temperatures. Body-centered cubic (bcc) refractory RHEAs, conversely, can display exceptional strength and compressive ductility at elevated temperatures, but are often compromised by poor lower-temperature behavior. We examine here the strength, ductility and toughness of these two classes of multiple principal-element alloys, and show that whereas some of the fcc HEAs exhibit among highest toughness values on record, even under extreme conditions of ultrahigh strain rates and liquid-helium temperatures, the bcc HEAs can display extremely *low toughness when subject to tensile loading. We explore the reasons for such distinct properties, and investigate why most bcc HEAs are markedly brittle, whereas a few, such as NbTaTiHf, can display remarkably high toughness over an extremely wide range of temperatures.*

2:00 PM +SF02.02.02

Tensile Properties and Phase Stability of Refractory High-Entropy Alloys *Easo P. George[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Ruhr-Universität Bochum, Germany*

Off-equiatomic and pseudo-binary subsets of the TiZrHfNbTa refractory high-entropy alloy (RHEA) were tensile tested to determine effects of composition on strength and ductility. Compositional effects on strength are largely due to effects on shear modulus. On a modulus-normalized basis, strength is relatively constant over a large range of compositions as long as the alloys retain their single-phase BCC solid solution structure. Ductility generally exhibited an inverse correlation with strength (i.e., followed the usual strength-ductility tradeoff). The equiatomic TiZrHfNbTa alloy was creep tested at temperatures to 1373 K. At the tested temperatures, this RHEA was significantly weaker in creep than a two-phase Ni-base superalloy (CMSX-4). It was also weaker than the single-phase solid solution matrix of CMSX-4 which has the close-packed FCC structure as opposed to the more open BCC structure of the RHEA. Additionally, stress-assisted phase decomposition was observed after the creep tests. To investigate phase stability in the absence of stress, the quinary VNbMoTaW and TiZrHfNbTa RHEAs and their lower-order equiatomic subsets (quarternaries, ternaries and binaries) were investigated at temperatures to 1473 K and times to 300 days. Consistent with Hume-Rothery rules, the former alloy and its subsets were mostly stable as single-phase BCC solid solutions given that their constituent elements are all BCC over the entire temperature range. In contrast, the latter alloy and its subsets, being composed of HCP and BCC elements, tended to phase separate. Effects of temperature (vibrational entropy), number of alloying elements (configurational entropy), and crystal structure were quantified and correlated with phase stability.

2:30 PM *SF02.02.03

Design of BCC—B2 Refractory Multi-principal Element Alloys *Tresa Pollock[1], Sebastian A. Kube[1,2] and Carolina Frey[1]; [1]University of California, Santa Barbara, United States; [2]University of Wisconsin, United States*

Refractory multi-principal element alloys show promise for high temperature structural applications beyond 1200 deg C. However, many single phase solid solution refractory MPEs do not retain a high level of strength beyond 1200 deg C. We show that in Ru-containing MPEs, strengthening is possible with Ru-containing B2 precipitates that are stable above 1200 deg C. The design and screening approach for identification of promising B2 – BCC matrix combinations will be described. Microstructures and properties in alloys containing RuHf, RuAl and RuTi B2 precipitates will be presented. Control of misfit to achieve coherent precipitates is demonstrated. Finally, implications for processing these alloys will be discussed.

High-Temperature Micromechanical Properties of $(MoTa)_{25}Ti_{25}V_{25}Zr_{25}$ High Entropy Alloy *Mahmut Erol, David E. Armstrong and Angus J. Wilkinson; University of Oxford, United Kingdom*

Refractory high entropy alloys have promising complexity and structural stability for next-generation nuclear reactors [1] and high-temperature applications [2]. A large number of compounds as single-phase solid solutions or multiphase options with additional precipitates from directly as-cast or triggered by post-treatment have been investigated in many studies [3], [4]. Thanks to the employment of low-activation refractory elements [5], these *high entropy alloys can demonstrate better characteristics to meet the requirements of design and material performance. These alloys have favorable combinations of high strength and chemical stability at elevated temperatures. Recently, Ayyagari and co-workers [6], [7] reported a BCC+BCC microstructure with V-rich decoration around W-Ta dominated phase. This alloy has met hardness stability at elevated temperatures. However, this equiatomic alloy could not provide sufficient ductility at room temperature because of more than 60 wt.% W-Ta content. As a conceptual alternative to WTaTiVZr, MoTaTiVZr alloy was produced via arc-melting. The amount of Mo and Ta was selected as 25 at.% to decrease the brittle phase ratio embedded in TiVZr plus less than 10 at.% Mo-Ta binder phase. V-rich decorations were also observed in both as-cast and homogenized forms. However, Ti distribution in as-cast form was much more homogenous than in Ayyagari's studies [6], [7]. The grain size stability and phase transition characteristic of* $(MoTa)_{25}Ti_{25}V_{25}Zr_{25}$ *was investigated after different homogenization treatments. The effects of selected homogenization treatments on microstructure and formation of inherent brittle precipitates were determined through X-ray diffractometer, scanning electron microscopy with energy dispersive X-ray, and electron backscatter diffraction analysis. After 1400 °C for 24 hours, V segregated to Mo-Ta rich phases whereas the binder phase decomposed to the Zr-rich and Zr-Ti dominated phases. Microstructural stability and micromechanical properties of* $(MoTa)_{25}Ti_{25}V_{25}Zr_{25}$ *alloy up to 600 °C will be discussed by nanoindentation analysis.*

From the Bottom Up and Back Again—Designing Oxidation Resistant High Entropy Alloys *Mitra L. Taheri[1], Elaf Anber[1], Sebastian Lech[1], David Beaudry[1], Loïc Perrière[2], Jean-Philippe Couzinie[2], Nathan Smith[2], Michael Waters[2], Charlie Brandenburg[3], Elizabeth J. Opila[3], James M. Rondinelli[2] and Christopher Wolverton[2]; [1]Johns Hopkins University, United States; [2], United States; [3]University of Virginia, United States*

Refractory high entropy alloys are plagued with limited oxidation resistance at high temperatures, despite their promise for use in aerospace and energy-related applications. Much research has been dedicated to additions of traditional passivating elements, such as Al, Si, and Cr, to refractory alloy systems, however achieving a continuous oxide scale has been elusive. Here we present a path toward continuous scales based on short range order, phase evolution, and epitaxial interfacial design unique to high entropy alloys. Our results show that aspects of high entropy alloys, such as short-range order, can be utilized as design tools in the compositional selection and *screening of high entropy alloys for oxidation resistance. Moreover, we find that the complexity of phase evolution and non-equilibrium oxides in high entropy alloys acts as a mechanism for oxide stability. Ultimately, this work provides a foundation for high temperature use of refractory high entropy alloys with oxidation mitigation.*

4:15 PM SF02.02.07

BCC Refractory MPEAs for Laser Processing (and Additive Manufacturing)—From Computational Models to Additive Manufacturing *Julia Chmielewska[1,2], Karol Kuglarz[1] and Christian Leinenbach[1,2]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]École Polytechnique Fédérale de Lausanne, Switzerland*

BCC refractory multi-principal element alloys (RMPEAs) exhibit significant potential for high-temperature structural applications (1000–2000 K) in fusion reactors, the space industry, and high-performance turbines. However, only a small fraction of their extensive and varied compositional design space has been explored, leaving many potentially valuable alloys undiscovered.

This study investigates the design and manufacturing of RMPEAs for fabrication by beam-based additive manufacturing technologies, focusing on enhancing phase stability at high temperatures and refining grain structures without requiring extensive post-processing.

The use of additive manufacturing (AM) techniques addresses challenges such as segregation and coarse grain formation during solidification, offering insights into RMPEA behaviour across various temperature regimes and cooling rates. Laser processing offers high cooling rates, which prevent the formation of highly segregated, dendritic structures commonly seen in arc melting or casting. It also shortens diffusion lengths, resulting in a more uniform chemical composition and smaller grains, thereby reducing the annealing time. Moreover, AM enables near-net zero-shape manufacturing, surpassing the potential problems of machining due to high hardness and material waste, which enhances sustainability.

Employing CALPHAD-based alloy screening procedures (TC-Python) and computational models, promising candidates of 3-element alloys within the Hf-Mo-Nb-Ta-Ti-Zr master system with anticipated (?) properties are identified. Metastable phase transformations within RMPEAs are exploited through in situ X-ray diffraction at elevated temperatures (1273 K) and ex-situ heat treatment at 1623 K. To uncover the laser processing potential of the newly designed alloys, the arc-melted samples have been laser-treated to evaluate the potential for manufacturing crack-free parts. Arc-melted, heat-treated, and laser-processed bulks have been characterized by SEM, EDS, EBSD, XRD, and nanoindentation.

Overall, this interdisciplinary approach combines computational modelling, alloy design strategies, and advanced manufacturing techniques to push the boundaries of RMPEAs. It contributes to the development of additive manufacturing technologies and paves the way for improved mechanical properties in extreme environments.

4:30 PM SF02.02.05

Processing-Microstructure Investigation of Nb-V-Zr and the Role of Compositional Segregation on Mechanical Behavior *Katharine Padilla, Nur A. Octoviawan, Sam Ehrman, Rohan Mishra and Katharine Flores; Washington University in St. Louis, United States*

Refractory high entropy alloys (RHEAs) have gained considerable attention for their potential as the next generation of high-temperature materials due to their unique design strategies and excellent mechanical properties. While tremendous progress has been made in this field, there is still a lack of knowledge on the effects of processing and composition on the microstructural development of these alloys. In this work, we apply a high-throughput synthesis technique to investigate the processing-composition-structure relationships in Nb-V-Zr. This medium entropy alloy is chosen as a model system as it forms the basis for many RHEAs that have been studied to date.

We use direct laser deposition to rapidly synthesize microstructural libraries under a wide range of heating and *cooling rates, as well as compositional libraries with varying Nb and Zr concentrations. BCC dendrites are observed, separated by two Laves phases, cubic C15 and hexagonal C14. Phase size, spacing, and morphology are correlated with laser power, travel speed, and composition. Compositional segregation is also observed in the microstructure, where the dendrites have a Nb-enriched center and Zr-enriched edges, while the interdendritic region is enriched in V. Transmission electron microscopy is used to investigate the coherency between these interfaces. Nanoindentation experiments are performed to investigate the role of compositional segregation on mechanical properties.*

4:45 PM SF02.02.08

Oxygen-Induced Hierarchical Heterogeneities and Enhanced Hardness in RMPEAs *David Beaudry[1], Michael Waters[2], Gianna Valentino[3], Daniel L. Foley[1], Elaf Anber[1], Jean-Philippe Couzinie[4], Loïc Perrière[4], Keith Knipling[5], Patrick Callahan[5], Benjamin W. Redemann[1], Tyrel McQueen[1], James M. Rondinelli[2] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Northwestern University, United States; [3]University of Maryland, United States; [4]Centre National de la Recherche Scientifique, France; [5]U.S. Naval Research Laboratory, United States*

Refractory multiprincipal element alloys (RMPEAs) offer superiority to incumbent high-temperature structural alloys due to high melting points and retained strength at elevated temperatures. Of this class of alloys, those containing Group IV and V elements possess adequate ductility, low density, and the necessary formability. However, these elements have dramatically different interactions with oxygen, which creates uncertainty in predicting oxide evolution and in alloy design for oxidation resistance. We used advanced characterization and Monte Carlo simulations to decipher the complex sub-surface phase evolution during high-temperature oxidation of Group IV-V RMPEAs. We found that a refined hierarchical microstructure of nanoscale suboxides and oxides forms, which leads to a gradient hardness increase up to 23 GPa while preserving the plasticity of the base metal. Criteria for expansion of this alloy design strategy to other composition spaces and interstitial elements will be discussed.

SESSION SF02.03: Exploring Microstructural Complexity—Advanced Characterization and Micro-Mechanisms

Single-Crystal Mechanical Properties of FCC High-Entropy Alloys *Haruyuki Inui, Le Li, Zhenghao Chen and Kyosuke Kishida; Kyoto University, Japan*

The plastic deformation behavior of single crystals of the FCC equatomic CrMnFeCoNi high-entropy alloy and its derivative quaternary (CrFeCoNi) and ternary (CrCoNi) medium-entropy alloys has been investigated in a temperature range of 10-1273 K. Deformation occurs via slip of the {111}<110> system exclusively in the whole temperature range for all alloys investigated. The CRSS values increase with decreasing temperature, especially below room temperature, so that the concept of 'stress equivalence' is obeyed for all alloys investigated. This is a clear indication that the strength of these alloys should be described by a mechanism based on solid-solution hardening. The CRSS values extrapolated to 0 K for polycrystals of equiatomic quinary, quaternary and ternary alloys are reported to be well scaled with the mean-square atomic displacement from the regular FCC lattice points (calculated based on density-functional theory). This seems also the case for the CRSS values at 0 K for *single crystals of the present three alloys, although some modifications are definitely needed. Deformation twinning occurs on the conjugate system in the form of the Lüders type deformation in the later stage of deformation at low temperatures in all of the three alloys. The correlation between the twinning stress and the stacking-fault energy in these alloys will be discussed. The occurrence of short-range ordering was confirmed in CrCoNi through the measuring of electrical resistivity, while conventional x-ray and electron diffraction failed to detect short-range ordering because of the very small difference in atomic scattering factor for the constituent elements in a wide range of scattering angle. The extent of short-range oredering in CrCoNi was proved to be the largest after annealing at 673 K. However, no significant variation of the CRSS values, twinning stress and the stacking-fault energy was noted upon the formation of short-range order by heat-treatment.*

8:30 AM *SF02.03.02

Imaging of Short Range Order with Electron Microscopy—From High Performance Alloys to Semiconductor Thin Films *Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States*

This talk will describe our recent results utilizing energy filtered diffraction, 4D-STEM and in situ TEM nanomechanical testing that provide insight into the determination and role of short range order (SRO) in materials. Examples will be presented from structural alloys such as α-titanium and the CrCoNi medium entropy alloy, as well as semiconductors such as a SiGeSn/GeSn multilayer. We will consider the role of both SRO and planar defects in the both the mechanical response (Figure 1) as well as structural determination via electron diffraction as a function of heat treatment in the CrCoNi MEA [1,2]. Lastly, we will discuss both the strengths and limitations of TEM methods for analyzing SRO in these systems, with particular emphasis on coordinated computational methods to simulate diffraction patterns in order to directly compare with experimental measurements [3].

9:00 AM *SF02.03.03

Strength-Ductility Synergy in Multicomponent Alloys with Hierarchical Microstructures *Jurgen H. Eckert[1,2]; [1]Austrian Academy of Sciences, Austria; [2]Montanuniversität Leoben, Austria*

Designing multi-scale heterostructures by taking lessons from nature provides a promising strategy for achieving excellent strength-ductility synergy in metals and alloys. The achievement of this goal usually requires intricate *multi-step thermomechanical processing, but this is still a challenge with cast alloys rather than wrought ones. This talk presents some routes for solving this problem, focusing on medium and high entropy alloys (MEAs/HEAs) and eutectic high entropy alloys (EHEAs) subjected to different processing routes for property optimization.*

For example, the cast $Cr_{30}Fe_{30}Ni_{30}Al_5Ti_5$ *(at.%) MEA exhibits a hierarchically heterogeneous structure involving precipitates at multiple length-scales. Microscale body-centered-cubic (BCC) grains are dispersed throughout a continuous face-centered-cubic (FCC) structural framework. Coherent* $L1_2$ *nanoparticles form in the FCC matrix, while abundant nanoparticles with hierarchical dimensions (i.e., of η, B2, and* $\eta/L2_1$ *phases) precipitate inside the BCC grains. The synergistic interactions between dislocations and multiscale precipitates which induce massive dislocation networks and stacking faults result in stable strain-hardening behavior, endowing the alloy with an exceptional combination of strength and ductility without the need for homogenization and complex processing. These features surpass known cast high and medium entropy alloys and offer implications for developing new high-performance cast multicomponent alloys.*

Further property tuning and optimization can be achieved through thermo-mechanical processing, including deep cryogenic treatment and tempering or through severe plastic deformation via equal channel angular pressing (ECAP) or high pressure torsion (HPT) – both for initially single-phase materials or for eutectic alloys via tuning grain sizes, grain boundary structures, dislocation networks and interactions, and precipitates, further allowing to tailor the mechanical properties. This may also involve transformation or twinning-induced plasticity (TRIP/TWIP) mechanisms helping or governing the deformation characteristics. In all cases hierarchical heterogeneous structures are achieved that help to create high-strength yet ductile materials with improved crack resistance and fatigue performance.

This talk will present recent results and examples for different MEAS, HEAs and EHEAS for optimizing microstructures and mechanical properties of multicomponent alloys through different processing routes.

9:30 AM SF02.03.04

Explicit Demonstration of Short-Range Order Through Synergistic Modeling-Characterization Investigation

Tianshu Li[1], Shunda Chen[1], Xiaochen Jin[1], Lilian M. Vogl[2], Shang Liu[3], Andrew M. Minor[2] and Jifeng Liu[3]; [1]George Washington University, United States; [2]University of California, Berkeley, United States; [3]Dartmouth College, United States

The significance of short-range order (SRO) in high-entropy materials (HEM) has been recently recognized but the intricacy and subtlety of SRO make it highly non-trivial to characterize SRO through conventional characterization approaches. Even the state-of-the-art characterization techniques are often shown insufficient to explicitly demonstrate the existence of SRO in HEM. For example, 4D scanning transmission electron microscopy (4D-STEM) can detect SRO at nanoscale through the appearance of diffuse diffraction patterns but multiple sources have been shown to potentially contribute to such diffraction signals. Atom-probe tomography (APT) probes both chemical and positional information of each atom in alloy's lattice, but its limited spatial resolution restricts APT's applicability to retrieve meaningful information of SRO in alloys. Therefore, an explicit demonstration of SRO requires synergistic efforts from both characterization and modeling on the same spatial scale. To achieve this goal, we recently developed two new modeling capabilities: (1) A physics-informed, statistical approach to recover Warren-Cowley SRO parameter in alloy from noisy APT data, and (2) A highly efficient and accurate machine-learning potential framework[1] to model SRO in alloys at the same scale of 4D-STEM and APT. Applying these new capabilities through a collaboration with advanced characterizations, we explicitly demonstrate the existence of SRO in group IV alloys, verifying our early theoretical predictions[2,3]. Importantly, this modeling-characterization synergy further enables mapping the spatially resolved diffuse diffraction patterns in 4D-STEM to different local SRO structural motifs, presenting a first-of-its-kind demonstration of in-depth investigation of SRO in any alloys. The developed approaches are also shown to be applicable in other alloys, thus opening the possibility of explicitly characterizing SRO in a wide range of HEM.

This work is supported by Department of Energy, Office of Basic Energy of Sciences under Award No. DE-SC0023412.

Peierls-Nabarro Modeling of Dislocations in High Entropy Alloys *William A. Curtin[1], Xin Liu[2], Bastien F. Aymon[2] and Terrence Moran[2]; [1]Brown University, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland*

Dislocations in alloys with random solute distributions, short-range order, or clustering have a range of competing length and energy scales that establish overall energy barriers to dislocation motion. The flow stress then depends on many different underlying atomistic material parameters and emergent length scales. To gain understanding and to guide theory development, we show how an extended Peierls-Nabarro (PN) model can enable highly efficient scale bridging along with parametric exploration of dislocation behavior as a function of material parameters. However, local fluctuations in the atomic forces acting on the dislocation cannot be measured using the atom-level virial stress. Studies then show that variations in the unstable fault energy have negligible effects on strength compared to stress fluctuations due to solute misfits, consistent with misfit-based theory. Comparisons of the extended PN model predictions to direct atomistic nudged-elastic band simulations of the dislocation energy landscape in a model bcc HEA show the fidelity/accuracy of the extended PN model and role of core structure. The PN model is then applied to study the configurations, energies, and motion of long, intrinsically wavy, dislocations with comparisons to analytic theory.

10:45 AM SF02.04.02
Stability and Growth Kinetics of Deformation Twin Embryos in Multicomponent Metastable BCC Ti-Based Alloys *Ganlin Chen[1], Dian Li[2], Yufeng Zheng[2] and Liang Qi[1]; [1]University of Michigan, United States; [2]University of North Texas, United States*

Deformation twinning provides critical plastic deformation mechanisms to tune the strength and ductility of *complex concentrated alloys. However, physical mechanisms that determine the types/magnitudes of twinning in these alloys (especially metastable BCC Ti-based alloys) are still unclear due to the complex potential energy landscape related to plastic deformations and diffusionless phase transformations. We applied computational and experimental studies to understand and tune the correlations between diffusionless phase transformations and deformation twinning in these alloys at various compositions and temperatures. First-principles calculations were performed to study the structures and energy stability of different phases related to the twinning path. Atomistic simulations with both classical and machine learning interatomic potentials were conducted to further analyze the nucleation and growth mechanisms of twin embryos in both binary alloys and multicomponent alloys. These atomistic simulation results combined with crystallographic theory can provide quantitative energetic criteria to select the twinning activities based on the phase stability in metastable BCC Ti-based alloys.*

Nanostructure and Dislocation Interactions in Refractory Complex Concentrated Alloy—From Chemical Short-Range Order to Nanoscale B2 Precipitates *Yi Yao[1], Jonathan Cappola[1], Wenjun Cai[2] and Lin Li[1]; [1]Arizona State University, United States; [2]Virginia Tech, United States*

Refractory complex concentrated alloys (RCCAs) have emerged as a promising class of structural materials, demonstrating exceptional mechanical performance in aggressive environments. However, the complex atomic environments, significant lattice distortion, and vast compositional space of RCCAs present challenges to understanding the mechanisms that govern structure-property relationships. In this study, we explore the dislocation mechanisms in three model quaternary RCCAs, namely Mo25Nb10Ta25W40 (at. %), Mo25Nb25Ta25W25, and Mo25Nb40Ta25W10 using large-scale atomistic simulations and machine learning based Spectral Neighbor Analysis Potential. Our atomistic simulations examine how the chemical composition and local ordering influence the mobility of both edge and screw dislocations, and how lattice distortion and diffuse anti-phase boundary energy (DAPBE) affect dislocation behaviors during nanostructural evolution. Notably, with the increase in Nb concentration in the model RCCAs, both DAPBE and lattice distortion are simultaneously enhanced as the chemical short-range order (CSRO) evolves into nanoscale B2 precipitates. This evolution results in high lattice distortion due to the lattice mismatch between B2 precipitates and the random matrix. Consequently, B2 nanoprecipitates provide a stronger pinning effect, hindering edge dislocation motion while promoting cross-slip of screw dislocations, leading to a reduced screw-to-edge ratio in slip resistance and mobility discrepancy. These findings offer valuable insights into dislocation behaviors and interactions with ordered precipitates, highlighting the importance of exploring non-equiatomic compositions and advancing beyond CSRO in RCCAs. This study has implications for optimizing alloy compositions and processing methods for superior performance in aggressive environments.

Probing Phase Stability in CrMoNbV Using Cluster Expansion Method, Calphad Calculations and Experiments *Siya Zhu[1], Amit Samanta[2], Jibril Shittu[2], Aurélien Perron[2], Chiraag Nataraj[3], Joel Berry[2], Joseph McKeown[2] and Axel van de Walle[4]; [1]Texas A&M University, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Sandia National Laboratories, United States; [4]Brown University, United States*

High entropy alloys (HEA), a novel class of materials with multiple principal elements, allow us to tune the properties within a wide composition range where the solid-solution phase is stable. However, it is difficult to experimentally determine the boundaries of the single-phase region. In this paper, we calculate the phase diagram of the CrMoNbV quaternary system, as well as its constituent binary and ternary subsystems, using a combination of the cluster expansion method and CALPHAD calculations. We further verify these results by carrying out experiments at two different compositions of the full quaternary system. Our work shows how these *computational tools can enable efficient discovery and development of new HEAs.*

Capturing Short-Range Order in High-Entropy Alloys with Machine Learning Potentials *Yifan Cao, Killian Sheriff and Rodrigo Freitas; Massachusetts Institute of Technology, United States*

Computational investigations of chemistry-microstructure relationships require atomistic models that act at the appropriate length scales while capturing chemical-bond intricacies, such as short-range order (SRO). Here we consider various approaches for the construction of training data sets for machine learning potentials (MLPs) for metallic alloys and evaluate their performance in capturing SRO and its effects on materials quantities of relevance for microstructural evolution. Based on this analysis we systematically derive design principles for the rational construction of MLPs that capture SRO. The resulting approach is demonstrated to have high physical fidelity by comparing the predictions directly to experimental measurements, such as enthalpy of SRO formation and SRO domain size.

Mechanical and Thermal Properties of Entropy-Stabilized Transition Metal Oxides *Keivan Esfarjani, Bikash Timalsina and Huy G. Nguyen; University of Virginia, United States*

Entropy-stabilized oxides have been materials of active research interest due to a high degree of lattice distortion and tunability. Lattice distortion plays a crucial role in understanding elastic constants and lattice thermal conductivity. In this work, a neuroevolution machine learning potential (NEP) is developed for the MgCoNiCuZnO5 compound, and its accuracy has been compared to density functional theory (DFT) calculations. Employing this NEP potential, lattice distortion, elastic constants and thermal conductivity have been quantified for this compound. In agreement with experimental findings, we have shown that the average lattice distortion of oxygen atoms is higher than that of all transition metals. The observed distortion saturation arises from the competing effects of minimum site distortion, which increases with increasing temperature due to enhanced thermal vibrations, and maximum site distortion, which decreases with increasing temperature. Furthermore, a series of molecular dynamics simulations up to 900 K were performed to study the stress-strain behavior. Elastic constants, bulk modulus, and ultimate tensile strength obtained from these simulations indicate a linear decrease in these properties with temperature. Finally, to gain some insight into thermal transport in these materials, we used non-equilibrium molecular dynamics simulations to compute the heat current autocorrelation and the spectral thermal conductivity. It is found that while the thermal conductivity κ of MgNiO2 decreases from 4.25 W/m.K at room temperature to 3.5 W/m.K at 900 K, it almost saturates (with maybe a small eventual decline) for the 5-component MgCoNiCuZnO5. This suppression for the binary compound is attributed to the stronger scattering of low-frequency modes at higher temperatures.

High-Throughput and Robust Materials Design Hypothesis Generation via a Large Language Model *Hyunseok Oh; University of Wisconsin–Madison, United States*

The increasing complexity of materials design requires advanced methods to manage and transfer extensive information across various domains. This research utilizes GPT-4, a large language model (LLM), to mimic one of the human design activities by synergistically combining mechanisms from research articles to generate materials design hypotheses. First, through prompt engineering, the model accurately extracts key information from individual articles using the materials system chart framework—a structured framework comprehending the dynamic interplay among Processing, Structure, and Property. Then, it synthesizes innovative hypotheses from this information, including design ideas for high entropy alloys with superior cryogenic properties and halide solid electrolytes with high ion conductivity and formability. Notably, recent publications have validated these hypotheses, demonstrating the LLM's ability to generate novel ideas not previously established in the literature. This LLM-assisted design approach enhances the potential for disruptive discoveries of new materials while maintaining scientific and engineering plausibility.

2:00 PM *SF02.05.02
Synthesis and Properties of Compositionally Complex Ultra-High-Temperature Ceramics *Ian D. McCue; Northwestern University, United States*

Ultra-High Temperature Ceramics (UHTCs) are promising materials for use in next-generation hypersonic platforms owing to their high melting points and excellent thermo-mechanical properties.One exciting aspect of UHTCs is that increasing the complexity of their composition leads to substantial property enhancements. For instance, refractory carbides (HfC, TaC, etc.) possess high mutual solubility and can be fabricated as compositionally complex carbides (e.g., $HfNbTaTiZrC_5$), which exhibit >50% increase in hardness over their individual constituents. However, the role of composition is muddled with stoichiometric departures associated with excess vacancy concentrations. In this talk, we will present a novel synthesis route to fabricating these materials by exposing precursor metallic alloys to reactive gases at elevated temperature, which enable the stoichiometry to be precisely controlled. In addition, this talk will address the governing kinetics of their synthesis, and their resulting mechanical and high-temperature oxdiation properties.

2:30 PM *SF02.05.03
Property-Targeted Compositional Design of RE_2O_3 High-Temperature Coatings *Elizabeth J. Opila[1], Rachel Rosner[1], Kristyn Ardrey[2], William T. Riffe[1], Alejandro Salanova[1], Prasanna Balachandran[1], Bi-Cheng Zhou[1], Jon Ihlefeld[1] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Oak Ridge National Laboratory, United States*

RE_2O_3 exhibit three crystal structures across the lanthanide series: hexagonal, monoclinic, and cubic, with all showing exceptionally high-melting temperatures (>2100°C) and excellent thermochemical stability. The cubic RE_2O_3, dysprosium through lutetium oxides, have isotropic thermal expansion with a reasonable match to Nb, making them suitable high temperature coatings for oxidation-prone refractory alloys. Multicomponent rare-earth oxides (MRO) allow the additional ability to target and optimize thermal expansion, resistance to molten deposits, and especially thermal conductivity, enabling their use as thermal barrier coatings in high-temperature, reactive environments such as turbine engines. Thermal conductivity of MROs has been shown to decrease with mixtures of RE_2O_3 with increasing mass and size variation. The larger, lighter, non-cubic lanthanide oxides, lanthanum through terbium oxides, mixed in a majority MRO cubic phase in non-equimolar proportions will precipitate as second phases once their solubility limit in the cubic RE_2O_3 is exceeded, enabling further reductions in thermal conductivity. In this work, MRO compositions are systematically varied to aid in achieving targeted thermal

conductivity, thermal expansion, and resistance to molten deposits. Powder mixtures were combined, ball milled, and sintered via spark plasma sintering. Room temperature thermal conductivity was measured using the laser-based time domain thermoreflectance method. Thermal expansion was determined by dilatometry or lattice parameter measurements as a function of temperature. Resistance to molten CaO-MgO-Al_2O_3-SiO_2 was quantified after exposure at temperatures of 1300-1500°C for times between 1 and 96h. Alternative processing methods for controlling the second phase size and distribution with additional ability for microstructural design will be discussed.

Thermophysical Property Tuning in Compositionally Complex Rare Earth Titanate and Zirconate Families

Katharine Page[1,2], Joshua Safin[1], Sean Drewry[1] and Jade Edward Holliman Jr[1]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

In multicomponent ceramics there are a variety of factors that determine phase selection and stability such as the configurational entropy of the system, the ionic radii of the constituent cations, and the propensity for vacancies, anti-site defects, and other types of crystalline disorder. The influence of these factors varies with the structural and chemical complexity of the crystal system, potentially giving rise to an expanded degree of physical property tuning in compositionally complex variants. We explore structure-property trends in two compositionally complex oxide families, titanate pyrochlores ($RE_2Ti_2O_7$) and zirconate fluorites ($RE_{0.5}Zr_{0.5}O_{2-x}$), taking advantage of the large diversity of ionic radii available in the Lanthanide series (RE=La to Lu, large to small). We present thermal conductivity and thermal expansion coefficient trends across the series, and we examine corresponding average and local atomic structures using X-ray and neutron diffraction and pair distribution function analysis. Various mechanochemistry and sintering pathways are shown to influence cation chemical short-range order and grain size control in compositions with promising property combinations. Structural stability is examined at extreme temperatures (~2800 °C) using aerodynamic levitation and laser heating, evaluating their suitability as potential next generation thermal barrier coatings. Determining the impact of high entropy configurations on pyrochlore and fluorite stability windows, defect formation, and other crystal-chemical factors, provides deeper understanding of possible design considerations for intrinsic property enhancement in these and other multicomponent complex ceramics.

4:00 PM SF02.05.05

The Role of Chemistry and Strain on Grain Boundary Structure, Energy and Composition in Two Transition Metal High Entropy Carbides *Tarek Haque, Marium Mostafiz Mou, Samuel Daigle and Donald Brenner; North Carolina State University, United States*

Segregation to grain boundaries is a well-established process in conventional materials that can affect stability, structure and mechanical properties. Solute atoms at grain boundaries, for example, can inhibit grain growth by establishing a local equilibrium that eliminates grain growth driving force, and through solute drag that produces kinetic stabilization. While well understood in metals and in many conventional ceramics, our current understanding of grain boundary segregation in high entropy ceramics is very limited. We have been using energies from Density Functional Theory in a Monte Carlo simulation to predict the structure and bonding of a Sigma=5 symmetric tilt grain boundary in the high entropy transition metal carbides (Hf, Mo, Nb, Ta, Zr)C and (Hf, Nb, Ta, Ti, Zr)C as well as their respective binaries. For the binaries the calculations predict a zig-zag structure formed by a lateral translation along the grain boundary interface that relieves lattice strain and forms undercoordinated cations. These grain boundary energies increase with increasing bulk carbon vacancy formation energy and with

increasing bulk modulus, reflecting two major contributions to the interface energy. For the high-entropy composition containing Mo, the calculations predict that Mo energetically prefers undercoordinated sites, consistent with its small vacancy formation energy in a rocksalt structure. They also predict that Zr energetically prefers sites near the grain boundary with large Voronoi volumes. This is consistent with a relatively large lattice constant and small bulk modulus for ZrC. The second composition replaces Mo with Ti, which has a similar small size but much higher vacancy formation energy. In this case, Nb energetically prefers undercoordinated sites, again consistent with it having the lowest carbon vacancy formation energy of the bulk materials within this composition, while Zr again prefers the lattice sites with larger volumes. These results illustrate the competing roles of lattice strain and chemistry in determining grain boundary structures, energies and composition in these materials.

Irradation-Induced Lattice Distortion Dependent on Ion Species in Refractory High-Entropy Alloys *Emily H. Mang[1], Annie Barnett[1], Daniel L. Foley[1], Wei-Ying Chen[2], Jaime Marian[3], Michael L. Falk[1] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Argonne National Laboratory, United States; [3]University of California, Los Angeles, United States*

Body-centered cubic (BCC) refractory high-entropy alloys (RHEAs) are proposed for the next generation of materials suitable for fusion reactor components due to their outstanding high-temperature strength, and radiation tolerant properties. It is widely believed that radiation tolerant properties in RHEAs originate due to inherent sluggish diffusion within the alloy, impacting vacancy and interstitial migration. While many studies report radiation tolerance in RHEAs, dynamic defect microstructural perspectives remain limited. This study investigates Mo-based alloys with varying degrees of chemical complexity to gauge the interplay of increasing solute effects under radiation. Ultimately, we probe the impact of vacancy bias on defect evolution through in situ experiments conducted using single- (1 MeV Kr^{2+}) and dual-beam (18keV He^{+} and 1 MeV Kr^{2+}) ion irradiation. The dual-beam condition is intended to impart vacancy stabilization bias, and consequently, we recognize striking impacts on global lattice distortion. Local divergence in structure produces interfaces that act as sites for dislocation annihilation, contributing to an overall reduction in dislocation size. The objective of this work is to discuss the microstructural implications of altering defect mobility in complex alloys, offering insight to dynamic lattice effects of RHEAs in radiation environments.

4:30 PM SF02.05.07

Synthesis and Characterization of Single Crystal Cantor-Like Alloys via Floating Zone Furnace *Alexander M. deJong[1], Satya Kushwaha[1], Allana G. Iwanicki[1], Suchismita Sarker[2], Benjamin W. Redemann[1], Hyun Sang Park[1], Tyrel McQueen[1] and Todd C. Hufnagel[1]; [1]Johns Hopkins University, United States; [2]Cornell University, United States*

Bulk single crystals of advanced alloys are useful in a variety of structural applications (such as turbine blades) and enable fundamental studies of structure and properties that are difficult or impossible with polycrystalline specimens. Of particular recent interest are compositionally complex alloys (including multiple-principle-element alloys) such as equiatomic alloy CrCoFeMnNi. We report here the synthesis of bulk fcc single crystals of several alloys in this family, including FeNiCo, FeNiCr, and FeNiCoCr, by the floating zone technique. We report on measurements of the structure of these single crystals from Laue x-ray diffraction, reciprocal space mapping, and electron backscatter diffraction (EBSD), as well as energy dispersive spectroscopy (EDS) mapping of compositional homogeneity. Finally, we discuss the measurements of single-crystal elastic constants using resonant ultrasound spectroscopy (RUS).

4:45 PM SF02.05.08

Synergistic Effects of Grain Boundary and Chemical Short-Range Order on Radiation Resistance in NiCoCr Alloys *Hyeonwoo Kim[1], Sangtae Kim[1], Miaomiao Jin[2] and Yang Yang[2]; [1]Hanyang University, Korea (the Republic of); [2]The Pennsylvania State University, United States*

Short-range order (SRO) in medium-entropy alloys (MEA) affects radiation resistance by reducing the diffusivity of irradiation-induced defects as lattice distortion increases. To gain insights into how SRO influences defect dynamics under irradiation, we conducted molecular dynamics-based cascade simulations on a NiCoCr alloy known for its high radiation resistance and hardness. Specifically, we explored the synergistic effects of SRO and grain boundaries (GBs) on irradiation resistance. The number of surviving defects in alloys with chemical SRO (CSRO) were similar to those in a random solution alloy (RSA) in both single crystal (SC) and low-energy GB configurations. Conversely, in high-energy GB structures, which act as defect sinks, CSRO exhibited more surviving interstitials with a fewer number of vacancies than those in RSA. These conflicting effects occur because SRO affects the efficiency of defect sinks, which preferentially absorb interstitials. These results demonstrate that the influence of SRO on radiation resistance depends on the presence of defect sinks.

Diffusion Enhancement by Frenkel Defects in NaCl-Type High Entropy Materials *Rikuya Ishikawa[1], Kyohei Takae[2], Yoshikazu Mizuguchi[1] and Rei Kurita[1]; [1]Tokyo Metropolitan University, Japan; [2]Tottori University, Japan*

High entropy materials (HEMs) have attracted attention as materials with excellent mechanical properties, irradiation resistance, ionic conductivity, and thermoelectric performance.
For instance, materials with high lithium-ion permeability and melting temperatures are desirable for use as separators in lithium-ion batteries to improve their safety. Consequently, developing HEMs with high diffusion coefficients for specific ions is of great interest. Although the macroscopic strength and crystal stability in HEMs are closely linked to the diffusion of atoms, there is a lack of understanding of the diffusion mechanism due to the complexity of the atomic interactions.
In this study, we focus on the high-entropy superconductor AgInSnPbBiTe5 whose superconductivity is robust against external pressure. The Coulomb potential is dominant in this material, which exhibits the NaCl structure at room temperature and pressure. We have investigated the superconductivity and structure experimentally, as well as the vibrational properties by molecular dynamics (MD) simulations. The simplicity and clarity of the Coulomb potential in these systems facilitate an in-depth investigation of diffusion over extended periods and large system sizes. We therefore considered that investigating the diffusion properties using MD simulations of this system would elucidate the diffusion mechanism of HEMs.
Here, we reveal that In+ spontaneously forms Frenkel defect and enhancing diffusion not only of In+ but also other cations. The charge plays a more crucial role than the size of the cation in the formation of Frenkel defects. Furthermore, as a result of enhanced diffusion, short-range order is formed by structural relaxation. This insight not only enhances comprehension of HEMs diffusion mechanisms but also develops HEMs with properties such

as self-healing from damage and high ion permeability, advancing the field of material science.

SF02.06.02

Effects of Al Addition on the Corrosion and Mechanical Properties of NbTaTiV High Entropy Alloy *S M Yeasin Habib[1], Zhe Fan[1], Kun Wang[2], Nafiz Ahmed Badhan[1] and Xuejun Fan[1]; [1]Lamar University, United States; [2]Alfred University, United States*

High-entropy alloys (HEAs) are known for their excellent microstructural stability, mechanical properties, and corrosion resistance owing to the high configurational entropy by multiple principal elements. NbTaTiV, a refractory HEA, is particularly interesting because of its high melting point (2275°C), good ductility with high compressive fracture strain (>40%), high yield strength and wear resistance. Alloying with other elements, such as Al, Cr, and Zr, has the potential to further improve these properties. In this study, we investigated the impact of Al addition at an equimolar ratio on the NbTaTiV HEA system, as it not only has the potential to improve the corrosion resistance and mechanical properties but also reduces the alloy's density and production cost.
The alloys were prepared by casting and homogenization. X-ray diffraction (XRD), backscattered electron scanning electron microscopy (BSE-SEM) and energy dispersive X-ray spectroscopy (EDS) techniques were used for the characterization of the alloys. To evaluate the corrosion resistance, electrochemical impedance spectroscopy (EIS) and potentiodynamic polarization experiments were performed in a 3.5wt% NaCl solution at room temperature. Optical microscopic photographs of the surface were taken before and after the corrosion experiments to detect the presence of pitting or crevice corrosion. The localized mechanical properties of the alloys, such as hardness and modulus, were measured using nanoindentation.
The XRD results revealed that both alloys are BCC solid solutions. The BSE-SEM and EDS images revealed a lower level of elemental segregation in the AlNbTaTiV HEA in contrast to the NbTaTiV HEA. The EIS results indicated that the addition of Al leads to an increase in the charge transfer resistance (~40%), which means higher corrosion resistance. However, the potentiodynamic test revealed that above 1.5V, the AlNbTaTiV HEA's passive film dissolves leading to pitting corrosion, whereas the NbTaTiV HEA formed a second metastable passive film that protected it from pitting. Nanoindentation tests showed that adding Al increases the hardness (~10%) and modulus (~10%) of the matrix. Al addition also increased the density of titanium precipitation, especially along grain boundaries, which may enhance the alloy's strength, hardness, creep resistance, and wear resistance.
In summary, adding Al to the NbTaTiV HEA can improve both the mechanical properties and corrosion resistance of the alloy, except in scenarios where pitting corrosion might occur. These findings contribute to the ongoing development of HEAs for better performance in various industrial applications.

SF02.06.03

Effect of Cr on the Corrosion and Localized Mechanical Properties of AlMoNbTi High Entropy Alloy *Nafiz Ahmed Badhan[1], Zhe Fan[1], Xinchang Zhang[2], Cheng Sun[3], S M Yeasin Habib[1] and Xuejun Fan[1]; [1]Lamar University, United States; [2]Idaho National Laboratory, United States; [3]Clemson University, United States*

This work evaluates the corrosion protection efficiency of AlMoNbTi and CrAlMoNbTi high entropy alloys in 3.5 wt% of NaCl solution at room temperature. Electrochemical impedance spectroscopy test by Gamry instruments was used in this evaluation. The results indicate that adding Cr in an equal molar ratio with AlMoNbTi increases the corrosion protection efficiency by 2.5 times. Additionally, the microstructural analysis by scanning electron microscopy reflects the heterogeneity in the microstructures of AlMoNbTi and CrAlMoNbTi. So, nanoindentation tests are performed to find the localized mechanical properties: hardness and elastic modulus, at different positions for these specimens. However, there is no significant difference in hardness and elastic modulus was *found between these two alloys. The hardness mapping, microstructures, and X-ray diffraction data indicate that all three specimens have at least two phases in their microstructures. Both specimens' experimental results are compared with conventional carbon steel alloy C1060 for better understanding the performance of these two alloys.*

SF02.06.04

High Entropy Alloying Strategy for Efficient Seawater Splitting and Metal-Air Battery Applications

Gokul Raj, Ravi Nandan, Kanhai Kumar and Karuna Kar Nanda; Indian Institute of Science, India

High entropy alloys (HEAs), an innovative type of material, have been investigated for their outstanding mechanical characteristics. Seawater electrolysis represents a crucial step in achieving sustainable production of carbon-neutral fuels like H2, O2, and industrially important Cl2. In this study, we present a practical approach involving FeCoNiMnCr HEA nanoparticles integrated into a conductive carbon matrix for efficient seawater electrolysis. Our analysis confirms their effectiveness in hydrogen, oxygen, and chlorine evolution reactions. HEAs on carbon black show triple functionality with promising kinetics, selectivity, and durability. Mott–Schottky measurements optimize band structure for enhanced performance. The HEACB catalyst achieves a water splitting net half-cell potential of 1.65 V with stability, along with metal air battery applications indicating its broad practicability.

SF02.06.06

A Statistical Approach to Retrieve Short-range Order Parameter in Complex Alloys from Noisy Atom-Probe Tomography Measurement

Xiaochen Jin[1], Shunda Chen[1], Shang Liu[2], Jifeng Liu[2] and Tianshu Li[1]; [1]George Washington University, United States; [2]Dartmouth College, United States

Short-range order (SRO) has been alluded to play a significant role in modulating various material properties in medium-entropy and high-entropy alloys, but a decisive characterization of SRO at nanoscale through quantifying the Warren-Cowley SRO parameter has been a challenging task. Atom-probe tomography (APT) can potentially be a useful technique to characterize SRO because in principle, APT probes both chemical and positional information of each atom in lattice. In practice, however, the limited spatial resolution of APT often leads to noisy raw data which yield a convoluted radial distribution function of atomic sites that restricts the applicability of APT in retrieving meaningful information of SRO in alloys. To address this issue, we develop a theory and a statistical approach to recover the Warren-Cowley SRO parameter from noisy APT data. The validity of our approach is verified through a large-scale benchmark GeSn alloy model which is created through our recently developed machine-learning potential[1]. In particular, the benchmark tests show that our approach can accurately recover SRO parameter when the perturbation length (standard deviation of distance between the measured atomic position and its true position) is < 2 Å, and can still qualitatively recover SRO even when perturbation increases to ~ 4 Å. Applying the approach to analyze real APT data in both GeSn binary alloy and SiGeSn ternary alloy, we have successfully recover the SRO parameters in these alloys, which show a qualitative agreement with both our prior theoretical modeling[2,3] and recent EXAFS measurement[4]. Importantly, the developed theoretical model and approach are generically applicable to different types of alloys, thus providing a robust framework to enable APT as an effective tool for quantitatively characterizing SRO in a wide range of compositionally complex alloys.

The Rule of Mixtures, a New Evans-Polanyi-Semenov Relation and Twinning Predictions for High Entropy Transition Metal Ceramics *Marium Mostafiz Mou, Tarek Haque, Samuel Daigle and Donald Brenner; North Carolina State University, United States*

High entropy ceramics, typically characterized by five or more components in roughly equimolar concentrations arranged randomly on one or more crystal sublattices, have the potential for outstanding mechanical properties as well significant challenges for understanding and predicting these properties. In this work, we have used first-principles calculations to probe the {111} twinning properties of Group IVB, VB, and VIB high-entropy transition metal carbides. We find that the twin boundaries are predictable through an optimized rule-of-mixtures based on the properties of individual metal carbide constituents near the twin plane. We also find that the unstable twin energy, which is a barrier along the <112> {111} gamma surface slip path, can be related to the twinning and stacking fault energies through an Evans-Polanyi-Semenov (EPS) relation. Typically used to describe a linear relation between activation energy and heat of reaction in a series of related chemical processes, we will show how this new application of the EPS relation leads to analytic relations for twinnability as a function of valance electron concentration for these materials.

SF02.06.08

Facile Synthesis of Medium Entropy Sulfides as Hydrogen Evolution Co-Catalysts with CdS for Photocatalytic Water Splitting *Yan Chen, Martin Nastran, Bernhard Fickl, Jakob Rath, Stephen Myakala, Hannah Rabl, Dogukan Apaydin, Alexey Cherevan, Dominik Eder and Bernhard C. Bayer; Technische Universität Wien, Austria*

In this work we introduce (MoWCoNi)S_x medium entropy sulfide nanoparticles from a facile, bottom-up, low-temperature solvothermal synthesis approach as effective hydrogen evolution reaction (HER) co-catalysts with CdS for visible light driven photocatalytic water splitting. We establish the relationships between composition, structure, amorphicity/crystallinity and catalytic activity in these non-layered, sulfur-deficient medium entropy sulfide nanoparticles. When hybridizing these medium entropy sulfides as HER co-catalysts with CdS we show that their long-term catalytic activity outperforms single-elemental sulfides from a similar synthesis route, which we suggest to possibly be related to sluggish diffusion effects in the medium entropy sulfides.
This work has been funded by European Research Council (ERC) grant HighEntropy2D.

SF02.06.09

Spall Strength of Pure Solids on the Periodic Table and Its Correlation with Known Thermomechanical Properties *Robert P. Swallow and Justin Wilkerson; Texas A&M University, United States*

We derive analytic expressions for the maximum tensile pressure achieved during cold hydrostatic tension by defect-free single-element monocrystalline solids characterized by atoms obeying the Lennard-Jones (LJ) potential. These analytic expressions estimate the ultimate spall strength of monocrystalline solids on the periodic *table which possess SC, BCC, FCC, HCP, or diamond lattices in terms of the two parameters of the LJ potential. We then generate estimates of the ultimate spall strength based on fitting the LJ potential to known thermomechanical properties of pure elements. Estimates of the ultimate spall strength based on fitting the LJ potential to the equilibrium lattice parameter, and either the cohesive energy, bulk modulus, or melting temperature all predict trends for solids on the periodic table of increasing ultimate spall strength with increasing period, and the element with the largest ultimate spall strength occurring near the middle of each period. The overall periodic table trends predicted by the LJ solid for ultimate spall strength agree with the ordering of magnitudes of experimental data for spall strengths from laser or particle beam induced spall of single crystal elements. We believe future work based on this method incorporating combining rules or more accurate force potentials would enable prediction of trends in the ultimate spall strength of novel element mixtures. These predictions could inform the design of new monocrystalline materials with high spall strengths without the need for fabrication or mechanical characterization.*

SF02.06.10

Graph-Based Topological Entropy Quantification for Assessing Complexity Across Diverse Systems

Taewoo Kang[1], Seong-Gyun Im[1], In-Young Jung[1] and Seok Joon Kwon[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University Institute of Energy Science and Technology (SIEST), Korea (the Republic of)

The structural configuration of a material is a critical determinant of its physical and chemical properties. By manipulating structural properties, researchers can engineer materials with desired characteristics. High-entropy alloys (HEAs) exemplify this principle, as their properties are governed by the disordered atomic arrangement within a solid solution, rather than a uniform ordered phase. Similarly, physically unclonable functions (PUFs) leverage the inherent physical complexity of materials to hash input signals, with performance directly linked to material complexity. Given the importance of structural complexity in material design, its quantification becomes paramount. Traditionally, thermodynamic configurational entropy has been employed to measure this complexity. However, this approach is limited to systems with rapid dynamics due to its requirement for extensive data sampling. To address these limitations, a novel method based on information theory and graph isomorphism was proposed. While this approach has shown efficacy for network-forming materials such as silica, its applicability to diverse material structures remains unproven. This study introduces a methodology for quantifying the configurational entropy of the general systems, utilizing graph isomorphism theory. Comparative analysis of thermodynamic configurational entropy and the proposed graph entropy for arbitrary systems revealed consistent trends between the two measures. Furthermore, it was also revealed that the proposed configuration entropy can be generalized to work on systems other than silicon networks, such as triangular lattices, square lattices, and even amorphous materials. These findings have significant implications for designing and optimizing high-entropy materials and PUFs, whose physical properties are largely dependent on structural complexity. The proposed methodology offers a more efficient and versatile approach to quantifying structural complexity across a broader range of material systems.

SF02.06.11

Electron and Phonon Transport in High-Entropy Amorphous Alloys

Chumin Wang, Fernando Sanchez and Vicenta Sanchez Morales; Universidad Nacional Autónoma de México, Mexico

Materials with randomly ordered multi-principal elements possess an extraordinary thermal stability, a good electrical conductivity and a poor thermal conductivity by phonons, respectively derived from their high entropy, metallic elements and arbitrary distribution of heterogenous mass. Moreover, many of these materials reduce their electronic energy via the Peierls distortion mechanism placing the Fermi energy at the limit of electronic band or in a pseudo energy gap, which may significantly enhance the Seebeck effect because it is proportional to the

asymmetrical electronic contribution around the chemical potential. In general, modelling the transport of electrons and phonons in such a complex random structure as high-entropy alloys (HEAs), out of the thermodynamic equilibrium, constitutes a true challenge for the solid-state physics, since the theoretical study should be fully carried out in the real space due to the structural disorder. In this work, we study the electronic transport by means of a two-band tight-binding Hamiltonian including the electron-phonon interaction for alloys working at high temperatures, while the thermal conduction by phonons is addressed within the Born-von Karman interatomic potential including the central and non-central restoring forces [1], as well as the anharmonic Umklapp processes. The substitutional disorder in HEAs is considered by using an improved virtual crystal approximation with the lattice distortions caused by the variation in element ionic radii modeled by means of aperiodically arranged dislocations. The combination of these two studies on the electronic and phononic transport, all carried out by using a previously developed real-space renormalization method [2], allows a detailed analysis of the thermoelectric figure of merit (ZT) [3]. The results show a remarkable enhancement of ZT in comparison with that of single-element crystals, which reveals the key participation of substitutional disorder and lattice distortions, causing a strong phonon scattering. In consequence, HEAs have been proposed as a suitable candidate for thermoelectric applications. Finally, the theoretical results are compared with experimental data obtained from rock-salt HEAs [4] observing a good agreement.

This work has been partially supported by projects UNAM-IN110823, CONAHCYT-CF-2023-I-830 and LANCAD-UNAM-DGTIC-039.

Microstructure and Mechanical Properties of Novel As-Cast and Additively Manufactured CoCrFeMo Alloy for Dental and Maxillofacial Implants

Dena Khazeni, Vidar Hansin and John Tibballs; University of Stavanger, Norway

Cobalt-chromium alloys are mainly used in dental and reconstructive surgery thanks to their mechanical properties and corrosion resistance. These prostheses and superstructures are traditionally made by casting and milling processes. The conventional cobalt-chromium alloy contains around 60% cobalt. There has been a recent focus on reducing cobalt consumption. This is primarily due to its high cost and potential toxicity when released into the body. In this work, we focus on replacing a high amount of cobalt with iron which is a more economical candidate. Additionally, production methods can also reduce cobalt consumption. Rather than casting and milling implants and prostheses, Additive Manufacturing (AM) can significantly reduce material waste. Laser Powder Bed Fusion (LPBF) is one of the additive manufacturing techniques that provides several benefits over the conventional casting method.

The objective of this paper is to investigate and compare the phases, microstructure and mechanical properties of the newly designed CoCrFeMo alloy fabricated by Laser Powder Bed Fusion (LPBF) with casting using techniques such as X-ray diffraction, Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), Vickers

micro-hardness (HV), tensile and bending fatigue properties.

The findings indicate that the as-cast specimen consists of an austenitic matrix (fcc) and precipitates of sigma phase. Moreover, TEM examination of the fcc matrix revealed the presence of numerous stacking faults. In contrast, the sigma phase formation in the as-printed specimen was fully suppressed due to the high cooling rate of the LPBF process leading to the formation of a bcc phase as the matrix along with a heavily faulted non-equilibrium phase.

Furthermore, the effect of the fabrication process, phase and microstructure evolution on the mechanical properties of the specimens was investigated. The cast sample exhibited higher hardness due to the formation of sigma phase. The as-printed specimen, despite the presence of high residual stress, showed better tensile properties with an ultimate tensile strength of 1200 MPa and 17% elongation, as well as significantly better fatigue strength and fatigue life in comparison to the cast samples. The fatigue strength of the as-printed specimen was 33% higher than that of the cast one. Additionally, fracture surface analysis revealed a transition from an almost brittle in the as-cast sample to a more ductile fracture in the failure zone of the as-printed specimens, which correlates with the observed mechanical properties.

The results highlight the potential of using the LPBF process to produce newly developed CoCrFeMo alloys with tailored microstructures and promising mechanical properties based on standard criteria and the loads applied to implants in the body.
Key words: CoCrFeMo alloy, Additive manufacturing, Laser powder bed fusion, Microstructure, Tensile test, Fatigue properties

Comparison of the Sliding Wear of Single-Phase F.C.C Carbon-Doped Fe40.4Ni11.3Mn34.8Al7.5Cr6 and CoCrFeMnNi High-Entropy Alloys with AISI 316 Stainless Steel at Cryogenic Temperatures

Aubrey Tang[1], Ian Baker[1], Francis E. Kennedy[1], Hansheng Chen[2], Simon Ringer[2], Min Song[3] and Elliot Alberts[1]; [1]Dartmouth College, United States; [2]The University of Sydney, Australia; [3]Central South University, China

Recent studies have shown that the excellent mechanical properties of high entropy alloys (HEAs) can be enhanced at cryogenic temperatures, making them potential candidates for low-temperature applications. However, very limited work has been done on understanding their cryogenic wear mechanisms. In this study, the sliding wear behavior of two f.c.c. HEAs, carbon-doped Fe40.4Ni11.3Mn34.8Al7.5Cr6 (CHEA) and equiatomic CoCrFeMnNi (Cantor alloy) were determined against a yttria-stabilized zirconia counterface at cryogenic temperatures. Sliding wear tests were run both in dry cryogenic sliding conditions and under liquid nitrogen cryogenic conditions (wet conditions). Scanning electron microscopy and energy dispersive x-ray analysis were used to characterize worn pin surfaces. The worn surfaces for each material type and condition showed evidence of plastic deformation and oxide formation. X-ray photoelectron spectroscopy further identified the different oxide types and was able to provide greater understanding on how specific oxides contribute to the wear behavior under each condition. Additionally, scanning transmission electron microscopy and atom probe tomography were used for CHEA and Cantor alloy samples to offer insight into the elemental distribution at a nanoscale and the

precipitation of any second phases. These results were compared with previous room temperature tests and with 316 stainless steel, a current material of choice for many cryogenic applications, at both room and cryogenic temperatures.

Additive Manufacturing of $Fe_{40}Co_{30}Mn_{15}Al_{15}$ Soft Magnetic Material via Laser Powder Bed Fusion *Aubrey Tang[1], Matilda Barker[2], Ian Baker[1], Wuxian Yang[3] and Wen Chen[3]; [1]Dartmouth College, United States; [2]Furman University, United States; [3]University of Massachusetts Amherst, United States*

Soft magnetic materials play a significant role in both the generation and conversion of electrical power for a wide range of energy applications. While our energy technologies continue to be modernized, soft magnetic materials in power electronics need to offer excellent performance under high switching frequencies which current existing soft magnetic materials struggle with. There is a clear need for developing novel soft magnetic materials that can keep up with our ever-evolving technologies. Additive manufacturing (AM) serves as a useful processing technique for easily testing and optimizing different novel alloy compositions and design structures with low processing costs. Research on AM of soft magnetic materials is still quite nascent but recent studies have demonstrated that laser powder bed fusion (LPBF) techniques were effective in producing components with high density and desirable magnetic properties. In this work, the effects of processing by LPBF on the microstructure and magnetic properties of the medium entropy alloy (MEA) $Fe_{40}Co_{30}Mn_{15}Al_{15}$ were investigated. The behavior of the AM-processed samples will be compared to its as-cast counterpart, which has excellent soft magnetic properties. The microstructure was analyzed using x-ray diffraction, scanning electron microscopy, energy dispersive spectroscopy and electron backscatter diffraction, while the magnetic properties were determined using vibrating sample magnetometry. This study investigated the correlation between the processing parameters and the degree of porosity, grain size, and magnetic properties.

SF02.06.15

Effect of Orientation and Composition on the Mechanical and Structural Properties of High-Entropy Fenicrcoal Nanoalloys *Sergio J. Mejia Rosales and Angel E. Amaro; Universidad Autónoma de Nuevo León, Mexico*

We implemented a set of molecular dynamics simulations of indentation to investigate the mechanical properties and structural evolution of FeNiCrCoAl nanoalloys with varying aluminum concentrations and crystallographic orientations with respect to the direction of indentation. The interactions were described using the Embedded Atom Method (EAM) potential as parametrized by Farkas (2020). The aluminum concentrations studied were 0%, 2.4%, 7.2%, and 11.2%. The crystallographic orientations examined were [001], [110], and [111]. In order to improve the identification of the structural phases obtained by common neighbor analysis (CNA) and dislocation extraction algorithm (DXA), the machine learning MultiSOM technique due to Aquistapace et al (2023) was also implemented. The results of the simulated nanoparticles were compared against the results obtained for bulk systems. We found that increasing aluminum content results in a decrease in Young's modulus, yield stress, and elastic limit across all orientations; in bulk materials, higher aluminum concentrations lead to increased disorder and formation of amorphous structures, particularly in orientations [001] and C. In [110] orientation, the increase in aluminum results in more HCP structures and fewer amorphous structures compared to orientations [001] and [111]. In nanoparticles, the relative hardening varies with orientation, with the plastic region being less defined and showing more stable zones with HCP structures in the [001] orientation. Orientations [110] and [111] exhibit higher and less variable dislocation densities in the elastic limit in the plastic region compared to orientation [001]. Shockley dislocations form at the boundaries between HCP lamellae and the rest of the material, and nanotwins and stable HCP structures form with increasing compression. Orientation [110] shows a stronger presence of HCP *structures with smaller amorphous regions as aluminum increases and, while we were able to identify nanotwins, these are less frequent and more difficult to identify compared to their presence at other orientations. At orientation [111] the nanoalloy displays a high density of dislocations and a significant presence of HCP and amorphous structures. HCP structures form diagonally with a tendency to interconnect at higher compressions, and nanotwins are more stable at lower aluminum concentrations but become less defined with higher aluminum content.*

Enhancing the Photocatalytic Hydrogen Evolution and Decomposition by Optimizing the Elemental Ratios in High Entropy Oxides (Fe-Co-Ni-Cu-Zn-O) *Yung-Chang Chiao[1], Wen-Wei Wu[1] and Yu-Cheng Chang[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Feng Chia University, Taiwan*

Adjusting the amounts of different elements added can significantly affect various properties of high entropy oxides (HEOs), such as structural stability, optical, and electrochemical properties. In this work, HEO with equimolar ratios of elements was synthesized using a simple solvent thermal method and thermal annealing. Subsequently, the amounts of different elements added were sequentially adjusted to synthesize HEOs with different parameters, which were applied in photocatalytic hydrogen evolution reaction and photodegradation efficiencies of organic pollutants to find the most suitable HEO as a photocatalyst. The optimal HEO was compared with equimolar HEO in various aspects of properties through relevant analyses. For instance, X-ray diffraction (XRD) analysis confirmed the generation of new alloy oxides after adjusting the amounts of elements added, and the interaction between different alloy oxides enhanced the photocatalytic efficiency. Moreover, the electrochemical analysis also showed that HEOs with adjusted the amounts of elements added possessed superior charge transfer rates and hydrogen evolution capabilities, significantly improving the drawbacks when using semiconductors as photocatalysts. Furthermore, the relevant analysis indicated that adjusting the amounts of elements added changed the band gap, making it more versatile for applications in the visible light range. Finally, cyclic tests demonstrated that the HEO prepared in this work maintained excellent structural stability and reusability after multiple photocatalytic experiments. The interactions among metals in HEOs deserves further investigation, as they hold significant potential for development in the field of photocatalysis.

SF02.06.17

Low Carbon Fabrication of High-Entropy Alloy via High Energy Milling and Hydrogen Reduction—A Study of Reaction Kinetics and Mechanical Behavior *Gertrude Mongella, Taehyeob Im, Minjong Kim and Gertrude Mongella; Hanyang University, Korea (the Republic of)*

High-entropy alloys (HEAs) are increasingly being recognized as excellent materials in various sectors such as the marine and defense fields due to their remarkable chemical and mechanical properties in extreme environments. This study attempts to fabricate and analyze CoCrFeNi as a notable high entropy alloy candidate through milling and hydrogen reduction because of its extraordinary mechanical characteristics as well excellent corrosion and oxidation resistance. In this study, an equimolar CoCrFeNi high entropy alloy was fabricated by the powder metallurgical process of high energy milling at 2400 r.p.m and hydrogen reduction at 1000 °C. Reaction kinetics of the resulting HEA nanopowder was investigated as a preliminary examination of the feasibility of hydrogen reduction of chromium oxide in chromium-based HEAs; as a function of milling time. Thermogravimetric analysis (TGA) was used to investigate the hydrogen reduction process with the utilization of the Kissinger-Akahira-Sunose (KAS) method being applied to the TGA results to determine the apparent activation energy and thermal stability. Scanning electron microscopy (SEM), energy-dispersive x-ray spectroscopy (EDS) mapping and X-Ray Diffraction (XRD) confirmed the nano sizing, homogeneity and phase transformation of the high entropy alloy from increasing milling time to after hydrogen reduction. The mechanical properties were observed via hardness and tensile tests.

The nano sizing of the HEA powder was confirmed to be from 500 nm to 50 nm reduction of particle size as milling time increased from 5 h to 30 h through SEM images; homogeneity of the elements was observed in EDS mapping results. The milled and hydrogen reduced HEA powder exhibited FCC phase peaks at the lattice parameter of 3.59 Å confirming the formation of solid solution and the reduction of particle size as milling time increased. The TGA results demonstrated a weight loss in the HEA powder during hydrogen reduction from 100 % to 71.94 %; with the reduction of activation energy occurring at two reactions, firstly from 387 to 245 kJ/mol and 474 to 22 kJ/mol. The hardness was observed to be around 160 HV and the tensile strength was observed to be around 712 MPa. These results provide the primary data for comprehension of the microstructural development of the CoCrFeNi high entropy alloy with increasing milling energy and time as well as the hydrogen reduction behaviour of the alloy so as to fabricate the most optimal structure for application in extreme environments with minimal carbon emissions. Therefore, the microstructural development of spherical CoCrFeNi nanopowder agglomerates fabricated by the hydrogen reduction process, was demonstrated to produce high entropy alloys as a potential alternative process for the conventional gas atomization process.

High Dimensional Thermoelectric Materials—Impact of Alloying on Scattering and Dopant Efficiency

Evelyn C. Peterson, Helen Chaffee, Kamil Ciesielski, Claire Porter, Colton Gerber, Andrew Novick, Svetlana Altshuler, Mason Jacketta and Eric S. Toberer; Colorado School of Mines, United States

Thermoelectric materials provide a promising platform for transforming waste heat into a sustainable source of electricity. However, the historical paradigm in thermoelectrics has been low dimensional alloys of binary semiconductors, which result in efficiencies inadequate for industrial settings. Recently, high entropy alloys (e.g. Bi-doped (Ge, Ag Sb)(PbTe)) have been found to exhibit improved efficiency[1]*. Such results are intriguing, as high entropy alloying decreases thermal conductivity while retaining excellent electrical conductivity and mobility. Given the presumed disorder induced in the lattice from high entropy alloying, such excellent transport is surprising.*

Our research investigates high-dimensional semiconductor chalcogenide alloys of general form (Ge,Sn,Pb)(S,Se,Te) and Bi-doping therein. Here, we seek to learn how configurational disorder impacts (i) electrical and thermal properties and (ii) extrinsic doping efficiency. To understand the impact of disorder on electronic and thermal properties, we synthesized bulk, polycrystalline samples with composition $(Pb_{1-x-y}))(Te_{1-x})(Bi_y)(Ge_{0.12}Sn_{0.32}Pb_{0.54}S_{0.12}Se_{0.27}Te_{0.61})_x$ *with* $0<x<1$ *and* $y = 0.01$*. For* $x<0.5$*, a nearly single phase sample emerges with rock salt structure. The resulting single-phase ingots were characterized to high temperature with Hall, resistivity, Seebeck, and thermal conductivity measurements. Promising figures of merit, zT, were found for heavily alloyed, single phase compounds, largely due to a reduction in lattice thermal conductivity in these highly disordered materials. To complement these experimental measurements, computation was used to investigate the extent of structural distortion within these alloys. DFT calculations were used to train a machine learned force field within NequIP and alloy supercell relaxations were performed with this force field. The extent of structural distortion was quite low, in support of the relatively high mobility of these samples.*

These findings motivate us to understand how alloying affects dopant efficiency and, further, impacts the overall figure of merit, zT. While dopant efficiency has been studied in unary and binary semiconductors, it is not clear that these lessons will translate to how dopants behave in high entropy alloys, given the different local environments that the dopant can inhabit. A suite of samples with varying y-values and $x = 0.4$ *were prepared; we measure the carrier concentration to find trends in dopant efficiency and compare these results to Bi-doped* $x=0$ *(i.e. PbTe) samples. These Hall measurements were conducted to high temperature to assess if the dopant efficiency varies significantly as the local configurational motifs evolve. Further, we measure a complete suite of thermoelectric* *properties to assess overall thermoelectric performance at high temperature.*

Through these efforts, we have cast light on how increasing structural disorder impacts mobility, lattice thermal conductivity, as well as doping efficiency. These understandings increase our understanding of dopants within high-dimensional spaces, and inform future research in optimizing zT values of thermoelectric materials.

SF02.06.19

Structural Effects on Redox Behavior in Mn-Based Perovskite Oxides for Solar Thermochemical Water Splitting *Vika Arzumanyan[1], Cijie Liu[2], Dawei Zhang[3], Jian Luo[3], Xingbo Liu[2] and Yue Qi[1]; [1]Brown University, United States; [2]West Virginia University, United States; [3]University of California, San Diego, United States*

A novel series of high entropy Mn-based perovskite oxides, $(Ln_{2/3}A_{1/3})MnO_3$ (Ln = La, Pr, Nd, Gd; A = Ba, Sr), which possess great potential for eco-friendly and low-cost solar thermochemical hydrogen (STCH) production, was studied using Density Functional Theory (DFT).
Starting with the single component $LnMnO_3$ and $AMnO_3$ systems, it was found that the oxygen vacancy formation energy depends solely on the charge of the A-site ions, which is higher for Ln^{3+} ions than the A^{2+} ions. Alloy Theoretic Automated Toolkit (ATAT) was used for creating quasirandom $(Ln_{2/3}A_{1/3})MnO_3$ mixed structures with orthorhombic Pnma symmetry ($(Gd_{2/3}Sr_{1/3})MnO_3$, $(Pr_{2/3}Sr_{1/3})MnO_3$, $(Nd_{2/3}Sr_{1/3})MnO_3$) and trigonal Rc symmetry ($(La_{2/3}Sr_{1/3})MnO_3$, $(Ln_{2/3}Ba_{1/3})MnO_3$).
In mixed systems, the lattice parameters obtained from DFT calculations showed a similar trend for Sr and Ba mixed systems, increasing with the ionic radius, which agrees with experimental data for Ba mixed systems. However, for $(Ln_{2/3}Sr_{1/3})MnO_3$ systems, experimentally reported lattice parameters did not change with increasing ionic radius, indicating possible stronger 3d-4f spin-orbital coupling, requiring high level of DFT calculations.
Oxygen vacancy formation energy distribution in mixed systems exhibited a clear dependence on the phase of the materials, with trigonal Rc structures having lower and more widespread formation energies compared to orthorhombic Pnma systems. Additionally, local structural distortion studies indicated that oxygen vacancy formation is more favorable in systems with trigonal symmetry.
Thermogravimetric analysis (TGA) of the redox capability of all $(Ln_{2/3}A_{1/3})MnO_3$ systems showed that Ba-mixed systems with trigonal symmetry have a higher vacancy concentration change ($\Delta\delta$) compared to those with orthorhombic symmetry. However, the TGA data for Ba-mixed systems do not correlate well with hydrogen production results, indicating kinetic also play an important role in H_2 production.

SF02.06.20

Advanced Synthesis of High-Entropy Alloy Nanoparticles (HEA-NPs) Through Fast Moving Bed Pyrolysis (FMBP) *Daniela Fonseca, Ricardo Castro and Martin Harmer; Lehigh University, United States*

High-entropy alloys (HEAs) are single-phase metallic materials composed of multiple elements in nearly equimolar ratios, gaining significant attention due to their unique chemical and physical complexity. One of their most impressive characteristics is the stability of their chemical and mechanical properties at high temperatures. HEAs composed of refractory elements like Cr, Mo, Nb, V, Ta, W, Zr, Ti, and Re exhibit good strength at elevated temperatures. For example, NbMoTaW and NbMoTaWV HEAs have been reported to achieve yield strengths over 400 MPa at 1600 °C, far surpassing the ~ 900 °C limit of conventional Ni-based superalloys [1]. One of the most common processing routes to obtain this material is through mechanical alloying. However, this method introduces several contaminants into the HEA microstructure, resulting in the formation of undesirable oxides, *nitrides, or carbides [2]. Meanwhile, several works have been developed in chemical synthesis of HEA nanoparticles (HEA-NPs) [3,4], demonstrating that HEA-NPs retain the same advantages as bulk HEAs at the nanoscale, while exhibiting increased specific surface area and higher surface energy [5]. A new Fast Moving Bed Pyrolysis (FMBP) strategy has been developed to prepare ultrasmall, highly dispersed, and contaminant-free HEA-NPs, comprising up to ten elements, ensuring high supersaturation of monomers and preventing phase separation [6]. The FMBP strategy offers promising avenues for industrial application, enhancing our understanding and utilization of these complex materials. In this work, we synthesized HEA-NPs based on Mo, Nb, Ta, Ti, Zr and Ru via FMBP. Graphene oxide was used as the support, along with 1,10-Phenanthroline ($C_{12}H_8N_2$, 97.0%) and the metal precursors. The GO was suspended in ultrapure Milli-Q water and ethanol (in a ratio of 5:1) and kept under ultrasound for 12 hours at 55 °C to achieve a homogeneous mixture. Then, 1,10-Phenanthroline was added in a ratio of 3:1 relative to the HEA-NPs. The different metal precursors were sequentially added according to their activity, in a ratio of 5:1 on GO. The solution was kept under ultrasound at 55 °C until dry. Once dried, the solution was poured into an alumina boat that had been previously rinsed and dried. For the FMBP, a sliding tube furnace (MTI Corporation OTF-1200X) was used. The alumina boat containing the HEA-NP solution was placed in a region outside the furnace heating zone. A vacuum pump extracted the gas for 30 minutes, followed by purging the tube with Ar gas for 30 minutes, keeping flowing Ar (100 sccm). The furnace was then heated to 650 °C, and the alumina boat was slid into the heating zone. After annealing at 650 °C for 2 hours, the furnace was naturally cooled to room temperature. Finally, the HEA-NPs were obtained and the agglomerated nanoparticles were broken down using a mortar and pestle. Transmission Electron Microscopy (TEM) analysis was conducted using JEOL 2100 and JEOL ARM 200CF microscopes, both operated at 200 kV. The nanoparticles were dispersed in high-purity isopropanol and sonicated for 15 minutes to achieve a homogeneous suspension. A droplet of this suspension was then placed onto Cu grids. X-Ray Diffraction (XRD) analysis was carried out using a Panalytical Empyrean X-Ray diffractometer with CuKα radiation (λ = 1.5418 Å). The FMBP strategy presents a significant advancement in the synthesis of high-entropy alloy nanoparticles, holding great promise for various applications in materials science. The successful synthesis and characterization of HEA-NPs with diverse elemental compositions underscore the potential of this method, paving the way for new innovations and industrial applications.*

Explainable Artificial Intelligence of Hydrogen Evolution Catalysis with High-Entropy Alloys Nanoparticles

Leandro Seixas Rocha[1,2]; [1]Mackenzie Presbyterian University, Brazil; [2]MackGraphe - Mackenzie Institute for Research in Graphene and Nanotechnologies, Mackenzie Presbyterian Institute, Brazil

Green hydrogen is a clean, renewable fuel that plays a crucial role in decarbonizing the economy. It stores energy efficiently, powering fuel cells for transportation and building applications, and catalyzes essential reactions for producing fertilizers such as ammonia. Traditionally, green hydrogen production has relied on platinum (Pt) nanoparticles. Yet, reducing the size of these nanoparticles to enhance surface area often diminishes their catalytic efficacy per site for the hydrogen evolution reaction (HER), a key process in green hydrogen production via electrolysis of water. Researchers are exploring alternative compositions and morphologies of metallic nanoparticles to discover novel catalyst materials for green hydrogen. Recently, high-entropy alloys, consisting of five or more nearly equimolar components, have gained attention due to the synergistic effects of their *compositional complexity. These alloys are particularly promising for catalysis and electrocatalysis applications. In our study, we investigate high-entropy alloy nanoparticles composed of AgAuCuPdPt, each with a size of approximately 1.2 nm (55 atoms), to assess their catalytic performance in HER. Utilizing first-principles computational simulations, we develop machine learning models to predict the Gibbs free energy of hydrogen adsorption, a key descriptor in evaluating catalyst efficiency. Our results show that the gradient boosting model predicts this descriptor with a mean absolute error of 0.1 eV for the test set. Moreover, we construct an explainable artificial intelligence model using chemical features like covalent radii, Pauling electronegativity, valence electron concentration, and geometric features such as coordination number and generalized coordination number. The model interprets the most relevant features through Shapley values, enhancing our understanding of catalyst behavior. Our descriptor, called quasigraph, combines these chemical and geometric features and performs comparably to other models using descriptors such as the smooth overlap of atomic positions (SOAP) and many-body tensor representation (MBTR), but with greater interpretability and explainability. This approach offers significant insights into the catalysis of HER using complex materials like high-entropy alloy nanoparticles.*

Unique Atomic Structure of FCC-HCP Dual Phase High Entropy Alloy after Low Temperature Annealing

Minseok Kim, Ji Young Kim, Kook Noh Yoon and Eun Soo Park; Seoul National University, Korea (the Republic of)

Strength and ductility are the most important physical properties in evaluating structural materials. Unfortunately, common strengthening strategies in most conventional alloys cause sacrifice of ductility inevitably and vice versa. Recently, however, high entropy alloy (HEA) is regarded as a good candidate that can overcome the strength-ductility trade off. It was shown that mechanical property of HEA could be enhanced by TRIP or TWIP behavior. Especially when dual phase high entropy alloy (DP-HEA), which is constituted by FCC and HCP phase, has multiple deformation mechanisms, strength and ductility showed good balance. Designing method for alloy which has various deformation mechanisms is controlling the stacking fault energy (SFE). SFE is well known as a key parameter which decide the deformation mechanism. By reducing the SFE, TRIP of TWIP mechanism is activated and even dual phase microstructure is stabilized at room temperature.

In the present study, we designed a DP-HEA by reducing the SFE which could be implemented by CALPHAD. Furthermore, we successfully designed a unique DP-HEA microstructure with nano-sized austenite film in hard martensite matrix. This lamellar microstructure of austenite and martensite could enhance the overall toughness of the HEA. Initial microstructure was constituted by FCC and HCP phase after homogenization and quenching process. Cold rolling and heat treatment were done to make a better microstructure for the subsequent low temperature annealing, which is crucial for the partial austenitization. After low temperature annealing, the DP-HEA exhibited a novel 'composite-like' microstructure with metastable austenite film in martensite HEA matrix. XRD was implemented to confirm that partial austenitization occurs after low temperature annealing. Phase fraction and morphology of austenite was analyzed by SEM and EBSD. It was possible to make fine alternating lamellar structure of FCC and HCP phase even at 573K. Furthermore, we could characterize atomic ordered structures in HCP martensite after low temperature annealing by the STEM analysis. This heterogeneous atomic structures in martensite could have an effect of strengthening, acting as an obstacle for dislocation moves. This result can provide a guideline on how to overcome strength-ductility trade off by precise tailoring microstructure in DP-HEA.

Metastable Beta-Titanium Multi-Principal-Element Alloys *Maximillian Adams, Niall Pastuszek, Mason Weems, Amy Clarke and Kester Clarke; Colorado School of Mines, United States*

Metastable beta-titanium multi-principal-element alloys (β-Ti MPEAs) are paving the way for exciting

materials science advancements, particularly for aerospace and automotive engineering industries. These alloys stay stable in the beta phase under normal conditions and transform into a martensitic phase when impacted, making them tougher and more durable thanks to the TRIP (Transformation-Induced Plasticity) mechanism and increased dislocation density. Our approach involves casting the material with minor compositional variations and optimizing it through heat treatment or thermomechanical processes. We will use XRD for phase identification, EBSD for phase and orientation analysis, and EDS for elemental composition to analyze our results. Exploring martensitic reactions, including TRIP, superelasticity, and shape memory, has practical benefits for industry and academia. In industry, such materials could make auto bodies better at absorbing energy during crashes. Fundamentally, this research helps us understand phase transitions more deeply and pushes the boundaries of materials science.

High Entropy Materials for Future Greener Batteries *Cynthia Huang, Amy Marschilok, Esther S. Takeuchi and Kenneth J. Takeuchi; Stony Brook University, The State University of New York, United States*

The High Entropy Materials (HEM) concept is appealing because it opens additional possibilities for the materials designer to incorporate more of the periodic table, including environmentally green elements. By adjusting the elemental ratios as well as the elemental selection, the structural and functional properties of the material can be tuned to create a family of related HEM. Through deliberate synthesis and detailed characterization, then drawing correlations among HEM properties and resulting electrochemical behavior, structure-function dependencies can be revealed. This presentation will provide specific examples of understanding HEM properties for greener future batteries utilizing synchrotron-based spectroscopy and diffraction in concert with electrochemistry to characterize the materials changes under battery use.

SF02.06.25

A High-Entropy Perovskite Cathode for Solid Oxide Fuel Cells *Hakan Yüce, Fatih Piskin, Berke Piskin and Gulhan Cakmak; Mugla University, Turkey*

In recent years, energy consumption has been increasing with technological and industrial developments. This leads to the search for clean, efficient, economical, and sustainable energy sources. Among these sources, ceramic-based solid oxide fuel cells, which are considered among the most efficient FCs, draw attention. The solid oxide fuel cell is an electrochemical energy conversion device that converts the chemical energy of the fuel directly into electrical energy, attracting great attention due to its high efficiency, fuel flexibility, and environmental friendliness. However, high operating temperatures (800°C− 1000 °C) cause the cells to be short-lived. Reducing the operating temperatures to 600°C − 800 °C is one of the effective approaches to solving this problem. $La_{0.7}Sr_{0.3}MnO_3$ LSM shows outstanding electronic conductivity, excellent electrocatalytic activity, and good stability for oxygen reduction in the temperature range of 800°C -1000 °C, but its electrochemical performance is significantly reduced at reduced operating temperature.

High entropy oxides have received increasing attention. High entropy oxides usually contain 5 or more elements with small proportions of minor elements and have high mixing entropy. They can be easily synthesized, produced, and analyzed. ABO3-type perovskite oxide is of interest for solid oxide fuel cells due to its unique dielectric, ferroelectric, pyroelectric, and catalyst properties.

Many high entropy oxides have been found to improve thermal characteristics, magnetic properties, catalytic activity, and energy storage and conversion performance, but have less application in solid oxide fuel cells. In this study, the potential application of $La_{0.5}Sr_{0.5}Co_{0.2}Fe_{0.2}Ni_{0.2}Cu_{0.2}A_{0.2}O_3$ (A=V,Al,Mg) perovskites in medium temperature *solid oxide fuel cells was investigated*

LSCFNC powder was synthesized using the sol-gel method. As starting chemicals, nitrates of all of the considered cations were used: $La(NO_3)_3$ ●$6H_2O$, $Sr(NO_3)_2$, $Co(NO_3)2$ ●$6H_2O$, $Fe(NO_3)_3$ ●$9H_2O$, $Ni(NO_3)_2$ ●$6H_2O$,$Cu(NO_3)_2$ ● $3H_2O$.

First, the stoichiometric amount of these nitrates was dissolved in distilled water, then citric acid was added to the solution. The molar ratio of all cations and citric acid in the mixture was 1:2. The solution was heated to 80°C with continuous stirring with the aid of a magnetic stirrer. The resulting gel was dried at 250°C for 2 hours to remove residual organics and nitrates. The dried gel was calcined at 700°C, 900°C, 1100 and 1300°C for 6 hours. The phase analysis of the powders was performed by using X-ray diffraction (Rigaku SmartLab X) using monochromatic Cu Ka radiation at 40 kV and 200 mA. The structures are refined using the Maud program to identify their crystal structure.

Yttria-stabilized zirconia (YSZ) with general formula $(ZrO_2)_{1-x}(Y_2O_3)_x$ and $0.08 \leq x \leq 0.1$, is the most studied electrolyte for SOFCs. The best conductivity value is obtained for the compound containing 8 mol% of yttrium oxide. In this study, zirconia powders stabilized with 8 mol% yttria were synthesized using the sol-gel process. $ZrO(NO_3)_2.xH_2O$ and $Y(NO_3)_3.6H_2O$ were dissolved in and mixed in ethylene glycol, citric acid, and purified water, respectively. Then, $Y(NO_3)_3.6H_2O$ was added to $ZrO(NO_3)_2.xH_2O$ solution drop by drop and mixed to make YSZ solution. After mixing, the temperature was raised to 80°C and the pH was adjusted to 3.6 with HNO_3. The resulting suspension was mixed until homogeneous. This white and milky mixture was dried at 120°C and sintered at 1200°C for 2 hours. The synthesis and analysis in this study are currently ongoing. In this circumstance, we will perform the analyses below:

1. A morphological analysis using a scanning electron microscope (SEM) and chemical analysis employing Energy Dispersive Spectroscopy (EDS) will be conducted to examine the physical characteristics and elemental composition of the samples.

2. Charge/discharge tests will be performed with symmetrical cell coating on YSZ.

SF02.06.26

Thermal Stability and Magnetic Properties of FeCoNiSiCuNb High-Entropy Alloy as a Magnetic Shielding Material in Wireless Charging Applications

Cheng-Hsien Yeh[1], Chia-Hua Hu[1], Hsuan-Ta Wu[2], Wen-Dung Hsu[1,1], Bernard Haochih Liu[1,1] and Chuan-Feng Shih[1,1]; [1]National Cheng Kung University, Taiwan; [2]Minghsin University of Science and Technology, Taiwan

An ideal magnetic shielding material should possess high magnetic permeability, high saturation magnetization, low coercive force, thermal stability, and high electrical resistivity. Typically, magnetic shielding materials use soft magnetic materials, which can be categorized based on their characteristics into iron-based sintered alloys such as silicon steel and ferrites. Iron-based alloys have advantages such as high magnetic flux density and magnetic permeability but suffer from low resistivity, leading to increased eddy current losses at high frequencies, which limits their usage. Ferrites, on the other hand, offer high resistivity, allowing for lower eddy current losses in high-frequency environments. However, their lower saturation magnetization compared to metallic soft magnetic materials restricts their use in high-power applications.
Soft magnetic materials are required to exhibit high saturation magnetization and low coercivity. Commonly used commercial soft magnetic materials, such as FeMnZn, offer magnetic shielding functions but typically show low saturation magnetization, poor high-temperature stability, and significant magnetic losses. In recent years, many

research groups have highlighted the superior soft magnetic properties of high-entropy alloys (HEAs). This research developed a novel HEA soft magnetic material for low-frequency magnetic shielding applications. The $Fe_{32.5}Co_{23.5}Ni_{25}Si_{15}Cu_{1}Nb_{3}$ HEA was synthesized through dry ball milling, followed by wet ball milling and annealing at 800 °C, exhibiting high saturation magnetization and excellent high-temperature stability. Compared to traditional magnetic shielding material FeMnZn, this HEA retains over 50% of its magnetism at 700 K and maintains a saturation magnetization of 22.8 emu/g even at 1000 K, whereas FeMnZn drops to nearly 0 emu/g at 600 K. At an operating frequency of 100 kHz, the real part of the permeability of FeCoNiSiCuNb HEA is increased by 2.25 times compared to FeMnZn. The higher magnetic permeability of the HEA results in a higher mutual inductance to self-inductance ratio, achieving a coupling coefficient of up to 0.84. The lower loss tangent of the HEA reduces eddy current losses, enhancing wireless power transmission efficiency by 19%. Finally, the FeCoNiSiCuNb HEA material was practically applied as the magnetic shielding plate of the transmitter coil in commercial wireless charging modules for mobile phones, successfully demonstrating the functionality of wireless charging. These findings highlight the potential of HEAs in improving the performance and efficiency of wireless power transmission systems, making them a promising material for future technological advancements in this field.

SF02.06.27

Solidification and Phase Transformation Behaviors of a Re Added Ni-Based High-Entropy Alloys *Won Sang Shin, Dae-Yoon Kim, Min-Seo Kim and Yoon-Jun Kim; Inha University, Korea (the Republic of)*

Like conventional Ni-base superalloys, the formation of $L1_2$ ordered structure in the Ni-based high-entropy alloys (HEAs) has been reported to confer favorable heat resistance, making them suitable for next-generation reactors and aircraft engine components. Consequently, numerous studies have performed focusing on improving the high-temperature strength and durability of HEAs with $L1_2$ structures. However, due to their multi-element composition, HEAs are more likely to form different phases and undergo phase transformations at elevated temperatures. These processes can destabilize the microstructure, leading to dissolution or excessive growth, which, in turn, reduces high temperature stability. To address these challenges, refractory materials are employed to limit atomic diffusion and reduce precipitate growth. Nevertheless, the interactions at the precipitate-matrix interface remain insufficiently understood. Therefore, in this study, we designed a Ni-based HEA by adding rhenium (Re) to the alloy composition: Ni48Co17Fe8Cr7Al5Ti5Nb3Mo2W1Re4 (wt.%). This alloy system was designed to have the $L1_2$ phase as the primary precipitate, guided by CALPHAD calculations. Remarkably, the Re-added alloy exhibited improved tensile strength at both room and high temperatures compared to conventional Ni-based alloys. To understand primary reasons behind the property improvement resulting from the addition of Re addition, we analyzed the segregation behavior of Re atoms employing in-situ synchrotron X-ray imaging and the Bridgman method to observe the solidification behavior. Additionally, microsegregation at the precipitate-matrix interface was examined utilizing optical microscopy and scanning electron microscopy. As a result, we found that Re not only controlled the growth behavior of Ni dendrites but also effectively suppressed precipitate coarsening at the precipitate-matrix interface during the solidification process.

SF02.06.28

Computational Analysis and Design of High-Entropy Nanoparticles—Integrating Atomistic Simulations with Scientific Pedagogy in Materials Research *Priyanshu Luhar[1], Lexi Hwang[2], Arpit Vaishya[2], Jeffrey Santner[2], Jane Dong[1] and Sungwook (Leo) Hong[1]; [1]California State University, Bakersfield, United States; [2]California State University, Los Angeles, United States*

This study aims to integrate atomistic modeling and simulations with science pedagogy to enhance the *understanding of chemical reactions in materials science among college students at minority-serving institutions. Participants in this study developed their own research topics in the field of high entropy materials and deployed reactive molecular dynamics (RMD) simulations. High-energy yield metal nanoparticles, particularly those containing Ti-Cu-Al components, have garnered significant interest due to their potential applications in controlled combustion and related fields. These nanoparticles, in various ratios, offer substantial energy release while maintaining stability and integrity. Our RMD simulations indicate that certain elements, when used as solid additives, significantly improve the combustion efficiency of the entire system. Specifically, mixtures of Ti and Al nanoparticles have demonstrated an excellent balance between energy yield and structural integrity. Our goal is to determine the optimal proportions and conditions to enhance the ignition and combustion of semi-solid hydrocarbon-based fuels. Previous studies have provided experimental data on the reactions of some metal nanoparticles. Building on our previous research, these simulations will advance the field of high entropy materials by facilitating the application of Ti-Cu-Al metal nanoparticles, offering valuable insights for engineering applications. Importantly, we believe our educational approach will enhance diversity within the community of researchers focused on computational modeling in materials science.*

This work is supported by the National Science Foundation under Grant Award numbers: 2247282 and 2247283.

Quantitative Study on Degree of Lattice Distortion and Solid-Solution Strengthening in Refractory High Entropy Alloys

Kangjin Lee[1], Kanghyun Park[1], Haeun Kang[2], Ji Hyun Lee[2], Chanho Lee[3] and Gian Song[1]; [1]Kongju National University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of); [3]Auburn University, Korea (the Republic of)

Refractory high-entropy alloys (RHEAs) have attracted outstanding properties like high strength and microstructural stability at elevated temperatures. In many RHEAs, the lattice distortion plays a major role in their excellent properties , which is caused by the random distribution of the constitutive elements that vary appreciably in atomic size. There have been many efforts to understanding of the solid-solution strengthening effect induced by lattice distortion in BCC single solid-solution RHEAs. The solid solution strengthening effect in high-entropy alloys is determined by two factors: the atomic size mismatch and the shear modulus mismatch, which are closely related with atomic size differences, shear modulus misfit and bonding energy misfit among elements. Especially, it has been reported that the yield strength of many RHEAs with single-phase BCC structure is enhanced by maximizing the lattice distortion. Thus, it is important to understand the relationship between degree of lattice distortion and its resulting strengthening effect to develop novel RHEAs with outstanding mechanical properties.

In this study, to establish the concrete relationship between the degree of lattice distortion and strengthening effect in the RHEAs, we attempted to validate the effect of the lattice distortion on solid-solution strengthening effect in HEAs by systematic alloy design. Specifically, we fabricated a number of equi-atomic refractory alloys, containing BCC single solid-solution phase. Their microstructure evolution and mechanical properties were systematically investigated using neutron diffraction, scanning electron microscopy, electron backscatter diffraction and universal testing machine.

SF02.06.30

Developing $L2_1$-Co_2TiAl Precipitate-Strengthened Ferritic Medium Entropy Alloys with Excellent High-Temperature Strength

Kanghyun Park[1], Kangjin Lee[1], Min wook Kim[2], Beomsu Park[2], Chanho Lee[3] and Gian Song[1]; [1]Kongju National University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of); [3]Auburn University, United States

We designed new ferritic medium entropy alloys to improve the high-temperature strength by forming L21-Co2TiAl precipitates, known as having better high-temperature properties than the Ni2TiAl structure. Specifically, the Ni element has been replaced with the Co element. Moreover, the Ti element has been adjusted since the structural evolutions of precipitates, such as composition, lattice misfit and size rely on the Ti content. For instance, the addition of 2 wt% Ti forms a semi-coherent Co2TiAl precipitate with a relatively low density of misfit dislocations. More Ti addition up to 6 wt % leads to an increased lattice misfit, which results in a reduction of the elastic strain field around the precipitates. It was found that the semi-coherent interface with a high level of the elastic strain field (2 wt % Ti), as compared to the precipitates with a high amount of misfit dislocations (4 and 6 wt % Ti), plays an important role in enhancing the mechanical properties at 973 K.

SF02.06.31
Improving Synthesizability Prediction of TiZrNb-Based High Entropy Alloys Using Bayesian Model and Advanced Input Feature Analysis *Aamir Malik[1], Haris Malik[2] and Ho Jin Ryu[1,1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]University of Toronto, Canada*

High entropy alloys (HEAs) exhibit great potential in improving the Ashby curves, where strength and ductility can be improved simultaneously, owing to their unique structural configuration. However, there is an inherent limitation in exploring the vast prospective compositional space generated by varying multiple principal elements (more than five for HEAs), thereby making it difficult to obtain optimal composition using conventional methodologies. This necessitates the development of strategies that can efficiently screen out the compositional space of HEAs for desired properties. Therefore, in this study, we developed a Bayesian model that can optimize Young's modulus and hardness of TiZrNb-based HEAs using the data reported in the literature. We employed variational inference to learn the posterior distribution of the model parameters. The predictions' synthesizability was further analyzed using positive and unlabeled (PU) learning procedure. Additionally, we calculated feature importance score for the TiZrNb-based alloy systems using methods such as permutation feature importance, Shapley Additive exPlanations (SHAP), and Local Interpretable Model-agnostic Explanations (LIME). The feature importance scores calculated by aforementioned methods help us better understand the complex relationships between various compositional and thermodynamic features with observed properties, such as Young's modulus and hardness. The technique developed in this study provides an effective roadmap to efficiently screen HEA compositional space for multiple properties of interest, thereby demonstrating how machine learning can aid in developing better alloys systems.

SESSION SF02.07: Transforming Material Design: Innovating High-Throughput Methods for Fabrication, Evaluation and Prediction
Session Chairs: Wen Chen and Katharine Flores
Wednesday Morning, December 4, 2024
Hynes, Level 2, Room 208

8:00 AM *SF02.07.01
Additive Manufacturing of Emerging Complex Alloys *Wen Chen; University of Massachusetts Amherst, United States*

The increasing demands for materials serving under extreme environments call for the development of emerging metal alloys with increasingly complex compositions. However, synthesis and processing of complex alloys via *traditional routes are challenging. Additive manufacturing, also called 3D printing, is a disruptive technology for creating materials and components in a single print. Harnessing the vast compositional space of complex alloys and the far-from-equilibrium processing conditions (e.g., large thermal gradients and high cooling rates) of additive manufacturing provides a paradigm-shifting pathway for material design. In this talk, I will present the potential of utilizing laser additive manufacturing and direct ink writing to produce metal alloys with engineered structural hierarchy across multiple length scales. These unique microstructures give rise to exceptional mechanical and functional properties that extend far beyond those accessible by conventional manufacturing. In addition, I will discuss the abundant opportunities enabled by additive manufacturing for high-throughput materials discovery to accelerate the pace of future materials search.*

8:30 AM *SF02.07.02
Accelerated Discovery of Nanocrystalline High-Entropy Alloys with High Strength and Thermal Stability *Yu Zou; University of Toronto, Canada*

Nanocrystalline (nc) metals are generally strong yet thermally unstable. High-entropy alloy (HEA) design stabilizes nanocrystalline materials and leads grain boundary hardening. electrodeposition is a relatively low-cost, highly scalable fabrication route for nanocrystalline materials that can be applied to almost any substrate shape or material, which also has industrial-scale infrastructure already in place. Here, we report the first comprehensive study on the synthesis and characterization of electrodeposited HEAs made from aqueous electrolytes, building on the groundwork of past work on electrodeposited HEAs. In addition, we also develop a combinatorial strategy to accelerate the discovery of nc-refractory HEA library with distinct thermal stability. Our study continues to build a framework for paving the way for developing new high-strength, thermally stable, and scalable nanostructured materials.

9:00 AM *SF02.07.03
Investigating Composition Space in Medium and High Entropy Alloys Using a High-Throughput Synthesis Approach *Katharine Padilla, Nur A. Octoviawan, Mu Li, Pravan Omprakash, John D. Cavin, Rohan Mishra and Katharine Flores; Washington University in St. Louis, United States*

The design of high entropy alloys often focuses on identifying near-equiatomic solid solution alloys; expanding these to include multiphase microstructures offers the opportunity to further enhance and control properties. Designing such multiphase, multi-principal element alloys (MPEAs) requires the ability to efficiently survey compositional space for phases and microstructures of interest using integrated experimental and computational methods. Guided by DFT and thermodynamic models of phase stability, our group applies a laser deposition-based synthesis method to rapidly produce alloy libraries with varying compositions. Processing parameters, including the laser power, travel speed, powder feed rate, and deposition order are varied, and their influence on the resulting microstructure and mechanical properties are assessed. This talk will focus on studies of the Nb-V-Zr-X system (X = Ti, Ta, Mo), which generally forms one or more BCC phases interspersed with intermetallic (Laves) phases. Compositional segregation and interphase boundary structures are examined in light of local measurements of mechanical behavior of the as-deposited and annealed materials. This work provides guidelines for predicting compositional effects on microstructure and properties, which will accelerate the design of MPEAs for high-temperature applications.

9:30 AM BREAK

10:00 AM *SF02.07.04
High Entropy Materials—The First Twenty Years *Daniel Miracle; Air Force Research Laboratory, United States*

The high-entropy concept has been defined, studied, questioned and expanded over the past twenty years. First claimed as a major new direction of materials science, it is fitting to re-evaluate the topic at this notable anniversary. The field has grown significantly beyond the initially conceived single-phase metallic solid solutions to embrace single and multi-phase materials for both functional and structural applications. As a further expansion, the high-entropy concept has been applied to metallic, semi-metal and ceramic materials. This talk opens with a brief introduction to the history of HEAs, including predecessor efforts prior to the dual landmark publications in 2004, and a quick description of its defining features. Commercially used functional and structural medium- and high-entropy materials will be highlighted, with the intent of illustrating promising directions for new HEA applications. This talk closes by describing an unanticipated role of HEAs – as a major motivation to develop and deploy autonomous research and development methods to a broader range of materials. The specific challenges that HEAs bring to autonomous research and development will be introduced and discussed.

10:30 AM *SF02.07.05

***Phase Stability and Short-Range Order in High-Entropy Ceramics** Izabela Szlufarska, Waqas Qureshi, Shuguang Wei and Dane Morgan; University of Wisconsin, United States*

High entropy ceramics are a new class of materials with properties that make them promising for applications in extreme environments, including high-temperature, radiation, and corrosion. One major challenge in advancing discovery of high-entropy ceramics lies in accurately predicting their single-phase stability and formation ability. Traditional CALPHAD approaches can be unreliable because of limited experimental data needed to fit free energy models used for predicting phase diagrams. Another type of approach that has recently gained popularity in literature is to identify descriptors that correlate with single-phase stability and that can be calculated in a high-throughput manner using ab initio methods. Examples of such descriptors include entropy forming ability, lattice strain, and disordered enthalpy-entropy descriptor. While these descriptors are easy to calculate, they are only proxies for the physics that controls phase stability and its transferability to new systems is an open question.

In the first part of the talk, we demonstrate that phase stability in high-entropy ceramics can be predicted directly using approximate free energies determined from ab initio calculations based on the density functional theory (DFT). We demonstrate applicability of this direct method on the examples of High Entropy Borides (HEBs) and High Entropy Carbides (HEBs). Our approach shows good agreement with existing experiments on these material systems. Our predictions also show a relatively good agreement with CALPHAD calculations and the discrepancies between DFT-based free energy calculations and CALPHAD can be traced to lack of thermodynamic data for mixing terms in CALPHAD. Using our model, we predicted several new single-phase compositions that have not been previously synthesized. Our approach based on DFT calculations has the advantage of being derived from fundamental thermodynamics. Consequently, the path to future refinements of the model is clear as it involves improving approximations made in DFT calculations of free energies.

In the second part of the talk, I will discuss our recent experimental discovery of chemical short-range (CSRO) order in HECs. The presence of CSRO has been previously reported in metal alloys, and it has been postulated in HECs based on results of atomistic simulations. Here, we demonstrate the existence of CSRO in two HECs using high resolution scanning transmission electron microscopy (HR-STEM) and 4D-STEM. We also demonstrate that the degree of CSRO can be altered by high-temperature annealing. The impact of the chemical short-range order on radiation resistance of HECs will also be discussed, providing scientific foundation for potential design of radiation resistance HECs.

11:00 AM SF02.07.06

Structurally Graded Refractory High Entropy Alloys Through Laser Tuning *Sebastian Lech[1], Loïc Perrière[2], Jean-Philippe Couzinie[2] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Université Paris-Est Créteil, France*

High Entropy Alloys (HEAs) represent a transformative class of materials characterized by their complex, multi-principal element compositions and properties exceeding those of conventional alloys. Among HEAs, Refractory High Entropy Alloys (RHEAs) stand out due to their remarkable thermal stability and mechanical strength, making them ideal candidates for the next-generation high-temperature applications in aerospace, nuclear, and defense industries. However, tailoring the microstructure and properties of RHEAs through processing to meet specific performance criteria remains a significant challenge.

Efforts in materials discovery increasingly rely on high-throughput computational and experimental techniques to stimulate the exploration of complex alloy systems, such as HEAs. High-throughput methodologies enable rapid screening of compositional spaces, accelerating the identification of promising chemical compositions with desired properties. Among various high-throughput screening methods laser metal deposition by directed energy deposition (DED) emerges as a technique that scales up to the bulk materials. By using multiple powder lines it enables obtaining graded structures using various mixing and printing strategies.

In the present work additive manufacturing by DED was used to fabricate structurally graded RHEAs from the Nb-Ti-Zr system. The ultrasonically atomized powder was deposited on various build plates acting as a reservoir for alloying elements. Optimization of printing parameters resulted in graded structure and properties along the build direction of the alloy. The compositional and structural changes were examined using scanning- and transmission electron microscopy. To explain the thermodynamics of solidification processes the calculation of phase diagrams (CALPHAD) method was utilized using Thermo-Calc software.

Our research demonstrates that laser tuning offers a powerful and flexible tool for developing structurally graded RHEAs with customizable properties. This advancement scales up the alloy design process and accelerates bulk-scale screening for alloys with enhanced properties and performance.

11:15 AM SF02.07.07

Accelerated Optimization of $(CoCuFeMnNi)_3O_4$ Composition for Oxygen Evolution Reaction via Combination of Thin-Film Materials Libraries and Spray-Flame Synthesis *Leon Müller[1], Valerie Strotkötter[2], André Oliveira[1], Corina Andronescu[1], Alfred Ludwig[2], Christof Schulz[1] and Hartmut Wiggers[1]; [1]Universität Duisburg-Essen, Germany; [2]Ruhr-Universität Bochum, Germany*

High Entropy Oxides (HEOs), such as $(CoCuFeMnNi)_3O_4$, are gaining attention due to their unique properties, particularly for electrochemical energy storage and conversion. HEOs exhibit the highest configurational entropy at equimolar compositions of cations, yet these compositions do not necessarily yield the highest electrochemical activity. The vast compositional landscape of multinary oxides necessitates a thorough investigation of different compositions for specific applications, such as catalytic activity [1]. High throughput synthesis allows rapid screening of numerous compositions, though it typically produces small quantities of materials or thin films. For upscaling, it is necessary to combine the findings from high throughput screening with scalable synthesis methods of the most promising materials for comprehensive electrochemical analysis and practical applications.

We use reactive co-sputtering of the HEO system $(CoCuFeMnNi)_3O_4$ on a 4'' wafer with compositional gradients of the cations to study their OER activity as a function of the cation ratio and to identify the most active compositions. To obtain a wide range of compositions, four sputter targets (Co, Cu, Fe, Mn/Ni) were used. The sputtered thin films *are a few hundred nm thick [2]. A materials library (ML) comprises 342 measurement areas. In each of these, the metal composition was determined by energy dispersive X-ray spectroscopy (EDX) and the crystal structure by X-ray diffraction (XRD). The electrochemical characterization to investigate their oxygen evolution reaction (OER) activity was conducted utilizing a scanning droplet cell.*

Based on the high-throughput results, HEOs with specific compositions were identified and synthesized in the form of nanoparticles on a gram scale using spray-flame synthesis (SFS). This synthesis method offers the possibility of producing nanoparticles with adjustable composition [3]. For comparison, materials with the highest and lowest amount of each transition metal as well as compositions with relatively high, medium and low electrochemical performance were synthesized. To correlate results from ML and SFS, the nanoparticles were characterized by EDX and XRD and their OER activities were studied utilizing a rotating disc electrode (RDE). Additionally, temperature-dependent structural changes were investigated by controlled heating and cooling in thermogravimetric analysis (TGA) coupled with simultaneous differential scanning calorimetry (DSC). Typically, the particles show high crystallinity and count median diameters below 10 nm. Rietveld-refinement of the X-ray diffractograms proved phase purity for most of the materials. The electrochemical performance of the materials synthesized in the spray flame follows similar trends as materials from the sputtered library.

Our approach enables an accelerated search for particularly suitable materials and their production in a scalable synthesis process.

11:30 AM SF02.07.08
Structural Evolution and Tensile Response of CrCoNi Medium-Entropy Alloy Thin Films *JungHun Park, Zhuo Feng Lee and Gi-Dong Sim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Medium/high entropy alloys (M/HEAs) have prospered in the field of metallurgy since their first discovery, as different combinations of principal elements resulted in unforeseen, yet impressive material properties. Face-centered cubic (fcc) CrCoNi MEA in particular has been highlighted for its superb work-hardening and thermal stability, but its practical use in structural applications is currently limited due to the low yield strength.
In this respect, CrCoNi MEAs with micro/nano-scale grain size and thickness have garnered scientific interest, because these dimensions effectively impede dislocation movement and strengthen the alloy. CrCoNi thin film in particular has demonstrated potential as a superb coating material, ascribed to its high corrosion resistance and hardness. However, the mechanical behavior of M/HEA thin films was mainly investigated by hardness measurement or micropillar compression, which may overlook the adverse effects of nano-scale defects. Therefore, this study examines the tensile response of submicron-thick CrCoNi films. Sputter-deposited CrCoNi thin films were shaped into freestanding dog-bone-shaped samples via photolithography-based microfabrication. Tensile tests were conducted with a custom-built micro-mechanical tester at a constant strain rate. From transmission electron microscopy (TEM), we discovered that as-deposited films comprise nanocrystalline columnar grains with high-density twin boundaries, stacking faults, and hexagonally-close packed (hcp) phases.

Annealing the films at 600 and 700 °C results in detwinning and de-faulting, grain growth, and Cr-rich $M_{23}C_6$ carbide precipitation. All films tested in this study possess high tensile strengths – 2.4 GPa in the as-deposited samples, and 1.8 GPa in the samples annealed at 700 °C.
Understanding the characteristics of equiatomic CrCoNi thin films also establishes a foundation for investigating non-equiatomic CrCoNi films. Delving into non-equiatomic variants of M/HEAs can pinpoint the effect of each principal element and potentially enhance important mechanical properties. This process could be time-consuming with bulk-scale characterization, but small-scale characterization can significantly accelerate sample fabrication and mechanical testing. This study also includes high-throughput characterization of Ni-rich CrCoNi thin film with a compositional gradient via the membrane deflection experiment (MDE), offering an overview of the film's tensile behavior at different chemical compositions.

11:45 AM SF02.07.09
Developing Highly Efficient First-Principles Neuroevolution Potentials to Understand Short-Range Order and Properties in Complex Alloy Systems—From Group-IV Alloys to High-Entropy Materials *Shunda Chen, Xiaochen Jin and Tianshu Li; George Washington University, United States*

Alloying plays a critical role in enhancing the properties and functionalities of various materials, such as Group-IV alloys, III-V alloys, medium-entropy materials, and high-entropy materials (HEMs). Group-IV alloys, known for their silicon compatibility, hold promise for electronic, photonic, and topological quantum applications. Similarly, III-nitride semiconductors are essential in optoelectronics and electronics, incorporating new functionalities such as ferroelectricity, ferromagnetism, and superconductivity to advance next-generation semiconductor and quantum technologies. HEMs, including high-entropy and complex concentrated alloys, high-entropy oxides/nitrides, and high-entropy metallic glasses, offer diverse applications due to their customizable properties. However, understanding the complex behavior of these alloy systems, particularly their short-range order (SRO), poses significant challenges. Accurate modeling with density functional theory (DFT) calculations is often limited by spatiotemporal constraints. To address this limitation, we develop highly accurate and efficient machine-learning interatomic potentials based on a neuroevolution potential approach, incorporating new insights into high-quality DFT dataset preparation. Our first-principles neuroevolution potentials (NEPs) help deepen the understanding of SRO and properties in complex alloy systems, from Group-IV alloys to high-entropy materials. The developed NEPs demonstrate superior accuracy and efficiency, elucidating intricate SRO behavior and their impacts on material properties. By bridging the gap between atomistic modeling and advanced characterization techniques such as APT and 4D-STEM, our approach offers promising pathways for advancing the fundamental understanding of complex alloy systems, marking a significant step forward in materials science.

Fatigue-Resistant CoCrMoNi Medium Entropy Alloys for Medical Devices *Koichi Tsuchiya; National Institute for Materials Science, Japan*

Aiming for the application to medical devices, $Co_{50-x}Cr_{20}Mo_{10}Ni_{20+x}$ (x = 0–15) medium entopy alloys were designed based on the FCC-HCP phase stability. Room temperature tensile tests revealed markedly high work-hardening rate and good strength–elongation balance of the alloys. X-ray diffraction (XRD) and Electron Backscatterd Diffraction (EBSD) analysis revealed that the dominant deformation modes gradually shift from the FCC-HCP transformation to deformation twinning with the Ni content, x. The observed good strength–elongation balance may be due to the TRIP and TWIP. In the tensile deformed samples of the x = 3–9 alloys, HCP phase and twins coexist.
The low cycle fatigue (LCF) behavior was investigated with a total strain amplitude of 0.02. The highest LCF lives were observed for the x = 6 alloy (6537 cycles). They are much higher than those of alloys currently used for coronary stents. These findings suggests that the formation of epsilon-twin bundles may be an important factor to obtain high LCF resistance.
Microstructures and mechanical properties of tubes and wires made of the MEA alloys as well as the property of a proto type stent will be also reported.

Thus work was partially supported by a Grant-in-Aid for Scientific Research on Innovative Area,“High-Entropy Alloys-Science of New Class of Materials Based on Elemental Multiplicity and Heterogeneity” through MEXT, Japan (contract no. 18H05451), by JSPS KAKENHI Grant Number 23HD1719, and by AMED under Grant Number JP24ym0126104s0102.

Control of $L1_2$ Precipitates and Their Impact on Mechanical Properties and the Corrosion Resistance of High-Entropy Alloys *Sang Yun Han and Chae Woo Ryu; Hongik University, Korea (the Republic of)*

The utilization of CoCrNiAlTi-type high-entropy alloys (HEAs) as high-temperature materials, particularly those reinforced by $L1_2$ precipitates, demonstrates significant potential. The formation of coherent $L1_2$ precipitates results from the competition between continuous precipitation (CP) and discontinuous precipitation (DP), which can be controlled by aging temperature, aging time, and grain size. The variations in these precipitates can be quantified through lattice misfit, facilitating the assessment of the stress fields surrounding the precipitates. This quantification is essential for optimizing their mechanical properties and performance.
In this study, HEAs exhibiting varying precipitation behaviors depending on heat treatment time and process were developed. The correlation between their mechanical properties and precipitation behavior was systematically analyzed. Furthermore, the enhancement of mechanical properties due to $L1_2$ precipitation was compared and analyzed alongside the superior corrosion resistance of these alloys. The study systematically investigates the impact of $L1_2$ precipitates on corrosion resistance, providing critical insights into developing materials that are not only mechanically robust but also exhibit exceptional resistance to corrosive environments. By quantifying precipitation behavior through lattice misfit and correlating it with mechanical and corrosion properties, this comprehensive analysis offers a clear direction for the development of HEAs optimized for extreme environments. The ability to quantify precipitation behavior using lattice misfit and analyze its correlation with mechanical properties and corrosion resistance is crucial for developing reliable models and simulations. This enables the precise control of microstructural features and guides the design of advanced materials for demanding applications.

4:30 PM SF02.08.03
Refractory Compositionally Complex Alloys with Coarse-Grained and Fine-Grained Regions Towards

Strength-Ductility Synergy *Carla Joyce Nocheseda, Peter K. Liaw and Eric A. Lass; The University of Tennessee, United States*

We demonstrate the feasibility of crafting single-phase solid solutions with exceptional ductility relative to most refractory compositionally complex alloys, using a computational thermodynamic approach, namely the difference in the Gibbs free energy between solid solution phases. Using this concept, non-equiatomic variants can readily be studied across a wide composition space. Furthermore, we deliberately manipulated its grain size and fabricated a heterogenous structure through conventional thermo-mechanical processing. Refractory compositionally complex alloys are promising candidates for high temperature structural applications but most are reported for poor ductility and negligible cold-workability at room temperature. Here, we will define what heterogenous structure is comprising of fine-grained regions results from inhibited grain growth, while coarse-grained are from grain growth within large deformation bands. A strengthening mechanism unique to heterogenous structure is verified through mechanical behavior and density analysis using electron backscatter diffraction. This gives rise to both high strength and high ductility in refractory compositionally complex alloys.

4:45 PM SF02.08.04

Direct Observation of Short-Range Order in High Entropy Alloys—Impacts on Corrosion and Phase Transformation *Elaf Anber[1], Debashish Sur[2], Annie Barnett[1], Daniel L. Foley[1], John Scully[2] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]University of Virginia, United States*

High entropy alloys (HEAs) have garnered significant attention due to their unique mechanical and structural properties. The local chemical ordering (LCO) within these alloys significantly influences their thermal and electrical conductivity, as well as aspects like diffusion and passivity. In this study, we investigated how LCO impacts several alloy characteristics, including corrosion resistance, magnetic properties, and phase transformation. Initially, we utilized Extended X-ray Absorption Fine Structure (EXAFS) technique to analyze short-range order (SRO) at the micrometer scale. Subsequently, we employed Extended energy loss fine structure (EXELFS) , a high spatial resolution technique in transmission electron microscopy (TEM), to quantify fluctuations in local chemical order over length scales ranging from 50 to 200 nm in CoCrNi medium entropy alloys. Our findings revealed that the bond lengths of Cr, Co, and Ni decreased after aging treatment, indicating variations in their bonding environments. Simulation analysis showed an increased preference for Cr-Cr bonding in the second shell after aging. Furthermore, we demonstrated that clustered Cr-Cr in CoCrNi alloys provides distinct advantages in both short-term and long-term passivation and breakdown regimes. Through this exploration, we aim to uncover the fundamental principles governing the atomic-scale behavior of these materials, thereby laying the groundwork for further advancements in alloy design

SESSION SF02.09: Unconventional Synthesis, Characterization and Modeling of Novel Functional Materials

Bridging the Gap Between High-Entropy Alloys and Ab Initio Thermodynamics of Dilute Solutions *Leandro Seixas Rocha[1,2]; [1]Mackenzie Presbyterian University, Brazil; [2]MackGraphe - Mackenzie Institute for Research in Graphene and Nanotechnologies, Mackenzie Presbyterian University, Brazil*

The field of high-entropy alloys has seen recent advancements through the development of new descriptors that aid in forming and stabilizing solid solutions. Initially, the formation of these alloys was primarily understood through configurational entropy. However, other critical properties have since been recognized as influential, including the enthalpy of mixing, Gibbs free energy of mixing, average melting temperatures, and valence electron concentration. These properties help determine whether a new composition will form solid solutions, multiple phases, or metallic glasses. One significant challenge has been determining the enthalpy of mixing. Traditional models and empirical data, such as those derived from the Miedema model or CALPHAD, are commonly employed for this purpose. However, these models often fall short when applied to many components, leaving numerous potential compositions without established parameters. Ab initio thermodynamic models, particularly those based on density functional theory (DFT), offer predictions and guide the development of high-entropy alloys with new compositions, circumventing the need for empirical parameters. Nevertheless, simulating disordered alloys with multiple components is challenging. The increased disorder and component count necessitate simulations of materials with large unit cells, which complicates high-throughput calculations. In this work, we present an ab initio thermodynamic model for high-entropy alloys, utilizing parameters determined from simpler and faster-to-calculate dilute solid solutions rather than nearly equimolar disordered solutions. We demonstrate that the enthalpies of mixing interpolated from these dilute solution models align remarkably well with experimental data for binary alloys. Furthermore, we have developed a multicomponent extension of this model for application to high-entropy alloys. Our findings also indicate that, at high temperatures, excess vibrational entropy is just as important as configurational entropy for predicting miscibility gaps and the formation of spinodal decomposition.

8:15 AM SF02.09.02

Probabilistic Prediction of Material Stability in High Entropy Alloys—Integrating Convex Hulls into Active Learning *Eric S. Toberer[1], Andrew Novick[1], Colton Gerber[1], Ryan Adams[2], Diana Cai[3], Quan Nguyen[4] and Roman Garnett[4]; [1]Colorado School of Mines, United States; [2]Princeton University, United States; [3]Flatiron Institute, United States; [4]Washington University in St. Louis, United States*

Active learning is a valuable tool for efficiently exploring complex spaces, finding a variety of uses in materials science. However, the determination of convex hulls for phase diagrams does not neatly fit into traditional active learning approaches due to their global nature. Specifically, the thermodynamic stability of a material is not simply a function of its own energy, but rather requires energetic information from all other competing compositions and phases. Here we present Convex hull-aware Active Learning (CAL), a novel Bayesian algorithm that chooses experiments to minimize the uncertainty in the convex hull. CAL prioritizes compositions that are close to or on the hull, leaving significant uncertainty in other compositions that are quickly determined to be irrelevant to the convex hull. The convex hull can thus be predicted with significantly fewer observations than approaches that focus solely on energy. Intrinsic to this Bayesian approach is uncertainty quantification in both the convex hull and all subsequent predictions (e.g., stability and chemical potential). By providing increased search efficiency and uncertainty quantification, CAL can be readily incorporated into the emerging paradigm of uncertainty-based workflows for thermodynamic prediction. We offer this method as a tool for effectively building a library of stable, high-entropy ceramics.

Further, the incorporation of machine learning-based force fields (e.g. NequIP) allows for the comparatively rappid determination of free energies in high entropy spaces. Uniting such ML-based potentials with CAL allows for efficient exploration of phase stability, local motifs, and local distortions from high symmetry Wyckoff positions. As a proof of concept, we calculate the free energy convex hull for the senary (Ge, Sn, Pb)(S,Se,Te), a relevant composition space for thermoelectrics with several competing crystal structures and a tendency towards strong *local distortions.*

8:30 AM SF02.09.03

Synthesis of High-Entropy-Alloy Nanocrystals with Controlled Surface Atomic Arrangements for Hydrogen Evolution Reaction *Chia-Ying Wu and Tung-Han Yang; National Tsing Hua University, Taiwan*

High-entropy-alloy (HEA) nanocrystals have recently attracted significant attention due to their exceptional physicochemical properties. These promising attributes can be attributed to the presence of multiple elements and the four core effects of HEAs. In comparison to random surface atomic structures, shape-controlled HEA nanocrystals exhibit distinct facets and thus surface atomic arrangements, resulting in markedly different properties and applications. However, due to the thermally stable state tending to form a spherical shape, there are no effective strategies reported in the literature for synthesizing shape-controlled HEA nanocrystals thus far. In this study, we provide a straightforward strategy for the synthesis of HEA nanocrystals with controlled surface atomic arrangements and mixing by integrating dropwise synthesis and seed-mediated growth. The synchrotron X-ray absorption spectroscopy (XAS) has confirmed the atomic mixing and coordination environment of HEA nanocrystals with well-defined surface structures. Our work offers a facile and robust strategy to obtain HEA nanocrystals with controlled facets and elucidates the principal growth mechanism in detail. Most importantly, these HEA nanocrystals exhibit significant enhancements in both electrocatalytic activity and durability for the hydrogen evolution reaction in both acidic and alkaline environments, surpassing HEA nanocrystals with random atomic arrangements and commercial Pt/C catalysts. This synthetic strategy can be extended to control the facets of multi-component high-entropy nanocrystals, thereby providing a versatile approach for designing advanced materials with tailored properties for various catalytic reactions.

8:45 AM SF02.09.04

Breaking the Heat Barrier—Colloidal Synthesis of Ultra-Small, Monodisperse High Entropy Oxide Nanocrystals *Jonathan Rowell[1] and Richard Robinson[1,2]; [1]Cornell University, United States; [2]Kavli Institute at Cornell for Nanoscale Science, United States*

Despite recent interest in high entropy materials, there have been no reports of high entropy oxide (HEO) nanocrystals synthesized using colloidal methods. Conventional synthesis methods focus on high temperatures (TΔS) to overcome enthalpy and form a multi-metal phase, often resulting in large, polydisperse nanocrystals. In contrast, colloidal synthesis – which involves precursor decomposition within an organic ligand matrix at low temperatures and ambient pressure – produces the highest-quality nanocrystals with minimal size dispersity and stable solutions without agglomeration.

In this work, we challenge the conventional belief that high temperatures are necessary to thermodynamically drive HEO formation. Instead, we focus on the kinetics of precursor to monomer conversion, hypothesizing that similar decomposition rates among precursors can achieve HEO phases at lower temperatures, improving size and size dispersion control. We successfully leverage the low solubility product (K_{sp}) of metal oxides to synthesize HEO nanocrystals at low temperatures, producing the smallest (<4 nm) and most monodisperse (<15% size dispersity) HEOs to date. Our findings demonstrate a promising approach for producing spinel HEO nanocrystals with excellent size and dispersity control. Additionally, we show that this method enables the tunability in the number of cations, incorporating fewer cations into the lattice (from 1 to 6) than the high-entropy 5-cation rule suggests. This finding indicates that multicomponent phase formation in spinel oxides is not necessarily entropically driven.

We apply these HEO nanocrystals as electrocatalysts, showing promising activity towards the oxygen evolution *reaction (OER) in alkaline media, with an overpotential of 345 mV at 10 mA/cm^2, only 75 mV higher than the precious metal RuO_2 catalyst at the same current density.*

One-Step Colloidal Synthesis of Thiospinel High-Entropy Sulfide Nanoparticles—Catalysts for Improved Oxygen Evolution Reaction *Talisi Meyer, Ching Chun Peng, Cheng-Yin Li, Andrew Zhao, Reilly Lynch, Thomas J. Ugras and Richard Robinson; Cornell University, United States*

High entropy materials have become of growing interest due to the synergistic benefits of the multi-metal systems, as demonstrated by the enhanced application performance of high entropy alloys, oxides, and halogens. Despite the promise of multi-metal sulfide systems in overcoming the performance barriers of their oxide counterparts, high entropy sulfides have received relatively little research interest compared to other high entropy systems. The reason for this is that many high entropy sulfide syntheses rely on complicated, multi-step, high temperature processes often resulting in large, polydisperse, or aggregated particles that lack stability and uniform compositions.

In this talk, I will highlight our recent success in synthesizing high entropy sulfide nanocrystals through a colloidal synthesis method using mild chemistry. We have developed two heat-up synthesis routes, creating the first examples of thiospinel high entropy sulfide nanoparticles and nanodiscs with uniform size dispersion. Through a one-step, heat up synthesis, we have demonstrated the incorporation of five or more cations (with each cation constituting at least 5% of the total cations), into the lattice of two unique systems, achieving a controllable size distribution of less than 15% while maintaining temperatures below 200° C.

Our first system incorporates a base of Ni, Co, and Fe cations, with additional incorporation of a variety of 2+ and 3+ metal cation (Mn, Ir, Ru, Al, Mo, Sr, Zn, Mg, In, and Cd). The method produces multiple permutations of high entropy sulfide nanoparticles that can be colloidally synthesized with only a five-minute heating time. Each of these nanoparticles show promising potential as electrocatalysts in the oxygen evolution reaction (OER) in alkaline media. Our best-performing system is the Ni-Co-Fe-Mn-In sulfide nanoparticles that are monodisperse in size (9.86 nm ± 10.9%) and show an overpotential as low as 285.5 mV at 10 mA/cm^2 for the OER reaction.

Our second system of focus is the first example of high entropy sulfide nano-discs using Ni-Co-Cu-Mn-Cr with triphenylphosphine and elemental sulfur. These nanodiscs exhibit an average diameter of 14.3 nm ± 11.3% and show promise for their performance potential due to their high surface area and unique facilitation of electron transport within the disc-like structure. Within this system, the surface ligands limit the directional growth resulting in discs. Multi-metal cation exchange allows the incorporation of various elements into the lattice including Sc, Sr, Mg, Mo, Zn, Cd, Ga, and V. High entropy metal selenides are also obtainable by replacing the elemental sulfur with elemental selenium within the synthesis. Our Ni-Co-Cu-Mn-Cr nanodiscs have also been investigated for their potential as electrocatalysts in the oxygen evolution reaction in alkaline media with overpotentials reaching as low as 340 mV at 10 mA/cm^2.

Each of our systems has shown improved performance, phase purity, and shape control compared to its unary, binary, ternary, and quaternary components. Our work provides two simplistic, low temperature, colloidal methods to the formation of highly complex, phase pure, low dispersity, gram-scalable sulfide nanocrystals.

9:15 AM SF02.09.06

Sol-Gel-Derived Mesoporous High-Entropy Spinel Oxide Thin Films for Electrocatalysis of the Oxygen Evolution Reaction *Marcus Einert; Technische Universität Darmstadt, Germany*

With the introduction of high-entropy oxides (HEO) as a novel class of materials, unexpected and interesting properties have emerged. A HEO consists of five or more ions occupying a single crystallographic site and inducing a high degree of configurational disorder, which increases the entropic contribution to the Gibbs free energy of formation, thus stabilizing their crystallographic structure. Significant efforts have been devoted to the development of new HEO phases; however, the large majority of synthetic approaches are based on solid-state, rather than sol-gel chemistry allowing only the preparation of micrometer-sized, low-surface-area particles. Sol-gel chemistry requires precise control of reaction kinetics in order to form uniform structures, which is most likely the reason why the preparation of ordered mesoporous HEO thin films by the soft-templating and evaporation induced self-assembly (EISA) approach has not been reported yet.

The presentation informs about sol-gel synthesis of (ordered) mesoporous $(CrMnFeCoNi)_3O_4$ *[1] and* $(CoNiCuZnMg)Fe_2O_4$ *[2] high-entropy spinel oxides prepared by dip-coating and EISA process. A synthetic route was developed, utilizing the unique copolymer (poly(ethylene-co-butylene)-block-poly(ethylene oxide), known as KLE, in order to obtain periodically ordered and 15−18 nm sized mesopores within the high-entropy ferrite (HEF) framework. [2] The meso-structured HEF electrodes were found to be crack-free on the nano- and macroscale. Time-over-flight secondary ion mass spectrometry and electron microscopy verified a homogenous distribution of all elements within the structure. The fundamental impact of a nanoscale framework on the electrocatalytic properties was investigated: mesoporous HEF applied as oxygen evolution electrocatalyst for water oxidation showed near-metallic electric conductivity, which was related to an electron hopping mechanism induced by the interaction of 3d-states of the inserted transition metals, and was found to improve OER performance. This novel high-entropy nanostructures can be considered as interesting candidate for energy conversion applications.*

Synthesis and Characterization of Rare-Earth High-Entropy Perovskites *Veerle Keppens, Rubayet Tanveer and William J. Weber; The University of Tennessee, United States*

Perovskite oxides ABO_3 *have garnered considerable interest in the scientific community due to their unique properties and wide-ranging potential applications. Adding complex compositional diversity, “high entropy” perovskites with 5 cations on a given lattice site offer the potential of tuning and combining properties, potentially revolutionizing applications in areas including energy storage, electronics, and photonics. Through careful selection of cations, we have applied the high entropy concept to synthesize a set of rare-earth perovskites* $REBO_3$ *(RE= La, Pr, Nd, Sm, Eu, Gd) with the B-site occupied by Sc, Al, Cr, Ni, and Fe in equimolar ratios. Using an extended set of characterization measurements, the effects of multi-component material design and rare earth selection on the electronic properties are explored.*

10:30 AM SF02.09.08

New Advances in Early Transition Metal High-Entropy Oxide Electroceramics *Robert J. Spurling, Saeed S.I. Almishal, Michael T. Marakovits, Arafat Hossain, Jacob Sivak, Chloe Skidmore, Nathaniel S. McIlwaine, Joseph*

Casamento, John Hayden, Ryan Spangler, Steven E. Perini, Susan B. Sinnott, Michael T. Lanagan and Jon-Paul Maria; The Pennsylvania State University, United States

High-entropy oxides unlock new potential for application-driven materials design. High configurational entropy bestows thermodynamic stability to structures with distinct local environments, which in turn give rise to diverse and tailorable properties. The $A_6B_2O_{17}$ (A = Zr, Hf; B = Nb, Ta) high-entropy oxides adopt a complex, disordered cation sublattice which induces a unique macroscopic dielectric repsonse, making them important candidates for electroceramics applications. Here, we investigate the interplay between strcuture and dielectric properties of disordered $A_6B_2O_{17}$ phases across length scales, from bulk ceramics to thin films.

Tandem in situ and ex situ X-ray diffraction identify $A_6B_2O_{17}$ stabilization temperatures which are consistent with calculations for a strongly cation-disordered sublattice. Reactive sintering at high temperatures (≥ 1300 °C) yields dense (> 95% $\rho_{Theoretical}$), phase-homogenous $A_6B_2O_{17}$ ceramics which are used for bulk dielectric measurements and as targets for thin film sputter deposition. Room temperature Hakki-Coleman measurements on bulk ceramics indicate a relative permittivity of ~60 with loss < 0.01. Modified temperature resonant post measurements indicate an atypical temperature-dependent dielectric response: we observe a positive permittivity temperature coefficient, suggesting contributions from a disorder-derived polarization mechanism. Dielectric measurements from sputter-deposited films corroborate bulk data. We observe a strong connection between oxygen partial and total pressure deposition conditions on film microstructure and morphology as well as electrical performance. X-ray diffraction, X-ray reflectometry, atomic force microscopy, and X-ray photoelectron spectroscopy highlight structural differences between films grown under different deposition conditions; this structural data is used to improve understanding of dielectric property trends. We explore extended solubility in $A_6B_2O_{17}$ phases and impacts from different solute cations on structure and electronic properties, including high field responses. We employ computational tools, including density functional theory and machine learning, to corroborate and elucidate experimental trends in both structure and property behavior.

10:45 AM SF02.09.09
Improving CO Oxidation Catalysis Over High Entropy Spinels by Increasing Disorder *Joshua Swindell, Gareth Tainton, Sarayute Chansai, Kerry Hazeldine, Mark Buckingham, Chris Hardacre, Alex Walton, Sarah J. Haigh and David Lewis; The University of Manchester, United Kingdom*

Developing earth-abundant heterogeneous catalysts that are simultaneously highly stable and active remains a key challenge within material science that requires novel design strategies. Transition metal spinel oxides exhibit desirable catalytic properties but are prone to long-term degradation. We present a significant improvement to the catalytic activity and long-term stability of spinel oxides (M3O4, where M is a combination of Cr, Mn, Fe, Co, Ni, Cu, and Zn) for CO oxidation by systematically increasing the configurational disorder. We revealed an impressive 63% reduction in the T10 value (temperature to reach 10% CO oxidation) by increasing the number of first-row transition metals within the spinel structure from 4 to 7 metals. The most disordered 7-metal spinel structure was also found to exhibit superior resistance to catalyst deactivation compared to the 4-metal spinel. A facile, versatile molecular precursor-driven approach to synthesizing a series of high-entropy spinel oxides (HESO) is also presented, along with comprehensive characterization of the crystal structure (XRD/atomic resolution STEM), elemental distribution (EDS), and surface (XPS).

11:00 AM SF02.09.10
Design of High Entropy Perovskites Oxides for Solid Oxide Fuel Cell Applications *Jyotsana Kala[1], Vicky Dhongde[1], Madhulika Gupta[2], Suddhasatwa Basu[1], Brajesh K. Mani[1] and Mohammad A. Haider[1]; [1]Indian Institute of Technology Delhi, India; [2]Indian School of Mines Indian Institute of Technology Dhanbad, India*

Abstract: *Perovskite oxides of a general formula of ABO_3 with rare earth element La at A-site and Mn, Co, and Fe at B site have received significant attention for low-cost electrode materials in energy storage devices [1]. The introduction of different cations through partial substitution at the A and B sites has provided a way to further augment and tailor the properties of perovskite oxides for a variety of applications [2]. However, the slow kinetics of oxygen reduction reaction, high overpotential, and surface instability remain a barrier, creating a demand of high-performance materials for energy storage devices. High entropy perovskite oxides could be potential candidates for high-performance oxygen electrode catalysts [3]. These materials, exhibiting synthesizability as single-phase entities with specific configurations, have attracted attention. While numerous descriptors have been proposed to predict the synthesizability of high entropy perovskite oxides, none, to the best of our knowledge, have successfully predicted a broad range of configurations. In this study, we conducted a comprehensive screening of reported high entropy perovskite oxide configurations from various experimental studies. Building upon the insights gained from the analysis of already synthesized perovskite oxide configurations, we propose a novel configuration, namely* $La_{0.2}Pr_{0.2}Gd_{0.2}Sr_{0.2}Ca_{0.2}MnO_3$ *(LPGSC), as a high entropy perovskite oxide. Theoretical and experimental investigations of the LPGSC configuration reveal significantly enhanced properties, particularly in terms of improved surface stability.*

Magnetic High Entropy Oxide for Water Pollutant Degradation *Sanjula Pradhan and Nand K. Prasad; Indian Institute of Technology (BHU), India*

This investigation reports the synthesis of a single phase equi-atiomic high-entropy oxide (HEO) with a novel composition (Mn 0.6 Cr 0.6 Co 0.6 Al 0.6 Li 0.6)O4 having a spinel structure. The sample was meticulously synthesized using the sol-gel technique followed by subsequent calcination at 700°C (973K) temperature. The phase formation was characterized through different techniques like X-ray diffraction (XRD) and Transmission electron microscopy (TEM). Data received via XRD and selected area electron diffraction pattern through TEM conclusively confirmed the successful formation of nanocomposite structures with desired phase compositions. Also, the magnetic properties such as M Vs H loop was observed at two different temperatures 300 K and 5 K with a field range of ±30 kOe. At 300 K, the sample demonstrates soft magnetic behaviour with a measurable coercivity (H C) of 38 Oe. However, at 5 K, the H_C *significantly increases to 2524 Oe, indicating a transition to a hard magnetic behaviour. Further in-depth analysis using X-ray photoelectron spectroscopy revealed the coexistence of diverse oxidation states within the constituent elements of the sample and studies were carried out to observe the synergetic effect of properties in the novel formed HEO. UV–vis DRS and Mott-Schottky, results indicate the catalyst's capability to degrade organic dyes via interaction with ROS generated through Fenton-like reactions with* H_2O_2*, photon absorption, or a combined photo-Fenton mechanism. The catalytic breakdown of methylene blue (MB), an organic dye, was found to be around 98% in the following 90 minutes via a Photo-Fenton type reaction mediated by* H_2O_2 *at room temperature.*

11:30 AM SF02.09.12

Enhancing Sodium-Sulfur Battery Performance with High Entropy MXenes— Mitigating Shuttle Effect and Boosting Electrochemical Performance *Saba Khan, Chandraveer Singh and Mohammedhossein Ghoncheh; University of Toronto, Canada*

Sodium-sulfur batteries (NaSBs) are strong candidate for large-scale stationary energy storage because they benefit from both double-electron redox process and the natural abundance of sodium and sulfur resources. However, their performance and lifetime are hampered by the poor cycling stability due to the shuttle effect during the discharge phase. One way to prevent the shuttle effect is by employing suitable materials as cathode additives. Here, we propose employing high entropy (HE) configurations of MXene Ti_2CO_2 (HE MXene) as cathode additives to suppress the shuttle effect. By using density-functional theory calculations, we investigate the binding energy, band structures, charge exchange and activation barrier energy of dissociation of Na_2S_n moiety. Our results show that the binding energies of Na_2Se_n on all 8 HE configurations of the MXenes are much stronger than those on the commonly employed organic electrolytes (DOL, DME) and the pristine MXene itself. In case of Na_2S, the chemisorption on MXenes is associated with dissociation of sodium ion and shown to have lower energy barriers for both the dissociation and percolation processes. On account of cocktail effect, all the HE MXenes exhibit highly enhanced density of states at the Fermi level, which are expected to enhance the electrochemical process during battery operation. The four most efficient HE MXene configurations have been identified and their performance in suppressing the shuttle effect has been discussed.

11:45 AM SF02.09.13
Effects of Iron and Vanadium Substitution in Mg0.5Al0.25Cr0.25Ni0.25 Multi-Component Alloys for NiMH Battery Application *Hakan Yüce[1], Fatih Piskin[1], Berke Piskin[1], Eli Grigorova[2] and Gulhan Cakmak[1]; [1]Mugla University, Turkey; [2]Bulgarian Academy of Science, Bulgaria*

Hydrogen energy is becoming an important part of a viable solution to worldwide climate change and atmospheric pollution. In this regard, hydrogen storage materials direct the research of rechargeable batteries.High entropy alloys containing Mg consist of an attractive system because Mg is light, cheap, and abundant, and has a high absorption capacity. Mg-containing alloys are an attractive candidate for solid-state hydrogen storage and can be further applied in electrochemical systems where the hydrogen atoms occupy the interstitial forming metal hydride (MH). A Ni/MH battery is composed of a Ni(OH) 2 positive electrode, a metal MH negative electrode and an alkaline electrolyte (KOH solution). The family of hydrogen storage alloys based on transition metals (TM) – Mg – Ni has attracted increasing attention in recent years. They can meet the general electrochemical performance requirements by exhibiting high discharge capacity, long durability, good rate capacity, admirable discharge capacity at low temperature and low self-discharge characteristics. In this direction, it is aimed to add these properties to Mg-based alloys by adding transition metals to Mg-based alloys. In this direction, it is aimed to produce Mg0.5Al0.25Cr0.25Ni0.25A0.25 (A=Fe,V) alloys.This alloy electrode will be prepared by melting in a vacuum arc melting furnace under argon atmosphere and with the help of SPEX Ball Mill the alloy will be reduced below 45 microns and then The crystallographic properties of the Mg0.5Al0.25Cr0.25Ni0.25A0.25 (A=Fe,V) alloy will be examined. The electrochemical results are aimed at performing charge/discharge tests on NiMH batteries using potentiostat/galvanostat and collecting electrochemical impedance spectrum (EIS) data on the cell.

High-Entropy Spinel Ferrite Nanoparticles Via Low-Temperature Synthesis for the Oxygen Evolution Reaction

Roland Marschall; University of Bayreuth, Germany

High-entropy oxides are a material class that is currently receiving rapidly increasing attention due to the large variety in composition and adjustable properties. Cooperative effects between different metal cations in the crystal structure in addition to entropic phase stabilisation have proven beneficial for electrocatalytic applications. Most synthesis methods, however, require high synthesis temperatures and long synthesis times, and often only yield selected samples in good phase-purity.

We herein present for the first time a microwave-assisted low temperature synthesis of earth-abundant high-entropy oxide nanoparticles. Phase-pure spinel ferrites (AFe_2O_4) of various compositions ranging from one to seven different A-cations were successfully obtained after only 30 min synthesis time at 225 °C. A detailed characterisation of their properties in relation to their composition was performed, and they were also employed for the alkaline oxygen evolution reaction (OER).

A partial replacement of Fe by Co moreover shows the high versatility of the synthesis that also allows for the simultaneous variation of the B-ion.

Moreover, we will present our latest results on preparing high-entropy thiospinel (M3S4) nanosheets with a similar low-temperature synthesis, incorporating up to 8 cations for entirely phase-pure electrocatalysts.

Synthesis of High Entropy Boride Using Atomic Hydrogen Via MW-Plasma *Bria C. Storr and Shane A. Catledge; The University of Alabama at Birmingham, United States*

We explore the synthesis of $MoNbTaVWB_{10}$ high-entropy borides (HEBs) in a reactive versus inert environments using microwave plasma. The dissociation of molecular hydrogen into atomic hydrogen allows the efficient reduction of metal oxide precursors, minimizing the loss of boron during heating. Our results demonstrate that the reactive hydrogen atmosphere promotes the formation of the hexagonal AlB2-type HEB structure at lower temperatures compared to an argon environment. X-ray diffraction analysis reveals that annealing at temperatures as low as 1750°C in hydrogen plasma produces a predominantly single-phase structure through the enhanced reducing capability of atomic hydrogen allowing for uniform crystalline structure. By comparing hydrogen and argon-rich environments, we further demonstrate, via scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX), the benefits of hydrogen plasma, including improved purity and consistent elemental distribution, highlighting its effectiveness in optimizing high entropy material synthesis.

Thermodynamic and Thermal Transport Properties of Entropy-Stabilized Oxide $MgCoNiCuZnO_5$—Effect of Stoichiometric Change *Keivan Esfarjani, Bikash Timalsina and Huy G. Nguyen; University of Virginia, United States*

The lattice distortion in a crystal has a significant effect on thermal transport properties. Such an effect is very prominent in entropy-stabilized oxides. Herein, using neuroevolution machine learning potential and molecular dynamics simulation we demonstrate that the lattice thermal conductivity of J14($MgCoNiCuZnO_5$) decreases from $2.60\pm0.2\ Wm^{-1}K^{-1}$ at 300 K to $2.07\pm0.05\ Wm^{-1}K^{-1}$ at 900 K, consistent with the experimental findings. The results show that the reduction in lattice thermal conductivity as a function of temperature in J14 is due to a decreased phonon mean free path. Next, the composition of zinc and nickel in J14 is varied by 30% to investigate the effect of stoichiometric change on the lattice thermal conductivity at room temperature. While more Zn causes more *distortions, an addition of Ni reduces distortions. Therefore, one expects related changes in the thermal conductivity. The results indicate that the composition with more zinc in J14 ($Mg_{0.2}Co_{0.2}Ni_{0.14}Cu_{0.2}Zn_{0.26}O$) and more nickel in J14 ($Mg_{0.2}Co_{0.2}Ni_{0.26}Cu_{0.2}Zn_{0.14}O$) have been thermodynamically stable within our simulation time. The lattice thermal conductivity with more zinc in J14 is 2.54±0.2 $Wm^{-1}K^{-1}$ and with more nickel in J14 is 2.77±0.2 $Wm^{-1}K^{-1}$ at room temperature. We find therefore that there is indeed correlation between the amount of distortions and the thermal conductivity in these compounds. These findings are supported by the fact that adding more zinc to J14 leads to a decrease in the phonon mean free paths, while adding more nickel to J14 leads to an increase in the phonon mean free paths at room temperature. The neuroevolution machine learning interatomic potential is beneficial to studying and tuning thermal transport properties such as lattice thermal conductivity for entropy-stabilized oxides.*

Molecular Size Effects and Entropic Solution Design in Multicomponent Aqueous Organic Solutions *Spencer P. Alliston[1], Chris Dames[1] and Matthew J. Powell-Palm[2]; [1]University of California, Berkeley, United States; [2]Texas A&M University, United States*

Predictive synthesis of aqueous organic solutions with desired liquid-solid phase equilibria – particularly Natural Deep Eutectic Solvents (NADES), which have anomalously low eutectic points -- could drive progress in diverse fields from industrial chemistry to cryopreservation, but is limited by the predictive power of current solution thermodynamics models. Few analytical models enable accurate liquidus and eutectic prediction using only bulk thermodynamic properties of pure components, requiring instead either direct measurement or costly simulation of solution properties. In this presentation, we demonstrate that a simple modification to the canonical ideal solution theory accounting to account for the entropic effects of dissimilar molecule sizes can substantially improve its predictive power and also offer new insight into the thermodynamic nature of aqueous organic solutions.

Specifically, we incorporate a Flory-like entropy of mixing term, which includes both the mole and volume fractions of each component, and derive size-dependent equations for the ideal chemical potential and liquidus temperature. We then use these relations to predict the binary phase diagrams of water and 10 organic solutes of varying sizes. We show that size-dependent prediction outperforms the ideal model in all cases, reducing average error in the predicted liquidus temperature by 63%, eutectic temperature by 45%, and eutectic composition by 43%, as compared to experimental data. Furthermore, by retaining the ideal assumption that the enthalpy of mixing is zero, we demonstrate that for aqueous organic solutions, much of the deviation from ideality that is typically attributed to intermolecular interactions may in fact be explained by simple entropic size effects. Following this, we apply an analogous method to predict phase equilibria in ternary and higher-order systems, and present an optimization method to minimize equilibrium temperatures in multicomponent aqueous solutions. In doing so, we further improve system behavior, substantially reducing the predicted melting point of solutions that remain over 0.8 mol/mol water. We also examine the problem using volume fractions, allowing for differing solution design in the case of different optimization parameters. Finally, we compare these predictions to standard DSC-measured solution behavior for representative multicomponent systems.

2:30 PM SF02.10.05

Towards Accurate Prediction of Configurational Disorder Properties in Materials Using Graph Neural Networks *Zhenyao Fang and Qimin Yan; Northeastern University, United States*

The prediction of configurational disorder properties, such as configurational entropy and order- disorder phase transition temperature, of compound materials relies on efficient and accurate evaluations of configurational energies. Previous cluster expansion methods are not applicable to configurationally-complex material systems,

including those with atomic distortions and long-range orders. In this work, we propose to leverage the versatile expressive capabilities of graph neural networks (GNNs) for efficient evaluations of configurational energies and present a workflow combining attention-based GNNs and Monte Carlo simulations to calculate the disorder properties. Using the dataset of face-centered tetragonal gold copper without and with local atomic distortions as an example, we demonstrate that the proposed data-driven framework enables the prediction of phase transition temperatures close to experimental values. We also elucidate that the variance of the energy deviations among configurations controls the prediction accuracy of disorder properties and can be used as the target loss function when training and selecting the GNN models. The work serves as a fundamental step toward a data-driven paradigm for the accelerated design of configurationally- complex functional material systems.

2:45 PM SF02.10.06

Development of Microstructural Resettable Alloy Via Segregation Engineering *Minseok Kim, Ji Young Kim and Eun Soo Park; Seoul National University, Korea (the Republic of)*

Although there is a limitation to reduce greenhouse gas emissions only through reduction of materials, reusing of materials could be one of the best method for reducing the total amount of greenhouse emission. Therefore, this study focused on developing a novel reusable alloy by resetting the mechanical properties after certain period of using. We suggest a unique alloy design method and resetting heat treatment which could save huge amount of energy cost and greenhouse gas emissions when it is commercialized. Mn was selected as a key alloying element, considered the segregation tendency and effect on phase stability in 9Cr steel system, which is widely used as a structural material. In the segregation engineering concept, the segregation tendency and the effect of the segregation to defects are most important factors which should be considered. In 9Cr steel, segregation of Mn to grain boundary could increase the local stability of the austenite phase. This could lead to partial reversion of grain boundary austenite when the temperature is precisely controlled. Since Mn segregation tendency in iron solvent is largest among 3d-transition metal, Mn is the best candidate to do the segregation engineering in 9Cr steel. After homogenization and air cooling, microstructure was constituted of fully martensite. During the subsequent annealing which is called reversion process, partial reversion occurs at the grain boundary by the Mn element which has been segregated and enhances the local reversion kinetics. Furthermore, we find out that this metastable austenite exhibit transformation induced plasticity (TRIP) behavior during deformation. As a result, the ductility of the 9Cr steel greatly increased with no significant reduction in strength. Since fresh martensite at the grain boundary which is transformed during deformation has high concentration of Mn, it could be partially transformed to austenite at relatively low temperature. Through precise control of this microstructural features and annealing condition, it was able to reset the microstructure after deformation. It was possible to implement a repetitive deformation and resetting process for resetting mechanical properties by controlling the reversible local phase transformation. Furthermore, we optimized the resetting process which is dependent on pre-strains that represent damage accumulated level. This results could suggest a novel approach method to develop a reusable metallic material which is becoming more important for the sustainable development.

Phase Evolution and Identification in Beta-Ti-Nb Alloys *Julia Puerstl[1], Ravit Silverstein[1], Florent Mignerot[1,2], Nicolo Maria della Ventura[1], Bailey E. Rhodes[1], Solene Dassonneville[2], Jeremiah Thomas[1], Thomas W. Cornelius[2], Glenn Balbus[1,3], Tresa Pollock[1], Carlos Levi[1], Anton Van der Ven[1] and Daniel S. Gianola[1]; [1]University of California, Santa Barbara, United States; [2]Aix-Marseille Université, France; [3]Lehigh University, United States*

The push for increased functionality and high temperature stability of future structural materials prompts

increasing attention towards body centered cubic (bcc) alloys, primarily refractory- or Ti-based. In light of the increased demand for sustainable alloying systems with simplified base element constitution, the present study focuses on investigations in the binary Ti-Nb system. As a sub-class of the bcc beta-Ti alloys, the Ti-Nb system is characterized by the presence of a metastable bcc structure at room temperature, and allows for a combination of the high temperature refractory stability of Nb with the remarkable ductility and functionality of Ti-based alloys.
Of interest is specifically the equimolar Ti-50Nb composition, which falls inside a predicted chemical spinodal. This spinodal can be tuned by the addition of oxygen, prompting a decomposition into Ti-rich and Nb-rich domains that can act as precursors for further phase transformations.
The present study investigated two aspects of these phase transformations through targeted addition of up to 1.4at%O in the Ti-50Nb system:
1) The thermally induced evolution of a hcp-bcc network during a controlled heat treatment within the chemical spinodal, as a strengthening mechanism in Ti-50Nb. This was facilitated by heat treatments of dehydrided powder alloys in a controlled O atmosphere.
2) The stress induced (martensitic) evolution of phases along the bcc to hcp transformation pathway prompted by subcooling into a metastable state from the single-phase bcc region, to promote low modulus pseudoelasticity [1]. This was facilitated by heat treatments of bulk samples prepared by arc melting with the addition of controlled amounts of TiO_2.
Significant changes in mechanical properties were tracked using a combination of thin foil tension and micropillar compression, and linked to hcp or martensitic phase evolution by detailed phase analysis on the basis of transmission electron microscopy (TEM) and micro-Laue diffraction. The results are presented in the framework of wider refractory multi-principal element alloy (RMPEA) performance, the role of impurity elements in bcc alloys, and the application of advanced diffraction-based characterization for the tracking of phase evolutions in these systems.

3:45 PM SF02.10.08
Tin-Induced Cocktail Effect in Biocompatible β-Ti Alloys *Norihiko L. Okamoto[1], Florian Brumbauer[2], Martin Luckabauer[3], Wolfgang Sprengel[2] and Tetsu Ichitsubo[1]; [1]Tohoku University, Japan; [2]Graz University of Technology, Austria; [3]University of Twente, Netherlands*

β-Ti alloys with the body-centered cubic structure offer unique properties for aerospace and biomedical applications but face challenges from the ω phase transformation, which can embrittle and stiffen them. Understanding and controlling this transformation is crucial for enhancing their performance. Traditionally, two ω transformation modes were identified: athermal and isothermal. Recently, a novel diffusionless isothermal (DI-)ω transformation was proposed [1], explaining anomalous phenomena in β-Ti alloys at ambient temperatures. This DI-ω transformation originates from inherent compositional fluctuations in the β phase: locally β-unstable regions with less β-stabilizing elements (Nb, V, Cr, Mo, etc.) gradually undergo ω transformation via a nucleation process [1]. Recently, β-Ti–Nb–Sn alloys, exhibiting both remarkably low Young's modulus and high strength, have successfully undergone clinical trials for use in artificial hip femoral components. Whereas Nb, similar to V, Cr, and Mo, stabilizes the β phase and moderately suppresses the formation of the ω phase that makes the alloy brittle, Sn is recognized for its capability of suppressing the ω phase despite being considered a “neutral” element that does not contribute to the stabilization of the β phase [2]. This apparent contradiction presents a fascinating aspect of alloy design, where an element not expected to stabilize the β phase contributes significantly to the prevention of detrimental phase transformations.
In the present study, we have unveiled the mystery behind the essential addition of the neutral Sn element to the biocompatible β-type Ti alloy to eliminate the ω-phase transformation. The difficulty in completely suppressing the ω transformation in β-Ti alloys lies in the persistent existence of nanometer-scale Ti-rich β-unstable regions, originating from inherent quenched-in compositional fluctuations [1]. Such locally unstable regions cannot be

eliminated solely by the addition of a conventional β-stabilizing element due to the limited scope for suppressing the local collapse of the $(111)_\beta$ planes. Utilizing the Ti-V-Sn model alloy system, we have substantiated that the role of Sn as a ternary element is to extend the β-stabilizing effect of the conventional β-stabilizing element beyond what would be expected under the assumption of linear dependence. In addition to this many-body effect, Sn atoms also serve as anchors for neighboring β-stabilizing elements, preventing phase separation at intermediate temperatures. These two synergistic effects lead to a comprehensive suppression of all modes of the ω phase transformation, exemplifying the so-called "cocktail effect".

Influence of Cr and V on the Quaternary Fetitaw Entropy Alloy *Ricardo J. Martins[1], António P. Gonçalves[1], José B. Correia[2], Magdalena Galatanu[3], Andrei Galatanu[3], Elena Tejado[4], Jose Pastor[4], Eduardo Alves[1] and Marta S. Dias[1]; [1]Universidade de Lisboa, Portugal; [2]Laboratório Nacional de Energia e Geologia, Portugal; [3]National Institute of Materials Physics, Romania; [4]Universidad Politécnica de Madrid, Spain*

Nuclear energy stands out as a promising source of energy production, relying on materials capable of withstanding demanding operational conditions with structural reliability. Tungsten (W) was chosen as the plasma-facing component and CuCrZr as the heat sink material. Key properties required for a material to serve as the plasma-facing unit include a high melting point, low sputter yield, and minimal tritium retention. However, existing material properties do not achieve the desired operational temperatures. Consequently, an intermediate layer is necessary to ensure these conditions while facilitating proper thermal transport between the materials and maintaining suitable working temperatures.
This work proposes a high entropy alloy $(CrFeTiTa)_{70}W_{30}$ and FeTiTaVW as a interlayer between W and CuCrZr. Therefore, this study is based on the influence of Cr and V on a medium entropy alloy FeTiTaW based on structural, thermal, and mechanical properties. The materials were milled for 2 hours at 350 rpm and consolidated via spark plasma sintering at 1100ºC under pressures of 70 MPa, with a holding time of 5-8 minutes. X-ray diffraction confirmed the formation of a body-centered cubic (bcc) structure in the FeTiTaW, $(CrFeTiTa)_{70}W_{30}$ and FeTiTaVW samples, while microstructural analysis revealed chemical segregation of Ti for all. $(CrFeTiTa)_{70}W_{30}$ mechanical properties displays a ductile-to-brittle transition temperature between 900ºC and 1000ºC, making this values similar to other refractory high entropy alloys. Moreover, the FeTiTaVW consolidated material's thermal conductivity and specific heat are almost constant from 25ºC to 1000ºC, and linear expansion increases with increasing temperature. On the other hand, specific heat and thermal expansion values are in between CuCrZr and W values. The FeTaTiVW high entropy alloy evidences a ductile behaviour at 1000ºC.

4:15 PM SF02.10.10
Challenges in the Design of Multi-Phase Multicomponent Alloys for Hydrogen Storage *Bruno Hessel Silva[1], Igor Spegiorin Vicente[2], Ricardo Floriano[2] and Sabrina Sartori[1]; [1]University of Oslo, Norway; [2]Universidade Estadual de Campinas, Brazil*

Hydrogen is considered a low-carbon emission energy vector with the potential to replace fossil fuels in certain applications. However, the implementation of hydrogen as an energy carrier faces challenges, particularly in technological aspects such as the efficiency and safety of hydrogen storage. In this context, metal hydrides emerge as a promising option for hydrogen storage, offering high volumetric efficiency under moderate conditions *of temperature and pressure. High entropy alloys, also generically known as multicomponent alloys, have drawn the attention of several research groups due to the increased number of systems and compositions that could be utilized as metal hydrides for hydrogen storage [1]. Several studies have reported the possibility of tailoring hydrogen storage performance through chemical compositional adjustments in systems that combine elements with both high and low affinity for hydrogen [1–3]. Most of these studies have focused on single-phase Body Centered Cubic (BCC) alloys and single-phase intermetallic compounds with the Laves C14 structure. However, a few recent studies suggest that multi-phase structures may offer advantages for the hydrogenation performance of multicomponent alloys, particularly in the activation and kinetics for hydrogen absorption [4,5]. In the present work, we will showcase new multi-phase multicomponent alloys designed for enhanced hydrogen storage behavior. The presence of refined morphological microstructural features will be discussed as potential contributors to improving the hydrogen storage properties of the studied alloys. Additionally, the benefits and challenges of using thermodynamic computational tools such as CALPHAD will be highlighted. Finally, we aim to provide a perspective for the next steps in the design of multi-phase multicomponent alloys for hydrogen storage applications, for example, how to define chemical compositions of the different phases to achieve compatible equilibrium pressures for hydrogen absorption/desorption and how to reach more sustainable compositions.*

4:30 PM SF02.10.11
Mechanical Behavior, Nanostructure Stability and Defect Evolution Mechanisms of Oxide Dispersion Strengthened NiCoFe Medium-Entropy Alloy Under High-Temperature Irradiation *Lukasz Kurpaska and Sri T. Nori; National Center for Nuclear Research, Poland*

To sustain extreme environments in advanced nuclear concepts, innovative structural materials with various compositional and microstructural designs have been explored for the past few decades. The current work investigates one such structural material developed recently, oxide dispersion strengthened (ODS)-NiCoFe, which uniquely combines various design strategies, such as the concentration solid solution alloys (CSAs), high-density grain boundaries, and nano oxide dispersion strengthening. The ODS-NiCoFe was examined following a high-temperature (580 C) Ni^{2+} irradiation up to a maximum of 121 dpa, to understand irradiation effects on the stability of the nanosized grains and oxide precipitates, mechanical behavior, and defect evolution. The enclosure of high-density grain boundaries and the ODS particles increased the hardness from 2 ± 0.1 GPa (NiCoFe) to 4.3 ± 0.9 GPa (ODS-NiCoFe) while irradiation hardening of 25% occurred in both NiCoFe and ODS-NiCoFe. Post-irradiation transmission electron microscopy observations indicated the physical stability of nanosized precipitates and grains and the presence of irradiation-induced dislocation loops as major defect structures. However, no significant voids were noticed. Similarly, molecular dynamics cascade simulations also revealed inhibition of the *growth of vacancy clusters. The simulations demonstrated the absorption of the mobile stacking fault tetrahedra containing trapped vacancy clusters at the grain boundaries and Shockley dislocation dominant chains mainly consisting of interstitial clusters that grow and move three-dimensionally in polycrystalline NiCoFe. These findings indicate high-temperature radiation tolerance of the novel ODS-NiCoFe. Thus, the current assessment presents a state-of-the-art structural material design strategy for advanced reactor applications.*

Cluster-Model-Based Composition Design Method for Fe-Cr-Ni-Based Medium- and High-Entropy Alloys

Shuang Zhang[1], Cunlei Zou[1], Wanyu Ding[1], Yajun Zhao[1] and Chuang Dong[1,2]; [1]Dalian Jiaotong University, China; [2]Dalian University of Technology, China

High-performance materials always possess specific chemical compositions, which strongly suggest the possible existence of some molecule-like structural units, in which the versatile but specific compositions are rooted. Our research group proposed the cluster-plus-glue-atom model in 2007, which is a short-range-order structural model that renders any structure with a structural unit consisting of a nearest-neighbor cluster plus a few outer-shell glue atoms. Here, the cluster-plus-glue-atom model is fully presented to show how to uncover the composition origin of high-entropy alloys. Examples are given in various industrial alloys with high-entropy feature, including stainless steels, superalloys, etc. Based on these composition analysis results, Fe-Cr-Ni-based medium- and high-entropy alloys with excellent mechanical properties are designed. The proposition of cluster-model-based molecule-like structural units supports a new perspective for the research of high-entropy alloys, facilitates the understanding of prevailing materials, and can be a useful tool to guide the exploration of new composition space.

Engineering and Controlling Bioinspired and Biohybrid Magnetic Microrobots Made From Living and Synthetic Materials *Simone Schuerle; ETH Zürich, Switzerland*

Delivering drugs effectively to targeted diseased sites remains a major challenge. Transmitting magnetic fields to guide drug carriers to specific locations is promising, however, current methods often struggle with physiological barriers and are limited to accessible areas. This presentation explores the engineering of magnetic microrobots powered by scalable torque-based actuation via rotational magnetic fields to enhance drug delivery to deep-seated tumors. This approach is particularly effective for microrobots with high anisotropy, which can be boosted by both the shape and magnetocrystallinity of the magnetic materials used. We demonstrate biohybrid microrobots—live bacteria augmented with magnetic nanomaterials—that combine chemotaxis as autonomous navigation with external magnetic control. This hybrid strategy improves tumor targeting compared to unactuated controls and can be optimized with spatially restricted rotating magnetic fields to reduce side effects. Additionally, we have developed synthetic microrobots from biodegradable hydrogels engrafted with patterns of magnetitenanoparticles. By applying dynamic magnetic fields during microfluidic fabrication, we create anisotropic capsule-like microrobots with strings of nanoparticles. These microrobots, actuated with rotational magnetic fields, effectively dissolve thrombi in vascular models and induce convection enhanced drug transport. These advances offer promising improvements in drug delivery and may advance the clinical use of magnetic microrobots.

Reprogrammable 3D-Printed Liquid Crystal Elastomer Actuators *Meg Coleman, Devesh Mistry, Viola Huf, Jaemin Lee, Robert Kay and Johan Mattsson; University of Leeds, United Kingdom*

Soft robotics has recently become an exciting field of research due their flexible and versatile properties, making them ideal for applications in biomimetics and artificial muscles [1]. Liquid crystal elastomers (LCEs) are unique materials that combine rubber-like elasticity with the orientational order of liquid crystals (LCs) and display the actuation properties required for these applications [2]. In this work, we demonstrate the fabrication of a 3D-printed LCE actuator, which is modified to allow reprogrammable operation.

Our LCEs are crosslinked main-chain LC polymers, where the chains consist of mesogens interspersed with spacer units. The mesogens within these LCE networks have the capability to align, thus resulting in a polydomain aligned LCE. To produce an effective actuator, however, overall alignment provided by a monodomain LCE is required, but such overall alignment is not inherent to the material and generally must be actively induced.

Here, we achieve excellent overall nematic monodomain alignment using the shear profile of 3D printing, where the final crosslinking is achieved by UV-curing [3]. The resulting LCE can be reversibly switched from the aligned nematic state to the unaligned isotropic state upon temperature change, thus undergoing a macroscopic shape change. Whilst this actuation is reversible, the permanent covalent crosslinking of the LCE means the material cannot be re-shaped after curing and can thus only actuate in a single ` mode'. The fabrication of a multimodal LCE actuator is desirable, as this would mimic the performance of naturally occurring actuation such as that seen *in cardiac or muscle tissue [1].*

To achieve this, we laminate the 3D-printed and cured LCE with a semi-crystalline polymeric material. The resulting bi-layered LCE composite is malleable upon melting of the crystalline domains and can be reshaped before reversibly actuating into its new shape. This composite LCE therefore demonstrates multi-mode actuation, and correspondingly acts as a reprogrammable actuator.

***Programmable and Reprocessable Multifunctional Elastomeric Sheets for Soft Origami Robots** Shuo Zhang[1,2], Qin Jiang[2], Xingxing Ke[2] and Zhigang Wu[2]; [1]Ningbo Institute of Industrial Technology, Buaa, China; [2]Huazhong University of Science & Technology, China*

Smart, soft, multifunctional robots that are tunable are contributing to remarkable advances in various fields such as medical and rehabilitative robots, human-machine interaction and intelligent homes. One of key factors in soft robot fabrication is to find flexible and efficient schemes to seamlessly introduce configurable structures, programmable actuations and various functions such as electrical and optical ones simultaneously upon implementation. In this study, we selectively modified elastomeric surface and subsequently penetrated those surfaces with an active particle infused solvent following with instantaneous drying. This allowed us to develop a novel method to program a proper design by employing origami strategies and to memorize locally heterogeneous swollen (deformation/folding) effects using the agglomeration of active nanoparticles on the surface. Moreover, such automatic folding can be erased by solvent retreatment and reprogrammed by repeating the above processes. Based on these findings, we established a platform technique to fabricate programmable and reprocessable/reconfigurable elastomeric sheets by varying detailed morphology patterns and active particles; in this way, we produced functional soft origami robots with a seamlessly integrated structure. The new technique makes it possible to achieve soft origami ferromagnetic robots with various active functions, for example, robots mimicking flowers that have petals bent in different angles and curvatures, low friction swimming robots, multimode locomotion carriers with gradient stiffness claws for protecting and delivering objects, and frog-like robots with adaptive switchable coloration responding to external thermal and optical stimuli.

9:00 AM *SF03.01.04
***Progressing Soft Robotic Functions Through Additive Manufacturing of Liquid Crystal Elastomers** Carlos Sanchez Somolinos[1,2]; [1]Instituto de Nanociencia y Materiales de Aragón, Spain; [2]Centro de Investigación Biomédica en Red de Bioingeniería, Biomateriales y Nanomedicina, (CIBER-BBN), Spain*

The ability to structure smart materials in three dimensions can provide soft robotic systems with sensing and actuation capabilities, as well as other advanced functionalities. In particular, digital fabrication techniques can achieve all of this with high reproducibility, scalability, and flexibility in design, making them a key enabling technology for the future development of soft robotic systems with potential impact in various technological areas, including microfluidics, photonics, and biomedicine. Liquid crystalline elastomers (LCEs) are particularly interesting materials in soft robotics as they have demonstrated great potential for implementing complex shape-morphing structures when exposed to stimuli such as heat, light, or humidity. Recent developments in LCE fabrication have enabled the creation of actuators and devices with digitally defined director patterns, enabling programmed shape morphing. [1-3] However, challenges remain, such as the limited availability of functionalities *and the miniaturization of structures. This lecture presents recent efforts carried out at the Advanced Manufacturing Laboratory, with an emphasis on advancing new functionalities and achieving finer feature sizes. [4-9]*

All-Fiber Electrofluidic Muscles—Soft Actuators with Unprecedented Design Freedom *Ozgun Kilic Afsar[1], Gabriele Pupillo[2,1], Gennaro Vitucci[2], Wedyan Babatain[1], Antonio Loconte[2], Hiorshi Ishii[1] and Vito Cacucciolo[2,1]; [1]Massachusetts Institute of Technology, United States; [2]Politecnico di Bari, Italy*

Soft fluidic muscles are ideal for active wearables and textile-based robots. Thin McKibben muscles, with diameters around 1 mm and lengths of several meters, can be woven into artificial textile muscles. However, most fluidic muscles need external, noisy, and bulky pumps, limiting integration, wearability, and portability.

We report the integration of ion-drag ElectroHydroDynamic (EHD) fiber pumps with McKibben fiber muscles, both in a compatible form factor (1-2 mm diameter) with textile fabrication techniques. We developed an antagonistic system with two thermoplastic polyurethane (TPU)-core McKibben muscle units and a TPU-based fiber pump unit in between. This results in an all-fiber electro-fluidic muscle that actuates when voltage is applied: the pump transfers liquid from the antagonist muscle, extending it, while the pressurized agonist muscle contracts. Optimizing electro-fluidic muscle performance requires careful system design to maximize mechanical output within the pressure and flow rate limits of fiber pumps.

We outline design considerations based on our analytical model and present robotic demonstrators in knitted, woven and bundled forms. The integrated muscle weighing less than 5 grams promises wearable robots with rapid response (< 1 sec) and power density (> 25 W/kg) comparable to human muscles. Achieving these performances require specific material, geometrical, and configuration choices.

Various electrode materials for EHD pumps are comparatively evaluated showing that platinum electrodes offer the highest stability and performance, achieving a 700 % increase (8 bars/m) over previous results at 10 V/µm. This substantial enhancement is due to the selection of electrode material, a larger electrode surface area in contact with the dielectric fluid, and the application of bias pressure for higher electric field operation.

From our analytical model, we found the maximum pressure the coupled system can reach is limited by cavitation on the pump's low-pressure side. For a 1 bar bias pressure, the safe operation is at 4 bars of relative pressure generated by the pump. This led to an optimal pump length of 350 mm and a maximum safe operation voltage of 8 kV.

We modeled and evaluated the coupled system in a symmetric configuration and proposed methods to increase cavitation thresholds, such as varying fiber muscle lengths and asymmetric loading, enhancing stroke and power density.

Utilizing these principles, we developed several robotic demonstrators:
- *An assistive glove was knitted enabling fingers' movement when the fiber muscles contract and relax. Two tendons are actuated by symmetric muscle pairs powered by a forearm-wrapped fiber pump. Activating the pump contracts a 1.5 mm diameter muscle and elongates the other, bending a bionic hand finger of 60° in < 1 second.*
- *A woven biceps and triceps muscle pair was asymmetrically configured, mimicking human anatomy. The woven structure consists of McKibben muscles as the warp and fiber pumps as the weft. A 10 McKibben biceps muscle exhibits 22% strain at 8 kV, bending the forearm nearly 90° in 1 second.*
- *An agonist 8-McKibben (1.75 mm diameter, 280 mm length) bundle with 2 pumps wound around it, in fluidically parallel configuration, was coupled with a symmetrical antagonist pair. The two parallel pump pairs are then fluidically connected in series, doubling the generated pressure and flow rate of the system. Activation results in the agonist muscle contracting by 40 mm and the antagonist extending by 30 mm, achieving a relative stroke of 70 mm in under 2 seconds.*

The integration of EHD fiber pumps with thin McKibben muscles facilitates compliant, untethered, silent and power-dense fluidic systems ideal for wearable robotic applications in assistive devices and exoskeletons. Future work will extend these integration principles to more complex all-fiber fluidic circuits, including entire robotic garments with distributed control of individual pump-actuator ensembles.

10:15 AM SF03.01.06

Soft Robots in Medical Device Design—Integrated Design, Manufacturing and Operation of Microscale Printed Compliant Mechanisms Using Topology Optimization *Holly M. Golecki[1], Sandra Edward[1], Kai James[2], Bryan Kaehr[3] and Tom Golecki[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Georgia Institute of Technology, United States; [3]Sandia National Laboratories, United States*

The promise of microrobots capable of navigation and manipulation in vivo could transform disease detection and treatment. To these ends, we have developed a hybrid material approach for microrobot assembly comprised of an optical path, an environmentally responsive actuator, and a printed compliant mechanism. The compliant exoskeletal gripper head can be autonomously actuated by stimuli-responsive materials (e.g., hydrogels, *elastomers) that respond to light, pH, and temperature. Toward the development of clinically relevant designs, we aimed to improve robot performance under physiological conditions, such as small changes in pH that may indicate disease. For this we employ a topology optimization approach—applied to the exoskeletal geometry—to maximize the mechanical output to environmental cues. This design-manufacture-operate optimization schema accounts for printed material properties, printer parameters, and hydrogel-environment interactions. Bringing manufacturing and operation conditions into the analytical design process facilitates robot design for specific tasks (e.g., retrieval/deployment of low to high-modulus payloads). We demonstrate that we can achieve marked improvements in design objective functions when parameters from design, fabrication, and operation are included. We also see in testing printed designs that we have good agreement between analytical and experimental results, tested in vitro. Though realizing topology-optimized forms has been well suited to additive manufacturing for static mechanics, we show that substantial increases in dynamic performance at micro/nano length scales is achieved by integrating the complementary processes of design, manufacturing and operation which, in turn, enables new robot designs optimized for specific operations such as grippers, sensors, displays, and active surfaces.*

10:30 AM *SF03.01.07
Multimaterial 3D Printing for Soft Robotics Applications *Hang (Jerry) Qi; Georgia Institute of Technology, United States*

3D printing (additive manufacturing, AM) where materials are deposited in a layer-by-layer manner to form a 3D solid has seen significant advances in the recent decades. 3D printing has the advantage in creating a part with complex geometry from a digit file, making them an idea candidate for making architected materials. Multimaterial 3D printing is an emerging field in recent years in AM. It offers the advantage of placement of materials with different properties in the 3D space with high resolution, or controllable heterogeneity, making them particularly attractive for robotics applications. However, developing multimaterial 3D printing is also challenging because of the difference in processing conditions for different materials. In this talk, we present our recent work in developing multimaterial AM methods. In the first approach, we present a new development where we integrate two AM methods, direct-ink-write (DIW) and digit light processing (DLP) into one system. In this system, the DLP prints complex bulk parts while DIW adds functional inks, such as conductive materials or liquid crystal elastomers. In the second approach, we recently developed a grayscale DLP (g-DLP) 3D printing method and rationally design polymer resin where we can print a monolithic part with a large property gradient, such as a modulus contrast of more than 30,000 times. We further explore how to use these multimaterial 3D printing techniques to fabricate shape morphing structures, including direct 4D printing of 2D lattice structures, lattice structures with changing shape driven by liquid crystal elastomers, and 3D lattice structures by gradient materials. We also demonstrate how these new printing methods can used for soft robotic applications.

11:00 AM SF03.01.08
Soft Robotics with Biodegradable, Self-Healing, Recyclable Conductive Coatings *Pietro Cataldi; Istituto Italiano di Tecnologia, Italy*

The advancement of robotics has made giant steps in recent years. For example, humanoid robots now have motion systems that are more advanced than those of most humans, as demonstrated by recent developments with Atlas by Boston Dynamics. However, robots still lack many fundamental properties intrinsic to human architecture. They are still constructed from materials far from human-like in terms of biodegradability, self-healing, and lightweight characteristics. Humanoid robots face a material science challenge to evolve into versions that truly resemble humans.
Considering this, we propose self-healable, recyclable, and biodegradable electrically conductive coatings

engineered as human-mimicking skins.[1] These coatings are based on green conductive inks that combine a soft biodegradable vitrimer binder with carbon nanomaterials and are applied simply by spray coating. The vitrimer ensures satisfying adhesion to diverse substrates and flexibility, conformability, self-healing, and recyclability of the conductive layer. This material is a sustainable alternative to standard conductive inks for flexible electronics and soft robotics. Tests for the live monitoring of SoftHand3, the grasping system many robots use worldwide, have yielded promising results. Incorporating biodegradable, self-healing, and lightweight ingredients advances materials for robots towards truly mimicking intrinsic human properties. The green nature of the ink, which uses only water and ethanol, along with its biodegradability and recyclability, makes it an appealing material to address the sustainability issues in today's robotics sector.

***Electromechanical Behavior of Deformable Materials for Soft Robotics** Amanda Koh; The University of Alabama, United States*

While robotics has revolutionized modern industry, their component materials have largely remained stagnant and unchanging. Silicon, steel, and copper may be ideal for their strength and durability in heavy manufacturing, but soft, more deformable, and lighter materials are needed for robots that will interact with humans, robots that can sense their environment, and robots that are more power efficient. Typically, polymeric materials are the go-to solution for soft materials, but polymers are insulators with little actuation capability on their own. Hydraulics have been used to create polymeric soft robotic components, but the necessary pumps are loud and heavy, negating the utility of the polymer components. Instead, polymer composites have emerged as an effective pathway to imparting useful electrical behavior to polymers by blending the soft materials with fillers that have the desired activity (conductivity, magnetism, etc.). While composites with rigid fillers enable polymers with enhanced conductance, inductance, or capacitance, there is typically a tradeoff in that these composites are more rigid and less deformable. Polymer composites that take advantage of liquid metals, i.e., metal alloys that are liquid at room temperature, can achieve the best of both worlds, high electrical performance and low modulus. Liquid metals are typically alloys of gallium, either gallium-indium or gallium-indium-tin (galinstan), with melting points well below room temperature and a self-passivating oxide shell. There is extensive research investigating the use of liquid metal composites for printing and sensing for applications that require significant deformation. Commonly, the research will look at a specific mode of deformation and track the impact of liquid metal on rigidity. This has led to a splintered understanding of the fundamental impacts of liquid metal on material deformability, and a challenge in designing composite materials particularly for scenarios that require deformation on multiple axes. Despite theoretical frameworks for liquid inclusions in a soft solid and updates to these models for core-shell droplets, our work finds that liquid metal polymer composites cannot be easily described across deformation modes and droplet sizes. This work will demonstrate the impact of liquid metal loading and droplet size on the tensile, compressive, and torsional modulus and delve into the mechanical and interfacial underpinnings for the demonstrated behavior. We have found that despite the large mechanical mismatch between the oxide shell and the liquid metal bulk, modulus behavior cannot be understood purely mechanically and an energetic framework must be used. The work presented is critical the full implementation of liquid metal polymer composites in soft robotics and fully deformable actuators.

11:30 AM SF03.01.10

***Model-Based Control of Handed Shearing Auxetics (HSA) Robots** Maximilian Stölzle[1,2], Daniela Rus[2] and*

Cosimo Della Santina[1]; [1]Delft University of Technology, Netherlands; [2]Massachusetts Institute of Technology, United States

While serial continuum soft robots have been intensively investigated in recent years, parallel soft robots are less studied despite exhibiting exciting properties such as an improved stiffness-to-weight ratio. One recent development in this field are HSA robots, which consist of multiple HSA rods that are connected at their distal end through a rigid platform. Twisting of the proximal end of an HSA causes the rod to elongate and enables complex motion primitives in 3D space. Recent work has investigated the mechanical characterization, simulation, and kinematic modeling of HSA robots, but control has yet to be tackled. In this work, we make a first step towards achieving task-space control by designing model-based regulators for planar motions—our approach considers essential characteristics of HSA robots, such as underactuation, shear strains, and varying stiffness. In prior work, we derived a dynamic model for planar HSA in Euler-Lagrange form and experimentally verified it. We notice that the resulting planar dynamics are underactuated and that the actuation forces are non-affine with respect to the control inputs, which are the motor angles. The latter is a peculiarity of these systems, rarely observed in other robots. Based on the model knowledge, we propose in this chapter two control strategies for planar HSA robots capable of regulating the end-effector towards a desired position in task-space. The first strategy performs steady-state planning to identify an admittable configuration and steady-state control input matching the desired end-effector position and then subsequently applies a P-satI-D feedback controller on the collocated form of the system dynamics. The second strategy directly regulates the end-effector position using a Cartesian impedance controller. This allows us to unite the soft robot's embodied intelligence with computational intelligence to guarantee compliance and interaction safety. In summary, we state our contributions as (i) a provably stable model-based control strategy for guiding the end-effector of the robot towards a desired position in Cartesian space with a configuration-space controller that combines an integral-saturated PID with a potential shaping feedforward term, (ii) a Cartesian impedance controller that allows combining the passive compliance of the HSA robot with active compliance in the control strategy, and (iii) extensive experimental verification of both control strategies.

Leveraging Phototactic Effects in Liquid Crystal Polymers for Model-Informed Actuation *Yu Jun Tan and Jinrun Zhou; National University of Singapore, Singapore*

Phototactic soft robotic systems can be controlled without the need for tethers through strategic manipulation of light-matter interfaces. Here, we introduce a novel phototactic soft actuator, LUMA (Light-responsive Untethered Model-informed Actuator), comprising liquid crystal polymers (LCPs) that are activated by divergent directional light. Systematic characterization of the bending behaviors of LCPs revealed tunable photophobic and phototropic responses dependent on incident illumination angle, intensity, and the design of light shields. We developed a predictive computational model, the Photo-Thermal-Mechanical (PTM) model, to capture complex deformation dynamics and enable the programming of intricate actuation profiles. Leveraging divergent light actuation and informed by the PTM model, we designed LUMA soft robots, including crawlers capable of reversible bidirectional motion and cargo delivery systems with controlled projectile trajectories. This investigation establishes design principles and modeling frameworks for harnessing diverse illumination profiles, enabling programmable and predictable phototaxis in soft robotic systems through strategic light-matter coupling. The innovative approach provides intuitive yet precise manipulation capabilities, advancing the field of phototactic soft robotics.

Wednesday Afternoon, December 4, 2024
Hynes, Level 3, Room 306

1:30 PM *SF03.02.01
Microelectronic Morphogenesis—From Modular Micro-Origami Robots to Microelectronic Life Oliver G. Schmidt; *Technische Universität Chemnitz, Germany*

Microelectronic morphogenesis (MIMO) is the creation of form and structure under microelectronic control [1], and relies on our previous work on self-folding [2] and self-locomoting [3,4] thin film electronic modules, now carrying tiny silicon chiplets between the folds, for a massive increase in information processing capabilities. MIMO addresses key challenges in the field of micro- and microrobotics [4]. For instance, by controlling the robots' materials elasticity with nanoscale precision, cell-sized picoforce springs with remarkably large and tunable compliancy can be fabricated – allowing articulated motion in microrobots as well as micromanipulations and force sensing well beyond state of the art [5]. The storage and delivery of energy for truly autonomous operation of microrobotic systems represents another key challenge in the field [6] and will be addressed by producing tiny deep-submillimeter on-board integrated batteries and biosupercapacitors [7,8]. Finally, the talk will reveal how microelectronic life could evolve from interacting modular microrobots that undergo self-learning and evolutionary development [1].

2:00 PM SF03.02.02
Q-Silsesquioxane Photoactuatable Sponges for Substance Uptake and Release *Joseph Furgal[1], Cory B. Sims[1], Ethan T. Chandler[1], Mehdi Erfani Jazi[1], Nai-hsuan Hu[1], Michael Norton[1] and Taylor Hughes[2]; [1]Bowling Green State University, United States; [2]Central State University, United States*

Recent work in the Furgal Laboratory at BGSU has focused on the development of photoactive silicon-based materials with high porosity, phototriggered formation of siloxane bonds, and the recycling of preformed polymeric systems such as silicones. We have developed a set of photoswitchable Q-silsesquioxane based hybrid 3D polymeric smart sponges with azobenzene actuation units. Reversible UV triggered actuation of up to 18.3% has been achieved, with excellent recovery using visible light to the native state. These smart materials also offer reversible modulus switching from 160 kPa in the swollen state to 500 kPa in the UV activated state. Various *substances were tested for uptake and release capabilities with polarity and size having the greatest impact on performance.[1] This photo-triggered behavior gives these materials high potential for use as reusable environmental remediators (i.e. PFAS), soft robotics, and biomedical applications. We have extended this work to incorporate functional groups within the network to adjust the internal polarities of the sponges to improve overall selectivity.[2] We have also been able to increase the overall photo-induced shrinkage of the materials to ~55% of their initial size by using asymmetric push-pull azobenzenes which give better isomerization to the cis form, greatly increasing their potential in controlled release applications. This presentation will discuss our development towards these photoresponsive systems.*

2:15 PM SF03.02.03

A Flexible Tubular Pump Using Electrowetting *Robert Hennig and Herbert R. Shea; École Polytechnique Fédérale de Lausanne, Switzerland*

We introduce sub-millimeter diameter flexible tubes capable of pumping liquids using electrowetting on a dielectric (EOWD). The pumps can power wearables thanks to their fiber format but can also enable applications in other areas like microfluidic dispensing.

EWOD describes the manipulation of droplets on dielectric surfaces using electric fields. Traditionally, EWOD is used to move, merge, and split droplets on a flat surface, primarily in lab-on-a-chip applications. Here we use EWOD droplet actuation for the first time in a tubular geometry, with a series of electrodes on the outside of the tube. The tube can pump any two alternating immiscible liquids, one being conductive and the other insulating. We demonstrate pumping with colored water and silicone oil. The droplets are moved step by step (from one electrode to the next), which allows for µl-precision control of the volume pumped. The pumps described here operate at 600 V. The actuating electrodes are not in direct contact with the pumping liquid avoiding electrically induced chemical reactions which could shorten the device lifetime.

Teflon or glass tubes with 100 µm wall thickness and 0.9 mm inner diameter serve both as the structure of the pump and as the dielectric. Indium tin oxide (ITO) ring electrodes of width 1.8 mm and spaced by 200 µm are sputtered on the outside of the tube and connected in three electrical phases. The ITO was patterned with sacrificial ethyl cellulose, which is inkjet printed on the tube using a custom rotating setup. The inside of the tube was dip coated with Cytop, ensuring low friction and high droplet contact angles. A central 50 µm diameter copper wire grounds the droplets inside the pump.

Since the tube and the electrodes are transparent, we can directly observe the droplet actuation and change in contact angle. We first placed a single water droplet inside the otherwise air-filled tube. Applying 800 V to an adjacent ring electrode creates an electrical field between the grounded droplet inside and the active electrode outside the dielectric tube. As a result, we observed the droplet change its contact angle and move within ~40 ms underneath the active electrode. The droplet stops moving once the overlap area between the electrode and the droplet is maximized. Activating the next electrode moves the droplet to that electrode. Every third ring electrode is connected to the same phase. When switching between the three phases at 24 Hz, the droplet reached continuous speeds of 80 mm/s.

We then filled the pump with alternating oil and water droplets, ensuring there is one water droplet every three electrodes. Applying a voltage to all electrodes of one phase actuates every adjacent water droplet. Our 0.9 mm diameter pump with 10 simultaneously actuated droplets (30 electrodes) moved liquids at 9 ml/min when switching between phases at 1.5 Hz. We report further data on pressure, which for this pump is estimated at 2 kPa.

We demonstrated EWOD pumping in a flexible tube geometry, achieving high-speed droplet movement and continuous pumping.

3:30 PM SF03.02.04

Electronically Integrated Microscopic Robots with PEDOT:PSS Actuators for Minimally Invasive Clinical Applications *Siyoung Lee[1], Melanie C. Hilman[1,2], D. K. Cullen[1,2] and Marc Z. Miskin[1]; [1]University of Pennsylvania, United States; [2]Corporal Michael J. Crescenz Veterans Affairs Medical Center, United States*

Electronically integrated microscopic robots are emerging as powerful tools for performing complex tasks at the microscale. Recent work has demonstrated robots that walk under onboard control, communicate with base stations, and transition between digitally specified states. In principle, these robots can be used in applications that require autonomous action and decision-making, ranging from microsurgery to microassembly. However, current approaches to actuation suffer from two major drawbacks that blunt adoption. First, existing actuators can easily be damaged in real-world environments by biofouling, chemical reactions, or mechanical fracture. Second, the force outputs of existing electronically integrated actuators are too low to support movement through stiff, viscous media like tissue.

To address these issues, we developed a fabrication protocol for electronically integrated microrobots with robust, high-force actuators. The robots use Poly(3,4-ethylenedioxythiophene): poly (styrene sulfonate) (PEDOT:PSS), an ionic electroactive polymer, as a microactuator and are powered by on-board silicon photovoltaic (PV) cells. The robots, each measuring 150 to 400 microns in size, can be mass-manufactured at a density of thousands per square centimeter using a fully lithographic semiconductor process and deployed massively in parallel with yields reaching 90%. Among conjugated polymers used for electrochemical microactuators, we find PEDOT:PSS is highly compatible with mass manufacturing processes based on solution processing and runs at compatible voltages and currents with the on-board electronics. We discuss and compare the actuation performance, including force density, actuation frequency, and electro-mechanical energy conversion efficiency, of the PEDOT:PSS bulk electrochemical actuators with other electronically controllable microactuators, such as those based on piezoelectric, thermal, surface electrochemical, and other bulk electrochemical types' materials. Moreover, we also discuss the potential for integrating onboard electronics, such as sensors, memory, and integrated circuits, to enable the robots to perform more complex tasks.

Finally, we show PEDOT: PSS-based robots are well suited to operating in biological media through direct experiments. We find that robots can be co-cultured with living cells for upwards of days without damaging the robots or the cells. These results help pave the way for future biomedical applications, such as minimally invasive clinical applications or drug delivery systems. As a specific application, we present ongoing work on using PEDOT:PSS microrobots to assist in nerve repair, mechanically stretching nerves to accelerate growth and directly guide nerve bundles to their target destinations.

3:45 PM *SF03.02.05

Advancing Robotic Materials and Devices Through Controlled Electric-Matter Interactions *Donglei (Emma) Fan; The University of Texas at Austin, United States*

Electric fields applied to particulate-dispersed aqueous solutions unveil a fascinating spectrum of interactions, categorized into electron transfer-driven chemical reactions and non-electron transfer-induced physical motions. These interactions pave the way for advancements in robotic materials and devices. In this talk, I will present our recent research on harnessing these effects to engineer robotic systems across a scale spanning from nanometers to decimeters. From nanoscale high-precision bioprobes capable of ultraprecision cell-signal *sensing, to chip-scale microbubble actuators for assembling cell-nanosensor arrays for drug screening, and decimeter-scale disinfection devices for practical water treatment, our innovations highlight the important potential of manipulating electric-matter interactions for applications in biological, medicine, and environmental technologies.*

4:15 PM SF03.02.06

i-wi—Stretchable Ionogel Wires for Soft-Bodied Robotics and Computation *Sergey Nechausov, Yi Jiang and Aslan Miriyev; Ben-Gurion University of the Negev, Israel*

Recent advances in technologies based on the functionality of soft matter have fostered the demand for flexible and stretchable conductors. Ideally, soft-material conductors would exhibit electrical conductivity and mechanical integrity under significant deformations while retaining the ability to return to their initial shapes and operate for a substantial number of cycles. However, state-of-the-art stretchable conductors suffer from trade-offs between material compositions, design and scale factors, electrical properties, durability, and precise fabrication methods, thus sacrificing critical parameters and hindering performance. The longstanding challenge in the field has been to co-develop reliable, stretchable, and highly electrically conductive bulk elastomers with precise fabrication methods for successfully transferring diverse signals over distances both at rest and in a stretched state. In this study, we developed, characterized, and showcased ***i-wi (ionogel wires)*** *— soft, stretchable, and 3D-printable ionic elastomers primarily designed for applications in soft-bodied robotics and computation. Blending imidazolium-based ionic liquids (ILs) with photopolymer compositions allowed us to obtain ionogels that synergistically combine significant elastic deformation with ionic conductivity and enable us to precisely 3D-print them using the vat photopolymerization method. We showcased that i-wi are capable of successfully transferring both AC and DC signals in various implementation scenarios, opening the horizon for myriad applications. We suggest that i-wi may become a core component of physically intelligent systems, including soft-bodied robots and computation, inflatable and shape-changing structures and constructions, and advanced medical and surgical devices.*

4:30 PM SF03.02.07

Functional Morphology and Hierarchy of Bioinspired Supercoiled Muscles *Sameh Tawfick, Qiong Wang and Samuel Tsai; University of Illinois at Urbana-Champaign, United States*

This talk will present a roadmap for elastic actuators inspired by natural muscles and their use in miniature robots requiring large mechanical work output.

First, I will describe the material microstructure and geometric mechanics of polymeric twisted and coiled polymer actuators (TCPA) made by twisting nylon fishing lines, and how these actuators use internal strain energy to achieve record breaking performance. These artificial muscles generate large contractile mechanical work mimicking natural muscles, which makes them suitable for robotics. Understanding the mechanism of nylon TCPA remains challenging due to the interplay between their intricate geometry, chirality, residual stresses, and material microstructure. I will present a material microstructure model with rod theory to analytically predict the equilibrium helical shape of the nylon TCPA after fabrication, and to explain the observed contraction mechanism upon stimulation. The first ingredient of the model is to treat nylon as a two-phase thermomechanical microstructure system capable of storing strain energy and exchanging it among the two phases. This is validated by characterizing the torsional actuation response of twisted and annealed nylon fibers. The second ingredient of the model is to use the classic Kirchhoff Rod Theory and add a necessary term that couples the bending and twisting energy. Validation with experiments shows that the model captures the equilibrium and longitudinal stiffness of the TCPA in both active and passive states, and the stimulated contraction under external load. Importantly, the model quantifies the influence of the stored energy level on the actuation performance.

Next, I will describe the construction of a bio-inspired hierarchical supercoiled muscle which demonstrates a passive force-displacement J-curve. This passive nonlinear stretching makes these new muscles suitable to antagonistic arrangements similar to their biological counterparts. I will describe their use to actuate the rope climbing robots and antagonistic weightlifting robots.

These examples shed light on the future of robotics propelled by new bioinspired materials, nonlinear mechanics, and unusual manufacturing processes.

4:45 PM SF03.02.08

Impact of Solvent Amount on the Structure and Actuation Properties of Liquid Crystal Elastomers *Jinsoo Choi[1], Woong-ryeol Yu[1] and Seung-Yeol Jeon[2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)*

Liquid crystal elastomers (LCEs) are soft elastic networks that have liquid-crystalline ordering and rubber-elastic properties. The nematic phase, where molecules (mesogens) are aligned, depends on intermolecular interactions and temperature. This unique phase endows LCEs with high energy-dissipating properties over a wide temperature range. When the temperature rises to a specific point, LCEs transition from the nematic to the isotropic phase and change their shape. This makes LCEs useful for various fields, especially as actuators.
While a lot of research has focused on modifying LCE components to alter their actuating properties, we studied how changing the solvent amount, which is removed after LCEs are polymerized, affects their actuation properties. We found that more solvent leads to higher actuation strains but lower stress, without altering the LCE composition. Notably, the actuation strain increased from 25.47% to 38.63% (almost 150% more) with temperature changes, while the actuation stress remained at 0.11 MPa. But too much solvent lowered the stress because there was less liquid crystal in the unit volume.
To understand these changes, we examined the LCE structure using polarized optical microscopy and wide-angle X-ray scattering. We observed that the rice pattern size, which reflects domain size, grows with more solvent. This is due to a lower cross-linker density per unit volume, leading to increased free volume size and facilitating easier domain rotation. Additionally, the distance between mesogens increases with more solvent, allowing for greater mobility of liquid crystals. Consequently, these changes enhance the stretchability and actuation of the LCE but reduce stress resistance. This study highlights that the amount of solvent used in LCE synthesis has a significant effect on the structure and properties of the polymer, providing a way to design a LCE with desired characteristics.

Machine Learning Assisted High-Throughput Synthesis and Design of Photodegradable Hydrogels *Maximilian Seifermann, Patrick Reiser, Pavel Levkin and Pascal Friederich; Karlsruhe Institute of Technology, Germany*

Due to the large chemical space, the design of functional and responsive soft materials poses many challenges but also offers a wide range of opportunities in terms of the scope of possible properties. We developed an experimental workflow for miniaturized combinatorial high-throughput screening of functional hydrogel libraries. The data created from the analysis of the photodegradation process of more than 900 different types of hydrogel pads are used to train a machine learning model for automated decision making [1]. Through iterative model optimization based on Bayesian optimization, a substantial improvement in response properties is achieved and thus expanded the scope of material properties obtainable within the chemical space of hydrogels in the study. It is therefore demonstrated that the potential of combining miniaturized high-throughput experiments with smart optimization algorithms for cost and time efficient optimization of materials properties. This paves way for AI-accelerated high-throughput experimental screening for promising responsive soft materials.

Dynamic Aquatic Camouflage System Mimicking Reef Squid Transparency *JunSeok Choe[1], Simon Kim[1], JunJin Ho[1], Bong Hoon Kim[1], Sang Min Won[2] and Seung Ho Han[3]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Korea Electronics Technology Institute, Korea (the Republic of)*

Animals in nature often employ camouflage for survival. One notable example is disruptive coloration, which breaks up outlines and obscures internal features, primarily utilized by terrestrial species to blend with their surroundings. In contrast, aquatic species often prefer optical transparency for camouflage, which regulates visible light transmission and suppresses light scattering. For instance, the reef squid Sepioteuthis lessoniana can achieve optical camouflage by adjusting the size of its chromatophores to control body translucency, thereby mitigating reflections from light sources such as bioluminescent predators or divers' flashlights. Such aquatic organisms also possess pigments that protect against UV radiation, favoring optical camouflage due to the open ocean environment.
Recent studies on active camouflage systems have focused on materials engineering that adjusts transparency and/or color in response to electrical, chemical, thermal, and humidity triggers. However, many of these camouflage materials are rigid, have fixed control circuits, limited color change capabilities, or are unsuitable for aquatic environments due to issues with heat and humidity. Therefore, this study developed a system that integrates a wireless control system (WCS) and an electrochromic display (ECD) to emulate the dynamic transparency modulation of reef squid, providing effective camouflage suitable for various aquatic conditions.
The ECD utilizes an electrochromic layer of tungsten trioxide (WO3) and a counter electrode of nickel oxide (NiO) filled with a lithium (Li)-based polymeric electrolyte, allowing transparency modulation from clear to dark blue (peak wavelength 438 nm) through electrically induced redox reactions. The response times for bleaching and coloration between 2.0V and -2.0V are 14.2 seconds and 35.2 seconds, respectively, ensuring rapid camouflage under aquatic conditions. The structure, with WO3 and NiO, is sputtered between indium-tin-oxide (ITO) films and filled with Li-based polymeric electrolytes, ensuring the ECD's flexibility. Durability tests showed a stable 35% transmittance change over 100 cycles, and mechanical bending tests with a radius of 20.3 mm over 1000 cycles indicated some optical performance degradation due to electrolyte adhesion weakening. Additionally, we confirmed the system's stability by exposing it to a phosphate-buffered solution at 60°C for 200 hours.
The WCS incorporates near-field communication (NFC) and Bluetooth, enabling remote control of the ECD's optical transparency through these wireless protocols. The wireless module functioned effectively in shallow water conditions (7 cm below the surface) with a high signal-to-noise ratio (126.98) and negligible latency (0.1 seconds) in a phosphate-buffered solution (pH 7.3, room temperature). Using polydimethylsiloxane (PDMS) as a waterproof substrate and encapsulation elastomer, the system maintained flexibility due to the low elastic

modulus of the encapsulation elastomer. At the same time, its hydrophobic nature ensured stable aquatic operation. Finite-element analysis indicated that the maximum strain of the electrode at a 6 mm bending radius was 0.54%, well below the fracture limit of 1%, and the copper film and elastomer interface remained stable under a 14.6 mm bending condition.

In summary, the integration of ECD and WCS developed a system capable of effective camouflage in various aquatic environments, mimicking reef squid's natural optical camouflage abilities. This system holds potential applications in aquatic exploration and biological research.

SF03.06.02

Modulating Mechanical Properties of Magnetc-Responsive Polymeric Nanocomposites for Technological Applications

Danilo B. Janes[1,2], Giulia S. Machado[1], Vitória Nicoleti[1], Paola Ferrari[1], Rubia F. Gouveia[1], Marcos V. Lorevice[1] and Edson R. Leite[1,2]; [1]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [2]UFSCar, Brazil

Stimulus-responsive polymeric nanocomposites exhibit properties modulated by incorporated nanostructures in response to stimuli (temperature, light, magnetic fields, etc.). These nanocomposites can act as intelligent materials, being interesting applications in technological areas such as robotics, automotive, packaging, textiles, among others. In this study, we developed nanocomposites based on poly(butylene-adipate-co-terephthalate) (PBAT) and Fe3O4@poly(1,4-butanediol) nanoparticles (IONPs), exploring their mechanical behavior under a magnetic field. The nanocomposite films were produced via tape casting, a method where a dispersion (PBAT and IONPs) is spread over a surface using a controlled blade (doctor blade) to produce a tape with uniform height. The films demonstrated homogeneity and high transparency, indicating excellent IONPs dispersion. By varying the IONP/PBAT mass ratio, films exhibited magnetic properties that increased with NPs content. In addition, thermal analysis (DSC and TGA) suggested that IONPs possess a polymeric molten shell, potentially indicating fluid iron-like behavior at room temperature, which could pave the way for magnetically responsive materials. The results included slight changes in the Young's modulus with the application of an external magnetic field, whose reflects on the IONPs orientation and stiffens the material. These findings hold promise for modulating mechanical properties by external stimuli and expanding the applications for technological areas, which can be used for the development of more effective and smart robotic systems.

SF03.06.03

Composition Optimization of Additively Manufacturable Magnetic Composite Silicones for Soft Robotic Applications

Rayan Basodan[1,2], Byoungyoul Park[2] and Hyun-Joong Chung[1]; [1]University of Alberta, Canada; [2]National Research Council, Canada

Magnetic composite silicones, soft silicone matrixes with magnetic micro particles dispersed within, are highly functional materials used in a variety of applications. Their stimuli responsivity to controllable external magnetic fields is especially useful in soft robotics used for biomedical applications, remote actuation, inductive heating, magnetostriction, and more. 3D printing of these magnetic composite silicones further enhances their functionality as it enables preprogramed actuation through magnetic alignment, as well as freeform manufacturing of intricate designs and patterns. Rheological modifiers such as fumed silica are necessary to enable direct ink writing of liquid solutions. This results in a composite soft material of two micro/nano additives in a soft polymeric matrix with components that have complex interactions between themselves and with each other. We studied the rheological, mechanical, and magnetic properties of additively manufacturable magnetic composite silicones with all possible composition permutations. We found that incorporating fumed silica into uncured silicones significantly increases viscosity at low shear while exhibiting shear thinning behaviour, both of which are necessary for 3D printing. On the other hand, incorporating magnetic particles into uncured silicone increases viscosity.

However, adding magnetic particles to silicone solutions that already contain fumed silica decreases viscosity instead. Maximizing the amount of magnetic particles in silicone is optimal for magnetic actuation, but the necessity of incorporating additional fumed silica significantly increases the stiffness of the composite materials that are desired to be soft. Understanding the interactions between micro neodymium magnetic particles, nano fumed silica particles, and the silicone matrix enabled us to find the optimal material for soft robotic applications. We then demonstrate the utility of this material through 3D printing of intricate auxetic structures which expand when exposed to an external magnetic field, further advancing the capabilities of magnetic soft robotics found in the literature.

Quadrupole Magnetic Tweezers for Precise Cell Transportation *Yanda Yang, Max Sokolich, Sudipta Mallick and Sambeeta Das; University of Delaware, United States*

This research introduces magnetic spherical microrobots in conjunction with quadrupole magnetic tweezers which can be used for cell transportation. The focus of the system is on navigating and manipulating cells within environments characterized by high cellular density. Demonstrating efficacy in moving cells through densely packed cell samples, the system underscores its potential to overcome common obstacles such as inaccurate target delivery. The findings from this study highlight the significant promise that microrobotic technologies hold in advancing medical applications, particularly in precise cell delivery mechanisms, setting a foundation for the future exploration and utilization of medical microrobots.

SF03.06.05

Designing for Biodegradation—Structural Materials for Sustainable Development *Cathy Cheng[1], Buse Aktas[2] and Robert D. Howe[1]; [1]Harvard University, United States; [2]ETH Zürich, Switzerland*

Biodegradation can play a critical role in advancing sustainability in urban and natural environments. Through incorporating biodegradable materials in large-scale structures, there is potential for significantly reducing pollution, as well as waste accumulation in landfills. Within robotics, autonomous underwater vehicles are increasingly utilized for environmental monitoring or sampling. However, decommissioned and unrecoverable robots become yet another source of marine pollution. These concerns can be mitigated with the design of large scale structures capable of complete and rapid biodegradation with negligible environmental impact.

Existing work on biodegradable components has thus far focused on materials and components, with characterizing and synthesizing biodegradable polymers, as well as designing biodegradable implantable devices or transient electronic devices [1,2]. Further, existing work with underwater robots makes only minor considerations toward environmental impact, to the extent of limiting size, power consumption, and perturbations [3]. To fully account for the end-of-life of robots, we must not only consider material properties and chemical degradation, but also load-bearing properties and structural disintegration.

In this work, we demonstrate a design framework for fabricating large-scale structures optimized for rapid and complete biodegradation. In targeting the fundamental loading conditions, load-bearing composites are constructed from layers such that mechanical loading is applied along the direction where the structure is strongest. The layers are joined by a rapidly degrading adhesive which fragments the structure and initiates orders-of-magnitude increase in the exposed surface area, enabling rapid degradation. We validate the principles for designing for biodegradation through assessing degradation rate via mass loss (compared with conventionally designed structures), as well as through mechanical testing. This work also proposes guidelines on designing for structures under compound loadings and for programmable degradation in response to a stimulus.

Enhancing Time Resolution of Single Element Acoustic Transducer—Reducing Minimum Measurable Distance with Metamaterials *Jiwon Seo and Sangmin Park; Yonsei University, Korea (the Republic of)*

Ultrasonic sensors are widely used for non-contact distance measurement in various fields. However, single element transducers have a limitation in minimum measurable distance due to the switching time between transmission and reception modes, which makes it difficult to measure the distance to nearby objects. This study proposes a method to reduce the minimum measurable distance of single element transducers using metamaterials. Specifically, we utilize Helmholtz resonator (HR) structures to slow down the propagation speed of sound waves, thereby allowing sufficient time for switching between transmission and reception modes. The slow sound characteristics of HR were theoretically reviewed, and the phase velocity reduction was confirmed through experiments and simulations. Additionally, we demonstrated an increase in time resolution by introducing a Gaussian pulse into the HR structure and observing the resulting signal delay. This method can be applied not only to HR but also to any metamaterial capable of reducing phase (or group) velocity.

SF03.06.07

Non-Thermal Plasma Modification of 3D-Printed Starch-Based Bio-Composites— Advancing Soft Robotics and Biocompatible Materials Through In Situ Corona Discharge Treatment *Alexis Gasca[1], Rajvardhan Patil[1], Derek Xiong[1], Parshwa Khane[1], Saquib Ahmed[2,2] and Sankha Banerjee[1,3]; [1]California State University, Fresno, United States; [2]Buffalo State College, United States; [3]University of California, Davis, United States*

This research explores innovative in-situ non-thermal plasma treatment techniques for 3D-printed starch-based bio-composites, aiming to advance the fields of soft robotics and biocompatible materials. Starch, selected for its natural abundance, cost-effectiveness, and inherent biocompatibility, serves as a promising alternative to synthetic polymers in these cutting-edge applications. The study focuses on tailoring starch granule-surface proteins (SGSP) to enhance flexibility and responsiveness for soft robotic actuators, while investigating the formation of adaptive networks under quasi-static corona discharge plasma conditions, crucial for creating dynamic, bio-inspired soft robotic structures. By analyzing plasma current-voltage behavior, the research aims to optimize bonding characteristics, improving the durability and performance of biocompatible implants and soft robotic interfaces. Advanced electron microscopy is employed to characterize surface modifications and microstructural changes, with emphasis on properties beneficial for tissue integration and soft robotic movements. Furthermore, the development of hybrid machine learning models facilitates the prediction and control of material properties, enabling the design of customized biocompatible materials for specific soft robotic applications. This research aims to expand the application of starch-based materials in soft robotics, focusing on creating flexible, responsive, and biocompatible structures. The integration of 3D printing technology with non-thermal plasma treatment offers a novel approach to fabricating materials with tunable mechanical and surface properties. By combining bio-inspired design principles with advanced material modification techniques, this study paves the way for next-generation soft robotic systems and biocompatible materials, potentially revolutionizing fields such as wearable technology, minimally invasive medical devices, and bio-integrated robotics.

SF03.06.08

Wireless Self-Oscillating Systems with Modular Design for Multi-Modal Motion and Versatile Functions *Yinghao Fu[1], Meng Li[2], Yu Wang[1] and Yanqing Lu[1]; [1]Nanjing University, China; [2]Massachusetts Institute of*

Technology, United States

Self-oscillating mechanism requires feedback loops that connect the material properties, deformation, and the external stimuli, to generate a motion constantly switching between multiple metastable states. These self-sustained actuating systems use unmodulated external stimuli, which is advantageous since these energy sources and controls are cheaper, less bulky, and easier to maintain. Utilizing their capabilities of generating continuous motions under unmodulated controls, self-oscillating material systems have been applied in soft robotics, material transport, energy conversion, and sensing.

Currently, self-oscillating systems are mainly demonstrated using the following driving mechanisms: reversible chemical reactions to convert chemical energy into kinetic energy, such as BZ reaction and the cis-trans isomerization of azobenzene; converting material volumetric change to motion such as moisture absorbent membrane swells and dehydrates in a humidity spatial gradient; using the different swelling rates of hydrogels in various solvents to cause buckling and generate wave-pattern self-oscillation movements. In recent years, the self-oscillation motion based on self-shadowing has gained much attention, with exemplary material systems such as liquid crystal networks and responsive hydrogels. These materials undergo photothermal deformation when irradiated by a light source; the deformation blocks the light or moves the prior irradiated area out of illumination, leading to the recovery of the deformed state and re-exposing the material to light, forming a cycle between the irradiated state and the shadowed state. This mechanism is advantageous in producing stable periodic self-oscillation.

A common limitation of these traditional self-oscillating mechanisms is that they require the whole or at least most of the self-oscillating actuators to be made up of specific materials, such as liquid crystal materials, humidity-sensitive materials, and hydrogels. This material requirement limits the mechanical properties and compatible operating environment, thus hindering the universality.

To address this gap, we propose a modular self-oscillating system using unmodulated light and magnetic fields. The self-oscillating system is composed of two components, a driving module and a functional module. The driving module provides active magnetic force to induce deformation in the functional module, and the functional module counteracts with elastic force under deformation. The generated motion is governed by the tug-of-war of the two opposing forces. The underlying mechanism to generate self-sustained oscillation is the negative feedback loop connecting the two forces and the deformation: the two forces are deformation-dependent and the system is out of equilibrium so that the deformation is dynamically adjusted.

The self-sustained oscillation in this work has collective advantages over other self-oscillating mechanisms. Besides having large oscillating amplitude and tunable frequency, the modular design to separate the driving module and the functional module makes the system versatile: the functional module can be changed or functionalized to meet the requirements of various applications, making multi-mode oscillation possible, such as bending, linear translation, twisting, and combination of these modalities to increase the complexities of motions that can be achieved. We demonstrate using a surface-patterned silk fibroin film as a dynamic display device, a reflector as a light scanning and detection device, and a piezoelectric polyvinylidene fluoride (PVDF) film to harvest electricity from the oscillation. We envision the multifaceted versatility of the self-sustained oscillation system—motion modalities, materials selection, and functions—will enable them to be readily used in various applications in a wide range of environments.

SF03.06.09

Role of Small Molecule Dopants on the Synthesis, Structure, Electro-Mechanical, Self-Healing Properties and Working Relationships of PANI/PAAMPSA Systems *Arya Ajeev and Evan K. Wujcik; University of Maine, United States*

Stretchable electronic polymer (SEP) sensors have attracted significant interest due to their distinctive properties

and versatile applications in the field of healthcare, artificial skin, human-machine intelligence etc. The development of lightweight, self-healable, stretchable, and high functioning components stands as a major requirement in wearable electronics, in consideration of the rigid metal and metal oxide-based sensors. In this work, the SEP system is composed of polyaniline (PANI), poly(2-acrylamido-2-methyl-1-propanesulfonic acid) (PAAMPSA) and small molecule dopants (SMDs). The polymer system is synthesized through the oxidative polymerization of aniline while, A-PAM acts as a template to guide the PANI polymerization. SMD and A-PAM acts as dopants and cross-linking agents. This study explores the effects of SMDs with functional groups—carboxylic (-COOH), sulfonic (-SO3H), and phosphonic (-PO3H)—on the PANI/PAAMPSA system, investigating their influence on the material's thermal behavior, morphology, self-healing abilities, and electro-mechanical properties. Sulfonic acid groups were found to enhance electrical conductivity due to their stronger acidity and ionic interactions. Among the SMDs investigated, 4-dodecyl benzene sulfonic acid exhibited a conductivity of 0.07 S/m and a Young's modulus of 39.76 kPa, while SMDs like pyrophosphoric acid, trifluoromethane sulfonic acid, and 5-sulfosalicylic acid dihydrate demonstrated exceptional stretchability, reaching up to 4000%.

SF03.06.11

Gripping and Buoyancy Control of Underwater Soft Robot Using Residual Stress *Minchae Kang, Suyeon Seo, Eunsol Park and Min-Woo Han; Dongguk University, Korea (the Republic of)*

A soft underwater robot can easily adapt to the environment and interact with various underwater organisms and structures. The soft robot proposed in this study uses the stress difference between two soft polymers. The residual stress formed during fabrication plays the role of gripping and buoyancy control. When the polymer membrane with high elasticity is fixed in a stretched state and then a polymer with relatively low elasticity is poured and cured, the structure forms a curvature and hardened inward due to the stress difference between the two materials. This curling phenomenon became the gripping mechanism of the soft robot. If an air layer is formed using a lubricant between the two polymer layers, the grip force and buoyancy can be adjusted with the amount of air injected into the device. The residual stress generated during the curing process causes the soft robot to maintain a structural curling state, thereby providing a tension that can be stably gripped even by small objects such as screws. When the amount of fluid is small, the soft robot can grip the object and put the object down with increased internal volume. By changing the volume of the internal fluid, buoyancy can be adjusted, and accordingly, the robot's position in the water can be moved up and down. Through the buoyancy model applying the Archimedes principle, the effect of the volume change of the internal fluid on the robot's density was analyzed. The soft robot rose from the bottom of the tank with increased buoyancy. In particular, the ability to adjust the position of an object to float or sink was experimentally verified by the amount of air injected. This soft robot can manage buoyancy in the water and move its position up and down by changing the volume of the internal fluid without relying on external devices. The buoyancy control system of this soft robot enables diversity and adaptability in water and can be used for underwater exploration and research.

This work was supported by the National Science Foundation through the Harvard University's Materials Research Science and Engineering Center DMR-2011754, the MOTIE (Ministry of Trade, Industry, and Energy) in Korea, under the Fostering Global Talents for Innovative Growth Program (P0017307) supervised by the Korea Institute for Advancement of Technology (KIAT) and National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No.2018R1A5A7023490).

SF03.06.12

Exploring Nonlinear Regime in Commercial Quartz Tuning Forks for Clocks, Robotics and Sensorics *Tim Smith and Oleksiy Svitelskiy; Gordon College, United States*

Timekeeping has always been an essential task for humanity. As society developed, it needed to define time more precisely, up to hours, milli-, micro-, and nano-seconds... Thus, the clock was invented. An essential part of every clock is a reference oscillator that defines time intervals with the needed precision. In a mechanical clock, a pendulum performs the reference function. As a pendulum swings with a second period, it activates a ratchet system at each oscillation that moves the clock one second forward. The more precise tasks require references based on different physical principles. In addition, the need for precise timekeeping has expanded to a broad range of devices, so almost every electronic device needs a clock. Every watch, computer, smartphone, TV, appliance, and radio set needs a clock. Each of these clocks needs a reference oscillator, for which quartz crystal resonators are typically used. Often, these resonators are shaped as miniature tuning forks whose resonant frequency is tuned precisely to 215 = 32768 Hz. Thus, by dividing this frequency 15 times by 2, one obtains precise 1-second long time intervals further counted by the electronics. The performance of such tuning fork resonators is the subject of our study.

The clock's precise work requires the reference oscillator's precise frequency, which is possible only if the tuning fork operates in a linear regime. Commercial tuning forks can be easily driven from a linear to a nonlinear regime, where the frequency depends on the driving amplitude, reducing the clock's precision. Meanwhile, the nonlinear regime is undesirable for the clock, but some other applications may benefit. For example, the quartz tuning forks may be used as sensors of various physical quantities, like mass or gas pressure. In these applications, the nonlinear regime of the tuning fork makes their sensitivity dramatically higher. Also, many fundamental physical aspects of the nonlinear regime and the transition between linear and nonlinear regimes remain unclear. Our goal is to shed more light on the problem.

We began our study by exploring the transition from linear to non-linear regime using a software-defined network analyzer. The network analyzer excites the fork to vibrate and records its amplitude and phase concerning the excitation signal. We have found that the resonance frequency of these forks depends on the excitation amplitude, even at relatively small levels (~ 0.05 V). As the excitation signal increases, the resonant frequency shift becomes progressively more significant. The measured resonant frequency depends on the direction of the frequency scan, exhibiting the classical behavior of a nonlinear oscillator characterized by a bifurcation region with the possibility of chaotic transitions between the branches of the resonant curve. Should this bifurcation appear when the oscillator is installed in a clock, it would introduce uncertainty in its measurements. However, if the fork operates as a sensor, the bifurcation makes it extremely sensitive to minor environmental changes. Our study shows that the behavior of this resonator can be modeled using the Duffing equation. Solving the Duffing equation for this oscillator numerically, one can determine the equation coefficients, such as spring and Duffing constants.

To gain deeper insight into the nonlinearity phenomenon, we are building an atomic force microscopy (AFM) system. This system will allow us to measure displacement at a particular point and map the tuning fork deformation as it vibrates. This work is in progress.

SF03.06.13

Design Study of Low-Profile Fluidic Actuators for Origami-Inspired Folding Structures *Eva Langenbrunner, Jannah Elrayess and Robert J. Wood; Harvard University, United States*

Soft actuators leverage material compliance to achieve complex motions beyond what is typically possible for more classical motor architectures. One common category of soft actuators uses a pressurized working fluid to drive the deformation of an elastomeric pouch. This class of inflatable fluidic soft actuators has practical benefits due to simple construction from quasi-2D sheets, enabling rapid and low-cost prototyping of energy-dense low-profile actuators compatible with challenging applications in self-folding origami-based devices. The proposed *pouch actuators combine elastomeric pouches of nearly arbitrary geometries with flexure-based folding mechanisms to apply controlled torques to drive self-folding. In prior work, flexure-based folding mechanisms employed the torque generated from a single pouch, which has been improved upon through various designs such as pleating structures, force conversion mechanisms, and series balloon configurations. For example, soft inflatable microactuators have demonstrated bending actuation by converting pouch expansion to torque by way of a compliant tendon.*

This presentation will describe efforts to build on past demonstrations of pouch-based folding actuators to examine the impact of the inflation chamber geometry on resulting motion and torque programmability. We leverage laminate-based 2D fabrication processes involving bonding thermoplastic elastomers to rigid substrates to construct inflatable fluidic actuators and simultaneously integrate with mechanical components that guide motion. We developed two actuators, the "thin-film pouch hinge" (TPH) and the "thin-film bellows hinge" (TBH), where the expansion of the pouch chamber volume drives contraction and generates angular displacement of the attached flexure hinge. We present a characterization of actuator and hinge displacement as a function of multiple geometric parameters. We find that, in the TPH designs, the pouch width determines the baseline angular deflection. In addition, we find that more complex pouch geometries (e.g., hourglass-shaped pouches) can further enhance displacement through 3D effects such as kinking of the pouch. Furthermore, we find that TBH actuator deflection depends critically on the tendon attachment distance to the hinge joint and the height achieved by the stacked inflatable pouches. We conclude with demonstrations of pouch actuators integrated with self-folding origami mechanisms, including flower-inspired designs that achieve multiple fold angles from a single pressure source.

SF03.06.14

Electrode Arrangement and Its Effects on Dielectric Elastomer Actuators *Sumin Jung, Minchae Kang and Min-Woo Han; Dongguk University, Korea (the Republic of)*

Dielectric Elastomer Actuators (DEAs) are devices consisting of an elastomer layer positioned between flexible electrodes, allowing control of mechanical displacement and velocity by adjusting voltage and frequency. Due to these characteristics, DEAs have attracted significant attention in various fields such as biomimetic robotics, artificial muscles, wearable devices, and micro-mechatronics. In particular, the performance of DEAs can vary significantly depending on the electrode arrangement, and systematic research in this area is crucial for the efficient design and exploration of new applications.

In this study, we analyzed the effect of electrode stacking position on the mechanical performance of DEAs. Specifically, we compared the behavior of DEAs with concentric and biased electrode arrangements. Samples were fabricated for both electrode configurations, and experiments were conducted to evaluate their performance. The DEAs were fabricated using acrylate oligomer for the dielectric layer and carbon nanotubes (CNT) for the electrode layers. Specimens with the two different electrode configurations were tested, with displacement measured in real time using a photonic sensor, and block force measured using a load cell. The frequency and amplitude were varied to analyze the performance differences between the two configurations in detail.

This study demonstrates the influence of electrode arrangement on the mechanical performance of DEAs and provides valuable reference data for future DEA design and applications in various fields.

SF03.06.15

Smart Robots Integrated with Fiber-Optic Sensors by Parameter Optimization in 3D Printing *Frank Chen; Holy Heart of Mary High School, Canada*

Robots have been well recognized for their increasing roles in carrying out physical tasks on various occasions. To *effectively manipulate objects in complex and changing environments with high precision, a robot must possess the capability to perceive conditions to decide when, where and how it interacts with surrounding objects, in which various sensors and controls are needed [1,2]. Many rigid and flexible electronic sensors, such as temperature, force, and pressure sensors, have been reported to play an important role in the manoeuvre of a robot. However, these individual electronic sensors are bulky, which usually measure single parameter only. To achieve smart robots with high performance, it is necessary to be integrated with sensors capable of realizing multimodal sensing.*

In this study, we propose and demonstrate fiber-optic sensors to be embedded into robots, which realize multimodal sensing and distributed sensing with enhanced capability and performance. Through this study, several types of microstructured fibers have been revealed to achieve multiparameter sensing, which include simultaneous measurement of parameters such as temperature, stress, salinity, vibration, to name a few among many possibilities. The microstructured fiber-optic sensors developed in this study can be embedded to robots through 3D printing technology. To satisfy the specific requirements of embedding fiber-optic sensors to robots, detailed experiments have been implemented to discover optimized parameters for 3D printing with different polymer materials in fused deposition modelling (FDM). The physical and chemical properties of 3D printing polymers play a crucial role in determining the quality of integration in a fiber-optic sensor embedded robot. The properties and fabrication parameters of several polymers in 3D printing, such as polylactic acid (PLA), acrylonitrile butadiene styrene (ABS), and acrylic styrene acrylonitrile (ASA), have been experimentally investigated and compared. The research in this study has demonstrated that 3D printing technology is a powerful manufacturing technology to achieve the integration of fiber-optic sensors in robots, realizing performance enhancement. Further investigation will enable us to overcome challenges to achieve further improvement in the sensing performance, degree of integration, and enhancement of functionalities.

SF03.06.16
Exploring the Influence of Lattice Distortion on the Properties of High Entropy Carbides (HECs) with Carbon and Metal Point Defects Using First Principles Study *Rachel Runge and Mina Lim; Gordon College, United States*

High Entropy Carbides (HECs) have been predicted the selection of candidate compositions with the phase stability from an entropy-forming-ability (EFA) descriptor from first principle. The predicted compositions are applied to disordered refractory five metal carbides, experimentally synthesized as rocksalt structure and measured their mechanical properties. We report in this work the results of DFT calculations that were carried out to explore the degree to which properties of high entropy carbides containing different five-atom combinations from the elements Hf, Nb, Mo, Ta, Ti, V, W, and Zr can be related to the properties of their respective Transition Metal (TM) binary compounds. Using Density Functional Theory calculations, we aim to investigate the effect of lattice distortion on the properties of HECs and their respective Transition Metal Carbides (TMCs : HfC, NbC, TaC, TiC, ZrC, MoC, VC and WC) with a focus on their sensitivity to point defects. This research primarily explores the bulk modulus of HECs and their TMCs by introducing carbon and metal vacancy point defects, and determining to what extent these properties can be predicted based on their respective TMCs compositions. Understanding these aspects is crucial for guiding the design and optimization of HECs. With an emphasis on the effect of lattice distortion on point defect energetics, we anticipate that this comprehensive study will provide valuable insights into how point defects influence the properties of HECs.

SESSION SF03.03: Materials and Engines for Magnetic Robots
Session Chairs: Veronika Magdanz and Abdon Pena-Francesch

Up-to-date as of November 14, 2024

Thursday Morning, December 5, 2024
Hynes, Level 3, Room 306

8:00 AM *SF03.03.01
Magnetically Actuated Jamming *Buse Aktas; ETH Zürich, Switzerland*

For robotic systems to have versatile interactions with their environment, their structural components need mechanical tunability, enabling them to match the mechanical impedance (stiffness and damping) of their environment. For example, they need to be stiff when precision is required, yet soft when conformability and adaptability is required. Jamming is a mechanical phenomenon in which a cluster of constituents exhibit dramatic changes in its bulk mechanical behavior when the coupling between the individual constituents is altered. Existing jamming actuation methods, such as pressure or voltage are not particularly compatible for robotic tasks in hard-to-reach and high-risk areas such as constricted areas inside the human body, because they require the structure to be tethered via tubing or wiring or require bulky on-board actuation mechanisms. Magnetic fields offer a solution to this problem by enabling remote actuation. Here, we will talk about how ferromagnetic composite materials can achieve programmable jamming behavior when an external magnetic field is applied. We outline design guidelines for magnetic jamming structures, and enable effective jamming behavior in multiple dimensions despite external magnetic fields along single directions. We model and describe the mechanical behaviors which are linked to the magnetic forces and torques. Our work demonstrates a novel jamming actuation modality which can have tunable directional control of mechanical properties such as stiffness, yield, and plasticity.

8:30 AM SF03.03.02
Simultaneous Inductive Sensing and Actuation of Magnetic Microrobots *Michael G. Christiansen[1], Lucien R. Stöcklin[1], Cameron Forbrigger[1], Shashaank Abhinav Venkatesh[2] and Simone Schuerle[1]; [1]ETH Zürich, Switzerland; [2]National University of Singapore, Singapore*

The incorporation of magnetic materials into biomedical microrobots is widely appreciated as an advantageous way to enable their wireless control and actuation. These properties can additionally offer a basis for noninvasive magnetic sensing. In particular, magnetic particle imaging (MPI) and magnetic resonance imaging (MRI) have been considered for the localization and closed-loop control of magnetic microrobots. Nevertheless, these strategies typically require switching between distinct actuation and sensing modes, which limits the duty cycle of each and neglects an opportunity to obtain simultaneous inductive feedback during actuation.

Here, we use a low frequency rotating magnetic field (1 to 100 Hz), to show that it is possible to simultaneously apply and sense magnetic torques associated with model microrobots. To accomplish this, our prototype apparatuses finely adjust phase and amplitude to achieve cancellation between a sense and compensation coil. In one setup, the background signal from the rotating field was suppressed by 90 dB, enabling the detection of a stray field as low as 1 μT from a micromagnet. In another setup, we illustrated the possibility for detecting torque transfer to magnetotactic bacteria employed as living microrobots. By combining an inductive sensing apparatus with a selection field, we observe selective delivery of torque to multiple microrobots within a working volume. The sensitivity of inductive detection using these techniques can be shown to compare favorably to alternative methods for measuring stray fields originating from the magnetic materials in microrobots. These concepts build toward future closed-loop control schemes for magnetic microrobots based on simultaneous actuation and sensing.

8:45 AM SF03.03.03

Designing Magnetic Materials for Clinical Microrobot Applications *Lukas Hertle[1], Hyeon Ko[1], Valentin Gantenbein[1], Sarina Nigg[1], Andrea Veciana[1], Fabian Landers[1], Hao Ye[1], Semih Sevim[1], Alberto Lopez[2], Marta Estrader[3], Josep Puigmartí-Luis[3], Bradley Nelson[1], Xiangzhong Chen[4] and Salvador Pane i Vidal[1]; [1]ETH Zürich, Switzerland; [2]Universidad Pública de Navarra, Spain; [3]Universitat de Barcelona, Spain; [4]Fudan University, China*

Magnetically guided microrobots are showing a tremendous amount of potential for future medical usage, opening the opportunity for externally controlled target drug delivery or enhanced diagnostics.(1, 2) In order to transition magnetic microrobots from laboratory research into clinical usage it is imperative to address multiple challenges. While recent breakthroughs in engineering have made electromagnetic navigation within a clinical setting feasible,(3) and advances in manufacturing have created opportunities for continuous micro-devices production,(4) clinical transition of microrobots is still hindered by the requirements placed on them within the human body. Biomedical microrobots must, for instance, provide tunable magnetic response, real time traceability, and adaptive functionality, all while simultaneously ensuring high biocompatibility and an inherent degradability from the patient's system.

The presented work will elaborate on the fundamental challenges that must be addressed to enable the clinical adaptation of untethered biomedical magnetic microrobots. We will further extend some possible material solutions for each of the aspects recently developed by leveraging the versatility of different chemical manufacturing processes. By creating three-dimensional composite structures of the different materials a hybrid drug delivery platform for biomedical applications is introduced, proving the feasibility of clinical microrobsot usage by smart material design.

Remagnetization for Reprogramming Hard-Magnetic Soft Actuators and Effects on Reliability and Performance *Matthew R. Clary[1], Emily E. Evans[2], Denys Makarov[3] and Joseph B. Tracy[1]; [1]North Carolina State University, United States; [2]Elon University, United States; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany*

Magnetic hysteresis in hard-magnetic materials, such as NdFeB, is routinely applied for programming the magnetization state and responses of hard-magnetic soft actuators. Applying magnetic fields for actuation can cause unintentional remagnetization of the structure, however. The resulting altered actuation behavior can signify degraded reliability or performance. A model of magnetization in NdFeB microparticle-based polymer composites is developed from magnetometry measurements, which makes possible quantitative prediction of remagnetization behaviors to facilitate the design of magnetic soft actuators with simultaneous high reliability and high efficiency. The onset of remagnetization occurs at magnetic fields substantially below the coercivity. A lifter serves as a simple model system for validating the model and for demonstrating reprogramming – purposeful remagnetization to predictably alter the behavior of the actuator for a new task. Figures of merit are introduced for quantifying the performance of actuators, where actuation with loads is especially susceptible to degraded *performance. Future extensions of the model developed here will make possible understanding and controlling remagnetization in complex systems.*

9:30 AM BREAK

Soft Organic Magnetic Materials Based on Macromolecular Radical Networks *Abdon Pena-Francesch; University of Michigan, United States*

Recent advances in magnetic materials have enabled new functions and capabilities in small-scale robotic devices. Most magnetic soft robots comprise heavy metals and rare-earth element magnetic particles and coatings, they often present corrosion, toxicity, and sustainability concerns as well as fabrication challenges. In contrast, organic magnetic materials present a metal-free opportunity to develop lightweight non-toxic magnets. We have developed metal-free, lightweight, intrinsically magnetic polymers based on stable organic free radicals. By directly incorporating nitroxide radical groups into a crosslinked polymer network, we can tune the magnetic and viscoelastic properties of the gels independently, opening the design space for metal-free magnetic gels. Although weaker than metallic ferromagnetic materials, these magnetic polymer gels exhibit lightweight, biocompatible, compressible, and bulk paramagnetic properties suitable for small-scale robotics applications, such as remote actuation, manipulation, and navigation through confined spaces. These intrinsically magnetic polymers open new opportunities for the design of fully organic magnetoactive materials and actuators for future biocompatible soft robotic applications.

10:15 AM *SF03.03.06
Magnetic Nanomaterials for Biomedical Microrobots *Xiangzhong Chen; Fudan University, China*

Magnetically driven biomedical microrobots require materials that exhibit strong magnetic properties to allow for efficient propulsion and precise navigation within complex biological environments. Many factors, such as magnetic responsiveness, biocompatibility, and ease of fabrication of magnetic materials, are critical to the performance of magnetic microrobots. In this talk, I will present our recent work on magnetic nanomaterials, focusing on their synthesis, physical characteristics, and applications in biomedical microrobots. We have developed robust synthesis approaches for producing iron-based magnetic nanomaterials with controlled size, shape, and magnetic properties, which are crucial for their performance in microrobotic systems. We also performed in-depth characterization to understand the underlying physics of these materials, including their magnetic response and interaction dynamics. Our findings highlight the significant potential of magnetic nanomaterials in advancing the field of biomedical microrobots. Looking forward, we anticipate that continued research and development will lead to innovative applications and breakthroughs in healthcare, offering new possibilities for treating diseases and improving patient outcomes.

10:45 AM *SF03.04.01

Critical Materials Embedded in Cancer Fighting Magneto-Aerotactic Bacterial Microrobots *Sylvain Martel; Polytechnique Montréal, Canada*

Medical robotics is expanding from surgical tasks to cancer therapy using microscopic robots designed to improve the efficacy of cancer therapy considering that cancer is presently the leading cause of death worldwide, accounting for nearly 10 million deaths per year according to the World Health Organization (WHO). The main advantages of these robotic agents carrying therapeutics include superior therapeutic efficacy through enhanced targeting with significantly less systemic toxicity compared to chemotherapy. But due to technological limitations, current artificial microscale robots as well as other delivery vectors are lacking critical characteristics and functionalities needed to significantly improve cancer treatments. Self-propelled flagellated magnetotactic bacteria (MTB) provide an alternative for the implementation of microscale medical robots allowing critical embedded functionalities beyond technological feasibility at such a scale. MTB provide not only self-propelling capability, hence eliminating the need for an external source for actuation, but also the possibility for directional displacement control using a weak magnetic field that can be scaled for human interventions. The therapeutic efficacy is further enhanced with the capability to stimulate certain immune cells as well as to autonomously target tumor hypoxic zones that are generally beyond the reach of traditional cancer treatments. But the proper implementation of these functionalities relies on specific materials. For instance, directional displacement control is based on an anisotropic chain with at least 10 membrane-bounded magnetite (Fe3O4) crystals, each with a diameter of approximately 70 nm and known as magnetosomes, that are synthesized in the bacterial cell during the cultivation process performed in fermenters under specific controlled environmental conditions. Pathogen-associated molecular patterns (PAMP) present at the surface of the bacterial cell and specifically the immunogenic potential of liposaccharide (LPS) is used to trigger an immune reaction required to enhance the therapeutic efficacy when combined with the release of the therapeutic payload. SN-38 (7-Ethyl-10-hydroxycamptothecin) is used as the therapeutic payload due primarily to its high cytotoxic activity. The therapeutic molecules are encapsuled in liposomes which are primarily composed of phospholipids. The liposomal formulation of SN-38 increases the solubility of SN-38, which is a relatively insoluble compound, and improves the pharmacodynamic (PD) profile as compared to SN-38 alone. The terminal amine groups on the outer membrane of the bacterial cell allows efficient bioconjugation of the liposomal SN-38 formulation. Therefore, the implementation of a biohybrid agent suited to transport and target specific tumoral regions that would result in optimal therapeutic efficacy while minimizing systemic toxicity relies on proper embedded functionalities that in turn can be implemented with specific materials, hence requiring critical choices of materials to guarantee the success of the implementation.

11:15 AM *SF03.04.02

3D-Printed Multi-Material Mechanisms Enhance Functionality in Small-Scale Mobile Robots *Sarah Bergbreiter[1], Ryan St. Pierre[2], Sukjun Kim[3], Gabe Smith[4] and Steven Man[1]; [1]Carnegie Mellon University, United States; [2]University at Buffalo, The State University of New York, United States; [3]University of California, San Diego, United States; [4]U.S. Army Research Laboratory, United States*

Materials found in insects contribute to incredible functionality at small scales. Kinematics and dynamics are often dictated largely by the mechanical properties of materials throughout the insect's body. Rigid materials can provide structural integrity, while softer elastic materials have been shown to provide energy storage, compliance, viscoelastic damping, and reduce damage during locomotion. As small-scale robots move from the lab bench to more realistic environments, they will need a wide range of materials to support traditional robot functions, such as sensing and actuation, but also provide the mechanical intelligence required to handle uncertainty in complex environments. However, the integration of various material components at the microscale is a significant challenge.

This talk will present our progress in the design of small-scale legged robotic systems that utilize new microfabrication processes to incorporate materials with widely varying moduli and functionalities to achieve greater robustness and complexity in smaller packages. We use two-photon polymerization to create complex robotic mechanisms from legs to manipulators. Two-photon polymerization still has a relatively limited set of materials when used with commercial resins. As such, we combine microscale 3D printing with more traditional manufacturing methods to broaden the material toolbox at small scales. We use molding to create more viscoelastic legs for faster running locomotion, encapsulation of liquid resins for hydraulic functionality similar to that found in spiders, and physical vapor deposition to add electrical functionality to our microscale 3D printed robots.

Results include a number of small-scale robotic systems designed for locomotion and manipulation. Legged microrobots (down to 1 mg in size) provide insights into simple design and control for high speed locomotion in small-scale mobile robots. A 1 mg robot uses a variety of leg materials and magnetic actuation to move over complex terrain and achieve running speeds up to 50 body length/s, and a 15 mg hexapedal robot that is electrically actuated can move forward, backward, turn, climb stairs, carry loads, and hop. Manipulators include a spider-inspired hydraulic microrobotic gripper and a millimeter-scale Delta robot with a bandwidth of approximately 1 kHz.

SESSION SF03.05: Micro- and Nano-Robotics II

Thursday Afternoon, December 5, 2024
Hynes, Level 3, Room 306

1:30 PM *SF03.05.01
Magnetic Ball Chain Robots for Minimally Invasive Medical Interventions *Giovanni Pittiglio[1,2,2]; [1]Harvard University, United States; [2]Worcester Polytechnic Institute, United States*

Magnetic continuum robots are highly effective for minimally invasive surgeries due to their simplified design and potential for miniaturization (1). The ability to make these robots in any size while increasing the strength of external actuation units has been recognized as a significant advantage. However, in practical clinical scenarios, the size and cost of external actuation units are primary concerns (2). Our research aims to find alternative catheter designs with a high magnetic content, allowing the use of small-scale and portable actuation units. This approach enables a more flexible operating room environment without requiring major changes to the current clinical workflow (3). Achieving this goal will allow easier clinical translation of magnetically actuated continuum robots.

In recent work, we explored the use of chains of spherical permanent magnets - magnetic ball chains - for designing magnetic continuum robots (4). These alternative designs combine the advantages of both permanent magnets and magnetic flexible polymers (1, 5, 6). Composed of permanent magnets, they offer a high magnetic volume and have distributed magnetization throughout their length. The magnetic balls bond due to their magnetic content and can slide and rotate relative to each other, forming highly flexible spherical joints.

Magnetic ball chain robots present a promising alternative to traditional magnetic catheter designs, offering *significant advantages due to their high magnetic content and exceptional flexibility (7). These attributes enable the robots to navigate complex anatomical structures with ease and apply substantial forces onto the anatomy, even when actuated by small external units. These properties are desirable in various minimally invasive medical procedures, such as endovascular and cardiac interventions.*

Our research highlights the potential of these robots to enhance clinical outcomes by providing precise and responsive control during cardiac ablation (3). The ability to achieve stable and strong contact with targeted tissues ensures more effective treatment of arrhythmias while minimizing the risk of collateral damage. Moreover, the high magnetic content of these robots allows for robust actuation, enabling them to perform demanding tasks with relatively simple and small external actuation units.

We explore the feasibility of developing compact and portable actuation units, a crucial step towards facilitating the clinical translation of this technology. The portability of these actuation units is particularly desirable, as it can significantly enhance the practicality and accessibility of magnetic ball chain robots in diverse clinical settings.

We will also discuss other potential clinical applications of magnetic ball chain robots, such as endoscopy and endovascular procedures, along with future directions and goals.

Nanorobotic 3D Microgels for Thermomechanical Stimulation of Biological Systems *Berna Özkale Edelmann; Technische Universität München, Germany*

The integration of small-scale robotics in biomedical sciences has led to unprecedent capabilities. Despite the advances in the field, ensuring user-defined communication between the devices and living matter, specifically mammalian cells, is still challenging. The ability to communicate with individual cells and regulate cellular processing with external stimulation during growth is particularly crucial for tissue engineering applications and stem-cell based regenerative therapies. In an effort to address this challenge, we developed nanorobotic 3D microgels that are capable of stimulating stem cells at single cell resolution, while providing direct feedback. The nanorobotic 3D microgels consist of a plasmonic nanocomposite, which is designed to mechanically and morphologically resemble mesenchymal stem cells. Relying on the synergistic relationship between plasmonic gold nanorods and thermoresponsive polymers, these microgels deform up to 20% when actuated by near-infrared light. We use microfluidics to encapsulate cells in the nanorobotic 3D microgels and apply compressive *force on encapsulated cells using light-triggered actuation. The applied force triggers intracellular calcium signaling in 3D encapsulated cells, which is dependent on the frequency, magnitude, and duration of the applied force. A thermoresponsive fluorescent probe provides immediate temperature feedback. Relying on a semi-experimental developed in my lab, the Microrobotic Bioengineering Lab (MRBL), we quantify the generated forces. The nanorobotic 3D microgel platform offers new and exciting capabilities in tissue engineering.*

2:30 PM *SF03.05.03
Additive Manufacturing to Obtain Functional Microrobotic Systems *Peer Fischer[1,2,3]; [1]Max Planck Institute for Medical Research, Germany; [2]Heidelberg University, Germany; [3]Yonsei University, Korea (the Republic of)*

The field of nano- and microrobotics takes inspiration from nature and strives to achieve mobile robotic systems of sub-millimeter size. However, building synthetic motors, machines, and robots 'bottom up', such that they can mimic biological matter and function autonomously or such that they can be controlled externally, is a fascinating challenge that requires a multidisciplinary approach. It is generally not possible, to directly translate actuation mechanisms and design-concepts from the macro- to the nanoscale. At this scale, different physical phenomena are important and there are no ready-made motors and no off-the-shelf parts. I will discuss fabrication methods that are additive and scalable and that offer the chance to couple to the structures to control them and realize microrobotic components and systems. A particular focus will be large scale, 'one-shot' additive methods based on holography in conjunction with light-driven and ultrasound-driven microrobotic systems.

3:00 PM BREAK

3:30 PM *SF03.05.04
Multifunctional Magnetoelectric Microrobots *Salvador Pane i Vidal; ETH Zürich, Switzerland*

An emerging family of robotic systems are untethered magnetic micro- and nanorobots, tiny vehicles that can move in their swimming environments by means of magnetic fields. One of the ultimate goals of small-scale robotics is to develop machines that can deliver drugs, or realize other medical missions in confined spaces of the human body. The recent rapid developments in small-scale robotics are undeniably related to advances in material science and manufacturing. However, while many applications have been demonstrated, aspects such as complex locomotion, multifunctionality, biocompatibility and biodegradability need to be further investigated for the successful translation of these devices to real applications. To this end, new material-based concepts and novel fabrication schemes are urgently required.

Our discussion will delve into the aspect of multifunctionality, particularly with the integration of magnetoelectric composite multiferroics in micro- and nanorobotic platforms. Magnetoelectric composite materials, consisting of both magnetostrictive and piezoelectric parts in intimate coupling, exhibit electrical polarization in response to magnetic inputs. As such these materials, can be used in micro- and nanorobotic platforms to deliver electric fields wirelessly using external magnetic fields. In this talk, we will particularly emphasize their application in electrostimulating cells and tissues, with a specific focus on potential implementations in the central nervous system. Specifically, we will show how these materials can be used to potentiate the proliferation of neuronal cells, stimulate their differentation into neuronal networks.

4:00 PM *SF03.05.05
Magnetics for Manipulation, Medicine, Manufacturing and Much More *David Sargent, Ankita A. Humne and Enea Masina; MagnebotiX AG, Switzerland*

Magnetism was known to our ancestors as early as the 6th century BC, when Thales of Miletus in Greece referred to lodestone. In addition to magical uses, lodestones - and later the related compass needles - were of great practical import for navigation for almost 2 ½ thousand years before inertial navigation and satellites took over. Many other applications at the macroscopic scale are central to modern technology – everything from doorbells to bending magnets in synchrotrons to magnetic data storage are direct applications of magnetism. As ever smaller sizes become the focus, the advantages of control using magnetic fields are especially evident – remote, non-contact actuation, with the ability to apply both forces and torques. The fact that many materials are transparent to magnetic fields allows a broad range of applications.
We will present examples using both hard and soft magnetic materials of various forms and structures, as well as heterogeneous and multifunctional devices. Derived structures can be used to both measure physical properties or provide localized stimulation at microscopic scales. Planned differences in internal magnetic structure can produce shape morphing in a field, and variation in internal mechanical properties or incorporation of specific molecules or surface functionalization can allow sensing of the micro-chemical environment at actively chosen positions. On a larger scale the incorporation of small magnets into specially designed catheters can greatly enhance the ability to access hard-to-reach places within the body and their use in human surgical intervention and targeted drug delivery is being actively developed.
All these applications are made possible with versatile magnetic field sources, often combined with other techniques to enable exciting results in ever more fields, as will be referenced in the course of the talk.

4:30 PM *SF03.05.06
Materials for New Functions of Micro/Nanorobots for Biomedical Applications *Hongsoo Choi; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)*

The performance of micro/nanorobots is largely influenced by the materials used in their construction. This presentation will explore a variety of micro/nanorobots engineered from distinct materials tailored to their specific functionalities. We will initially discuss robots made from quantum dots (QDs) and magnetoelectric (ME) nanoparticles, focusing on their application in medical and biological fields. QDs enhance capabilities in bioimaging through shortwave infrared (SWIR) imaging, which offers deep tissue penetration without ionizing radiation. We will introduce a QD-based magnetic guidewire designed for X-ray-free detection and precise magnetic navigation under SWIR imaging. Additionally, QDs have been utilized in the fabrication of microrobots using a photocurable photoresist, processed via two-photon polymerization (TPP). These microrobots are detectable by SWIR systems, enhancing their applicability in targeted medical applications. ME nanoparticles have been employed to develop nanorobots capable of stimulating neuronal cells through external magnetic fields. These magnetoelectric nanorobots show promise for applications in deep brain stimulation, featuring remote actuation and electrical stimulation capabilities without direct contact. Overall, the integration of QD and

ME nanoparticles into micro/nanorobots opens up new possibilities for advanced biomedical applications, demonstrating significant potential in medical procedures and targeted therapeutic interventions.

5:00 PM *SF03.05.07

Magnetic Microrobots for Highly Targeted Therapeutic Interventions *Veronika Magdanz[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada*

Current drug therapies for major global health issues such as cancer, are characterized by low targeting and hence many systemic side effects. In fact, only 1% of cancer drug reaches the tumour site, highlighting the ineffectiveness of systemic drug treatment[1]. Another example is urinary tract infections (UTIs), the 3rd most common type of infection in humans, affecting 150 million people each year worldwide[2]. UTIs are the most frequently encountered healthcare associated infections in long term care residents, which can lead to significant morbidity and mortality[3]. In addition, the use of catheters increases the likelihood of infection almost 40 fold and thus, UTIs are one of the most common reasons for resident hospitalization and considerable antibiotic use in long term care settings. There is an urgent need for more targeted, active delivery strategies to enhance current therapies.

Recently, the development of drug delivery strategies involving actively moving nano-and microrobots has been an emerging field due to many promising benefits[4]: reduced drug dosage, leading to less side effects and reduced secretion of pharmaceuticals into the environment; drug delivery independent of the blood flow thanks to active delivery mechanisms, and remote trigger mechanisms providing active and controlled drug release. Current advances in nano-and microrobotics include local drug delivery to bladder and cervical cancer demonstrated in in vitro studies and animal models[5-7]. In this presentation, advances toward local drug delivery in the urinary and reproductive tract with the help of cargo-loaded soft magnetic micro-and millirobots will be presented.

8:30 AM SF03.07.01

Photothermally Powered Microbots for Assembly of Microtumors and Drug Screening *Philipp Harder and Berna Özkale Edelmann; Technische Universität München, Germany*

Novel nano- and microbots are increasingly used in various biomedical settings, demonstrating promising results in cell transport, tissue building, and cancer research. These devices offer significant advantages over conventional methods due to their small size, ability to operate in confined spaces, and biocompatibility. Novel fabrication methods and material modifications result in biocompatible cell-like micromachines, enabling them to interact with tissues. The incorporation of nanoparticles allows untethered guided actuation and locomotion in biological environments. However, many of these promising technologies lack multifunctionality and are limited in sensing or actuation.
Our research presents a practical solution in the form of biocompatible, soft microbots made from RGD-peptide-modified alginate. These microbots, equipped with gold nanorods for photothermal heating, can be optically addressed. By incorporating components such as Rhodamine B, we enable live temperature sensing and stress mapping in self-assembled 3D microtumors. Using the HT1080 fibrosarcoma cell line, we develop a robust biofabrication method to create RGD-functionalized microbots as scaffold structures for single cells and microtumors. This platform allows the assembly of cellular constructs ranging from single-cell resolution to 3D microtumors, hundreds of micrometers in size, demonstrating its potential in tissue engineering and cancer research.
Our research demonstrates the practical applications of these microbots. We can transport single cells in vitro and assemble microbots into human-made constructs with precision. Moreover, we can induce calcium uptake in 3D at temperatures above 37°C and observe changes in intracellular calcium diffusion times. This level of control allows us to operate windows at different temperatures, from mild hyperthermia to noxious heat. We embed microtumors in collagen hydrogel to mimic in vivo-like conditions for studying cancer cell invasion. By applying on-demand photothermal heat, we observe a combinatory positive effect of reduced invasion of the highly aggressive cancer cell line when heating in 3D to temperatures above 59°C in the presence of a chemotherapeutic drug. These results highlight the potential of our platform in single-cell transport, tissue construction, and dual-phototherapeutic drug screening in vitro.

Biohybrid Microrobots Regulate Colonic Cytokine and Epithelium Barrier in Inflammatory Bowel Disease
Zhengxing Li; University of California, San Diego, United States

Cytokines are pivotal in the pathogenesis of inflammatory bowel disease (IBD), yet existing therapeutic strategies often fall short, presenting limited efficacy and significant adverse effects. Here, I unveil a novel biohybrid robotic system, designated as 'algae-MΦNP-robot,' engineered to dynamically neutralize colonic cytokine levels. This cutting-edge system amalgamates motile green microalgae with macrophage membrane-coated nanoparticles (MΦNPs), enabling efficient, real-time capture of pro-inflammatory cytokines 'on-the-fly'. The algae-MΦNP-robots surpass static counterparts by facilitating continuous cytokine removal, optimizing spatial distribution, and prolonging retention within the colon. Encapsulated in an oral capsule, the system is protected from gastric acidity and activates precisely at the disease site. This biohybrid robot not only modulates cytokine levels but also expedites the repair of damaged epithelial barriers. In murine IBD models, the algae-MΦNP-robot capsule exhibits superior prophylactic and therapeutic outcomes and an exemplary biosafety profile. Collectively, our algae-MΦNP-robot system represents a transformative approach for the effective management of cytokine-mediated inflammation in IBD, offering substantial advancements in both treatment efficacy and safety.

Biocompatible Chemical Nanobots and Their Applications in Biomedicine _Samuel Sánchez Ordóñez; Barcelona Institute for Science and Technology, Spain_

Engineering medical nanomotors/nanobots will imply the use of biocompatible materials and bio-friendly propulsion mechanisms. Our strategy comprises the use of biocatalysts such enzymes for converting biologically available fuels, such as the urea contained in the urine, into a propulsive force. Moreover, nanoparticles' chassis are generally recognized as safe (GRAS) material, FDA or EMA approved materials.
In my talk, I will present how we bioengineer hybrid nanobots combining the best from the two worlds: biology (enzymes) and (nano)technology (nano- micro-particles) providing swimming capabilities, biocompatibility, imaging, multifunctionality and actuation in vitro and in vivo. I will present some of the proof-of-concept applications of biocompatible nanobots such as the efficient transport of drugs into cancer cells and 3D spheroids (1), the imaging of swarms of nanobots in vivo in confined spaces like the bladder of living mice (2). Moreover, I will present our recent advances in the treatment of bladder cancer in mice using radionuclide-labelled nanobots (3) and crossing mucus layers present in the colon of mice (4).

Magnetoelectronics for Magnetically Aware Soft-Bodied Robots _Denys Makarov; Helmholtz-Zentrum Dresden-Rossendorf, Germany_

Motion sensing is the primary task in numerous disciplines including industrial and soft robotics, prosthetics, virtual and augmented reality appliances. In rigid electronics, rotations, displacements and vibrations are typically monitored using magnetic field sensors. Here, we will discuss on the fabrication of flexible, stretchable and printable magnetoelectronic devices. The technology platform relies on high-performance magnetoresistive and Hall effect sensors either deposited or printed on polymeric foils. These skin conformal flexible and printable magnetosensitive elements enable touchless interactivity with surroundings based on the interaction with magnetic fields. This is relevant for soft robotics [1] and human-machine interfaces based on smart skins [2-4] and smart wearables [5]. In particular, reconfigurable magnetic origami actuators [1] can be equipped with ultrathin and lightweight magnetosensitive e-skins [6], which help to assess the magnetic state of the actuator (magnetized vs. non-magnetized), decide on its actuation pattern and control sequentiality and quality of the folding process. The on-board sensing adds awareness to soft-bodied magnetic actuators enabling them to act and be controlled similar to conventional robotic devices [7]. Magnetic soft robots can be designed to perform complex collaborative tasks being driven using magnetic far fields [1] and near fields [8]. The use of magnetic near fields of on-board *electromagnetic coils to drive embedded permanent magnets can provide the demanded tuneability to the mechanical strength of grippers working with objects of different stiffness including biological tissues [9]. Furthermore, we will introduce printed magnetic field sensors that can be flexible [10], stretchable [4], and capable of detection in a broad range of magnetic fields. By an appropriate choice of the polymeric binder, these solution processable magnetoelectronics can self-heal upon mechanical damage [11]. This research motivates further explorations towards the realisation of eco-sustainable magnetoelectronics. To this end, we will discuss biocompatible and biodegradable magnetosensitive devices, which can help to minimise electronic waste and bring magnetoelectronics to new application fields in medical implants and health monitoring.*

10:30 AM *SF03.08.02
Cognitive Robotics for Surgery—Elevating Efficiency in the OR *Franziska Mathis-Ullrich; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany*

The increasing use of robots has changed surgical practice in recent years. Precisely controllable instruments and integrated sensor technology enable minimally invasive operations and provide medical staff with additional - often processed - information. Following today’s standard-of-care surgical robots with rigid or actuated instruments, such as the Da Vinci or the Senhance systems, controllable and flexible continuumrobots are now being explored. These compliant robotic instruments are designed to navigate with high precision through the body and around obstacles while reducing the risk of tissue damage. Regardless of their kinematic structure, the next generation of surgical robots will learn from human experts and medical data. This paves the way for context-sensitive, cognitive learning robots that can perceive their environment, learn from surgeons, and assist (semi-) autonomously during surgical steps, enabling true and natural co-operation with human surgeons.

To make this vision a reality, we focuses on both structure and cognition of next generation surgical robots. We utilize machine learning methodologies to provide learning software for cognition-guided robotic assistance during *surgery. Further, we investigate minimally invasive and sensorized continuumrobots to provide inherently safe and dexterous smart surgical instruments.*

Cognitive Robotic Assistance

Surgical robots are entering the market with varying degrees of automation. However, (so far) no system exists that operates fully autonomously. The next generation of robotic assistants is represented by cognitive surgical robots that understand their environment and provide context-sensitive support to a human surgeon as required. Natural partnership between a human and a robotic assistant gives rise to the idea that every team member (human or artificial) does what they do best. Human abstraction skills and creative solution finding is assisted by robotic precision and fast interpretation of surgical data, adding value to both the surgeon and the patient.
Machine learning techniques allow a robot to learn surgical behavior during laparoscopic surgery, or in catheter navigation. In particular, we explore reinforcement learning and imitation learning methods where multiple decentralized agents share a goal and cooperatively learn a common task through training or from expert demonstrations. This methodology enables a human operator to take over control of one or multiple instruments during critical surgical phases or during situations with high policy uncertainties.

Sensorized flexible Instruments

As surgical robots with rigid or articulated instruments became standard of care in many hospitals, international research moved into a new direction. Flexible robotic systems and steerable catheters have been explored for use in otherwise hard-to-reach organs and regions of the body. Flexible continuumrobots allow interaction with soft tissue in several clinical applications, as the compliant structure of these robots minimizes the risk of damage. Due to the often highly complex kinematics of long and flexible continuumrobots, their control is not trivial. Analytical approaches to modeling and controlling these continuous structures with increasingly high numbers of degrees of freedom are currently facing limitations. Therefore, our approach to extend and combine classical methods with advanced path planning and machine learning holds the potential for precisely controllable flexible smart robotic instruments for surgery that are designed to adapt to their environment inside the human body. By collecting motion data from continuumrobots and integrated sensors, this methodology renders it possible to predict the precise motion and counteract, if required. In the long term, surgical continuumrobots and flexible steerable instruments hold the potential for even less invasive surgery and promise efficiency and safety for surgeons and patients.

11:00 AM SF03.08.03

Superstrong Artificial Muscle Fibers with Dynamic Percolation Behavior *Inho Kim[1], Sang Ouk Kim[2] and Wei Gao[1]; [1]California Institute of Technology, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)*

Stimuli-responsive soft materials with high compliance and adaptability are crucial for robotics, enabling intricate actuation and motion across challenging environments. Artificial muscles are essential in the progress of soft robotics, aiming to replicate the complex movements of biological systems. In this study, we introduce super-strong 'Hercules' artificial muscle fibers and bundles, which exhibit contractive actuation through an extrusion 3D printing technique. These fibers are designed with a composite structure that incorporates highly exfoliated graphene sheets into a stimuli-responsive liquid crystal elastomer matrix. The synergistic interaction among the fillers within the actuator matrix results in contraction with outstanding actuation performance, attributed to a dynamic percolation behavior of the fillers. This unprecedented behavior effectively strengthens the composite fibers and enables an electrical switching effect, particularly in the contracted state. Consequently, this represents the first instance of simultaneous actuation and real-time signal monitoring within a robust artificial muscle fiber, making it highly suitable for practical applications. Leveraging mechanically compliant structures, *our artificial muscle fibers were seamlessly integrated into durable bundles and high-performance soft robotics.*

11:15 AM *SF03.08.04

***Wearable Bioadhesive Ultrasound** Xuanhe Zhao; Massachusetts Institute of Technology, United States*

Continuous imaging of internal organs over days could provide unprecedented information about one's health and diseases and shed new insights into developmental biology. However, this is unattainable with existing wearable devices. Here we report a bioadhesive ultrasound (BAUS) device, which consists of a thin and rigid ultrasound probe robustly adhered on the skin via a soft, tough, anti-dehydrating and bioadhesive couplant. The BAUS device provides 48-hour continuous and simultaneous imaging of multiple organs including blood vessels, muscle, heart, gastrointestinal tract, diaphragm, and lung for the first time. This talk will focus on BAUS' impacts on VR and robotics.

SESSION SF03.09: Materials for Robotic Sensors and Actuators

Hynes, Level 3, Room 306

1:30 PM SF03.09.01

***Fabric Jamming as an Enabler for Gentle Yet Effective Robotic Grasping** Niccolo Pagliarani[1,2], Alessandra de Maio[3], Alexia Le Gall[1,2] and Matteo Cianchetti[1,2]; [1]The BioRobotics Institute, Italy; [2]The Department of Excellence in Robotics and AI, Italy; [3]University of Pisa, Italy*

Layer jamming is a technology that adjusts the stiffness of layered materials, such as plastic or paper sheets, within a flexible elastic bag by adjusting the internal pressure. Among other applications, this stiffness tuning is valuable for soft grippers and manipulators to stabilize grasping and enhance the output force. However, despite its impressive stiffness capabilities, this technique struggles in scenarios requiring high conformability like ultra-gentle grasping. The system's compliance in its soft state is relatively low, especially at the layer level, resulting in poor shape-conforming behavior, in contrast, using fabric sheets as filler offers a more promising solution. This allows for greater flexibility and adaptability, enhancing the system's ability to conform to various shapes while maintaining the desired level of stiffness when jamming is induced. At atmospheric pressure, the fabric layers can slide on top of each other while keeping a two-dimensional flexibility. However, when the internal air is removed, the pressure difference causes the layers to adhere firmly, significantly increasing friction and preventing movement. The use of both knitted and non-knitted fabrics is investigated as layers of the variable stiffness assembly. Their variable stiffness capabilities are evaluated, and their double-curvature capabilities are demonstrated through their integration into a soft gripper. The gripper utilizes an origami-based pneumatic chamber that inflates to form a double-curvature shape, enveloping the target object with a larger contact area compared to finger-based grippers. This innovative design, combining fabric jamming and origami structures, enables the gripper to transition between soft and stiff states. This allows for effective shape-locking when necessary, without compromising its kinematic capabilities. The result is a lightweight, compact, and squeezable soft gripper, capable of handling highly delicate objects with precision and care. In particular, this research paves the way for a new generation of ultra-gentle soft grippers for confined spaces, such as food handling or manipulating small organs and soft tissues in minimally invasive surgery. Moreover, these advanced soft grippers may offer enhanced versatility, squeezability, and stiffness tuning, which are essential for dealing with the high *unpredictability of unstructured environments.*

1:45 PM SF03.09.02

Enhanced Attractive Force via Tip Rotatability in Beam-Type Electrostatic Chuck for Advanced Robotic Applications *Sanchuan Xu, Yuki Taoka and Shigeki Saito; Tokyo Institute of Technology, Japan*

This study elucidates the enhancement of attractive force achieved through tip rotatability in beam-type electrostatic chucks (BESCs). Both analytical and experimental validations demonstrate a significant increase in attractive force with improved tip rotatability. This advancement is pivotal for achieving reliable, repeatable, and non-destructive large-scale thin-film manipulation, with potential applications in automated robotics systems within the semiconductor and OLED screen production industries.

Current manipulation technologies in the semiconductor and OLED screen production sectors face challenges in handling flexible films and curved plates. Unlike conventional mechanical grippers, BESCs provide uniform force distribution across curved surfaces, making them ideal for managing various targets. The beams in BESCs offer flexibility, enabling compliance with diverse surface geometries. However, performance and stability issues arise from misalignments between the beam tip and the target, especially during repeated operations. This study addresses these issues by incorporating torsion springs to introduce tip rotatability, and by analyzing the impact of rotatability on attractive force.

An analytical solution was derived by examining the force-moment equilibrium of the BESC-target system under quasi-static conditions. The system was divided into three components: the beam, the spring, and the target. The analysis concentrated on the critical timepoints of full-contact breakage and detachment, yielding formulas that relate target angle, tip rotatability, and maximum attractive force. The findings indicate a positive correlation between tip rotatability and maximum attractive force, regardless of target inclination. The analysis confirmed that the highest achievable attractive force corresponds to the full-contact electrostatic force and diminishes as tip rotatability decreases.

*Experimental verification involved three BESC devices, two with spring constants of 0.009 N*mm/deg and 0.03 N*mm/deg respectively, and one without rotatability. The results showed a 102.7% increase in maximum attractive force for the BESC with a 0.009 N*mm/deg spring constant, and a 50.1% increase for the BESC with a 0.03 N*mm/deg spring constant, compared to the non-rotatable BESC on a flat surface. Similar enhancements were observed on inclined surfaces, corroborating the analytical predictions.*

In conclusion, this study clarifies the beneficial effect of tip rotatability on the maximum attractive force in BESCs. The presented analytical approach, validated by experimental results, provides a foundation for designing advanced BESC arrays capable of high-precision, large-area object manipulation. These findings contribute significantly to the development of robotic systems with enhanced manipulation capabilities, applicable in various technological domains including biomedicine, bionics, and minimally invasive medicine.

2:00 PM SF03.09.03

Highly Stable Ladder-Type Conjugated Polymer Based Organic Electrochemical Transistors for Low Power and Signal Processing-Free Surface Electromyogram Triggered Robotic Hand Control *Zhongliang Zhou and Wei Lin Leong; Nanyang Technological University, Singapore*

Organic electrochemical transistors (OECTs) based complementary inverters have been considered as promising candidates in electrophysiological amplification, owing to their low power consumption, and high gain. To create *complementary inverters, it is important to use highly stable p-type and n-type polymers with well-balanced current. In this work, we improved the electrochemical stability of p-type ladder-conjugated polymer based OECT through an annealing process where it maintained its doped-state drain current from 76 % to 105 % after 4,500 cycles in ambient environment. We next present an OECT-based complementary inverter made from p-type and n-type ladder-conjugated polymers (PBBTL and BBL) that possess ultra-low power consumption (~170 nW), high gain (67 V/V) and high noise margin (92%) with full rail-to-rail swing. Furthermore, we demonstrate its potential in amplifying the envelope of surface electromyography (EMG) for robotic hand control. The high variation in the output (0.35V) allows the amplified EMG signals to be directly captured by commercial analog-to-digital converter, which in turn controls the robot hand to grasp different objects with low delay and low noise. These results demonstrate the capability of OECT inverter based amplifier in future signal processing-free human machine interface, particularly useful for prosthetic control and gesture control applications.*

2:15 PM SF03.09.04

Data Driven Long-Term Energy Efficiency Prediction of Dielectric Elastomer Artificial Muscles *Ang Li[1,2], Codrin Tugui[2] and Mihai Duduta[2,1]; [1]University of Toronto, Canada; [2]University of Connecticut, United States*

Dielectric elastomer actuators (DEAs) are electro-mechanical transducers driven by electric fields. They can be made from all solid-state materials, allowing them to operate under extreme environments, be scalable in size, and be capable of self-sensing. Their potential applications span robotics, haptics, and optical instruments. However, practical adoption is hindered by the absence of a material design framework and a non-destructive performance evaluation system. This research introduces a data-driven framework to predict long-term DEA energy efficiency using short-term electrical property measurements. The DEA datasets are generated from single-layer pre-stretched actuators made with different electrode and elastomer materials, being tested for 30 minutes using a custom-made testing instrument. First, experiments were conducted to develop an empirical understanding of the electro-mechanical energy conversion mechanism and the impact of material choices during DEA actuation. Second, data-driven models were applied to the datasets to predict energy efficiency at 30 minutes using as short as 1 minute of electromechanical measurements. DEAs Third, the potential of generalizing this framework was investigated by adopting transfer learning to predict the 3-hour energy efficiency of single-layer DEAs using as short as 1-minute input data and to extend the predictions on devices made of a multi-layer architecture. Transfer learning is an ML strategy that fine-tunes a pre-trained model on a larger dataset, then adapts it to a smaller, high-value dataset with limited samples, leveraging knowledge transfer to enhance prediction performance in data-scarce scenarios. Despite significant differences in behavior between single-layer and multi-layer DEAs, transfer learning bridges the gap in performance predictability, highlighting the need for data-driven approaches to performance prediction. We believe the proposed data-driven framework can evolve into an intelligent system for accelerating new material discovery by predicting performance and providing device optimization strategies.

2:30 PM BREAK

3:00 PM SF03.09.05

Increasing the Performance of EHD Fiber Pumps by Scaling and by Changing to a More Sustainable Working Fluid *Yichi Luo, Jean-Baptiste Chossat, Martijn Schouten and Herbert R. Shea; École Polytechnique Fédérale de Lausanne, Switzerland*

Electrohydrodynamic (EHD) fiber pumps are flexible millimeter-diameter tubes that generate fluid flow when a high voltage is applied. These pumps consist of a polymer shell in which two helical copper electrode wires are embedded, such that they are in electrical contact with the liquid. The fiber form factor is well-suited for *integration in fluidic-driven wearable robots. In our earlier work (Smith et al., Science 379, 2023) we reported fluidic powers of approximately 20 mW/m at 6.4 kV, using the hydrofluoroether dielectric liquid novec-7100, which will however no longer be commercially available past 2028.*

Here we report 5x improved pump performance by two means: using different fluids and varying pump diameter. To measure the EHD fiber pump's performance across a broad range of fluids, a change in the polymer shell material was necessary. By switching from thermoplastic polyurethane (TPU) to polypropylene (PP), we ensured chemical compatibility with a wide range of fluid candidates, including fluorinated organic fluids, nonfluorinated organic fluids, and organosilicon fluids, focusing on non-toxic choices. We built an automated test platform to systematically record pump metrics including generated pressure, flowrate, efficiency, and fluidic power, as a function of applied voltage. We also explored the effect of changing liquid and varying tube inner diameter and electrode spacing. Several liquids showed performance on par or even better than novec-7100.

Using a nonfluorinated organic fluid (3-methoxybutyl acetate) and by scaling the pump diameter while keeping a constant inter-electrode spacing, we achieved a fivefold improvement in the maximum fluidic power output, reaching over 100 mW/m. Generating 1 W of fluidic power now requires 10 m of pump, nearly within reach of our manufacturing equipment.

We used a 1-meter-long EHD fiber pump to drive a thin McKibben actuator, lifting a 500 g weight by 1.5 cm within 6 s, illustrating the promise of EHD fiber pumps for fluidic wearable robots.

3:15 PM SF03.09.06

Magnetoactive Janus Particle Swarms for Information Display, Memory and Encryption *Zenghao Zhang, Joerg Lahann and Abdon Pena-Francesch; University of Michigan, United States*

Magnetic microrobots have drawn attention due to their untethered actuation, fast response, easy to miniaturize and flexible control mechanisms. While actuation of a single magnetic robot is relatively straightforward, the design and control of robotic swarms to achieve programmed synchronized and asynchronous motions remains a challenge. Here, we develop a microrobotic swarm system based on responsive magnetoactive Janus particle (MAJP) with programmable magnetization that can rotate individually with external magnetic fields to present different color states at the surface for multiple programmable functions. MAJP microrobots were designed with tunable structure and properties, i.e., encoded swarming behavior and fully reversible switching mechanisms, to enable programmable dynamic display, non-volatile and semi-volatile memory, Boolean logic, and information encryption functions in soft, wearable devices. MAJPs and their unique swarming behaviors open new functions for the design of multifunctional and reconfigurable display devices, and constitute a promising building block to develop the next generation of soft physical computing devices and responsive metamaterials.

3:30 PM SF03.09.07

The Delta Motor—A High-Speed, Multi-Degree-of-Freedom, Flexure-Based Piezoelectric Motor *Noah T. Jafferis[1] and Robert J. Wood[2]; [1]University of Massachusetts Lowell, United States; [2]Harvard University, United States*

As size scales are reduced to the millimeter and sub-gram regime, electromagnetic rotary motors have reduced performance due to physical scaling effects that affect friction, current density, and heat dissipation. In this regime, piezoelectric actuators are a useful alternative due to their high energy density (a few J/kg), high efficiency, and increasing power density at small scales. However, converting their linear motion into rotary motion without significant energy losses remains challenging, and while such devices can provide high torque, bandwidth, and precision, they typically have low rotational rates. When multi-degree-of-freedom (DOF) motions are needed, these challenges are exacerbated, with few examples of multi-DOF motors at the millimeter-scale.

Here we present our recently published work on 'The Delta Motor', a novel 130-mg multi-modal piezoelectric *motor that can produce both rotational and translational motion of its output axle. In rotational mode, rotational rates up to 30,000 RPM (much faster than typical piezoelectric motors) and torques of 2.5 μNm have been demonstrated, while in translational mode, free displacements of ±0.6 mm and blocked forces of ±100 mN have been achieved at frequencies up to 500 Hz. The motor operates by using a flexure-based delta mechanism, which implements universal joints via closely-spaced laminated in-plane and out-of-plane joints, to convert the oscillatory motion of three piezoelectric bending actuators into the motion of a variable-transmission crank-shaft in 3D space. This crank is then used to rotate the main output axle. In contrast to most piezoelectric motors, which utilize some form of frequency-leveraging such as stick-slip or traveling-wave based approaches, this means that the output axle of the Delta Motor is rotated at the same frequency as the oscillation frequency of its internal bending actuators, which allows the motor to reach very high rotational rates without requiring high-frequency operation of the internal actuators (e.g., 30,000 RPM is achieved at 500 Hz). In addition, because the output is connected to the input actuators, the rotational rate is independent of the load torque up until blocked torque is reached. Since the crank can be commanded to move along arbitrary trajectories within a small 3D volume, the output axle can be translated as well as rotated. This multi-modal capability enables many possibilities for interesting new applications in microsurgery and microrobotics. For example, the Delta Motor could be used as a miniature drill press by providing a translational force while rotating the output axle at high speed. Switching between different output shafts could be enabled by translating the output axle to different positions, then activating the rotational mode. Rotation has been demonstrated together with linear translations up to ±280 μm. Activating the translational mode and the rotational mode simultaneously could be useful for microrobot limb actuation, such as 'figure-eight' wing flapping and comparisons between flapping wings and rotary propellers at the insect scale.*

3:45 PM SF03.09.08

A Hot-Plugging Pinch Valve with Pressure-Controlled Logical Functions *Jing Xu[1], Seunghee Jeong[2,1], Hugo Nguyen[1] and Klas Hjort[1]; [1]Uppsala University, Sweden; [2]Harvard University, United States*

Soft wearable robots utilize innovative textiles to create a mechanically active interface with human body. Compared to exoskeletons, they are more comfortable because they do not constrain the wearer's joints with rigid structures. These robots are lightweight, conformal, and compliant. With minimal disturbance, they can not only enhance the abilities of healthy individuals by improving walking or lifting efficiency, but also assist those with muscle weakness or physical and neurological disorders. They can also be used in high-force kinesthetic haptics for training and entertainment. However, the miniaturization and integration of a large-scale and complex control system, with bulky and heavy actuators and energy units, pose significant challenges before the wearer can move autonomously in a soft wearable robotic suit. One aspect of these challenges is that the control valve is typically rigid and bulky.

To address this issue, designing proper valves is crucial. Research on valves has grown significantly, displaying examples such as soft bi-stable valves and logic-enabled valves integrated with textiles. However, integrating these valves into pneumatic systems typically requires cutting out the tubing and reconnecting it. This process introduces considerable workload and increases the risk of leakage, especially in high-pressure applications. In the design and prototyping of wearable soft robots, the functionality and ease of application of control valves are greatly enhanced if they can be integrated into an operational system, for example, through a hot-plugging feature. In this work, we proposed a type of pinch valve with several notable characteristics. The basic working principle is that a silicone elastomer tube is pinched between a stiff ridge and a stiff plate, separately controlled by two soft pneumatic actuators. The application of the valve is significantly enhanced by a slotted frame, which provides a hot-plugging function as it allows the operational tube to be inserted into the valve without being cut. The valve is characterized by three crucial properties: (i) Flexibility in integration: the hot-plugging function allows for flexible integration of the valve into the system. (ii) Pressure control: it has the capability to open and close high-pressure *systems using a lower control pressure, with a pressure ratio of at least 5. (iii) Logical functions: by controlling the pressure of the independent control actuators, the valve supports logical functions of NOT, NAND, and NOR gates, without the need to alter the pneumatic connections. Leveraging the NAND gate's ability to detect when a signal input goes low, we demonstrated that the valve, with its NAND gate, can transform an unsecured gripper into a secured gripper.*

4:00 PM SF03.09.09
Biocompatible Ionogels for Electroactive Actuators *Giao Nguyen, Bin Ni, Gabriela Y. Ananieva, Cédric Vancaeyzeele, Frédéric Vidal and Cédric Plesse; CY Cergy Paris Université, France*

The development of soft robotics is challenging and exciting for wide range of field from industry to medicine. Its development is tied to the availability of efficient, flexible and soft actuators. Among actuators, electroactive actuators are the most promising and are considered as artificial muscles that gain more and more interest. Their light-weight, miniaturizable and stimuli-responsible are their major advantages. They are usually considered to be use in applications that are in interaction with human such as in haptics, e-textiles, biomedical device... Consequently, biocompatible materials are required in the development of electroactive actuators. Among the latter, those based on ionic motion mechanism such as ionic electroactive polymers, ionic polymer metal composites or carbon nanotubes (CNT)-based actuators allow large deformation under low stimulation voltage. In these actuators, ionic source plays an important role and in order to allow in-air actuation, the electrolyte must be kept in self-standing state and in contact with the electroactive materials. Ionogel is among the best solution for use as ionic source. They are polymer networks containing a continuous phase of ionic liquid. They inherit from the polymer networks their self-standing state, their softness and stretchability. On the other side, ionogels derive from ionic liquids the high ionic conductivity and their stability in air.
Here we present the synthesis of a biocompatible ionogel suitable for use as ionic source in electroactive actuators. The ionogel was synthesized in one-pot photopolymerization using biocompatible liquid precursors mixture including acrylate-based monomers, ionic liquid and initiators, leading to materials that are highly ionically conductive reaching 1.9 mS/cm, soft and stretchable (Young modulus <1 MPa and elongation at break ~ 75%). As a demonstration for the use of biocompatible ionogel, coiled CNT yarns actuators was fabricated. The working principle of the actuator is based on the accumulation of ionic species on CNT upon charging under the electrochemical double layer configuration. This accumulation of ions allows the swelling of the CNT coils leading to a linear contraction of the actuators. To be able to operate in air, two coiled carbon nanotube (CNT) yarns coated with the ionogels were fabricated and assembled together. They act as working and counter electrodes in a two-electrode electrochemical system of an electroactive actuator. The actuator exhibited a maximum contractile stroke of 1.78% under low voltage stimulation (4V) in open air. The actuation performance remained unchanged after 16h in-air actuation. The synthesized biocompatible ionogels has demonstrated their potential to be used as solid electrolyte under ionic coating form, suitable for open air operating electroactive actuators.

4:15 PM SF03.09.10
Tenjamity—Tensional Jamming Based Self-Deployable Mechanical Metamaterials *Wenzhong Yan, Talmage Jones, Christopher L. Jawetz, Ryan H. Lee, Jonathan Hopkins and Ankur Mehta; University of California, Los Angeles, United States*

Recent advancements in robotics demand materials that can adapt dynamically to varying conditions, offering both flexibility and robustness. However, designing materials that possess self-deployment and post-deployment continuously tunable mechanical properties remains a challenge, notwithstanding its importance. Here, we introduce a class of mechanical metamaterials utilizing the contracting-cord particle jamming (CCPJ) mechanism, designed for robotic systems requiring adaptive morphology, stiffness, and damping. Our metamaterials feature *networked chains with beads threaded with interlocking conical concavo-convex interfaces along contracting actuators, inspired by push puppets. This design allows for precise self-deployability and extensive tunability in stiffness and damping within three-dimensional metamaterials. In their slack state, these networks conform to various shapes, but upon actuation, they self-assemble into predetermined configurations. Further contraction dynamically tunes the mechanical properties through particle jamming, maintaining structural integrity with minimal changes.*

Experimental and numerical exploration of CCPJ-based beams reveals that varying applied contracting tension induces particle jamming within engineered beads, significantly enhancing mechanical properties. For example, a self-deployed beam in a bending-dominated configuration achieves over 35 times increased stiffness and a 52% change in damping under 120 N of external tension. Adjusting the beads' conical angle influences self-deployability and mechanical tunability due to geometric and frictional nonlinearities. We further characterize CCPJ-based cubic unit cells, composed of identical unit beams, demonstrating the feasibility of constructing various configurations while retaining advantageous attributes. Comparisons between bending-dominated and stretching-dominated cells confirm a preference for bending-dominated structures, with a cubic cell showing a 32-fold stiffness change and a 40% reduction in damping.

To illustrate the practical application, we integrate actuators such as electrically-driven thermal artificial muscles and motor-driven cables, enabling rapid, on-demand self-deployment, self-retraction, and stiffness tuning in larger-scale metamaterials. This research introduces a new class of materials capable of adapting in situ, paving the way for advanced applications in soft robotics, reconfigurable architectures, and space engineering.

SESSION SF04.01: 2D Materials and Monolayers

Session Chairs: Jianlin Liu and Farida Selim
Monday Morning, December 2, 2024
Hynes, Level 3, Room 311

10:30 AM *SF04.01.01

Pushing the Limits of 2D Janus Layers *Seth Ariel Tongay; Arizona State University, United States*

Named after the two faced Roman God Janus, 2D Janus layers contain two different atomic types on its top and bottom faces. Previous theoretical studies have shown that broken mirror symmetry together with large change transfer across the top and bottom face opens up completely new quantum properties including Rashba effect, colossal Janus field, dipolar excitons, and Skyrmion formation. Despite the theoretical advances in the field, experimental results are still limited due to limitations in high quality 2D Janus layer synthesis. In this talk, I will introduce recent discoveries made at Arizona State University towards different types of Janus layers. The growth process relies on Plasma enhanced low pressure chemical vapor deposition (PE-LPCVD). With this all room temperature technique, our team can synthesize different Janus layers as well as their vertical / lateral heterojunctions, and Janus nanoscrolls. Further studies from our team will introduce on-demand fabrication of 2D Janus layers with unique in-situ growth capabilities that allows us to collect spectroscopy data during the course of Janus material growth. Results are presented along with microscopy, spectroscopy, high -pressure studies, and electronic transport datasets for complete understanding of these systems.

11:00 AM SF04.01.02

Twisted $MoSe_2$ Homobilayer Behaving as a Heterobilayer *Arka Karmakar; University of Warsaw, Poland*

Heterostructures (HSs) formed by the transition-metal dichalcogenides (TMDCs) materials have shown great promise in next-generation optoelectronic and photonic applications. An artificially twisted HS, allows us to manipulate the optical, and electronic properties. In this talk, I introduce our latest work [1] on the understanding of the complex energy transfer (ET) process governed by the dipolar interaction in a twisted molybdenum diselenide ($MoSe_2$) homobilayer without any charge-blocking interlayer, i.e., in atomically closed proximity. We fabricated an unconventional homobilayer (i.e., HS) with a large twist angle by combining the chemical vapor deposition (CVD) and mechanical exfoliation (Exf.) techniques to fully exploit the lattice parameters mismatch and indirect/direct (CVD/Exf.) bandgap nature. This effectively weaken the charge transfer (CT) process and allows the ET process to take over the carrier recombination channels. We utilize a series of optical and electron spectroscopy techniques complementing by the density functional theory calculations, to describe a massive photoluminescence enhancement from the HS area due to an efficient ET process. Our results show that the electronically decoupled $MoSe_2$ homobilayer is coupled by the ET process, mimicking a 'true' heterobilayer nature.

Radiation Defect Engineering in Hexagonal Boron Nitride Films *Minsuk Seo[1], Leonardus Bimo Bayu Aji[1], Sreya Vangara[2], Sang Cheol Kim[2], Yan-Kai Tzeng[2], Yilong Zhou[1], Liwen Wan[1], Bo Wang[1], Tae Wook Heo[1], Chang-Eun Kim[1], Luis A. Zepeda-Ruiz[1], Steven Chu[2] and Sergei O. Kucheyev[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Stanford University, United States*

Hexagonal boron nitride (hBN) is a wide-band-gap semiconductor with several emerging applications. Ion bombardment can be used to fine-tune hBN properties for specific applications. However, the synthesis of wafer-

scale hBN films with desired characteristics and thicknesses exceeding ~50 nm remains challenging. Here, we describe radiofrequency-plasma-assisted deposition of polycrystalline hBN films. Film growth is guided by simulations and in-situ plasma diagnostics. We show how the main properties of as-grown films can be controlled by the deposition source design and process variables. We then systematically study damage buildup in these hBN films irradiated with kiloelectronvolt energy ions with different masses (He, N, Ne, Ar, and Xe) and dose rates. Irradiation experiments are complemented by molecular dynamics simulations of the formation and evolution of point defects. Emphasis is on the role of BN polymorphism and transitions between cubic and hexagonal BN phases under ion bombardment. Our results reveal a critical role of intra-cascade defect processes in hBN damage buildup.
This work was performed under the auspices of the U.S. DOE by LLNL under Contract DE-AC52-07NA27344.

11:30 AM *SF04.01.04
Exploring 2D Graphene as Atomic Armor to Protect Uranium from Ambient Corrosion *Yongqiang Wang; Los Alamos National Laboratory, United States*

Uranium (U) is a nuclear material with tremendous technological importance. One outstanding challenge in preserving its intrinsic nuclear properties is its high susceptibility to ambient corrosion. The corrosion, initiates at surfaces and interfaces, can form different phases, alter the dimensions of components, and even cause surface spalling, thus degrade the nuclear performance. Protective coatings are effective means to prevent metals from corrosive environments. However, anticorrosion coatings, when applied to actinides including U, faces a unique challenge from self-irradiation, which can degrade coatings' integrity by radiation damage and thus compromise the long-term efficacy of the applied coatings for corrosion protection.
This research aims to explore the feasibility of 2D graphene coating as atomic armor to protect U from ambient corrosion. Compared with traditional vapor-deposited film coatings, the defect formation in 2D material coatings is randomly distributed across layers, thus drastically reducing gas permeation paths. This unique 2D characteristics enables us to use significantly thinner coatings to achieve required anticorrosion efficacy; thus, can better preserve nuclear properties of the U material by minimizing unwanted "impurities" from the anticorrosion coatings itself.
Ion beams are used to mimic U self-irradiation environments including high energy alpha particle ionizations and heavy daughter product recoil cascades; thus, the accelerated irradiation doses of years and decades equivalent U-shelf lifetime can be effectively evaluated at the laboratory scale. Raman spectroscopy is used to evaluate irradiation stability of our 2D graphene coatings. Sieverts corrosion techniques are used to evaluate anticorrosion efficacy of the 2D graphene coatings when uncoated and coated U surfaces are exposed to hydrogen gas environments.

SESSION SF04.02: Point Defects in Functional Materials
Session Chairs: Elzbieta Guziewicz and Jianlin Liu
Monday Afternoon, December 2, 2024
Hynes, Level 3, Room 311

1:30 PM *SF04.02.01
Defects and Doping in Unconventional Semiconductors *Anderson Janotti; University of Delaware, United States*

In order for semiconductors to be useful in electronics or optoelectronics, it is crucial to control impurity *incorporation and intrinsic point defect formation, often down to parts per million and sometimes even at parts per billion. As technology advances from group-IV (Si), III-V (GaAs, InP, InGaAs), and II-VI (CdTe) semiconductor compounds and their chalcopyrite derivatives (CIGS) to semiconductors with more complicated crystal structures, in 2D or 3D, chemical compositions, or much wider band gaps, the questions of what point defects are prevalent and how to dope these materials p and n-type always arise, challenging both experimentalists and theoreticians. Here, from a theoretical perspective based on density functional theory within standard and beyond approximations, we discuss the fundamentals of doping and defect physics in 2D materials based on transition-metal dichalcogenides, wide-band-gap 3D oxide semiconductors (Ga_2O_3 and $CaSnO_3$), and organic-inorganic halide perovskites, i.e., materials of current interest to the development of devices. We focus on dopability (both p- and n-type), carrier localization, doping bottlenecks, and possible compensation mechanisms. We hope these insights not only contribute to the fundamental understanding of the physics of defects, but also pave the way for the development of next-generation electronic and optoelectronic devices with enhanced performance and functionality.*

This work was funded by the National Science Foundation (NSF) Award #OIA-2217786, and the NSF University of Delaware Materials Research Science and Engineering Center (MRSEC) grant DMR-2011824.

2:00 PM *SF04.02.02

Point Defects in High Purity AlN Substrates *Mary Ellen Zvanut, Shafiqul Mollik and Mackenzie Siford; The University of Alabama at Birmingham, United States*

The class of semiconductors with bandgap greater than ~ 4 eV, conventionally referred to as ultrawide bandgap semiconductors, are excellent candidates for material applications under extreme conditions. In particular, AlN with one of the largest bandgaps (6.2 eV) is predicted to withstand electric fields in excess of 15 MV/cm, making it one of the top choices for the next generation of high power electronics [1]. Future power devices will also benefit from the radiation hard piezoelectric properties [2]. To understand why these remarkable properties are realizable, it is helpful to look at the atomic level and investigate the point defects which can sometimes trigger, and other times minimize, degradation incurred by extreme conditions. Point defects in the as-grown material may be responsible for the premature electrical breakdown under large electric fields, and additional defects may be generated during ionizing radiation. The talk begins with a review of four different types of point defects found in as-grown AlN bulk crystals, and then summarizes radiation-induced centers.

Two different AlN crystals were studied. Both were grown by physical vapor transport, but the concentration of the typical impurities, C, Si, and O, differ by two orders of magnitude – 10^{19} cm^{-3} in one and 10^{17} cm^{-3} in the other. The point defects were studied by electron paramagnetic resonance (EPR) and photo-EPR. Whereas the former leads to chemical and structural identification of the defect, the latter can enable measurement of the defect level. Basically, photo-EPR is an optical absorption measurement performed on a specific, known defect.

The sole EPR center observed in the crystals with high impurity concentration is D5 [3], commonly reported as a deep donor. However, comparison of the EPR parameters with those recently calculated by theory indicate conclusively that the EPR spectrum is due to a neutral carbon atom sitting on a nitrogen site, C_N^0. Photo-EPR measurement yield an acceptor level, $C_N^{-/0}$, about 2 eV above the valence band edge, which corresponds well with the calculated level. The high purity samples revealed three additional spectra. One is thought to be a shallow donor, often attributed to O_N. Again, recent calculations rule this out, but Si substituting for Al is a reasonable alternative candidate. The other two EPR spectra have not previously been identified in AlN. Both have an electron spin (S) greater than ½ and must be induced by either 430 nm or 265 nm light. One may be simulated assuming S=3/2 and a weak hyperfine interaction with two or three Al, suggesting that the defect may be a simple aluminum vacancy or one coupled to Si or O as has been suggested by theoretical studies. At this time, there is not sufficient information on the second EPR spectrum in the high purity material to comment on its origin. Nevertheless, either *defect could be a significant factor in achieving successful application of AlN under extreme electric fields. Furthermore, their presence indicates that lowering the impurity content reveals new defects which may present unforeseen challenges to production of high quality AlN.*

Point Defect and Proximal Interface Induced Modification of Er^{3+} Optical Transitions in Single Crystal Er_2O_3

Hongrui Wu[1,2], Adam Dodson[3,2], Andrew O'Hara[4], Yongqiang Wang[5], Benjamin J. Lawrie[6], Agham Posadas[7], Jimmy Davidson[2], Anthony Hmelo[2], Alex Demkov[7], Leonard Feldman[8] and Norman Tolk[2]; [1]Brandeis University, United States; [2]Vanderbilt University, United States; [3]Sandia National Laboratories, United States; [4]Western Michigan University, United States; [5]Los Alamos National Laboratory, United States; [6]Oak Ridge National Laboratory, United States; [7]The University of Texas at Austin, United States; [8]Rutgers, The State University of New Jersey, United States

Rare earth ions, such as Er^{3+}, are receiving increased attention for modern telecommunication technologies, radiation damage and temperature sensing in nuclear technologies, and for emerging quantum information science applications. This is due largely to the fact that the 4f-4f electronic transitions in rare-earth ions are well-shielded from their environment by filled 5s and 5p orbitals which permits the 4f-4f electronic transitions to retain atomic-like character with low spectral diffusion. Our results demonstrate that the photophysical properties of solids incorporating Er_2O_3 depend on defect content. In particular, we characterize the influence of defects and proximal interfaces on the temperature dependance of photoluminescence (PL) emission intensity of Er^{3+} in molecular beam epitaxially grown single crystal Er_2O_3 thin films on silicon. The samples were subjected to 30 keV He^+ ion beam irradiation with fluences from $1*10^{12}$ atoms/cm^2 to $1*10^{15}$ atoms/cm^2 to introduce ion irradiation damage up to 0.045 dpa (displacement per atom). Surprisingly, the defects induced by ion irradiation result in significant enhancements in PL intensity from specific Er^{3+} transitions. In addition, an unexpected non-linearity in erbium emission was observed as a function of decreasing thin film thickness. We discuss these effects in terms of the influence of defects on the crystal site symmetry of the host lattice and on the deviation from crystallinity near interfaces.

2:45 PM SF04.02.04

Impacts of Point Defects on Shallow Doping in Cubic Boron Arsenide—A First Principles Study

Shuxiang Zhou[1], Zilong Hua[1], Kaustubh Bawane[1], Hao Zhou[2] and Tianli Feng[2]; [1]Idaho National Laboratory, United States; [2]The University of Utah, United States

Cubic boron arsenide (BAs) stands out as a promising material for advanced electronics, thanks to its exceptional thermal conductivity and ambipolar mobility. However, effective control of p- and n-type doping in BAs poses a significant challenge, mostly as a result of the influence of defects. E.g., the p-type behavior in pure BAs samples is claimed to be produced by impurity, rather than intrinsic defects, from previous computational studies. Here we employed density functional theory to explore the impacts of the common point defects and impurities on p-type (Be_B and Si_{As}) and n-type doping (Si_B and Se_{As}). We identified the most favorable point defects formed by C, O, and Si, including C_{As}, O_BO_{As}, Si_{As}, $C_{As}Si_B$, and O_BSi_{As}, which all have formation energies of less than 1.5 eV. Based on

these point defects, for p-type, only the O impurity detrimentally affects Si_{As} doping. However for n-type dopings, C, O, and Si impurities are all harmful. Interestingly, the antisite defect pair As_BB_{As} benefits both p- and n-type doping. While it is clear that n-type doping of BAs requires more caution in removing impurities, the doping limitation analysis presented in this study can potentially pave the way for strategic development in the area of BAs-based electronics.

3:30 PM *SF04.03.01
Silicon Carbide—Extreme Conditions from Bulk Growth to Device Operation *Caleb Kent; Wolfspeed, United States*

Silicon carbide, once considered too difficult to grow with sufficient quality for applications in power electronics, is now widely used in electric vehicles, for inverters in renewable energy, and many high-power industrial applications. SiC devices can better withstand high voltage, heat, radiation, and harsh chemical environments compared with previous Si based devices while improving efficiency with lower switching losses and a higher power density. Many of the same material characteristics that result in a stable device make bulk growth a challenge. SiC is grown commercially by physical vapor transport and requires precise control at temperatures up to 2500C which severely restricts the options for crucible components. Development of novel high temperature materials could be useful to reduce costs, increase capacity, and speed the transition to SiC based power electronics. This presentation will cover the fundamentals SiC material properties, use cases, and crystal growth.

4:00 PM *SF04.03.02
Recent Advances in Ultra-wide Bandgap AlGaN and Ga2O3 Materials and Devices *Yinxuan Zhu[1], Sushovan Dhara[1], Ashok Dheenan[1], Andrew Allerman[2], Andrew Armstrong[2], Brianna Klein[2] and Siddharth Rajan[1]; [1]The Ohio State University, United States; [2]Sandia National Laboratories, United States*

Ultra-wide bandgap (UWBG) semiconductors such as high Al-content AlGaN and Gallium Oxide can provide significantly higher breakdown electric field than wide bandgap semiconductors such as GaN, and can provide excellent performance due to the higher breakdown electric field which leads to high Baliga Figure of Merit (for power switching) and high Johnson Figure of Merit (for high-frequency power amplification). This presentation will some areas where exciting progress on materials and device engineering is bringing us closer to high-performance III-Nitride (AlGaN) and Gallium Oxide electronics.

In the first part of this presentation, we will share recent results from work on lateral high-frequency AlGaN transistors. We will discuss simulations that show that better delay-breakdown combinations than possible in any material system today. We will then focus on two key experimental challenges associated with lateral UWBG AlGaN transistors – contact engineering, and extreme electric field management. We will show recent work from our team that uses advanced heterostructure engineered contacts to achieve state-of-art low contact resistance

(< 3.5 x 10^{-7} Ohm-cm^2) to ultra-wide bandgap AlGaN. We will also discuss approaches to exploit the high breakdown field (> 8 MV/cm), applying high-permittivity BaTiO3 dielectrics to lateral transistors to prevent premature Schottky junction breakdown.

In the second part of the presentation, we will discuss our recent work on epitaxy, heterostructure design, and electrostatics to achieve high-performance -Ga_2O_3 lateral and vertical electronic devices and photodetectors. We will first discuss recent advances in materials growth and device design for lateral structures which enabled promising transistor demonstrations in the Gallium Oxide material system. Inserting an extreme-permittivity dielectric between the metal and semiconductor is an elegant way to prevent premature tunneling. Overlapping the gate with extreme-permittivity dielectric enabled Gallium Oxide transistors with excellent breakdown voltage (> 600V) with a short gate-drain spacing of < 1.1 , corresponding to a breakdown field > 5.5 MV/cm. We will discuss our recent work on vertical Gallium Oxide electronics. -Ga_2O_3 trench Schottky barrier diodes fabricated through a Gallium atomic beam etching technique, with excellent field strength and power device figure of merit, were demonstrated. Reverse breakdown field strength of greater than 5.10 MV/cm is demonstrated at a breakdown voltage as of 1.45 kV.

We acknowledge funding from Army Research Office DEVCOM UWBG RF Center (program manager Dr. Thomse Oder), Department of Energy/ National Nuclear Security Administration under Award No. DENA0003921, AFOSR GAME MURI (Award No. FA9550-18-1- 0479, project manager Dr. Ali Sayir), and Air Force Research Laboratory and Strategic Council for Higher Education under Agreement No. FA8650-19-2- 9300.

4:30 PM SF04.03.03

Enhanced Thermoelectric Efficiency of ZnO-Based Transparent Tandem Thermoelectric Generators *Hyunjin Joh[1], SeongMin Park[1], WooJun Seol[1], Hyeon Jun Lee[2] and Ji Young Jo[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Kangwon National University, Korea (the Republic of)*

Transparent thin film thermoelectric materials are essential to utilize waste heat from optoelectrical devices such as hybrid solar cells, smart augmented reality (AR) glasses, and smart windows. Zinc oxide (ZnO) is a widely used transparent material for thin film thermoelectric devices because of its wide bandgap (3.37 eV), nontoxicity, chemical and thermal stability.[1, 2] However, a low thermoelectric figure of merit (ZT) of ZnO-based thermoelectric materials (ZT < 0.5), [3] resulting in the low output power density (power generation capacity per unit area), limits their application in conventional thermoelectric generator(TEG). An introduction of a Tandem structure TEG consisting of vertically stacked thin films can be a strategy to enhance the heat-collecting efficiency and output power density since the devices connected in series provide the integration of the thermoelectric voltage of each TE legs.[4]
Recently, a thin-film TEG with a metal–insulator–semiconductor (m-i-s) structure has been demonstrated with enhanced thermoelectric performance.[5] This m-i-s structure, however, has an intrinsic drawback for transparent applications due to the high light absorption by the metal layers. Additionally, the low Seebeck coefficient and high thermal conductivity of the metal layer can result in a decrease in the average performance of Tandem structure TEG. Here, we aim to enhance the performance of the transparent Tandem structure TEG by stacking transparent n and p-type ZnO based thermoelectric materials vertically.
We successfully fabricated a transparent Tandem structure TEG using Al-doped ZnO for the n-type thermoelectric layer, Cu-doped ZnO for the p-type thermoelectric layer, and aluminum oxide for the insulating layer on the quartz substrate. Atomic layer deposition (ALD) was employed to deposit thin films systematically. The stacked structures and thicknesss of each layers were observed in transmission electron microscope images, and XPS depth profile. 2% Al-doped ZnO thin film and 1% Cu doped ZnO thin film showed -150μV/K, and 90μV/K of Seebeck

coefficient at single layer, respectively. After the n-i-p structure is assembled, TEG showed -220μV of voltage difference for 1 K of temperature difference. The voltage difference increased as the TEG layers increased, and reached the maximum value at 10 layers. The output power of the TTEGs also enhanced with the number of stacked layers, and achieved the highest output power of 100 nW.

Exploring Negative Permittivity in ($La_{1-x}Sr_x$)FeO_3—Insights and Implications *Rajni Baranwal and Shail Upadhyay; Indian Institute of Technology (BHU), India*

Materials exhibiting negative permittivity have attracted considerable scientific interest in recent years due to their potential applications in electromagnetic shielding, capacitors, transistors, antennas, inductor design, and other electronic devices. Negative dielectric constants (NDC) are commonly observed in metals below their plasma frequency, a phenomenon resulting from the plasmonic oscillation of free electrons. The negative dielectric properties of metals have driven the exploration and fabrication of metamaterials, where tunable negative permittivity is achieved through the precise design of the geometric dimensions and configurations of metallic components. However, identifying systems with negative dielectric properties remains a challenging endeavor, and there are relatively few reports available on such materials. The investigation undertaken encompasses a systematic exploration into the structural, electrical, and functional attributes of ($La_{1-x}Sr_{x)}FeO_3$ compositions across a range of x values (0.1,0.2,0.3,0.4,0.5). Synthesis of the specimens occurred via the solid-state synthesis route. The orthorhombic crystalline structure, similar to that of $LaFeO_3$, exhibited persistence across the entire spectrum of compositions examined, indicating minimal structural deviation consequent to the inclusion of $SrFeO_3$. Elemental profiling and surface morphology evaluation were performed, likely employing SEM or EDX methodologies. Dielectric study was conducted in the temperature range 40°C- 500°C revealing the negative dielectric permittivity across the room temperature to high temperature. The intricacies of relaxation conduction mechanisms were scrutinized to elucidate the electrical behavior of the materials under diverse conditions. These analyses facilitated a deeper comprehension of the interplay between structure and dielectric properties attributes within the materials. Collectively, these findings afford a comprehensive insight into the ($La_{1-x}Sr_{x)}FeO_3$ system, offering avenues for further exploration and application, particularly in fields reliant on multifunctional materials.

SESSION SF04.04: UWBG I: Diamond and Related Materials

Diamond, an Ultra Wide Bandgap Semiconductor—Challenges for Power and RF Electronic Applications

Robert J. Nemanich, Harshad Surdi, Yu Yang, Franz A. Koeck, Stephen M. Goodnick and Trevor Thornton; Arizona State University, United States

Great strides in diamond wafer technology and diamond epitaxy have inspired new concepts for diamond electronics particularly for power conversion and RF applications. For diamond, the ultra wide bandgap supports high fields, the high electron and hole mobilities support low resistance and bipolar current transport, and the highest bulk thermal conductivity enables high power applications. A specific example includes PIN diodes that demonstrate current density greater than 100 kA/cm2 and high frequency operation in receiver protect circuits. However, the relatively high activation energy of substitutional p- and n-type dopants in diamond has limited the development of diodes and field effect transistors. This presentation highlights two approaches to mitigate this limitation. At the center of this research is growth of high purity, epitaxial diamond layers by plasma enhanced CVD.

The first approach considers diodes that operate much like a vacuum tube where injected carriers drift at the saturation velocity in the applied field. The current transport, which is described by the Mott Gurney expression, is considered as space charge limited current. High current PIN diodes prepared with epitaxial intrinsic and n-type (phosphorus doped) layers are described. An updated figure of merit for diamond power diodes considering this effect is discussed.

Another alternative to substitutional impurity doping is interface charge transfer at a diamond-dielectric interface. Optimized configurations result in the formation of a hole accumulation layer, which is not limited by thermal activation. However, the hole transport shows a mobility that is much lower than predicted. It is widely accepted that the low mobility is due to scattering from the near interface negative charges transferred into the dielectric layer.

Following the concept of modulation doping at heterostructure interfaces, we have proposed and demonstrated a dielectric layer configuration that results in a nearly ten-fold mobility increase for the accumulated holes at the diamond interface. In this approach MoO_3 is used as the charge transfer dielectric, and Al_2O_3 is employed as the modulation doping spacer layer. The charge transfer is driven by the energy difference between the diamond valence band and the charge transfer states in the MoO_3. The relative distribution of the charge near the interface is deduced from photoemission spectroscopy. The thickness of the spacer layer is shown to affect the hole accumulation layer.

The advantages and limitations of space charge limited current and interface charge transfer doping will be presented. New approaches including photo-enhanced doping will also be described.

Research supported by the U.S. Department of Energy (DOE) Office of Science, under Award No. DE-SC0021230 and the NSF through grant DMR-2003567.

9:00 AM SF04.04.02

Optical and Electrical Control of Conductivity and DX-Like Deep Donors in Ge-Doped AlN *Jiahao Dong and Rafael Jaramillo; Massachusetts Institute of Technology, United States*

Optically-triggered AlGaN power handling devices are of interest to mitigate the electromagnetic interference and reduce the complexity of gate drivers. In these devices, optically-activated carriers can modulate the gate charge and threshold voltage; these are called photo-gating effects. However, due to the wide band gap of these semiconductors, photo-generated carriers based on band-to-band transitions require ultra-violet illumination sources, which are challenging to integrate. It would be far easier to use visible light to excite sub-band gap, *defect-to-band transitions, if sufficient device functionality can be achieved.*

In this work, we demonstrate optical and electrical control of conductivity in highly Ge-doped epitaxial AlN. Group IV dopants, such as Si and Ge, form deep donor levels in Al-rich AlGaN, that behave like DX defects. They are typically undesirable because they limit the equilibrium conductivity, but they also produce giant and persistent photoconductivity. We made Schottky contacts on epitaxial AlN thin films, with Ge concentration of $2x10^{18}$ *cm*^{3} *and higher, and measured the spectral photoconductivity. We observe a photoconductive response threshold energy of 3 eV, far below the 6.1 eV band gap of AlN. Sub-band gap excitation can increase the conductivity by 10,000 times, compared to the dark current, and the photoconductivity persists for hours after light exposure. The same films are extremely resistive in the dark at equilibrium. These are all signatures of defect-assisted photoconductivity and DX-like defects.*

Illumination can switch on conductivity quickly, but the persistent (e.g. hours-long) decay times limit the device concept. We previously demonstrated that conductivity in materials with DX-like defects can be rapidly switched by electrical charge injection at suitably-designed heterojunctions, achieving orders-of-magnitude faster response than using light, of interest for hysteretic electronic devices for memory and computing [1, 2]. Here, we demonstrate the usefulness of this concept for conductivity switching in AlN: we show that voltage pulses after illumination can suppress the persistent photoconductivity in seconds instead of hours. Also, the persistent current levels can be reconfigured and programmed with voltage pulses of variable amplitude and duration. We explain our results with a model of charge state transitions of DX-like defects in the contact space charge region.

Our study enhances fundamental understanding of deep, DX-like donors in AlN. Persistent photoconductivity due to defect-to-band transitions excited by visible light, combined with rapid electrical reconfigurability, makes doped AlN promising for optically-triggered power handling devices. The programmability of the persistent photocurrents may also make these devices of interest for memory and neuromorphic computing.

Band Alignment of Ultra-Wide Bandgap $(In_xGa_{1-x})_2O_3$ ***and AlN Heterojunction—An XPS Analysis*** *Maria Sultana, Anna Collingwood and Ariful Haque; Texas State University, United States*

The heterojunction system comprising InGaO/AlN exhibits remarkable potential for various advanced electronic applications, such as deep UV photodetectors, high-electron-mobility transistors, and high-power electronic devices. The β-$(In_{0.11}Ga_{0.89})_2O_3$*/AlN heterojunction holds significant promise for developing ultrafast responsive deep UV photodetectors with optimal spectral coverage and minimal leakage current. Conversely, the κ-*$(In_{0.15}Ga_{0.85})_2O_3$*/AlN heterojunction is expected to achieve a sheet carrier density an order of magnitude greater than that of AlGaN/GaN heterojunctions. Therefore, this research focuses on studying the pulsed laser deposition (PLD) growth parameter optimization and the valence and conduction band offset (VBO and CBO) measurements of β-*$(In_{0.11}Ga_{0.89})_2O_3$*/AlN and κ-*$(In_{0.15}Ga_{0.85})_2O_3$*/AlN heterojunction to facilitate the development of these next-generation electronic devices. Due to the extreme surface roughness of the AlN wafer, ε-*$(In_{0.15}Ga_{0.85})_2O_3$ *was formed instead of κ-*$(In_{0.15}Ga_{0.85})_2O_3$*. PLD growth optimization experiments revealed that depositing the metastable ε-*$(In_{0.15}Ga_{0.85})_2O_3$ *requires a moderate temperature, high oxygen pressure, and high laser energy density. The XPS-based Kraut's band alignment approach yielded CBO and VBO values of 3.23 and 1.45 eV for β-*$(In_{0.11}Ga_{0.89})_2O_3$*/AlN heterojunction, and 2.482 and 0.87 eV for ε-*$(In_{0.15}Ga_{0.85})_2O_3$*/AlN. The reason behind the high VBO observed for β-*$(In_{0.11}Ga_{0.89})_2O_3$*/AlN heterojunction could be assigned to the higher valence band edge binding energy of β-*$(In_{0.11}Ga_{0.89})_2O_3$ *than the ε-*$(In_{0.15}Ga_{0.85})_2O_3$*. These outcomes suggest that the heterojunctions will effectively inhibit carrier leakage, as the high CBO will create a significant obstacle for electron transport through the heterojunction.*

9:30 AM *SF04.04.04
Quantum Embedding Study of Strain and Charge Induced Stark Effects on the Nv^{-} Center in Diamond and Applications for Detection of High-Energy Particles *Cyrus Dreyer[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Flatiron Institute, United States*

The second quantum revolution promises to provide novel electronic devices including quantum computers for solving problems impossible for classical computation, and communications networks with unprecedented security. However, the area where this promise has already resulted in utility is "quantum metrology," where quantum states are used as sensitive probes of external stimuli, e.g., electric and magnetic fields. One of the most mature platforms for such metrology is via a microscopic point defect in diamond, the so-called NV^{-} color center, which involves a missing carbon atom in the diamond lattice next to a nitrogen substituting a carbon atom. This defect has been demonstrated as a powerful nanosensor for quantum metrology due to the sensitivity of the optical and spin properties to external electric and magnetic fields, as well as strain fields in the diamond lattice. We have recently proposed that such defects could be used to turn diamond into a sensor of high-energy particles via the recoil traces they create in the diamond lattice. In this talk, I will describe first-principles computational calculations based on density-functional theory (DFT) and quantum embedding methods aimed at validating this idea. We first calculate the Stark effects, i.e., the energy shits and splitting of many-body states of NV^{-} from nearby strains and electric fields, which requires going beyond DFT because of the nontrivial electron correlations in the defect states. Then, we demonstrate with calculations of defects likely to be created in recoils of atoms in the diamond lattice that nearby NV^{-}'s to such events can be used to detect the resulting strain.

Insights for Achieving High Conductivities in Ga_2O_3 and $(Al,Ga)_2O_3$ Alloys Using Hybrid Functional Calculations *Joel B. Varley; Lawrence Livermore National Laboratory, United States*

Gallium oxide continues to rapidly develop as a candidate for next-generation power electronics owing to its large band gap, controllable conductivity and the availability of large single-crystal substrates grown from the melt. Of significant interest is the formation of alloys with Al to form $(Al_xGa_{1-x})_2O_3$ (AlGO), which lead to a significant increase of the band gap analogous to the AlGaN system, but spanning a much larger rage of ~4.8 eV-8.6 eV. AlGO also exhibits the possibility of different crystal structures and lattice constants, leading to a number of possible epitaxial relationships beyond the wurtzite AlGaN system. Despite this promise, a number of questions remain as to the effectiveness of controllable donor doping and how to overcome the possibility of compensation in the limit high Al-contents, similar to that in AlGaN. Here we assess n-type doping of Ga_2O_3 in different polymorphs and consider the prospects of doping in the larger-gap Al-containing alloys using first-principles modelling approaches based on hybrid functional calculations. We consider a number of dopants such as the typical group-IV elements, as well as lesser-explored transition-metal donor dopants that have been identified as effective alternatives. We *also discuss the role of cation vacancies in the different polymorphs, which are known to be potentially problematic sources of compensation for n-type doping. Our results identify composition regimes in AlGO alloys that may be most effectively targeted for increased band gaps and effective donor doping, with composition regimes specific to particular dopant species. These results provide guidance for doping in Ga_2O_3 and related alloys incorporated into heterostructure devices.*

P-type Ga_2O_3 Epilayers Grown on Sapphire Substrate by Phosphorus-Ion Implantation Technology and Relative PN Diode Application *Ray-Hua Horng, Fu-Gow Tarntair and Xin-Ying Tsai; National Yang Ming Chiao Tung University, Taiwan*

In this study, various phosphorus-ion implantation techniques, incorporating low, medium, and high doses, were used to investigate the electrical properties of unintentionally doped β-Ga_2O_3 heteroepilayers, which were grown on sapphire substrates by metalorganic chemical vapor deposition.
The low-dose implantation involved phosphorus ions at concentrations of 1.6×10^{13}, 1×10^{12} and 2.5×10^{12} atoms/cm^2, administered at implantation energies of 100, 50, and 40 keV, respectively. The medium-dose implantation utilized phosphorus ions at concentrations of 1.6×10^{14}, 1×10^{13} and 2.5×10^{13} atoms/cm^2, at the same implantation energies. Finally, the high-dose implantation employed phosphorus ions at concentrations of 1.6×10^{15}, 1×10^{14} and 2.5×10^{14} atoms/cm^2, with implantation energies of 100, 50, and 40 keV, respectively. The implantation parameters were also simulated using the Stopping and Range of Ions in Matter software, while the actual concentration of phosphorus ions was measured via secondary ion mass spectrometry. Subsequently, Ni and Au were deposited on the annealed phosphorus-implanted β-Ga_2O_3 epilayers, followed by rapid thermal annealing at 600°C in a nitrogen environment for one minute, for Hall measurement. The electrical properties of the phosphorus-implanted β-Ga_2O_3 epilayers were assessed through Hall measurements. Notably, the β-Ga_2O_3 epilayers implanted with middle and high doses displayed p-type behavior.
The phosphorus-ion implanted Ga_2O_3 was not only demonstrated to be the p-type. Special epilayer structure has also been designed to obtain the pn diode. It was the UID Ga_2O_3 layer first, then ion implanted phosphorus into Ga_2O_3 and thermal annealing to active phosphorus and obtain p-type Ga_2O_3. After, regrew the n-type Ga_2O_3 on the p-type epilayer. Finally, the pn diode was fabricated using the mesa and electrodes deposition. Detailed processing and device performance will be discussed detail in the conference.

11:30 AM SF04.05.03

Overcoming Polarons to Achieve p-Type Conductivity in Ultrawide-Bandgap Oxides *John L. Lyons[1] and Anderson Janotti[2]; [1]U.S. Naval Research Laboratory, United States; [2]University of Delaware, United States*

A major shortcoming of ultrawide-bandgap semiconductors is their lack of bipolar doping. For some ultrawide-bandgap oxides, n-type conductivity has been demonstrated, but p-type conductivity is in general inhibited by a strong tendency to form self-trapped holes (small polarons). This problem especially afflicts Ga_2O_3, which is among the most promising UWBG oxides, but in which polaronic hole trapping causes acceptors to have ionization energies exceeding 1 eV. Related materials, such as $LiGa_5O_8$, also suffer from hole trapping. Recently, rutile germanium oxide (r-GeO_2), with a band gap near 4.7 eV, was found to break from this paradigm. Though calculations found holes trapped much less strongly, the predicted acceptor ionization energies are still relatively *high (~0.4 eV), limiting p-type conductivity [1,2]. Since r-GeO_2 appears to be an outlier, perhaps due to its crystal structure, the properties of a set of rutile oxides are calculated and compared. Our hybrid density functional calculations here show that rutile TiO_2 and SnO_2 strongly trap holes at acceptor impurities, in agreement with prior studies. However, self-trapped holes are found to be unstable in r-SiO_2, a metastable polymorph of silica with an 8.5 eV band gap. Group-III acceptor ionization energies are also found to be lower in r-SiO_2 than in the other rutile oxides. Furthermore, acceptor dopants have sufficiently low formation energies such that compensation by donors (such as oxygen vacancies) could be avoided, at least under O-rich limit conditions. Based on the results [3], it appears that r-SiO_2 has the potential to exhibit the most efficient p-type conductivity when compared to other UWBG oxides.*

Robust Multimodal Thermometers Based on Gallium Oxide Microwires *Manuel Alonso-Orts[1], Ruben J. Neelissen[1], Daniel Carrasco[2], Marco Schowalter[1], Andreas Rosenauer[1], Emilio Nogales[2], Bianchi Mendez[2] and Martin Eickhoff[1]; [1]Universität Bremen, Germany; [2]Universidad Complutense de Madrid, Spain*

Optical transduction for temperature sensors is an attractive approach that allows both a non-contact-mode and remote measurement of local temperature. Optical sensors can operate as luminescent or interferometric sensors, depending on the observable parameter to quantify the temperature. In the case of Ga_2O_3, Cr doped crystals can be used to monitor the local temperature through the study of the evolution of the characteristic R-lines of Cr^{3+} ions in this host. This has been probed to work nicely in the low temperature range, up to room temperature, since above RT, the R-lines emission overlaps with the broad phonon-assisted band due to the electron-phonon coupling. On the other hand, interferometric sensors can operate at higher temperatures, if the material system holds optical resonances.
In this work, we present the multimodal sensor behavior of the luminescent and interferometric properties of optical microcavities based on Cr doped Ga_2O_3 microwires, in which the optical mirrors are Distributed Bragg Reflectors (DBR) built by a suitable combination of alternate layers of TiO_2/Al_2O_3 fabricated by Atomic Layer Deposition (ALD) to favor optical resonances in the near-infrared broad band related to Cr ions in Ga_2O_3. The results show that the system can operate as a thermometer with a 1 K resolution, from low up to high temperatures. The robustness of the temperature sensor has been assessed against laser irradiation, liquid environment and stability at high temperatures. The results confirm the potential of this device to work under extreme conditions.

SESSION SF04.06: UWBG III: Ga2O3 and AlN

Ga_2O_3 and AlN—Ultra-Wide Bandgap Semiconductors for Power and RF Electronics *Huili G. Xing; Cornell University, United States*

It's of little surprise that there has been a consistent drive toward the use of wider bandgap materials for power and RF electronics. After all, the wider the bandgap, the greater the breakdown field, opening the door to making devices with a higher breakdown voltage for the same material thickness. Furthermore, the saturation velocity of mobile carriers in ultra-scaled devices tends to be about 1-2 x 10^7 cm/s in most semiconductors.
However, nature is not always that generous. Typically, a move to a wider bandgap is accompanied by more challenging doping, point defect control, ohmic contacts, quality junctions, along with difficulty in making high-quality native substrates. Ga_2O_3 and AlN are among the promising contenders, given their large bandgaps, availability of large-size bulk substrates (>2 inches), and heterojunctions. But both lack p-type. AlN possesses high thermal conductivity – slightly worse than that of copper but Ga_2O_3 has a low thermal conductivity – worse than that of sapphire.
Given all these promises and obstacles, is it possible to harvest all the benefits in AlN and Ga_2O_3 and demonstrate devices that are superior to those made from SiC and GaN? I will reflect on our efforts in seeking answers to these questions in the past many years researching on power and RF devices with a focus on Ga_2O_3 and AlN [1-7].

Delineation of Incoherent and Coherent Phonon Contributions to Thermal Transport in Semiconductor Superlattices Theodore Maranets, Haoran Cui and Yan Wang; University of Nevada, Reno, United States

Thermal transport in semiconductor superlattices and other metamaterials with secondary periodicity can be significantly influenced by phonon coherence. In superlattices, which are composed of alternating layers of two or more materials, a minimum thermal conductivity is observed as the period thickness decreases to a few atomic layers. This phenomenon is attributed to a transition between significant phonon-interface scattering and the emergence of wave-like phonons that travel through interfaces unimpeded. This transition is explained by the presence of two distinct types of phonon modes: "incoherent" phonons, which follow the dispersion relations of the superlattice base materials, and "coherent" phonons, which follow the dispersion relation of the superlattice itself. Currently, a spectral analysis of the relative contributions of these two phonon types to the thermal conductivity of superlattices and modified superlattices, such as structures with aperiodically arranged interfaces, is lacking. The atomistic wave-packet method is a powerful tool for directly simulating both incoherent and coherent phonon transport, with a unique capability to specify both wavelength and spatial coherence length. However, previous wave-packet studies on superlattices and other materials have used arbitrary values for coherence length, lacking rigor in finite-temperature physics. In this work, we propose a new methodology using temperature-dependent coherence lengths for the first time in wave-packet simulations to compute phonon *transmission spectra at finite temperatures. The results are then correlated with finite-temperature molecular dynamics simulations to estimate thermal conductivity, allowing us to directly delineate the frequency-dependent relative contributions of incoherent and coherent modes to thermal conductivity. Utilizing this technique, we rigorously analyze coherent and incoherent phonon transport in AlN/GaN superlattices at the mode level. The insights gained from our work open avenues for extreme manipulation of the thermal conductivity of semiconductor superlattices, which have critical applications in high-power devices and photonics, through specific control of different phonon modes.*

Monolayer ScN Coupled with Ferroelectric ScAlN for E-Mode GaN HEMT *Jiangnan Liu, Ding Wang, Md Tanvir Hasan and Shubham Mondal; University of Michigan, United States*

As the needs for cleaner energy and electric vehicles keeps growing, there is an inevitable demand for high efficiency power electronics, and group III-nitride materials such as aluminum nitride (AlN), gallium nitride (GaN) and their alloys have been demonstrated to have superior properties in power device applications due to their wide bandgaps. In the meantime, the polarization-induced 2-dimensional electron gas (2DEG) formed between the nitride heterostructure makes them great materials in high-electron-mobility-transistors (HEMTs). However, most (Al)GaN HEMTs operate in the depletion-mode (D-mode) which reduces the power efficiency while increasing the complexity in circuit design. Extensive research on GaN HEMTs have been focused on achieving enhancement-mode (E-mode) operation by recessed gate structure, fluorine plasma treatment and p-GaN gates yet these structures will suffer from poor stability or limited threshold voltage (V_{th}) tunability. Recent works on incorporating oxide-based ferroelectric materials coupled with charge trap layers in GaN HEMTs have shown to be another route to achieve E-mode operation yet it mostly requires an ex-situ deposition of the ferroelectric layer and a relatively thick charge trap layer. Over the past few years, a novel nitride ferroelectric nitride material, scandium aluminum nitride (ScAlN) has emerged in various applications due to its high breakdown field, high Curie temperature, etc. and can be grown in-situ with conventional HEMT structure in molecular beam epitaxy (MBE) or metal-organic chemical vapor deposition (MOCVD) system. Here, we present a fully-epitaxial E-mode HEMT with ferroelectric ScAlN gate coupled with monolayer scandium nitride (ScN) serves as the charge trap layer and AlGaN/GaN channel. The threshold voltage can be tuned to 1.3 V and shows great stability with a large ON/OFF ratio more than 10^7. Complete structure from the AlGaN/GaN interface to the ScAlN/ScN gate are grown in MBE system under ultra-high vacuum to provide clean heterostructure interfaces, enabling a low subthreshold voltage (SS) of 61 mV/dec, which is close to the Boltzmann limit. This provides a pathway to implement wide-bandgap materials in efficient power devices with fail-safe operation.

2:30 PM SF04.06.04

Defect Engineered Functional Properties in Ferroelectric Aluminum Nitride *Kyle Kelley[1], Bogdan Dryzhakov[1], Steven Randolph[1], Chloe Skidmore[2], John Hayden[2] and Jon-Paul Maria[2]; [1]Oak Ridge National Laboratory, United States; [2]The Pennsylvania State University, United States*

The recent discovery of ferroelectricity in cation-substituted aluminum nitride has sparked significant interest within the ferroelectrics community. Aluminum nitride boasts highly desirable properties such as a wide bandgap, excellent electrical resistance, exceptional thermal conductivity, and an extremely high phase transition temperature, while also being compatible current semiconductor fabrication workflows. However, its inherent high coercive field poses a challenge for its deployment in low-energy applications. This study investigates strategies to mitigate the coercive field in boron-substituted aluminum nitride, focusing on ion irradiation and the effects of varying thin film thickness. Optical spectroscopy, scanning transmission electron microscopy, and piezoresponse force microscopy are employed to analyze the influence of defects on the coercive field. By elucidating these *mechanisms, this research aims to advance our understanding of coercive field reduction strategies in boron-substituted aluminum nitride, paving the way for its broader integration into the next generation of high power electronic and optoelectronic devices.*

2:45 PM SF04.06.05

Enhancing Moldability and Thermal Conductivity of Epoxy by Incorporating Long Alkyl Chains into Liquid Crystal Polymer Mesogens *Jiseon Choi and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)*

As electronic technology advances, the miniaturization and integration of devices are accelerating. While these changes offer numerous benefits and drive technological progress, they also present spatial limitations that can lead to thermal issues affecting device performance. Addressing these thermal challenges is crucial for future technological advancements. <div> </div> <div>This study explores the enhancement of moldability and thermal conductivity of epoxy, commonly used in the electronics industry, by adding long alkyl chains of varying lengths to the mesogen of Liquid Crystal Polymers (LCPs). The plate-like structure of the LCP mesogen's aromatic ring promotes easy stacking, and the incorporation of alkyl chains can reduce the melting and curing points compared to traditional LCPs. Consequently, this material exhibits higher thermal conductivity than conventional commercial epoxies and offers improved molding capabilities.</div> <div> </div> <div>To achieve this, a series of LCP mesogens with different lengths of alkyl chains were synthesized and integrated into a commercial epoxy resin. The thermal properties of the resulting composites were characterized using advanced thermal analysis techniques. The composites demonstrated significantly reduced melting and curing points, enhancing their processing capabilities.</div> <div> </div> <div>Based on this study, the integration of LCP mesogens with varying alkyl chain lengths into commercial epoxy resin successfully improved the thermal conductivity and moldability of the composites. The resulting materials exhibited lower melting and curing points, enhancing their processing capabilities. These advancements suggest the potential for broader applications in the electronics industry, particularly in addressing thermal management challenges. This discovery of a new LCP holds potential for advancements in electronic technology and other industries, contributing to future technological stability and development.</div>

Ga2O3 and ZnGa$_2$O$_4$ Ultra Wide Band Gap Materials Fascinating Electronic Properties *Ekaterine Chikoidze[1], Zeyu Chi[1], Corinne Sartel[1], Yves Dumont[1], Amador Perez-Tomas[2] and David Rogers[3]; [1]Université Paris-Saclay, France; [2]ICN, Spain; [3]Nanovation, France*

A new generation of UWBG semiconductors will open new territories for higher power rated power electronics and solar-blind deeper ultraviolet optoelectronics. Gallium oxide - Ga2O3 (4.5-4.9 eV), has recently emerged pushing the limits set by more conventional WBG (~3 eV) materials such as SiC & GaN as well as for transparent conducting oxides (TCO) like In2O3, ZnO and SnO2 to name a few. Indeed, Ga2O3 as the first oxide used as a

semiconductor for power electronics, has sparked an interest in oxide semiconductors to be investigated (oxides represent the largest family of UWBG). Among these new power electronic materials, AlxGa1-xO3 may provide high- power heterostructure electronic and photonic devices at bandgaps far beyond all materials available today (~8 eV) or ZnGa2O4 (~5 eV) enables spinel bipolar energy electronics for the first time ever.
While there are several n-type transparent semiconductor oxides (TSO) for optoelectronic applications their required p-type counterpart oxides are known to be more challenging. We have demonstrated that Ga2O3 is also the intrinsic (or native) p-type TSO. [1] A low activation energy of conductivity as E_{a2} *= 170 ± 2 meV was determined, associated to the [endif]-->native acceptor defect complex. The incorporation of Zinc impurity effects the electronic properties of Ga2O3 thin films grown by MOCVD technique in a very divers way. When Zn is <1%, ie. doping case, the conductivity of* Ga_2O_3*:Zn film was remarkably increased by three orders of magnitude, showing a long-time stable room-temperature hole conductivity with the conductivity activation energy of around 86 meV.[2] While "alloying" case resulting to ZnGa2O4 (Eg~5eV) spinel structure with both n and p type native conductivity thanks to cation inversion. [3,4,5]*

In 2019, we first reported [6] a two-dimensional electron gas (2DEG) onto β-Ga_2O_3*, a solid that is a pure insulator in its bulk but has a metallic conductive termination presenting a two-dimensional conductive channel at its surface.* β-Ga_2O_3 *thin films exhibited degenerate semiconductor conduction with a room temperature* $n = 8\times10^{18}$ cm^{-3} *electron concentrations and* μ *= 19* cm^2/Vs *Hall electron mobility. Under the Thomas-Fermi approximation, the sheet charge concentration of the 2DEG is* $n_s \sim 2\times10^{14}$ cm^{-2}*. This 2DEG was found to be resistant to high dose proton irradiation (2 MeV, 5 ×* $10^{15}cm^{-2}$ *dose) and was largely invariant (metallic) over the phenomenal temperature range of 2 K -850 K. In 2023, we first reported [7] a two-dimensional hole gas (2DHG) onto*β-Ga_2O_3*. Although two-dimensional electron gases have been realized in a number of semiconductor surfaces, examples of two-dimensional hole gases (2DHG) - the counterpart to 2DEG - are still very limited.*

Ga2O3 Semiconductor Gas Sensors for Operation at High Temperature *Andriy Zakutayev; National Renewable Energy Laboratory, United States*

Electronic devices that can operate in extreme conditions are required for a broad range of electronic and energy applications. For example, high-temperature hydrogen gas sensors are needed for use in other manufacturing technologies where current semiconductor such as Si have limitations. In contrast, emerging (ultra) wide-bandgap (UWBG) semiconductors such as SiC, GaN, Ga_2O_3 *can operate at high temperature. The* Ga_2O_3 *is particularly promising for this application, because it is natively robust to oxidation, and since has much lower projected wafer* *cost.*

In this talk, I will provide a research update about our progress towards developing Ga2O3 semiconductor devised that can operate as hydrogen gas sensors for operation at 600C and higher ambient temperature. The role of p-type heterojunction contacts to n-type Ga2O3, such as NiO or Cr2O3, will be discussed. The importance of reaction and interdiffusion layers at these and other heterogeneous interfaces will be emphasized.

4:30 PM SF04.07.03

Engineering Dielectric and Field Plate for High Field and Thermal Management in High-Power Vertical β-Ga_2O_3 Schottky Diodes *Ahsanul Mohaimeen Audri[1], Chung-Ping Ho[2], Jingjing Shi[2] and Esmat Farzana[1]; [1]Iowa State University of Science and Technology, United States; [2]University of Florida, United States*

The ultra-wide bandgap (UWBG) semiconductor, β-Ga_2O_3, has gained great interest for high-power electronics due to its large bandgap of (4.8eV), high breakdown field (8 MV/cm), and the availability of native substrates. These advantageous properties also make them attractive candidates for extreme environment applications that necessitate operation under high electric field, high temperature, and harsh radiation. However, a key requirement for robust high-power devices is to have ability to manage extreme heat and high field effects to prevent accelerated thermal or electrical failure. This is particularly challenging for β-Ga_2O_3 devices due to the low inherent thermal conductivity of β-Ga_2O_3 (11 -24 W/m K), which is an order of magnitude lower than other (U)WBG semiconductors. To circumvent this limitation, efficient β-Ga_2O_3 device design strategies need to be developed that can address both high field and thermal effects in high-power applications. However, to date, most vertical β-Ga_2O_3 device reports have focused on maximizing the device performance by managing high field effects, without incorporating thermal considerations. Although thermal management of β-Ga_2O_3 devices have been investigated, the existing reports predominantly focused on lateral device structures, keeping vertical β-Ga_2O_3 power switches largely unexplored. Hence, an electro-thermal co-design of vertical β-Ga_2O_3 Schottky barrier diodes (SBDs) is fundamentally required since vertical devices are the preferred choices of multi-kV power switches compared to the lateral counterparts.

Towards this goal, we explored vertical β-Ga_2O_3 SBD by engineering device design and field management strategies that can address both high field and thermal management. For field plates, we investigated a stack of high-permittivity (κ) dielectric ($BaTiO_3$ or TiO_2)/AlN where the top high-κ dielectric will maximize field reduction and bottom AlN will enhance heat transport at β-Ga_2O_3 interface. The AlN is utilized as insulator due to its poor electrical conductivity but excellent thermal conductivity (up to ~340 $Wm^{-1}K^{-1}$), high critical breakdown field (15.4 $MVcm^{-1}$), and higher conduction band offset (ΔE_C =0.6 to 1.34 eV) with β-Ga_2O_3 compared to $BaTiO_3$ (ΔE_C~0.08 eV), which can enable enhanced heat transport, high field sustainability, and reduced leakage at the field-plate interfaces.

Here, we performed Silvaco TCAD modeling to obtain Joule heat power profile in vertical β-Ga_2O_3 SBDs of 10 μm drift layer (doping $1x10^{16}$ cm^{-3}) with field-plate (FP) formed using $BaTiO_3$ (250 nm, κ=150) versus stacked $BaTiO_3$ (150 nm)/AlN (100 nm). For the $BaTiO_3$ FP SBD, a concentrated Joule heat hotspot was found to appear at Schottky contact edge near field plate. However, the peak Joule heat power was reduced by 80% with $BaTiO_3$/AlN FP due to the enhanced transport by AlN at interface. Moreover, at reverse bias, the peak field of $BaTiO_3$/AlN FP SBD appeared in AlN which has higher breakdown field than β-Ga_2O_3. Thus, the complementary properties of two UWBG materials can improve both high field and thermal management of vertical β-Ga_2O_3 SBDs.

We also explored a combined edge termination with deep mesa etch and $BaTiO_3$/AlN FP. The deep etch was reported to improve high-voltage performance of vertical β-Ga_2O_3 SBDs by terminating high field at anode edges [1]. We obtained that the deep etch can also further decrease the concentrated thermal hot spot at Schottky edges, with a monotonic reduction of Joule heat power by 14%, 26%, 36%, and 44% observed for etch depths of 1, 2, 3, and 4 μm compared to the planer SBD.

To gain insights about the thermal boundary conductance (TBC), we are investigating TBC across AlN/β-Ga_2O_3 and $BaTiO_3$/β-Ga_2O_3 interfaces using the Landauer approach. We also fabricated AlN/β-Ga_2O_3 and TiO_2/β-Ga_2O_3 structures on HVPE-grown 10 µm β-Ga_2O_3 wafers for electrical and thermal characterization, which will be reported at the conference.

Discovery of Unamorphizable Semiconductor *Andrej Kuznetsov; University of Oslo, Norway*

Radiation tolerance is determined as the ability of crystalline materials to withstand the accumulation of the radiation induced disorder. Nevertheless, for sufficiently high fluences, in all by far known semiconductors it ends up with either very high disorder levels or amorphization. Here we show that gamma/beta (γ/β) double polymorph Ga_2O_3 structures exhibit remarkably high radiation tolerance [1]. Specifically, for room temperature experiments, they tolerate a disorder equivalent to hundreds of displacements per atom, without severe degradations of crystallinity; in comparison with, e.g., Si amorphizable already with the lattice atoms displaced just once. We explain this behavior by an interesting combination of the Ga- and O- sublattice properties in γ-Ga_2O_3. In particular, O-sublattice exhibits a strong recrystallization trend to recover the face-centered-cubic stacking despite the stronger displacement of O atoms compared to Ga during the active periods of cascades. Notably, we also explained the origin of the β-to-γ Ga_2O_3 transformation, as a function of the increased disorder in β-Ga_2O_3 and studied the phenomena as a function of the chemical nature of the implanted atoms. As a result, we conclude that γ/β double polymorph Ga_2O_3 structures, in terms of their radiation tolerance properties, benchmark a class of universal radiation tolerant semiconductors.

Ion Irradiation Induced Phase Transformation in -Ga_2O_3 Through In Situ Ion Irradiation in a TEM *Djamel Kaoumi[1], Bruno Caruso[1], Angelica Lopez Morales[1], Ryan Schoell[1], Andrej Kuznetsov[2] and Farida A. Selim[3]; [1]North Carolina State University, United States; [2]University of Oslo, Norway; [3]Arizona State University, United States*

This research reports the effects of radiation damage and temperature on the stability and semiconductor properties of gallium oxide (Ga_2O_3). Along with considering how the semiconductor properties (electrical and optical) are affected, it is important to understand the irradiation response of a Ga2O3 single crystal in terms of its structure using in-situ irradiation in a TEM. Characterizing the phases present at different irradiation doses through the use of electron diffraction can reveal transition doses and, in turn, phase stability. This is all the more important than Ga2O3 is known to be polymorphic that can be present in six different phases: α, β, γ, δ, ε and κ. Monitoring radiation effects in terms of possible phase changes and radiation damage (black dot and loop formation) is critical to understanding the possible changes in physical properties. In the literature, a phase *transformation from β to κ was reported in bulk Ga2O3 at room temperature for a given dose [1]. Later, it was reported that the actual phase forming was γ and not κ. In order to bring more light onto this irradiation induced phase transformation, a systematic study is needed not only to further investigate the mechanisms of the phase transformation in Ga2O3 but also the effect of temperature in a timely manner (which has not been reported in the literature). For that matter, in situ irradiations in a TEM were done using 1 MeV Kr ion irradiation of Ga2O3 TEM foils processed through Focused Ion Beam Lift out method. The gallium oxides samples were grown either by Czochralski (CZ) or Edge-defined Film-Fed Growth (FFG) techniques. Detailed Diffraction Pattern analysis was performed as a function of irradiation dose, which brought more insight onto the phase transformation and temperature dependence, which will be reported in this presentation. The experiments showed that phase transformation does not require implantation of ions as the ions travel through the foil in our case. The possible mechanism will be discussed in this presentation.*

Beta to Spinel Phase Transition and Photoluminescence Properties of MgGaO Thin Films Grown by Molecular Beam Epitaxy *Tianchen Yang, Chengyun Shou, Abdullah Almujtabi, Quazi S. Mahmud, Edward Zhu, Yuan Li and Jianlin Liu; University of California, Riverside, United States*

This study explores the phase transition behavior and photoluminescence (PL) characteristics of MgGaO thin films grown via plasma-assisted molecular beam epitaxy, with varying Mg atomic percentages ranging from 0 to 15.26%. Systematic investigation reveals distinct phase boundaries: MgGaO films exhibit pure β-phase at lower Mg concentrations (0-4.05%), a coexistence of β-phase and spinel phase at intermediate Mg levels (6.71-12.04%), and complete transition to pure spinel phase at higher Mg concentrations (13.31-15.26%). Structural analysis via X-ray diffraction confirms these transitions and identifies corresponding changes in lattice parameters. Comprehensive PL studies, encompassing room temperature measurements as well as power and temperature-dependent analyses, have revealed distinct emission spectra and mechanisms intrinsic to β-MgGaO and spinel $MgGa_2O_4$*. These investigations have elucidated defect energy levels associated with various entities such as self-trapped holes (STH), deep donors from oxygen vacancies, deep acceptors involving Mg on Ga sites, and acceptor complexes formed with Ga and O, which are pivotal for advancing optoelectronic applications of these materials. This research enhances our understanding of MgGaO alloy phase evolution and provides insights for optimizing ultra-wide bandgap semiconductor devices.*

Probing Charge Trapping of High k Dielectric Stacks Under Ionizing Radiation *Devika Mehta, Christopher R. Allemang, Aldo I. Vidana, Jeffrey Ivie and Shashank Misra; Sandia National Laboratories, United States*

The integration of high k dielectrics in metal-oxide-semiconductor (MOS) devices has been revolutionary for advancing conventional semiconductor devices due to their low leakage and thermal stability at exceedingly low effective oxide thicknesses. Under extreme conditions such as high energy x-ray exposure, electron-hole pairs are generated in the dielectric stack and subsequently trapped, in the form of oxide trapped charge or as interface traps, which will create charge buildup, resulting in a measurable shift in the flatband or threshold voltage of a MOS capacitor or MOS field effect transistor (MOSFET), respectively. Here, we evaluate and report the response of multilayer dielectric stacks to x-ray exposure, with a focus on understanding charge trapping between layers, in an effort to understand the behavior of these materials and their interfaces under extreme conditions.
Dielectric films of HfO_2 *and* Al_2O_3 *are successively grown via atomic layer deposition (ALD) and fabricated into*

MOS capacitors on a p-type Si substrate with an aluminum top gate. The thicknesses and layering of the dielectric layers were selected to assess how charge is generated, tunnels and recombines. Charge can be trapped via a mismatch in mobility between holes and electrons as well as engineered by the order in stacking of the dielectric layers, which form energy barriers generated by offsets in their respective valence and conduction band edges and/or through band bending at equilibrium. As these charges travel through these layers and recombine to ultimately restore the flatband voltage, we aim to characterize their transport through the following measurements.

Initial characterization includes a multi-frequency capacitance-voltage (CV) measurement to study the interface trap density. Throughout ionizing radiation dosing, single high-frequency CV measurements are performed to evaluate the dependence of flat-band voltage shift on dose. After dosing, a series of CV measurements are performed as a function of time to analyze room-temperature annealing which yields information on the placement and movement of these charges.

10:30 AM *SF04.09.01

Recent Progress in Crystal Growth and Defect Evaluation of Gallium Oxide *Kohei Sasaki and Akito Kuramata; Novel Crystal Technology, Inc., Japan*

Although the band gap of β-gallium oxide (β-Ga_2O_3) is about 4.5 eV, 1) a shallow donor level can be formed by doping with donor impurities, and the carrier concentration can be controlled over a wide range (10^{15}-10^{20} cm^{-3}) at room temperature. In addition, as in the case of Si and GaAs, large-diameter bulk single crystals with high quality can be obtained by using the standard melt growth method. Although the impact ionization rate of β-Ga_2O_3 has not been measured yet, the breakdown electric field strength is estimated to be about 6-8 MV/cm from the breakdown characteristics. 2, 3) Because of these attractive features, the development of β-Ga_2O_3 power devices has been vigorously pursued over the past ten years.

Because of its large band gap, β-Ga_2O_3 can normally operate as a semiconductor even in high-temperature environments where Si devices cannot operate. The material is also expected to have high radiation hardness, and various evaluations have been conducted to this end.4) For device application, it is important to establish a technique for producing crystals with low defect densities and to understand the distribution of defects in a wafer; these requirements are not limited to devices meant to operate in severe environments, but also apply to general power devices. In this talk, I will explain recent progress in crystal growth technology of β-Ga_2O_3 and the latest trend in crystal defect evaluation.

Various methods, such as the Czochralski method, edge-defined film-fed growth (EFG) method, 5) and vertical

Bridgman method, have been investigated for β-Ga_2O_3 bulk crystal growth. For power-device applications, it is essential to increase the diameter of the wafer to 6 inches or more. At present, the EFG method has the largest diameter, with 6-inch wafers having been demonstrated. One of the future problems with β-Ga_2O_3 bulk crystal growth is its high cost. Each of the above-mentioned growth methods uses an expensive metal crucible, which greatly affects the fabrication cost. Recently, a new method that does not use a metal crucible has been studied. Epitaxial methods, including molecular beam epitaxy (MBE), 6) halide vapor phase epitaxy (HVPE), 7) and metalorganic vapor phase epitaxy (MOCVD), have been studied as ways of growing β-Ga_2O_3. These methods have advantages and disadvantages, and it is expected that their development will advance in parallel for the time being. At present, HVPE is widely used to grow thick films with low-donor concentrations for vertical devices, and MBE or MOCVD is widely used to grown thin films for horizontal devices.

X-ray diffraction, the etch pit method, X-ray topography, and transmission electron microscopy, i.e., methods that have been used on other semiconductors, have been used to evaluate the crystal defects of β-Ga_2O_3. In particular, emission microscopy is useful for studying the relationship between device characteristics and defects.8) The quality of wafers has been improved by utilizing these technologies. On the other hand, there is a problem that a nondestructive defect inspection method has not been established. In particular, the widely used photoluminescence and cathodoluminescence methods that work on GaN and SiC cannot be used to inspect β-Ga_2O_3wafers. Here, I would like to summarize the progress made so far on a defect evaluation technique and its prospects.

Orientation Control of Anatase Nb-doped TiO_2 Epitaxial Thin Films by Mist Chemical Vapor Deposition

Reiichi Ueda[1], Tomohito Sudare[1], Yumie Miura[1], Ryo Nakayama[1], Ryota Shimizu[1], Naoomi Yamada[2], Kentaro Kaneko[3] and Taro Hitosugi[1]; [1]The University of Tokyo, Japan; [2]Chubu University, Japan; [3]Ritsumeikan University, Japan

[Introduction] Anatase titanium dioxide (TiO_2) thin films attract considerable attention in the field of catalysis[1], sensors[2], and electronic devices[3]. The physical properties of anatase TiO_2 thin film generally depend on their crystallographic orientation. The underlying substrate plays a crucial role in controlling the orientation. To date, orientation control has been achieved using $LaAlO_3$ (LAO), $SrTiO_3$ (STO), $[LaAlO_3]_{0.3}[SrAl_{0.5}Ta_{0.5}O_3]_{0.7}$ (LSAT), and Y-stabilized zirconia (YSZ) substrates with pulse laser deposition and sputtering methods[4]. However, few reports exist on controlling crystallographic orientation besides [001] and [012] orientation.

The mist chemical vapor deposition (CVD) method is excellent at controlling the crystal growth orientation. In the film formation process, the chemical reactions of precursors in the mist and the epitaxial effects from the substrate work concertedly. As a result, metastable crystal phases often appear[5]. On this basis, we employed mist CVD to fabricate epitaxial anatase Nb-doped TiO_2 (TNO) thin films and investigate the influence of the substrate, aiming to control the crystallographic orientation.

[Experimental method] TNO epitaxial thin films were fabricated using a hot-wall type mist-CVD. LAO (100) and α-Al_2O_3 (0001) single-crystal substrates were used. To prepare the precursor solution, titanium tetra-isopropoxide,

$Ti(OC_3H_7)_4$, and niobium ethoxide, $Nb(OC_2H_5)_5$ were dissolved in hexane. The substrate was put in the furnace, and the precursor solution was atomized in the glass bubbler and introduced to the electric furnace by the flow of nitrogen gas (99.99%). The 20 nm thick film was deposited on the substrate by keeping the temperature at 500 °C for 40 minutes. Subsequently, the as-deposited films were subjected to vacuum annealing treatment. The crystal structure, crystallinity, and crystallographic orientation of the thin films were characterized by X-ray diffraction (XRD) measurement. The electrical transport properties were evaluated using the van der Pauw method.

[Results and Discussion] When TNO was deposited on LAO (001) single-crystal substrate, (001)-oriented epitaxial thin films with (112)-orientation secondary domains were formed. This is consistent with cases in other deposition methods. In contrast, (112)-orientated anatase-TNO were formed when the films were deposited on α-Al_2O_3 (0001) single-crystal substrate. Interestingly, although α-Al_2O_3 (0001) single-crystal substrate has been used for rutile TiO_2 epitaxial thin films in physical vapor deposition, (112)-oriented anatase TiO_2 is formed in mist-CVD. Furthermore, we measured resistivity along the in-plane direction. The obtained films on α-Al_2O_3 (0001) and LAO (100) show 2.7×10^{-2} and 7.6×10^{-4} Ω cm at room temperature, respectively. This is reasonable based on a larger effective mass of TiO_2 for [001] direction than for [100] directions[6]. These results provide fundamental insights for accessing unexplored physical properties by achieving epitaxial thin film growth with unprecedented orientations by selecting single-crystal substrates in the mist-CVD process.

Characteristics of Atomic Layer Deposited SnO_2 by Al Doping at Various Positions

Jangho Bae, Taeyoon Lee, Soohyun Yoon, Dowook Lee, Heejun Yoon and Hyeongtag Jeon; Hanyang University, Korea (the Republic of)

Tin dioxide (SnO_2), which has a low melting point and wide bandgap (3.5~4.0eV), has properties suitable for applications such as transparent conductive oxide thin film transistors and active layers. However, SnO_2 has high conductivity and has the property of reducing the on/off current ratio, so research on lowering the off current is necessary to improve the electrical properties. In addition, the SnO_2 thin film contains many defects such as oxygen vacancies, making it difficult to control carriers and impurities in the thin film. The doping process using atomic layer deposition (ALD) has the advantage of reducing off-current and accurately contolling thickness. Among the dopant elements used as acceptors in SnO_2 thin films, aluminum (Al) has a higher oxidation potential (1.66V) than Sn (0.04V). Therefore, Al atoms react more strongly with oxygen than Sn, reducing oxygen vacancies in SnO_2.

In this study, we examined the effect of Al dopants used as the acceptor in SnO_2 with various doping positions of Al_2O_3 for lowering the oxygen vacancies and improving $I_{on/off}$ ratio. Al doped SnO_2 (SnO_2:Al) thin films were deposited using thermal ALD with precursors of TDMA-Sn, TMA and O_3 as a reactant. Post-deposition annealing was carried out in an oxygen atmosphere to diffuse Al atoms uniformly and lowering oxygen vacancies of SnO_2 thin film and

SnO_2:Al thin films deposited with different Al_2O_3 doping positions. The positions of Al were controlled by inserting twenty Al_2O_3 cycle into the bottom, middle, and top positions out of 121 cycles (10nm thickness) using supercycle ALD method. X-ray photoelectron spectroscopy (XPS) was used to analyze the chemical bonding state and compositions of SnO_2 thin film and SnO_2:Al thin film. It was confirmed that the SnO_2:Al thin film contained low impurity (<3%) such as carbon and nitrogen. Additionally, the oxygen vacancies within the SnO_2:Al thin film reduced significantly compared to undoped SnO_2 thin film. Hall measurement analysis was examined to determine the electrical properties of SnO_2 thin film and SnO_2:Al thin film. Compared to the undoped SnO_2 thin film, the carrier concentration value decreased from 4.15×10^{22} to 6.12×10^{16}. Through this study, we examined the effects of various doping positions on Al-doped tin dioxide thin films by comparing their structural, chemical, and electrical properties.

11:30 AM SF04.09.04

DFT-Informed Kinetic Monte Carlo Simulation of Multiphase Thin Film Growth *Anter El-Azab and Ahmad Ahmad; Purdue University, United States*

Multiphase thin films grown via Pulsed Laser Deposition (PLD) technique have gained a significant attention in recent years due to their unique physical functionalities. In films with pillar-in-matrix configurations, vertical interfaces induce interesting physical, optical and chemical properties. Despite extensive experimental reports on multiphase film growth, a theoretical comprehension of the growth mechanisms and the influence of structure on properties is still lacking. In the case of growth morphology, it is known that both kinetic and thermodynamic factors are important but the relative roles of these factors are not yet understood. In this seminar, we report on a recently developed multiscale computational model of film growth. This model is based on kinetic Monte Carlo (kMC) simulation of film deposition and growth that is informed by Density Functional Theory (DFT) parameterization of diffusion and bonding energetics, and a continuum solution of the elastic strain arising from mismatch in the heterogeneous film system. The elastic problem resulting from lattice and thermal mismatch between the substrate, matrix and pillar materials is cast in the form of Representative Volume Element (RVE) with average constraints and solved using Fast Fourier Transform (FFT). The kMC simulations reveal the impact of the PLD growth conditions on the output morphology. Furthermore, DFT investigations of the impact of strain on the bonding and diffusion of adatoms/molecules on the surfaces reveal that the local strain can play a significant role in the phase separation mechanism of oxide-metal systems. The simulations are performed for Au-CeO_2 film system deposited on $SrTiO_3$ (001) substrate.

Fermi-Level Mediated Acceleration of Flash Sintering of Oxide Ceramics *Qin-Kun Li, Evgeni Penev and Boris I. Yakobson; Rice University, United States*

"Flash" processing is a powerful versatile method for quick synthesis of a wide variety of materials, which is hard to achieve by any other methods [1,2]. This ultrafast process can swiftly realize in practice what is identified through high-throughput materials screening as a target for practical use. Flash sintering of functional metal oxide ceramics is one of the best examples. The similarity in flash-processing conditions possibly underlies a common mechanism, yet the mechanisms of the reactions and the physics behind remain speculative. Equipped by first-principles calculations, we unravel [3] how charge compensation and equilibrium of a range of defects in the prototypical yttria-stabilized cubic ZrO_2 (YSZ) lead to Fermi level shifts at different stages of flash, thereby accelerating cation migration for fast mass transport and sintering kinetics. The charge transition of the Zr vacancy, V_{Zr}^q, reduces its volume diffusion barrier by 2 eV, in V_{Zr}^{-4} state during flash, relative to V_{Zr}^0 before the surging of flash current. The V_{Zr}^q charge state is changed by the presence of nonstoichiometric defects, Y substitutions on Zr as electron acceptor favor V_{Zr}^0 before flash, whereas excessive oxygen vacancies thermally generated at the onset of

flash sintering donate electrons to conduction band edge, leading to Fermi level upshift and thus favoring V_{Zr}^{-4}. The proposed mechanism of Fermi-level driven cation diffusion scheme for YSZ has considerable bearing on the general theory of flash sintering techniques in oxide ceramics and other functional materials. This work is supported by the Office of Naval Research (N00014-22-1-2788).

Material Advancements in High-Power Module Packaging for Traction Inverters in Electric Vehicles *Achim Strass; Nexperia Germany GmbH, Germany*

Power modules are core components of inverters and converters in solar power plants, data center power supplies and in electric vehicles. Their packaging technology has a critical impact on system performance, reliability and lifetime. Due to their superior material properties, wide bandgap (WBG) semiconductors like Silicon Carbide (SiC) and Gallium Nitride (GaN) enable the application of power electronics at higher temperature operation, higher frequencies, and higher efficiencies as compared to silicon (Si).

Conventional single sided cooled frame-type power modules have been one of the most common package structures for automotive applications. However, this design constrains the performance of both traditional IGBT and future SiC power modules due to parasitic inductance and heat dissipation challenges. Recent advancements in power module packaging technologies—including concept, material, and process innovations—have emerged in response to increased performance expectations for power semiconductors.

We provide an overview of cutting-edge automotive power module packaging materials and processes, emphasizing their application in traction inverters for electric vehicles. We examine the driving factors behind modern packaging and interconnect technology development, highlighting the transition from frame-type to compact plastic-molded power modules. Molded modules offer greater flexibility and are often custom designed for specific inverter environments. Currently, the highest thermal performance is achieved with thin double-sided cooled power modules.

Recent advancements in robust topside interconnection technologies for WBG semiconductor power devices are crucial to meeting the demanding lifetime requirements of new high-end electric vehicles. Nexperia has introduced the copper clip interconnect technology for robust high-power cascode GaN devices. For die attach, Cu sintering has a high potential to replace state-of-the-art Ag sintering because of process simplification and material cost saving.

The latest trend in power module packaging involves embedding power semiconductor devices into printed circuit *boards (PCBs). Significant technical progress has been made in this area, where integrating semiconductor dies into the circuit board significantly reduces converter size. This integration shortens current loops, resulting in lower interconnection resistances and parasitic inductances, which in turn enhances system-level efficiency by reducing conduction and switching losses.*

Shallow Defect States in ZnO and ZnO:N Films—Effect of Strain and Surface Proximity on Grouping of Acceptors and Donors

Elzbieta Guziewicz; Polish Academy of Sciences, Poland

Strain can significantly modulate structural, optical and electronic properties of semiconductors [1]. The corresponding mechanism is usually regarded in terms of the twist, extension or contraction of chemical bonding causing the crystal lattice deformation. In case of ZnO, effect of strain is doubly interesting. Firstly, because this transparent semiconductor can be applied in flexible electronics, secondly, because strain in ZnO influences formation energy of defect states, and thus their abundance.

As recently established, the large variation in the conductivity values of ZnO, reaching 4 orders of magnitude for undoped material, is caused by the presence of defect complexes which include point defects, hydrogen and, in the case of a doped material, also a dopant. These complexes are origin of shallow donor and acceptor states that strongly change the conductivity of the material.

We present experimental results of scanning electron microscopy (SPEM) experiments performed on ZnO and ZnO:N films cross-sections that account for grouping acceptors and donors in separate crystallites [2]. This finding is confirmed by the cathodoluminescence (CL) images showing separated acceptor and donor emission areas in polycrystalline ZnO and ZnO:N films [3,4]. Density Functional Theory (DFT) calculations point out that the complexes involving zinc vacancy (V_{Zn}), hydrogen and nitrogen (in the case of ZnO:N) provide complexes-related acceptor states [4]. Hydrogen stabilizes formation of the $V_{Zn}N_O$ complex, but the appearing $V_{Zn}N_OH$ complex is found to be a deep acceptor. DFT calculations show that strain facilitates the formation of acceptor complexes, so they are easily created under appropriate strain/microstrain conditions or near the surface. This theoretical finding may explain the origin of acceptor and donor grouping in different crystallites. In fact, acceptor and donor complexes in ZnO and ZnO:N involve distortion of the crystal lattice, so it may be assumed that strain and/or microstrain may play an important role in grouping of acceptors and donors in crystallites with different strain. This hypothesis was verified by low-temperature photoluminescence study that reveal that the intensity of acceptor-related emission strongly depend on the structure of ZnO and ZnO:N films [5]. This finding is confirmed by cathodoluminescence images taken on the ZnO:N/Si films cross-sections showing the acceptor and donor domains situated in different crystallites in polycrystalline ZnO:N films [4]. The grouping of donors and acceptors sheds new light on the problem of the uniqueness of the electrical parameters reported for p-doped ZnO. It also gives some hope for a stable acceptor conductivity in this material in case of appropriate strain conditions.

Progress and Challenges of Lead Halide Perovskite Nanocrystals as Future Scintillators *Sergio Brovelli; University of Milano-Bicocca, Italy*

The use of scintillators for detecting ionizing radiation is crucial in various fields, such as medicine, nuclear monitoring, homeland security, and space exploration. Lead halide perovskite nanocrystals (LHP-NCs) embedded in plastic matrices are emerging as promising scintillator materials. These materials address the drawbacks of traditional scintillators, such as inorganic crystals and plastic scintillators, while leveraging their strengths. Notably, using LHP-NCs as nanoscintillators in polymer waveguides not only offers a scalable solution but also has the potential to enhance scintillation performance. This enhancement is due to the unique photophysics of quantum-confined materials, which offer size-tunable emission spectra that align perfectly with the spectral sensitivity of light detectors and ultrafast sub-nanosecond scintillation kinetics resulting from the recombination of multi-excitons generated by ionizing radiation. However, significant challenges remain, such as affordably scaling up synthesis to the multi-gram level, embedding LHP-NCs in optical-grade nanocomposites without compromising their optical properties, and gaining a deep understanding of the fundamental aspects of nanoscale scintillation mechanisms. In this talk, I will present our recent advancements in fabricating nanocomposite scintillators based on LHP-NCs. I will discuss several approaches for effective integration into plastic waveguides, including nanocrystal functionalization strategies, defect passivation, and advanced polymerization techniques. The interaction between nanocrystals and different matrices will be examined, and fundamental aspects of scintillation photophysics will be explored, including particle size and fine structure effects, aiming towards highly efficient and ultrafast scintillation.

4:00 PM SF04.11.02
Optoionics—A New Opportunity for Ionic Conduction-Based Radiation Detection *Thomas Defferriere[1], Colin T. Gilgenbach[1], Matthias Muller[2], James Christian[2], James M. LeBeau[1] and Harry Tuller[1]; [1]Massachusetts Institute of Technology, United States; [2]Radiation Monitoring Devices, United States*

We recently demonstrated the ability to use photogenerated charge carriers to modulate the grain boundary resistance of a model polycrystalline oxygen solid electrolyte thin film (Gd-doped CeO_2)[i]. These findings were inspired by the recognition that above bandgap light is well known to reduce band bending at interfaces by providing additional charge carriers which screen potential barriers. While our initial observations were limited to thin films due to short absorption depths of above bandgap light, we then demonstrated that the same concept is applicable using gamma radiation, characterized by much deeper penetration depths than UV (nm vs. mm)[ii]. We showed that we could reproduce similar optoionic effects in a bulk ceramic of Gd-doped CeO_2 (1mm thick) and that reversible resistance modulation on the order of ~10^3 near room temperature could be obtained. In this presentation, we discuss how our findings demonstrate new radiation detection device concepts that rely on modulation of ionic currents at grain boundaries in solid electrolytes rather than the collection of photogenerated charges carriers in single crystalline semiconductors. This paves the way for new, inexpensive, low-power, and *miniaturizable solid-state detection devices that can operate in harsh environments. We will discuss our approaches for engineering impedance, radiation sensitivity and response time with the aim of achieving high-performance detection. This phenomenon is yet another example of the rapidly developing field of Opto-ionics, allowing for contactless triggering of ionic conduction in solids, and is expected to apply to other classes of ion-conducting solid electrolytes (Li^+ or H^+), thus paving the way to a broad new class of radiation detecting materials.*

Sensitized Triplet-Triplet Anihilation in Nanostructured Polymeric Scintillators Allows for γ/neutrons Pulse Shape Discrimination *Luca Pollice[1], Xueqian Hu[2], Davide Rigamonti[3], Irene Villa[1], Michele Mauri[1], Marco Tardocchi[3], Francesco Meinardi[1], Christoph Weder[2] and Angelo Monguzzi[1]; [1]University of Milano-Bicocca, Italy; [2]University of Fribourg, Switzerland; [3]Consiglio Nazionale delle Ricerche, Italy*

Scintillation counters are an important family of radiation detectors that record the photon emission of scintillating materials in response to incident radiation. They are widely used in high-energy physics experiments, nuclear threat detection and power plants and medical dosimetry.

Organic liquid and plastic scintillators can not only identify, but also distinguish high-energy neutrons and charged particles from gamma-radiation background by exploiting the pulse shape discrimination (PSD). The PSD technique consists of a time-gated analysis of the transient voltage pulses generated in the photodetector of the scintillation counter. This analysis allows to assess the relative intensities of the fast and slow components of the scintillation signals, i.e., prompt and delayed emission, which in turn depend on the nature of the incident radiation and therefore constitute the base of the discrimination process.

However, achieving efficient PSD with plastic scintillators, which are attractive due to their mechanical robustness, economic effectiveness, and manufacturability compared to liquid or crystalline scintillators, has proved to be challenging. This study demonstrates that is possible to perform PSD, discriminating α-particles and neutrons from γ-rays with a time response that is better than that of commercial scintillators by exploiting nanostructured polymeric scintillators. These scintillators can be synthesized under ambient conditions in a one-pot procedure and are made of a cross-linked solid polymer matrix in which non-polar liquid nanodomains are embedded. These nanodroplets contain a triplet-triplet annihilation (TTA) active scintillating dye [1-2] and enable efficient, localized bimolecular energy transfer processes that are typically hard to achieve in solid polymers. Moreover, the liquid like molecular dynamics in the nanodroplets facilitates the energy transfer process and allows the solubilization of triplet sensitizer that is difficult to include in solids.

We show that the incorporation of this triplet sensitizer, even at ultra-low concentration, further enhances the sensitivity and discrimination ability of the scintillator compared to its non-sensitized counterparts [3].

The proposed material platform has an unprecedented compositional versatility in comparison to alternative *plastic scintillator designs, in particular with respect to the choice of the dye pairs that can be embedded. Furthermore, the TTA efficiency reached thanks to this design is impossible to achieve in conventional bulk amorphous plastic scintillators. Consequently, we anticipate that this easy-to-handle material platform will spark future developments of high-tech ultrasensitive detectors that enable the efficient and fast radiation/particles discrimination and detection of rare, low-energetic events.*

Micro-Structural and Scintillator Quality Evaluation of Cerium-Doped Lutetium Yttrium Oxyorthosilicate

Umanga De Silva[1], Darrin Byler[1], Kurt Sickafus[1], Caitlin Kohnert[1], Chris Morris[1], Stuart Miller[2], Todd Haines[2,3] and Stuart Baker[2]; [1]Los Alamos National Laboratory, United States; [2]National Security Technologies, LLC, United States; [3]Supporting Naval Research Lab, United States

Cerium-doped lutetium yttrium oxyorthosilicate (Ce-LYSO) is commonly utilized as a scintillator material in medical imaging and security scanners due to its high density, high light yield, and short decay time. This research investigates how varying particle sizes (from >250 μ to <20 μ) and sintering temperatures impact the grain sizes, pore sizes, and the distribution and density of pores in Ce-LYSO polycrystalline scintillators. Different grain sizes were produced by sintering Ce-LYSO polycrystalline powder at temperatures of 1600°C, 1700°C, and 1800°C under air, and pressing at 300 MPa. The study also looks into how combining different particle size ranges can enhance scintillator quality and how temperature influences grain and pore sizes and density. Finally, the performance of the synthesized Ce-LYSO scintillators was evaluated under X-ray imaging conditions at 225kVp, and the light yield results were reported. It is hypothesized that higher sintering temperatures and polycrystalline particle sizes result in fine-grained Ce-LYSO ceramics with superior scintillator quality.

Ultrafast Scintillating Hetero-Ligand Metal Organic Frameworks with Engineered Stokes Shift for Detection of Ionizing Radiation

Angelo Monguzzi; University of Milano-Bicocca, Italy

The Stokes shift is an important property of luminescent materials, defined as the energy difference between the absorption band maximum and the emission spectrum maximum frequencies. Its extent crucial in photonic devices because it enables to estimate in a first approximation if a specific emitter would be affected by reabsorption of its luminescence. If the Stokes shift is lower or similar to the bandwidth of the absorption and emission spectra, the consequent 'inner-filter' effect can heavily limit the lighting performance of bulk devices, and, in the worst cases, it can also affect the kinetics of the luminescence generation. Conversely, if the Stokes shift is larger than the system spectral bandwidths this effect is avoided. Thus, reabsorption-free materials are highly desirable for several applications such as fluorescence imaging, enabling to obtain high contrast images with limited excitation stray light, avoiding the use of expensive filtering component or time-consuming image post-processing. For solar applications, to realize luminescent solar concentrators without reabsorption of the condensed radiation. Similarly, the sensitivity of scintillating detectors for ionizing radiation would greatly benefit from the use of fast emitters with no reabsorption showing maximum light output intensity without effects on the

scintillation pulse timing, as required by the most advanced medical imaging, detection and metrology techniques. High efficiency, large Stokes shift emission and scintillation is obtained by realizing hetero-ligand Metal-Organic Framework (MOF) nanocrystals. [1] [2] Two fluorescent conjugated polyacene ligands of equal molecular length and connectivity, yet complementary photophysical properties, are co-assembled by hafnium oxy-hydroxy clusters, generating highly crystalline MOF. The fast diffusion of singlet molecular excitons in the framework given by the fine tuning of the ligand molecular orbitals properties, coupled to the achieved fine matching of co-ligands absorption and emission properties, enables to achieve an ultrafast activation of the low energy emitting ligands by diffusion-mediated non-radiative energy transfer in the ps time scale. [3] [4] In the optimized composition, MOF nanocrystals show an excellent scintillation yield of 13000 ph MeV^{-1}*, with an actual Stokes shift of 1.3 meV and emission lifetime of 700 ps. This large Stokes shift suppresses the reabsorption of fast emission issue in bulk devices, pivotal for a plethora of applications in photonics and photon managing spacing from solar technologies, imaging, and detection of high energy radiation. [2] Coupled to the ultrafast emission properties of the system, this allowed to realize a prototypal metascintillator for high-resolution/hi-rate of g-rays detection.*

Understanding and Predicting the Performance of Laser Diodes Under Irradiation *Blas P. Uberuaga; Los Alamos National Laboratory, United States*

Optoelectronic devices such as laser diodes often find service in extreme conditions where their performance might degrade. Thus, understanding and predicting that performance becomes paramount. However, such devices are often very complex, precluding a fundamental understanding of their properties. Here, we undertake a research effort to both make and model a simple laser diode with the goal of developing a predictive capability of its performance under irradiation from first principles.

We synthesize a simple GaAs laser diode structure and characterize the radiation-induced changes in structure and defect content, using microscopy to probe mesoscale changes in microstructure and electronic structure as well as a range of spectroscopies to examine the properties of the defective material. These properties are then correlating with changes in the overall lasing performance of the device.

In parallel, we develop models of the same device structure, using density functional theory defect thermokinetics to develop a cluster dynamics model of damage that is then input into a device-level model. The device model predicts how those defects influence the light output and the lasing power of the device. These are compared to our experimental results to understand what defects are most responsible for any observed changes in the device performance seen in our experimental efforts.

This effort provides new insight into how radiation-induced defects impact the performance of laser diodes and ultimately can lead to new strategies to mitigate those effects. In this talk, I will provide a summary of where we are in our efforts and the physical insights we have gained to date.

9:00 AM SF04.12.02

Multilayer Metascintillators Based on High Light Yield Nanocomposites Enable Ultrafast Time Coincidence Resolution *Irene Villa[1], Matteo Sala[1], Matteo Orfano[1], Valeria Secchi[1], Carsten Lowis[2], Vojtech Zabloudil[2], Etiennette Auffray[2], Martin Nikl[3] and Angelo Monguzzi[1]; [1]University of Milano-Bicocca, Italy; [2]CERN, Switzerland; [3]The Czech Academy of Sciences, Czechia*

Fast and highly emissive scintillators are requested for many advanced applications where high signal-to-noise ratio is required in a short time window. For example, to detect high rate events avoiding pile up in high energy physics experiments at the energy and intensity frontiers, coping with the challenges of unprecedented event rate and severe radiation environment; or to quickly acquire high quality images at low dose in medical applications, like in time-of-flight positron emission tomography (TOF-PET) imaging technique, where coincidence time resolution (CTR) of tens of picoseconds time resolutions are desired. Plastic scintillators fulfill the requirement of fast emission but unfortunately, their low density results into a low stopping power of high energy radiation as well as into an inadequate scintillation light yield - the ratio between the number of emitted photons and the energy deposited in the system – that is lower than the one of top inorganic scintillators. This, detrimentally limits the collected light output and consequently the detector sensitivity, especially in those applications where small detectors are required. A common strategy to improve their is the loading of polymeric scintillators with high Z elements or dense nanoparticles (NPs) to enhance the stopping power of liquid and polymeric conjugated scintillators. [1] [2] [3] Here a composite polymeric scintillator consisting in a scintillating polymeric PVT matrix embedding the BBQ scintillating dye and loaded with hafnium oxide NP is presented. By exploiting the localized radiosensitization effect of the heavy NPs, [1] we finely selected and tuned the material composition and the component properties in order to maximize the radiation's energy deposition, its harvesting and its conversion to emissive molecular excitons. The system properties have been investigated by means of steady state and time resolved photoluminescence and scintillation spectroscopy. In the best configuration, the nanocomposite shows a = 60000 ph MeV^{-1}, which surpasses any commercial plastic scintillator, and fast scintillation with 0.15 ns and 1.6 ns of rise and decay time, respectively. [5]

This fast and highly scintillating nanocomposite has been coupled to bismuth germanate oxide (BGO) realizing a prototype multilayer heterostructured scintillator pixel of 3x3x3 mm^3 of TOF-PET imaging. [4] Upon interaction with 511 keV g-rays, the energy sharing between the dense BGO, which stops the radiation, and the lighter nanocomposite is observed. This process activates the nanocomposite's fast emission enabling an excellent ultrafast coincidence time resolution (CTR) of 120 ps full width half maximum (FWHM), [5] which is about half of the one given by BGO and other crystals used in commercial scanners.

A Unique Multifunctional Neodymium(iii) Luminescent Temperature and Pressure Sensor with Slow Relaxation of Magnetisation and Unprecedented High-Pressure Behavior *Adam Gorczynski, Dawid*

Marcinkowski and Dominika Pretka; Adam Mickiewicz University, Poland

The ever-increasing demand for high-powered electronics with low power consumption, along with the challenges posed by the Big Data Problem, necessitates the development of high-density data storage systems with multifunctional capabilities.[1] Molecular nanomagnets, or Single Molecule Magnets (SMMs), may offer a solution, as their magnetic properties are inherent to the molecule, enabling device miniaturization. However, a significant challenge in creating high-performance storage media is managing temperature, as the electric current generates heat, which impairs the system's functionality.[2] Currently used gauges can only monitor temperature in bulk systems and their performance is limited by magnetic interference. Therefore, integrating the properties of a molecular nanomagnet with a luminescent thermometer into a single compound will not only allow for temperature monitoring of SMM-based devices, where temperature is crucial for the molecule's ability to retain magnetization and function as magnetic memory, but also help in understanding the process of heat generation in nanoscale devices.[3]

On the other hand, pressure sensors are becoming increasingly important across various applications, as converting pressure input into electrical signals is crucial in electronic systems. This multidisciplinary area merges material sciences with the engineering of fundamental system device technologies.[4] The most commonly used materials in luminescence manometry are inorganic systems, such as oxides, fluorides, phosphates, and vanadates, activated with different d-block or f-electron metal ions. However, their widespread application is limited by complex reaction conditions (high temperature and pressure, solubility), reproducibility of synthesis, and the homogeneity of individual samples.

Hence, we present the first well-defined bi-modal Nd(III) complex for simultaneous optical pressure and temperature sensing.[5] The multifunctionality of this system was demonstrated through temperature and pressure-dependent luminescence changes and field-induced SMM behaviour. High-pressure single-crystal X-ray diffraction, measured up to 5.0 GPa, revealed an unprecedented phase-change behavior and associated negative linear compressibility. In the α phase, strong pressure-induced absorption and emission changes are observed, allowing it to function as temperature-independent and highly-sensitive luminescent manometer (emission line shift in the NIR range: $\Delta\lambda/\Delta p$ = 2.85 nm/GPa). Furthermore, the pressure-independent band intensity ratio of Nd(III) Stark components are used as thermometric parameters, so that the designed optical sensor enables remote temperature monitoring from approximately 80 K to nearly 500 K. Moreover, field-induced slow relaxation of magnetization was observed, with a magnetization reversal barrier comparable to other state-of-the-art Nd(III) systems. Facile syntesis and unique behaviour renders this multifunctional supramolecular platform to become easily expanded to a broader range of systems for enhanced understanding of the observed phenomena.

Strategy for the Improvement of Radiation Hardness in Scintillating Materials by the Study of Localized Traps

Francesca Cova; University of Milano-Bicocca, Italy

The detection of ionizing radiation is at the heart of many strategic applications in both science and technology, including high-energy/particle physics, space exploration, medical diagnostics, border security, and industrial and environmental monitoring. In all such areas, indirect detectors are frequently used, that include scintillating materials converting the energy deposited by ionizing radiation into UV or visible photons, which are then turned into electrical signals by coupled photodetectors.

Scintillation light originates from radiative transitions at intrinsic centers or dopants used as activators: therefore, a fast and efficient transport to the luminescent centers of carriers generated upon the interaction between ionizing radiation and the scintillating material is fundamental in the scintillation process. The efficiency and speed of carrier transfer through the host matrix are affected by the presence of defects, leading to trapping levels in the forbidden energy gap, which can temporarily capture migrating charge carriers, either delaying their radiative recombination at emission centers or decreasing the overall scintillation efficiency. Experimental investigations on traps are aimed at finding their characteristic parameters, like the thermal depth, the frequency factor, and the order of kinetics, that enable to predict their lifetime at a given temperature and, consequently, their expected influence on the scintillation process. Sometimes, also the microscopic nature of such defects can be disclosed. Therefore, the study of the characteristics and role of defects in the scintillation mechanism becomes essential in the science of scintillators and has seen significant progress in the recent years, extending from inorganic single crystals to glasses, ceramics, and hybrid systems like colloidal semiconductor nanocrystals, metal-organic frameworks, and polymeric nanocomposites.

Several studies were devoted to single crystalline scintillators that usually show well-localized intragap electronic levels [1]; in contrast, an in-depth analysis of the role of point defects and of their close interplay with luminescent activators in the recombination processes governing the scintillation emission is not commonly encountered concerning amorphous materials, such as silica, due to the difficulty of disentangling trap levels subjected to inhomogeneous broadening [2,3]. On the other hand, polycrystalline ceramics [4] and nanocrystals [5] are recently emerging as promising new classes of scintillating materials; however, despite their potential, as of today, few examples tackled in depth the mechanism leading to scintillation light, as well as not much is known on the details of trapping and detrapping processes involved in their scintillation emission.

In this context, I discuss an effective approach based on the combination of thermally stimulated luminescence, temperature-dependent steady-state and time-resolved radioluminescence for the investigation of the role of trapping sites in scintillating materials and for the determination of the effects of long-term and high dose ionizing radiation exposure. Specifically, the results obtained on various classes of materials are outlined, moving from amorphous silica and bulk crystals to polycrystalline garnet ceramics and nanostructured materials.

Radiation and High Temperature Effects in Wide Bandgap Electronics *Md Abu Jafar Rasel[1], Nahid Sultan Al-Mamun[1], Sergei Stepanoff[1], Aman Haque[1], Christopher M. Smyth[2], John Watt[2], Douglas Wolfe[1], Fan Ren[3] and Stephen Pearton[3]; [1]The Pennsylvania State University, United States; [2]Los Alamos National Laboratory, United States; [3]University of Florida, United States*

Performance and reliability of microelectronic devices are governed by the mechanical strain. Typically, strain engineering implies uniformly distributed strain. However, we offer a different perspective by hypothesizing that very small but localized strain (or stress) may have significant impact on the overall behavior of AlGaN/GaN high electron mobility transistors (HEMTs). Micro to nanoscale confined mechanical stress fields may develop unavoidably and are ignored because their spatial average is insignificant. We exploit high resolution techniques such as transmission electron microscopy (TEM) and micro-Raman spectroscopy to spatially resolve the stress field in GaN HEMTs to demonstrate the stress localization and then radiation effects.

To study stress localization effects on the global electrical characteristics, we introduced a highly localized strain relief by milling a 20×30 μm^2 micro trench about 70 μm deep on the backside of an 800×840 μm^2 size HEMT die. The resulting local relaxation of in-plane residual strain was mapped using micro-Raman technique. Our results show that a decrease of only 0.02% strain can decrease the overall output saturation current up to ~20 %. The drop of output current is attributed to reduced two-dimensional electron gas (2DEG) sheet carrier density and electron mobility due to the strain relief in the device layers. However, the mechanistic process of strain relief also causes defect generation at the interfaces, which increases leakage current. Our technique for localized strain re-distribution could be an effective tool to surrogate the influence of inherent localized strain build-up across the channel of electronic devices.

To study radiation effects, we exposed the HEMTs to gamma rays (up to 10 megaRads dose at 180 kiloRads per hour). We report the thermal and mechanical responses in terms of the changes in lattice strain and temperature, which were simultaneously characterized by changes in phonon frequency of E2 (high) and A1 (LO) from on- state and unpowered/pinched off reference states. Lower doses of radiation improved the electrical properties, however degradation initiated at about 1 megaRads. We observed about 16% decrease in saturation current and 6% decrease in transconductance at the highest dose. However, leakage current increase by 3 orders of magnitude was the most notable radiation effect. We observed temperature increase by 40% and mechanical stress increase by a factor of three at dose of 10 megaRads compared to the pristine devices. Spatial mapping of mechanical stress along the channel identifies the gate region as mechanically affected area, whereas the thermal degradation was mostly uniform. Transmission electron microscopy showed contrast changes reflecting high vacancy concentration in the gate region. These findings suggest that localized stress (mechanical hotspots) may increases vulnerability to radiation damage by accommodating higher concentration of defects that promote leakage current.

Finally, we present experimental results on a novel concept of electron wind force driven room temperature annealing of GaN and SiC devices. This technique was applied on Gamma irradiated HEMT and SiC diodes. We demonstrate full recovery of the HEMTs irradiated to 10 mega-Rads gamma radiation. About 200% performance improvement was recorded for the SiC diodes. Our hypothesis is that mechanical stress waves are instrumental in eliminating interfacial defects.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

The Effects of Proton Irradiation on the Current-Voltage and Capacitance-Voltage Measurements of GeSn/Si

Photodiodes *Kevin K. Choe[1], John W. McClory[1], Bruce Claflin[2], Grzybowski J. Gordon[2] and Christina L. Dugan[1]; [1]U.S. Air Force, United States; [2]Air Force Research Laboratory, United States*

Future of optoelectronic devices focus on Ge_xSn_{x-1} alloys. GeSn (germanium tin) alloy-based devices provide the same benefits of a Mercury Cadmium Telluride (MCT) detector but are smaller, lighter, a tunable bandgap, and are less expensive due to compatibility with current complementary metal oxide semiconductors. This research investigates the impact of 40 keV and 2 MeV proton irradiations on the current-voltage (I-V) and capacitance-voltage (C-V) measurements of a GeSn/Si heterojunction photodiodes with Sn content ranging from 2% to 8%. Recent progress in non-equilibrium remote plasma-enhanced chemical vapor deposition growth techniques have enabled the crystalline growth of up to 10% Sn concentration GeSn without surface segregation. Several experimental studies in the literature currently prove GeSn achieves a direct bandgap in the range of 6%-9% Sn content which opens up opportunities for a cost-effective, tunable next-generation optical device. This study examines the effect of proton irradiation on various parameters such as ideality factor, series resistance, rectification ratio, built-in potential, and carrier concentration from the current-voltage (I-V) and capacitance-voltage (C-V) characteristics as a function of Sn content and proton irradiation are evaluated.

Dislocation Dynamics Under an Extreme Electric Field *Yu Zou; University of Toronto, Canada*

For decades, the movement of dislocations has been widely observed in crystalline solids under mechanical loading. However, the goal of manipulating dislocation motion via a non-mechanical field alone remains elusive. In this presentation, I will present real-time observations of dislocation motion controlled solely by using an external electric field in ionic crystals —the dislocations can move back and forth depending on the direction of the electric field. This work reveals the non-stoichiometric nature of dislocation cores and determine their charge characteristics. Both negatively and positively charged dislocations are directly resolved, and their glide barriers decrease under an electric field, explaining the experimental observations. This study provides direct evidence of dislocation dynamics controlled by a non-mechanical stimulus and opens up the possibility of modulating dislocation-related properties.

11:30 AM SF04.13.04

Self-Healing Radiation Sensors for Harsh Environments *Pavao Andričević; Dansk Fundamental Metrologi A/S, Denmark*

In today's landscape, characterized by geopolitical tensions, emerging nuclear threats, and a resurgence in nuclear energy utilization, the need for robust radiation sensing technology is of major importance. Due to the destructive nature of radiation, current sensors are prone to device degradation and performance deterioration, which necessitates often recalibration or replacement. This is impractical in remote applications such as nuclear reactors, submarines, or outer space. To address this challenge, we explore the potential of self-healing materials to revolutionize radiation sensing technology.

Hybrid halide perovskites stand out as a prime candidate. They offer direct radiation sensing, capable of identifying and quantifying a wide range of high-energy radiation, including X-rays, gamma rays (γ-rays), and neutrons.[1]-[3] Unlike the market-leading materials such as zinc-alloyed CdTe, perovskite single crystals can be grown from abundant and low-cost raw materials in solutions at near room temperature without the need for high-capital-demanding infrastructures. However, their key advantage, compared to commonly used radiation detection materials, lies in their ability to repair themselves, i.e., to recover their initial characteristics and performance when no longer subjected to the damaging radiation source.

In this study, we investigated the performance of a perovskite-based detector in a neutron-gamma mixed field.

Devices fabricated from methylammonium lead tribromide ($MAPbBr_3$) single crystals were tested in the cavity and core of a experimental zero-power reactor. The detectors' photocurrent response showed a strong correlation with known gamma dose rates and neutron count rates, without any signs of performance deterioration or material degradation. To further assess the impact of radiation damage, specifically neutron, X-ray diffraction, and electron paramagnetic resonance analyses were performed. $MAPbBr_3$ single crystals were irradiated within the reactor core and by a Pu-Be neutron source at liquid nitrogen temperature. Our findings indicate that the perovskite material can withstand the nominal in-core operation conditions of the reactor, experiencing cumulative thermal and fast neutron fluences on the order of 10^{12} cm^{-2} and 10^{11} cm^{-2}, respectively. Additionally, it endures irradiation at liquid nitrogen temperature, corresponding to a fast neutron fluence of approximately 10^{10} cm^{-2} and a gamma radiation dose of about 50 Gy, confirming only the temporary creation of defects. No signs of long-term deterioration were observed, indicating a potential self-healing effect.

Understanding this self-healing mechanism in perovskite could pave the way for sensors that autonomously recover during radiation exposure, significantly extending their operational lifetimes. Future research will utilize nanoelectronic characterizations, including c-AFM and KPFM, to investigate the conductive properties and defect dynamics of perovskite samples under various environmental stresses. This investigation will not only enhance our understanding of radiation resilience but also broaden the applicability of perovskites across diverse optoelectronic devices. Ultimately, perovskite-based sensors could become the cornerstone technology for reliable radiation detection in the most demanding conditions.

Variation in the Transport Characteristics of YBCO Step Edge Josephson with Ar^+ Ion Irradiation

Sandeep Kumar and Neeraj Khare; *Indian Institute of Technology Delhi, India*

Josephson junctions are pivotal for superconducting electronics, enabling advancements in quantum computing, magnetometry, and energy-efficient digital circuits. These developments hold promise for modern physics and engineering applications [1]. Devices based on high temperature superconductors (HTS) can exhibit superconductivity at temperatures easily attainable using single stage cryocoolers or liquid nitrogen. Their figure of merit is often characterized by the I_cR_n product, where I_c represents the critical current, and R_n is the normal state resistance of the junction [2].

In this work, we report the fabrication of step edge grain boundary Josephson junctions using the pulsed laser-deposited $YBa_2Cu_3O_7$ (YBCO) film on single crystal MgO (100) substrates and study the effect of Ar^+ ion irradiation on the junction parameters. Step edge junctions with a step height of ~ 400 nm and step angle of ~ 35° are fabricated using photolithography and ion beam milling techniques, confirmed using atomic force microscopy (AFM). The width and length of the microbridge across the step are 2 μm and 100 μm, respectively, confirmed using scanning electron microscopy (SEM) technique. The junction area is irradiated with Ar^+ ions for time durations varying from 1 to 6 mins.

All the step edge junctions (SEJs) exhibit the DC Josephson effect. It is observed that with irradiation time, the critical temperature of the junctions and the critical current (I_c) decrease, while the normal state resistance R_n increases significantly, leading to a high value of the I_cR_n product. After irradiation for 4 mins, I_c as low as 70 μA and R_n as high as ~ 9.4 Ω have been obtained at 77 K, so that the value of the I_cR_n product is obtained to be ~ 0.66 mV, which is sufficiently good for many practical applications. The mechanism responsible for the decrease in I_c and increase in R_n could associated with the oxygen vacancies created by the ion irradiation, which causes the suppression of superconducting parameters as the superconducting properties critically depend on the concentration of the oxygen atoms. Also, the junction behavior is observed to change from SNS type to SIS type *junction for increased irradiation time.*

Advanced Materials for High-Temperature Solid-State Converters of Thermal and Concentrated Solar Energy

Alessandro Bellucci[1], Eleonora Bolli[1], Marco Girolami[1], Matteo Mastellone[1], Stefano Orlando[1], Andrea Orsini[1], Riccardo Polini[2], Raffaella Salerno[2,1], Antonio Santagata[1], Veronica Valentini[1] and Daniele M. Trucchi[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Roma Tor Vergata, Italy

High-temperature solar cells and thermal energy converters are possible by exploiting hybrid mechanisms, such as thermionic-thermoelectric generation [1], thermionic-photovoltaic conversion [2, 3], and photon-enhanced thermionic emission (PETE) concept [4], which represent novel and promisingly efficient (>50%) mechanisms for the exploitation of concentrated sunlight.
Ultrashort laser pulses can tailor the optical properties of concentrated sunlight absorbers by maximizing solar absorption and selectivity thanks to surface periodic nanostructures [5]. Solar thermionic energy converters with surface nanotextured surfaces have already been demonstrated to enhance the selective absorption in prototypes based on nanodiamond emitters. More advanced PETE converters rely on the concept that engineered semiconductor photocathodes can provide an efficient electron emission, obtained by a synergistic combination of photogeneration and thermionic emission. Surface nanotexturing induced by ultrashort laser treatments can also tailor the electronic properties of semiconductors so that PETE cathodes can be drastically enhanced in terms of photosensitivity even to sub-bandgap radiation.
Specifically, in the case of black diamond, surface nanotexturing combined with surface-hydrogenation on the opposite film side is proposed as a radically new and potentially effective PETE cathode up to temperatures of 700 °C. CVD diamond is transparent to solar radiation due to its wide bandgap, consequently, black diamond technology was developed to drastically increase its absorption coefficient (solar absorptance even >99% in the double-textured samples [6]) and photogeneration capability under sunlight irradiation. A final p-type/intrinsic structure merges the technologies of surface texturing by fs-laser, boron-implantation for the formation of a buried p-type layer, and laser-induced graphitic microchannels, to form an innovative defect-engineered black diamond cathode for the conversion of concentrated sunlight. Results under a high-flux solar simulator is reported and discussed by demonstrating for the first time the PETE effect at temperatures from 300 to 500 °C.
But there is more. Ultrathin nanocrystalline diamond [7,8] emitters deposited on surface-nanotextured silicon can be a viable and cost-effective solution for PETE converters [9], as well as perovskite-based PETE cathodes, currently under development for linear-focus concentrators.

Ti_3AlC_2 MAX Phase as Strategic Material for Stealth Application *Durgabatee Rout[1], Lokesh Saini[2], Durgamadhab Mishra[1], Raj K. Jani[2] and Sampat R. Vadera[1]; [1]Indian Institute of Technology Jodhpur, India; [2]Defence Laboratory Jodhpur, India*

This study focuses on the synthesis and characterization of the Ti_3AlC_2 MAX phase for microwave absorption application. Ti_3AlC_2, belonging to the family of layered ternary carbides and nitrides, with the general formula $M_{n+1}AX_n$, where n=1-3, M represents an early transition metal, A represents group IIIA or IVA elements, and X is either nitrogen or carbon, exhibits a unique combination of metallic and ceramic properties. MAX phases are considered to be one of the most promising radar absorbing materials in high-temperature applications due to their excellent structural stability, oxidation resistance, and good electrical conductivity. Ti_3AlC_2 MAX phase was successfully synthesized using the mechanically activated self-propagating high-temperature synthesis method (MASHS), employing commercially available pure titanium, aluminium, and carbon black as starting materials. A primary phase composed of Ti_3AlC_2 MAX phase with minimal impurities was achieved by precisely optimizing the molar ratios of Ti, Al, and C. An ideal molar ratio of 3:1.8:1.5 produced the desired outcomes. The as-synthesized powder has been characterized using XRD, FESEM, and Raman. The thermal properties and electrical conductivity of the material were also studied using TGA and four-probe technique respectively. Furthermore, Ti_3AlC_2/Al_2O_3 composites with varying Ti_3AlC_2 weight percentages in Al_2O_3 matrix were prepared and investigated for microwave absorption properties. The composite with 10wt% of Ti_3AlC_2 has shown very high return loss value of -62dB at a very low thickness (1.8mm) at 10.2GHz frequency. Further, a bandwidth of 3.4GHz (9-12.4 GHz) has been observed with RL value ≤ -10 dB.

3:00 PM SF04.14.03
Micro-Scale Depth-Resolved Control of Elastic, Optical and Structural Inhomogeneities in Swift Heavy Ion Irradiated Spinel *Zhandos Utegulov[1], Vladimir Bessonov[1], Kairolla Sekerbayev[1,2], Azat Abdullaev[1,2], Vladimir Skuratov[3] and Jacques O'Connel[4]; [1]Nazarbayev University, Kazakhstan; [2]National Laboratory Astana, Kazakhstan; [3]Joint Institute for Nuclear Research, Russian Federation; [4]Nelson Mandela University, South Africa*

Due to its high temperature properties and good resistance to fast neutrons and ions, magnesium aluminate spinel

($MgAl_2O_4$) is a promising ceramic candidate material for inert matrix nuclear fuel energy applications, as well as for photonics, electronics, crystal phosphors, and laser media in harsh radiation environment. However, to what extent spinel's structural, mechanical and optical properties are tolerant to swift heavy ion (SHI)-based fission products, remains to be investigated. To emulate the radiation damage by SHIs, spinel in its crystalline form was irradiated by Bi ions with energy 710 MeV at the ion dosage varied over the range of 10^{10} - 6 x 10^{12} ions/cm^2 derived from the high energy ion accelerator.

Post-irradiation depth profiling of photolimunescence (PL) micro-spectral peak intensities revealed a sharp color center-driven emission enhancement at a depth of 24 μm, at which the highest radiation-induced nuclear displacement damage is expected according to SRIM profile calculations. On the other hand, the spatial profiling of compressional and shear acoustic wave velocities, probed by the Brillouin light scattering micro-spectroscopy, revealed a close correlation with depth-dependent electron energy losses.

With the rise of ion fluence there is a general decrease in the speed of sound, and therefore in the elastic properties. However, the irradiated spinel structure tends to get stiffer at depths approaching maximum nuclear damage. Due to radiation-induced stress the structure gets even more stiff than that of the pristine spinel at depths extending to 30 – 40 μm. Normalized photoelastic coefficients also demonstrate a similar depth-dependent behavior. Maximum losses in photo-elastic property are scaled with those in ionization energy, especially with the increase of irradiation fluence. This depth-resolved Brillouin spectral behavior is confirmed by high resolution transmission electron microscopy, indicating the existence of latent tracks with a diameter of 4-5 nm in an almost intact matrix of crystalline spinel for doses up to 10^{12} ions/cm^2.

At the maximum ion fluence of 6 x 10^{12} ions/cm^2, a multimode Brillouin spectra are observed, corresponding to different crystalline and amorphous phases taking place at depths extending to 80 μm, at which the tracks tend to overlap and form a mixture of crystalline and amorphous phases with the latter ones having weaker elastic properties compared to those of the crystalline matrix. The interplay between nuclear and ionization losses are discussed in terms of micro-scale PL, elastic and photo-elastic inhomogeneities taking place in SHI irradiated spinel. Extreme SHI-driven ionization processes can be employed to sense and control sizeable opto-mechanical functionality in spinel similar to what was recently found in compound semiconductors [2].

3:15 PM *SF04.14.04
Quantum Critical Phase of FeO Spans Conditions of Earth's Lower Mantle *Vladimir Dobrosavljevic; Florida State University, United States*

Earth's interior consists primarily of an insulating rocky mantle and a metallic iron-dominant core. Recent work has shown that mountain-scale structures at the core-mantle boundary may be highly enriched in FeO reported to exhibit high conductivity and metallic behavior at extreme pressure-temperature (P-T) conditions. However, the underlying electronic processes in FeO remain poorly understood and controversial. Here we systematically explore the electronic structure of B1-FeO at extreme conditions with large-scale theoretical modeling using state-of-the-art embedded dynamical mean field theory (eDMFT). Fine sampling of the phase diagram at more than 350 volume-temperature conditions reveals that, instead of sharp metallization, compression of FeO at high temperatures induces a gradual orbitally selective insulator-metal transition. Specifically, at P-T conditions of the lower mantle, FeO exists in an intermediate "quantum critical" state, characteristic of strongly correlated *electronic matter. Transport in this regime, distinct from insulating or metallic behavior, is marked by incoherent diffusion of electrons in the conducting* t_{2g} *orbital and a band gap in the* e_g *orbital, resulting in moderate electrical conductivity (~* 10^5 *S/m) with modest P -T dependence as observed in experiments. FeO-rich regions in Earth's lowermost mantle could thus influence electromagnetic interactions between the mantle and the core, producing several features observed in Earth's rotation and magnetic field evolution.*

The Fabrication of Conductive and Corrosion-Resistant Oxide Thin Films for Fuel Cells and Hydrogen Generation Devices *Taisei Hattori[1], Takashi Tanaka[2], Kouichi Matsuo[3], Yuuji Oda[3], Tsutomu Araki[1] and Kentaro Kaneko[1]; [1]Ritsumeikan University, Japan; [2]EYETEC Co., Ltd., Japan; [3]Iwasaki Electric Co., Ltd., Japan*

In recent years, fuel cell-based power generation technologies have been the subject of study as part of efforts towards a decarbonized society. In Polymer Electrolyte Fuel Cells (PEFCs), both the positive and negative electrodes are in a corrosive environment of high temperature and high humidity, and current must be drawn from both electrodes. Consequently, the separator must have both high corrosion resistance and electrical conductivity. Furthermore, the use of costly titanium and carbon mixtures as separators is currently prevalent. For this reason, our laboratory has reported on cost reduction by coating inexpensive stainless-steel separators with SnO_2 *and* In_2O_3*, which have both corrosion resistance and high electrical conductivity [1][2]. Furthermore, hydrogen is expected to become a next-generation energy source that does not emit carbon dioxide when used, and water electrolysis, which can generate hydrogen in combination with zero-emission power sources such as renewable energy, is being studied for a sustainable society [3][4]. Among these, Proton Exchange Membrane Water Electrolysis (PEMWE) has attracted attention due to the high purity of the hydrogen gas that can be extracted and the ability to operate at high current densities. Furthermore, PEMWE exposes the separator to higher potentials (≥ 2 V vs. RHE) than fuel cells (0.7 V), necessitating the development of higher performance corrosion resistance and electrical conductivity. In this study, experiments were conducted to demonstrate the possibility of applying Tin Oxide (*SnO_2*) and Indium Oxide (*In_2O_3*), which have been the subject of previous research, not only to fuel cell separator coatings but also to separators for water electrolysis.*
Low-resistance SnO_2 *and* In_2O_3 *films were formed on Ti and Stainless Steel (SUS304) substrates, respectively, using Mist Chemical Vapor deposition (CVD) method. The contact resistance was measured for the vertical component of the sample using the four-terminal method. For the corrosion resistance test, a constant potential polarization test was conducted in a sulfuric acid solution (*H_2SO_4*, pH 3) to simulate the internal environment. The test duration was 72 hours, with a potential of 2 V vs. RHE applied. The contact resistance of the* SnO_2 *and ITO films on Ti substrates was 7.6 m*Ω*cm*^{2} *and 6.4 m*Ω*cm*^{2}*, respectively. These values are below the US Department of Energy (DOE) technical target contact resistance for fuel cells (10 m*Ω*cm*^{2}*), indicating that the resistance of the deposited oxide materials is well below the target value for separator applications. The resistance values of* SnO_2 *and ITO thin films formed on stainless steel for separator applications were 11.5 m*Ω*cm*^{2} *and 8.1 m*Ω*cm*^{2}*, respectively. The contact resistance of uncoated stainless steel alone was measured to be 50.1 m*Ω*cm*^{2}*, indicating the usefulness of the conductive oxide film as a coating material. The elevated contact resistance observed on the*

SUS substrate in comparison to the Ti substrate is postulated to be attributable to the formation of a thermal oxide film at the interface between the SUS and the oxide, resulting from the heating effects of the mist CVD method during film formation. Consequently, it is anticipated that a further reduction in resistance can be achieved through the optimization of the substrate pre-treatment. Therefore, further lowering of resistance can be expected by carrying out substrate pre-treatment. Furthermore, the test solution of SnO_2 on Ti substrate after a constant potential polarization test was analyzed by ICP-AES, and it was confirmed that neither the Sn contained in the film nor the Ti component of the substrate eluted, indicating good corrosion resistance.

SF04.15.03

High-Pressure Low-Temperature Characterization of $ZnPS_3$ for Energy Applications

Vivian J. Santamaria Garcia[1,2], Abhishek Mukherjee[1], Damian Wlodarczyk[3], Ajeesh K. Somakumar[3], Piort Sybliski[3], Ryan Siebenaller[4], Emmanuel Rowe[5,6,7], Saranya Narayanan[3], Michael Susner[4], Andrzej Suchocki[3], Luis M. Lozano[2], Julio L. Palma[8] and Svetlana V. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Tecnológico de Monterrey, Mexico; [3]Polish Academy of Sciences, Poland; [4]Air Force Research Laboratory, United States; [5]National Research Council, United States; [6]Middle Tennessee State University, United States; [7]Vanderbilt University, United States; [8]The Pennsylvania State University, United States

We present an experimental and computational study of high-pressure and cryogenic-temperatures properties of $ZnPS_3$. Belonging to the metal thio(seleno)phosphate family (MPX_3, X = S, Se) of layered materials, $ZnPS_3$ has been identified as an exceptional inorganic electrolyte for solid-state batteries, which are more environmentally friendly than conventional lithium batteries. Its potential is attributed to its high ionic conductivity with a low diffusion energy barrier, high electrochemical stability, and mechanical strength, which can be enhanced in the presence of water vapor [1,2]. Furthermore, $ZnPS_3$ has significant photocatalytic activity for hydrogen generation, given its dimensional tunability and plentiful active P and S sites that facilitate hydrogen adsorption and desorption [3,4]. Our research on $ZnPS_3$ delves into its phase and thermal stability. We employ high-pressure (HP) low-temperature (LT) Raman and photoluminescence (PL) spectroscopy, supported by first-principle calculations using density functional theory (DFT). The HP Raman data reveals two minor phase transitions at ~6.75 GPa and ~12.5 GPa. Our DFT calculations extend the study to hydrostatic pressures beyond the experimentally feasible range and predict a semiconductor-to-semimetal transition at ~100 GPa, confirming reliable semiconductor behavior under extreme conditions.

Temperature-dependent properties are estimated using the quasi-harmonic approximation, combining pressure and temperature effects [2]. The anticipated changes in the band gap align with those derived from low-temperature absorption measurements. X-ray diffraction at cryogenic temperatures allowed us to calculate the thermal expansion coefficient for $ZnPS_3$ and compare it with known semiconductors based on ionic conductivity and band gap. Our calculations show that $ZnPS_3$ has a relatively high band gap, which is modestly tunable by strain, crucial for preventing electronic leakage in solid-state batteries. $ZnPS_3$ strikes a good balance between high ionic conductivity and minimal electronic leakage. Additionally, its low thermal expansion coefficient revealed in our study enhances its suitability for energy storage applications. The combination of divalent ionic conduction and low thermal expansion in $ZnPS_3$ offers increased energy density, improved stability and safety, and consistent performance across various temperatures. These properties make $ZnPS_3$ a promising material for next-generation solid-state batteries.

Defect Engineering in Two-Dimensional Pentagonal $PdTe_2$—Tuning Electronic, Optical and Magnetic Properties

Poonam Sharma, Vaishali Roondhe and Alok Shukla; Indian Institute of Technology Bombay, India

Recently, the successful synthesis of the pentagonal form of $PdTe_2$ monolayer (p-$PdTe_2$) was reported [Liu et al. Graphene 2023]. In this work, we present an extensive first-principles density-functional theory (DFT) based computational study of vacancies in this material. Our study covers the evolution of the electronic, optical, and magnetic properties of various defect configurations and compares those to the pristine monolayer (p-$PdTe_2$). We find that V_{Pd} (V_{Te}) is the most stable defect in the p-$PdTe_2$ monolayer with 0.95 (1.65) eV of formation energy in the Te-rich (Pd-rich) limit. Moreover, V_{Te} is found to significantly alter the electronic properties of the system due to the emergence of additional states in the band region, which is also responsible for charge carrier trapping. The defect complex V_{Pd+4Te} is found to induce spin-polarization in the system with a total magnetic moment of 1.87 μ_B . The obtained low diffusion energy barrier of 1.13 eV (in-plane) and 0.063 eV (top-bottom) corresponding to V_{Te} indicates the posibility of its facile migration, as revealed by AIMD simulations as well. In order to guide the experimentalists, we also simulated the scanning-tunneling microscope (STM) images corresponding to all the defect configurations and computed the electron-beam energy for creating such defect configurations. In the optical absorption spectra, some finite peaks below the main band edge are noticed in each defect configuration that is found to be absent in the pristine system, making absorption spectra a distinctive parameter to identify different defect configurations. Our study will open the prospects of defect engineering in this and related materials with the aim of tuning their electronic, optical, and magnetic properties from the point of view of device applications.

SF04.15.05

Highly Efficient Water Molecule Heating Technology Based on Semiconductor Multilayer

Tomoki Otsuka[1], Ryuichi Matsuda[2], Toshiya Watanabe[2], Saki Ota[2] and Kentaro Kaneko[1]; [1]Ritsumeikan University, Japan; [2]Mitsubishi Heavy Industries, Ltd., Japan

Water and most organic solvents have light absorption originating in the 3 μm band. For the realization of ideal heating system, optical bandpass filters are one of the efficient ways to transmit light having specific wavelength[1]. Optical band pass filters are realized by dielectric multilayers consisting of materials with different reflectance, such as SiO2/TiO2. However, they are thermally unstable[2], and further number of layers are required to achieve advanced performance. In this study, we propose a corundum-structured semiconductor multilayer film based on α-Fe_2O_3 (n=2.79[3]) and α-Ga2O3 (n=1.74[4]). Its small lattice mismatch (1.3%) and high crystallinity has the

potential to solve problems of conventional dielectric multilayers. Furthermore, we design a new semiconductor multilayer mirror by them, which is expected to significantly improve the energy efficiency of water heating system. This mirror is designed to transmit in the 3 μm band (water absorption wavelength) and reflect in other wavelengths. Our heating system uses the light reflected by this mirror to heat the blackbody. The heated blackbody radiates containing 3 μm band again, so that light energy that does not originally contribute directly to heating can be re-used.

In this study, a designed multilayer film is a stacked structure of α-Fe_2O_3 *and* α-Ga_2O_3*, with a total of six layers. The calculated optical property is that transmits in the 3 μm band and reflects in the 2 μm and 4 μm bands, and the energy efficiency gains are 30% compared with a non-mirror heating. Furthermore, the refractive index and extinction coefficient, which are necessary for the design, were measured in our group. This is because they have rarely been measured for* α-Fe_2O_3 *and* α-Ga_2O_3 *thin films prepared by mist CVD. The multilayer was deposited by mist CVD, which is suitable for this study because it is simple and allows the deposition of oxide semiconductors with very high crystallinity. In most cases, c-plane sapphire substrates are superior in terms of crystallographic orientation. However, in this report, m-plane sapphire substrates were used to suppress κ-phase mixing, which is a factor in the deterioration of surface flatness over large areas.* α-Fe_2O_3 *was grown at 500°C and* α-Ga_2O_3 *at 475°C. Therefore, thermal stability of at least 500°C or lower is expected.*

First, α-Fe_2O_3/α-Ga_2O_3*/sapphire interface was observed by TEM for microstructure analysis of interface. The results showed that each interface was atomically flat. Furthermore, STEM-EDS showed each element uniformly distributed. SEM observations, which were crack-free over a wide area, also reinforce that* α-Fe_2O_3 *and* α-Ga_2O_3 *are suitable for this mirror.*

The results of the two-layers film was satisfactory, and six-layers film was produced based on this results. The difference in thickness of each layer of the designed multilayer film and produced film was at most less than 7% by cross-sectional SEM. With this design, assuming a homogeneous film, a layer thickness error of less than 10% has little effect on the optical properties. Regarding the measurement results of optical properties, the transmittance in the 3 μm band was as high as the design value (80% or more), and the 2 μm and 4 μm bands also showed characteristic reflectance properties. In addition, there was no strong absorption in the near- and mid-infrared regions, and the absorption wavelength in the far-infrared region was almost consistent with the designed value. The improvement in energy utilization efficiency calculated from these measurements was about 24%, suggesting that multilayer films with new applications and functions have been realized using oxide semiconductors with a corundum structure.

SF04.15.06

Crystal Growth of Yttrium Oxide on Carbon Substrates *Mahiro Ushida[1], Satoshi Torimi[2], Takahiro Morishita[2] and Kentaro Kaneko[1]; [1]Ritsumeikan University, Japan; [2]Toyo Tanso Co.,Ltd., Japan*

In film forming and etching systems that utilize plasma, it is important to form excellent insulator thin films that coat conductive base materials to ensure their insulating properties. The insulating property of a material tends to be higher when the forbidden bandwidth (band gap) is large. Oxides with ionic bonding have a huge band gap due to their large difference in polarity, and there are many excellent insulating materials available. Among them, yttrium oxide is an insulating material used in various semiconductor manufacturing processes. Currently, aluminum metal is the main base material, but a high-temperature environment is expected in next-generation equipment for 3D-NAND. Therefore, a base material with high heat resistance is required. In this study, we focused on isotropic graphite, which has both heat resistance and electrical conductivity, as a base material. The experiments were conducted using a methanol solvent from a previous study. [1]

In this study, two growth methods were selected: the solution method and the mist CVD method. In the solution method, the solute is dissolved in a solvent, dropped onto a substrate, and transported to a heat source, where the process is repeated to deposit the crystals. The mist CVD method uses an ultrasonic transducer to atomize the material solution, and transports the atomized material solution to the substrate using gases such as nitrogen and oxygen to achieve thin film growth. In both methods, an electric furnace was used as the heat source for film deposition. For the solution method, yttrium acetylacetonato n-hydrate [$Y(C_5H_7O_2)_3 \cdot nH_2O$] was selected as the precursor solute and completely dissolved in a solution of 95% methanol [CH_3OH] and 5% water [H_2O] at a concentration of 0.1 mol/L. The substrate was isotropic graphite and the growth temperatures were 200, 300, and 400°C. Experimental results showed that red powder adhered to the substrate as the temperature increased. Scanning electron microscopy (SEM) observation of the substrate surface and composition analysis by energy dispersive X-ray spectroscopy (EDS) showed amorphous with a yttrium content of 20%. A thin film was formed on the top of the carbon substrate, and insulation resistance measurements were taken vertically between the bottom, where the carbon was bare, and the top, which was covered with a Y_2O_3 insulating film, yielding a resistance of 100MΩ, confirming the insulation properties. In the mist CVD method, the same precursor solutes and solutions as in the solution method were selected, and all solutions were completely dissolved while changing the concentration. The substrate was isotropic graphite and the growth temperature was 400°C. Scanning electron microscopy (SEM) observation of the substrate surface and composition analysis by energy dispersive X-ray spectroscopy (EDS) revealed an amorphous state with a yttrium content of 24%. Insulation resistance measurements were performed as in the solution method, and a resistance value of 500 Ω was obtained. A blue interference film was also visible visually. More detailed experimental details and growth rates will be presented on the day.

SF04.15.07
Si-Doped HfO_2—Enhancing Pyroelectric Properties for Next-Generation CMOS Compatible Self-Powered Devices *Uthra Bharathi[1,2,3], Pankaj B Agarwal[2,3] and Md. Ataur Rahman[1]; [1]RMIT University, Australia; [2]Academy of Scientific and Innovative Research, India; [3]Central Electronics Engineering Research Institute, India*

In search of advanced materials to drive the evolution of self-powered devices, Si-doped hafnium oxide (HSO) emerges as a promising candidate due to its remarkable pyroelectric properties. This study investigates the mechanisms behind the enhancement of the CMOS-compatible HSO thin film pyroelectric properties, aiming to accelerate their functionality within self-powered photodetectors. Through experimental analysis, we demonstrate that Si doping significantly improves the pyroelectric property. These enhancements are attributed to the induced structural modifications and the stabilization of the non-centrosymmetric phase, essential for pyroelectric activity. In addition, the formation of Schottky interface between Ti and HSO layer contributes to the enrichment of overall output current. The optimized Pt/Ti/HSO/Pt/Ti/SiO2/Si stack exhibit a pyroelectric coefficient surpassing that of undoped HfO_2 and proclaimed Si-doped HfO_2 by a substantial margin, making them ideal for integration into next-generation self-powered devices. This advancement paves the way for innovative applications in pyroelectric energy harvesting, motion detection, infrared detection, gas sensing, and beyond, aligning with the increasing demand for sustainable and efficient electronic solutions.

SF04.15.08
N-Type Conductivity in Single-Phase r-GeO_2 Thin Films *Yuri Shimizu[1,2], Toya Yagura[1,2], Toyosuke Ibi[1], Isao Takahashi[1] and Kentaro Kaneko[3,1]; [1]Patentix Inc., Japan; [2]Graduate School of Science and Engineering, Japan; [3]Ritsumeikan University, Japan*

Rutile-structured germanium dioxide (r-GeO_2) is attracting attention as a next-generation power device material

with a large bandgap (4.68 eV) [1], and both p-type and n-type conductivity are theoretically predicted [2]. The reason for this is that when it is possible to create p-type and n-type materials using doping techniques, there will be no need to create expensive Fin-FET structures, and it will also be possible to apply it to normally-off MOSFETs, which account for over 90% of the power semiconductor market. However, due to high saturation vapors pressure and similar formation energies of crystal polymorphs, it is a hard work to produce single phase r-GeO_2 films. N-type conductivity has been confirmed in alloy thin films mixed with tin dioxide (r-SnO_2),which is easy to crystallize. [3]. However, alloy thin films has smaller band gap against r-GeO_2 because band gap of r-SnO_2 is 3.7eV. From the view point of future power device applications and social implementation, fabrication of conductive single-phase r-GeO_2 is a milestone technology. In this study, we fabricated n-type conductive r-GeO_2 thin films and structural and electrical property evaluation are conducted. In this study, we fabricated n-type conducting thin films because controlling the conductivity of single-phase r-GeO_2 films is more important than that of mixed phase films from the perspective of device applications.
Atmospheric pressure CVD systems with ultrasonic transducer were employed to create r-GeO_2 thin films on rutile-structured titanium oxide (r-TiO_2) (001). We chose Sb ion as an n-type dopant and evaluated the structure and electrical properties using X-ray diffraction (XRD) measurement devices and Hall effect measurements system. From XRD 2Θ/ω scanning measurement, 2Θ peaks derived from 002 of r-TiO2 substrate and r-GeO_2 thin film were confirmed the others peaks from other crystal phases were not detected. These results indicate obtained thin films were oriented grown on the substrates and these are single-phase films. N-type doped thin films were also grown on r-TiO_2 substrates using these growth condutions. The molar cncentarations (mol%) of Sb dopant in the precursor source solutions were varied as 3, 5 or 7 mol%. Hall effect measurements were performed on each sample using van der Pauw method. Electron carrier densities were confirmed as around 10^{20} / cm^3 for all samples. The electron liabilities were recorded as 6 or 12 cm^2/Vs for the sample with 3 mol% or 5mol% Sb dopants in the source solutions, respectively.
On the day of the presentation, we plan to discuss the results of detailed electrical and structural characterization.

SF04.15.09

Polymorphic Phase Transition in β-Ga_2O_3_Formation of Gamma-Ga_2O_3 Phase via Ion Implantation *Elzbieta Guziewicz[1], Mahwish Sarwar[1], Renata Ratajczak[2], Oksana Volnianska[1], Aleksandra Wierzbicka[1], Adam Przezdziecki[3] and Wojciech Wozniak[1]; [1]Polish Academy of Sciences, Poland; [2]National Center for Nuclear Research, Poland; [3]Warsaw University of Life Sciences - SGGW, Poland*

Gallium oxide (Ga_2O_3) is an ultra-wide bandgap semiconductor (E_g~ 4.6 – 4.9 eV) of interest for many applications, including optoelectronics. Undoped Ga_2O_3 emits light in the UV range, that can be tuned to the visible region of the spectrum by rare earth dopants. Ion implantation is a renowned technique used for materials' doping. In spite of many advantages such as controlled introduction of dopants in concentrations exceeding the solubility limits, it also causes a damage of the crystal lattice which might be partially eliminated by post-implantation annealing.
We have studied the defect accumulation process in beta-Ga_2O_3 single crystal subsequently implanted with Yb ions to fluences ranging from $1e^{12}$ to $5e^{15}$ at/cm^2 [1]. The RE depth profile was analyzed by the SIMNRA calculations, while the Monte Carlo McChasy simulations were used to quantify the defect distributions. Channeling Rutherford Spectrometry (RBS/c) results supported by McChasy simulations reveal a complex transformation of defects upon ion irradiation which can be assigned to a complex geometry of a monoclinic crystal structure of beta-Ga_2O_3. Irradiation with a fluence of $1e^{14}$ at/cm^2 or higher results in untypical bimodal shape of the RBS/c spectra, indicating a new form of defect that develops for higher fluences [1]. High-resolution XRD study demonstrates an

increase of strain and the presence of the gamma-Ga_2O_3 phase in as implanted samples. The g-phase with a defected spinel crystal structure disappears after annealing which means that a reversible crystalline-to-crystalline transformation can be achieved by ion implantation and annealing of the beta-Ga_2O_3 single crystal. Density Functional Theory calculations indicate a few possible causes of this polymorphic transformation which are (i) implantation-induced disorder in the cation sublattice, (ii) similarity of anion sublattices in both crystallographic phases, (iii) similar crystallographic volumes of beta- and gamma-Ga_2O_3. The ability to create the g phase is of great application importance as the intrinsically defective gamma-Ga sublattice of the defected spinel structure is nearly insensitive to new point defects, hence gamma-Ga_2O_3 is extremely resistant to irradiation [2].

Effects of Sm-Doping on the Giant Magnetocaloric Effect in EuTiO3

Zachary Ritchey, Jacob Pfund, Pawan Dubey, Menka Jain and Prabhakar Singh; University of Connecticut, United States

Motivated by the need for viable replacements for cryogens such as liquid helium which are limited resources in high demand for research applications and increasingly used in industry, we have pursued the development of solid-state magnetic materials for low-temperature refrigeration applications in the liquid helium regime. To achieve this goal, samples of pure and samarium-doped europium titanate bulk materials were prepared by the sol-gel method. Our samples were confirmed to be phase pure and highly crystalline by X-ray diffraction and elemental purity of the samples was confirmed by energy dispersive spectroscopy. Our Sm0.15Eu0.85TiO3 (SETO) sample showed an increase in the peak magnetization and had no observed spin freezing as seen in EuTiO3 (ETO). Further, the magnetic entropy change at the Néel temperature around 5.7K and the Refrigeration Constant were increased for SETO compared to the ETO for the 5T field change. Improvement in the entropy change of the SETO was also observed to be large in the low field regime (0-1 T), where applications of magnetic materials for adiabatic demagnetization refrigeration are most practical.

SF04.15.12

Investigation into the Corrosion of NITE-SiC/SiC in Molten FLiNaK Salt

Keshav Vasudeva, Wande Cairang, Weiyue Zhou and Sara Ferry; Massachusetts Institute of Technology, United States

The study presented is part of a wider effort to evaluate NITE-SiC/SiC as a candidate structural material in the Liquid Sandwich Vacuum Vessel (LSVV) concept for ARC-class fusion energy devices. The LSVV design proposes the use of a non-conductive structural material shell made of NITE-SiC/SiC enclosing a conductive liquid (like molten lead). This assembly is contained within the liquid immersion blanket, thereby exposing the outer walls of the shell to LiF-BeF2 (FLiBe) for extended periods. Given the difficulty in using FLiBe owing to the toxicity of Beryllium, FLiNaK is chosen as a surrogate salt in this preliminary study.

SiC/SiC composites - silicon carbide (SiC) matrix reinforced with unidirectional SiC fibers - fabricated by a nano infiltration and transient eutectic-phase (NITE) have been chosen as the leading candidate material for this application owing to the decreased porosity in the matrix as compared to the composite fabricated by Chemical

Vapor Infiltration (CVI).
We will present the results of a comprehensive investigation into the effects of static corrosion on NITE - SiC/SiC composites after exposure to LiF-NaF-KF, typically referred to as FLiNaK. Existing studies have looked at the corrosion of stoichiometric SiC in such salts, however, through this study, emphasis is put on understanding the effect of the sintering additives (Al2O3, Y2O3 and SiO2) on the corrosion behavior. The microstructure of the samples will be characterized before and after corrosion through Scanning Electron Microscopy and Energy-dispersive X-ray spectroscopy. X-Ray Photoelectron Spectroscopy will be used to probe the charged states on the surface and shed light on the corrosion mechanisms of the material in presence of the sintering additives. X-Ray Diffraction will then be used to study the phases present on the surface.
Static corrosion tests are conducted in a dedicated, argon-filled glovebox using high purity salt held in glassy-carbon crucibles for 100 and 400 hours at 800C .

SF04.15.13

ZnO-Doped Tin-Based Oxides P-Type Transparent Conductive Oxides for Solar-Cell Electrodes *Hsing A. Chang, Yi-Wei Chang and Tri R. Yew; National Tsing Hua University, Taiwan*

The demand for clean energy is rapidly expanding the market of solar panels. Transparent conductive oxide (TCO) materials allow light to pass through a solar cell while efficiently conducting the electricity generated within a device without sacrificing light absorption due to using opaque metal wires as electrodes to collect currents. As a result, TCOs surpass metal wires in efficiency when used as solar cell electrodes. Furthermore, they exhibit excellent chemical stability and durability, enabling long-term stable operation under various environmental conditions. Therefore, using TCOs as solar cell electrodes is a promising approach to drive further development and application for solar energy technology.

This work focuses on developing p-type TCOs using ZnO-doped tin-based oxides. These materials are chosen for their high bandgap and suitable valence difference to achieve p-type carrier conductivity. Zinc oxide is used as a dopant to replace high-valence elements, thereby increasing hole concentration to improve electrical conductivity. The fabrication process involves forming the sputtering targets of ZnO-doped tin-based oxides through solid-state sintering. Subsequently, ZnO-doped tin-based oxide thin films are deposited on glass substrates using radio-frequency (RF) magnetron sputtering. Those films are then annealed under various conditions to optimize their electrical conductivity and transparency.

The crystal structure of ZnO-doped tin-based oxides is analyzed with an X-ray diffractometer (XRD). Their morphology and composition are examined by scanning electron microscopy (SEM) and energy-dispersive X-ray spectrometry (EDX), respectively. The optical transparency properties of ZnO-doped tin-based oxide thin films are analyzed by a UV-visible (UV-Vis) spectrophotometer. Four-point probes are used to analyze the resistivity of materials. This work aims to provide novel ZnO-doped tin-based oxide materials for p-type TCOs as potential electrodes for solar cells.

SF04.15.14

Porous Metals with Enhanced Mechanical and Magnetic Properties by Ultra-Fast High Temperature Sintering *Chaolumen Wu, Melody Wang and Wendy Gu; Stanford University, United States*

Porous metals are attractive engineering materials due to their high gas/liquid permeability, high strength-to-weight ratio, low density, and excellent energy absorption. Among the various fabrication methods, powder metallurgy stands out as a promising approach for fabricating porous metals with a well-defined network of interconnected pores. However, conventional furnace sintering is time-consuming and energy-inefficient. In *addition, the inherent porosity of these materials compromises their mechanical strength and facilitates rapid crack growth. Thus, researchers have developed structural porous materials such as sandwich composites and bamboo-like gradient porous structures to enhance the mechanical properties of porous materials. Despite these advances, efficient fabrication methods for complex structural materials remain lacking. In this work, porous metals with strong mechanical properties are fabricated by ultra-fast high temperature sintering (UHS) of iron powders. UHS achieves high temperature sintering in less than 30 seconds, resulting in strongly connected porous structures. The short sintering time leads to small grain sizes, which further enhance the mechanical properties. Moreover, we have successfully fabricated sandwich or bamboo-like structural porous metals with robust interlayer connections using a one-step UHS process. Mechanical testing of UHS samples reveals significantly higher flexural strength and modulus compared to furnace-sintered samples with equivalent porosity. Furthermore, the porous iron metals demonstrate low magnetic core loss at high frequencies due to their small grain sizes and high porosity, highlighting their potential for practical applications in electrical machines, inductors, and transformers.*

Microstructure and Long-Term Reliability of Ultrasonic-Assisted Solder Ball Joints *Jinsoo Yoon[1,2] and Taesung Kim[2,2]; [1]Samsung Electronics Semiconductor, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)*

Due to the implementation of various environmental regulations, vehicles using internal combustion engines are being replaced by electric vehicles. Consequently, the demand for electronic components that drive electric vehicles is increasing. Power semiconductors, which control and distribute electric energy, are being replaced from Si-based to SiC-based semiconductors. SiC-based semiconductors have high power conversion efficiency and are stable in high temperature and high voltage environments. However, since SiC operates at higher temperatures than Si, there is increasing attention on high melting point solders (Au, Zn-based), metal nanoparticle sintering, and transient liquid phase (TLP) bonding technologies.

With the advancement of power semiconductors, securing the reliability of electronic components has become a significant issue. Particularly, the ultrasonic-assisted soldering process has the potential to contribute to reducing soldering time and enhancing the reliability of solder joints. Ultrasonic energy accelerates the interaction between Cu and Sn through the cavitation effect, promoting the formation of a complete intermetallic compound (IMC). The objective of this study is to analyze the microstructure of joints formed through the ultrasonic-assisted soldering process and to evaluate the mechanical properties and reliability of the joints through long-term reliability tests.

In this study, solder paste was prepared using Sn-58Bi solder (Type 4), Cu powder (4 μm), and flux. The prepared paste was printed on a Cu substrate using a stencil printing method, and a Cu chip was mounted on the printed paste. The ultrasonic-assisted soldering process was performed under various soldering conditions, and high-temperature storage (HST) tests and thermal cycling (TC) tests were conducted for long-term reliability evaluation. Additionally, the microstructure of the soldered joints was observed using a scanning electron microscope (SEM). As a result, the soldering process utilizing ultrasonic energy significantly reduced the soldering time to approximately 6 minutes due to the cavitation effect induced by the ultrasonic waves. These results are expected to contribute to improving the reliability of power semiconductors and electronic components.

SF04.15.16

Enhanced Thermal Conductivity Epoxy Resin via Star-Shaped Crystalline Amine Curing Agents *Soojeong Jeong[1,2], Myung-Chul Park[2] and Ho Sun Lim[1]; [1]Sookmyung Women's University, Korea (the Republic of); [2]CNATECH CO, Ltd, Korea (the Republic of)*

The semiconductor technologies are escalating, driven by the growing demands for highly improved techniques and multi-functional devices. This advanced semiconductor generates extreme heat, thermal management has become critical for enhancing performance and extending the lifespan. Epoxy resin is commonly used as a thermal dissipation material due to its excellent adhesion properties and mechanical strength, but it has the drawback of low thermal conductivity around 0.2 W/mK. In this study, we designed a novel epoxy resin formulated with a star-shaped crystalline amine curing agent with high thermal conductivity. The unique crystalline structure of the curing agent, characterized by four aromatic rings connected by carboxyl groups, promotes rapid phonon transportation through the bulk and rigid structure. As a result, the pristine epoxy resin cured with this curing agent exhibits about 20% higher thermal conductivity (~0.26 W/mK) than conventional epoxy resin. Moreover, when it is manufactured as composites, our epoxy composites demonstrate a significantly enhanced thermal conductivity, over 50% higher than conventional epoxy composites. In conclusion, this new epoxy resin can handle high temperatures effectively and be adopted as a thermal interface material and encapsulant in next-generation semiconductors.

SF04.15.17

Exploring Strategies to Grow p-Type and n-Type Copper Oxides for Transparent Conductive Oxides Applications

Ana Laura Pérez-Martínez, María d. Aguilar-del-Valle and Arturo Rodríguez-Gómez; Universidad Nacional Autónoma de México, Mexico

Thanks to their interesting optoelectronic properties, copper oxides interest the academic community [1]. One of its most promising applications is the manufacture of transparent conductive oxides (TCO). Unlike high-performance TCOs such as fluorine-doped tin oxide (FTO), indium tin oxide (ITO), and aluminum-doped zinc oxide (AZO), most TCOs based on copper oxides are p-type semiconductors [2]. The latter is because, in copper oxides, there is a "Chemical Modulation of the Valence Band" (CMVB) that is produced by hybridization between the 2p orbitals of oxygen and the closed-shell $3d^{10}$ of copper [3]. The CMVB produces shallower acceptor levels in the valence band (VB), which in turn causes the Fermi level to be closer to the VB and obtain a p-type semiconductor with acceptable hole concentrations and mobilities. Due to the above, the number of works that report TCOs of n-type copper oxide is minimal [4,5]. However, controlling the type of semiconductor in copper oxide TCOs would be very useful since some translucent applications that require n-p junctions based entirely on copper oxides could be developed.

In this work, we use an in-house direct-current sputtering system to reproducibly grow p-type and n-type copper oxide TCOs. For p-type TCOs, we used a 99.9995% pure copper target deposited with a power of 60 W and a deposition time of 3 s. These copper films were subjected to a 360-hour "aging" treatment in an air atmosphere with a temperature ranging between 28 and 32 °C. This procedure produced Cu_2O TCOs with an average transmittance of ~ 67% in the visible range of the spectrum, a conductivity of 0.048 S/cm, and a hole concentration of 3.4×10^{16} holes/cm^3. On the other hand, by using a deposition power of 20 W for 6 s and followed by a heat treatment at 400 °C for 20 minutes, we were able to obtain a TCO that we identified as single phase (Cu_2O) with an average transmittance of ~70% and a charge carrier concentration of 2.3×10^{16} electrons/cm^3. We identify that the average roughnesses of our copper oxide TCOs are not always reproducible nor low enough to generate an adequate depletion region in a possible n-p junction. We estimate that if future depositions allow us to decrease average roughness, our deposition strategies could allow us to form functional translucent diodes based exclusively on copper oxide.

Enhanced Decontamination of Chemical Warfare Agents Using Photo-Thermal Effects of UIO-66-NH2 and TOCN Composites *Haechan Cho; Chung-Ang University, Korea (the Republic of)*

The decontamination of chemical warfare agents (CWAs) remains a critical global challenge due to the severe threats these agents pose to human health and safety. Among various materials investigated for CWA decontamination, UIO-66-NH2 has emerged as a highly effective agent due to its remarkable chemical stability, high surface area, and functional amine groups that enhance its reactivity with toxic compounds.
In this study, we present a novel composite material combining UIO-66-NH2 with TEMPO-oxidized cellulose nanofibrils (TOCN) via a refined microwave synthesis approach. The integration of TOCN not only ameliorated the agglomeration issues but also enhances environmental stability of the MOF. And the composite showed notable responsiveness to visible light and exhibited effective photocatalytic activity against a spectrum of CWAs. This composite material represents a promising advancement in the field of CWAs decontamination, offering a multifunction approach towards addressing global security challenges.
Our findings highlight the potential of integrating nanomaterials to develop advanced functional composites for environmental and defense-related applications. The implications of this research extend beyond CWA decontamination, offering insights into the design of next-generation materials with tailored functionalities.

SF04.15.20
Influence of Strain and Point Defects on the Electronic Structure and Related Properties of (111)NiO Epitaxial Films *Bhabani P. Sahu, Poonam Sharma, Santosh K. Yadav, Alok Shukla and Subhabrata Dhar; Indian Institute of Technology Bombay, India*

NiO is one of the few wide bandgap semiconductors, where stable p-type doping is achievable. The material has a rock salt crystal structure with a bandgap reported to be 3.6-4 eV. NiO exhibits antiferromagnetic behaviour with Neel temperature of 525 K. It also has a very high chemical and thermal stability. All these make NiO a promising candidate for a wide range of device applications that include exchange bias systems, spintronic devices, UV photodetectors and UV-light emitting diodes. Nevertheless, NiO is a classic example of Mott-Hubbard charge transfer insulator making it interesting from basic physics point of view as well. It is noteworthy that Ni-deficiency related defects are commonly believed to be the origin of unintentional p-type doping often reported in as grown NiO layers. These defects, whose formation probability depends on the Ni and oxygen flux ratio during growth, can control not only the conducting state of the layer but also the band-structural properties as a whole. An additional factor influencing the band-structure is the strain present within the film. It is to be noted that the biaxial strain in the epitaxial layers can originate from the lattice and/or thermal expansion coefficient mismatches between the grown layer and the substrate. Presence of defects/impurities can also cause hydrostatic strain in the film. There are studies, which show that the strain development along specific crystallographic direction has the maximum influence on the band structure in certain oxide materials, like $La_{0.7}Sr_{0.3}MnO_3$, $SrRuO_3$ and SnO_2. Chen et.al. have experimentally investigated the variation of in-plane lattice parameters due to Mg doping in (111)NiO. The study reports an expansion of the lattice only along in-plane directions as a result of Mg incorporation, which further leads to the enhancement of bandgap of the grown layer. It should be noted that the coexistence of hydrostatic and biaxial strains can cause an effective unidirectional strain in the film. Even though there are widely existing studies on NiO, detailed experimental and theoretical investigations of strain-induced changes of its band *structural properties are still lacking. In this work, we undertake a combined study of experiment and theory to understand how the presence of strain and different native defects affect the electronic properties of this material. Here, we have carried out a systematic investigation of structural, electrical and optical properties of (111)NiO epitaxial films grown on c-sapphire substrates using pulsed laser deposition (PLD) technique at various growth temperatures and laser fluences (used to ablate the target). Films grown with higher laser fluence, are found to be embedded with Ni-clusters crystallographically aligned within the (111)NiO matrix. X-ray diffraction study shows the coexistence of biaxial compressive and tensile hydrostatic strains in these samples, which results in an expansion of the lattice primarily along the growth direction. This effective uniaxial strain ($\varepsilon_{\perp}$) has been found to lower the bandgap of NiO, which is validated by DFT-based band structure calculations. The study further suggests that the samples grown with Ni-deficient (low laser fluence) and Ni-rich (high laser fluence) conditions are populated with V_{Ni}+O_I and V_O+O_{Ni} defect complexes, respectively. P-type conductivity observed for the samples grown with Ni-deficient condition can be attributed to V_{Ni}+O_I defects, which is contrary to the common belief that Ni-vacancies (V_{Ni}) are responsible for unintentional background hole concentration often found in NiO.*

Pseudocapacitive Titanium Oxynitride Nanowires by Pulsed-Laser Deposition for Ultra-High Capacitance Supercapacitors *Joan Ejeta[1], Panupong Jaipan[1], Simon Gelin[2], Zixiao Shi[3], Jonghyun Choi[4], David Muller[3], Ismaila Dabo[2], Kristen Rhinehardt[1] and Dhananjay Kumar[1]; [1]North Carolina Agricultural & Technical State University, United States; [2]The Pennsylvania State University, United States; [3]Cornell University, United States; [4]Pittsburg State University, United States*

Titanium-based metal oxynitrides, TiN_xO_y (TiNO), are promising materials for energy conversion and storage. Rocksalt TiNO films, synthesized in-situ using pulsed laser deposition and a varied oxygen partial pressure, were recently found to exhibit high electrochemical performance, with overpotentials for water oxidation that can be as low as 290 mV at 10 mA/cm^2 [1]. It has also been shown that the bandgaps of TiNO films can be optimized for solar-to-hydrogen conversion by modulating the nitrogen-to-oxygen content [2]. In this presentation, we report the synthesis and electrochemical performance of multifunctional 2-dimensional (2D) TiNO thin films and 1-dimensional (1D) TiNO nanowires for electrochemical energy storage. The synthesis uses a binder-free, non-clean room-specific pulsed laser deposition method which enables to achieve nanowires with excellent crystallinity and high chemical homogeneity. The cyclic voltammetry measurements show that the specific capacitances of the TiNO nanowires (2,725 mF.cm-2) are nearly six times more than those of the TiNO thin films (400 mF.cm-2). These high specific capacitances are on par with the highest values reported for the recently top-tier nanoscale electrode materials. First-principles simulations suggest that they originate from the high concentration of surface-active sites on TiNO materials, combined with the higher effective surface area of nanowires.

Advancing Nanopatterning of Gallium Nitride Research with Sequential Infiltration Synthesis *Prachi Sarwara, Mahua Biswas and Uttam Manna; Illinois State University, United States*

The field of nanopatterning of inorganic materials has attracted significant attention in research labs and industries, including optoelectronics and photonics, due to their unique properties at the nanoscale and the compact geometry that helps in developing new devices with higher efficiency and better performances. Gallium Nitride (GaN), a group III Nitride material is one of most widely researched and utilized material for optoelectronic and power electronic research because of their wide bandgaps leading to emission in the Ultraviolet (UV) and

Visible wavelengths and robustness leading to withstand high temperature and pressure. The growth of nitride materials is in general challenging because of high-temperature requirements and lattice mismatch with conventional substrates like Silicon. In the applied nanomaterials chemistry lab at ISU, we are developing a nanopatterning method of GaN at comparatively lower temperatures (100-150°C) with easy integration steps to existing technology using a method called Sequential Infiltration Synthesis (SIS). SIS involves the alternate deposition of distinct precursor chemicals onto a patterned polymeric substrate to form the compound material, where the patterned polymer serves as a guiding matrix, enabling selective infiltration for well-ordered and large-scale deposition of materials in the nanoscale. Using SIS can lead to new, cost-effective substrate-independent nitride-based optoelectronic device applications. For nanopatterning GaN, we use polystyrene-b-polymethylmethacrylate (PS-b-PMMA) self-assembled nanostructures as a guiding pattern and infiltration of the inorganic GaN based and nitrogen-containing precursors in sequence to form nanoscopic patterns of GaN. The polymers are etched out by a plasma etching at the end to form GaN only nanostructures. We investigate the growth mechanism of these nitride inorganic materials using Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Electron Spectroscopy (EDS), and Fourier Transform Infrared Spectroscopy (FTIR).

SF04.15.23

Microstructural Analysis of Mechanically-Alloyed Tungsten-Titanium-Chromium and Carbon-Based Ultra-High Temperature Ceramics *Silas Dorsky[1], Jhen-Bahn B. Li[2], Daniel Lim[3], Sylvie Liu[4], Brandon Qi[5], Bowen Tian[6], Philip Colman[7], Michael Lotwin[8], Miriam Rafailovich[8], Abhinav Sharma[8] and David Sprouster[8]; [1]The High School for Math, Science and Engineering at City College of New York, United States; [2]Northern Valley Regional High School at Demarest, United States; [3]Staten Island Technical High School, United States; [4]Hefei Thomas School, China; [5]Davis Senior High School, United States; [6]College Station High School, United States; [7]Lehman College of the City University of New York, United States; [8]Stony Brook University, The State University of New York, United States*

Rising global energy demands, in conjunction with increased awareness of the climate crisis, have instituted a need for reliable, clean energy, which can be sourced through nuclear fusion power. However, it is necessary to develop materials resistant to the extreme radiation doses and high-temperature environments intrinsic to nuclear fusion reactors. Previous research has shown that a material's microstructural properties such as grain size and grain boundary density can impact its ability to shield against neutron irradiation. Hence, the objective of this research is to analyze the microstructural characteristics of two candidate material classes fabricated through direct current sintering: firstly, ultra-high temperature ceramics (UHTCs) tungsten carbide (WC) and vanadium carbide (VC) with and without silicon carbide (SiC) additives, and secondly, mechanically-alloyed tungsten-titanium-chromium (W-Ti-Cr) with varying levels of chromium concentration.

Four UHTC specimens (WC, WC with 4% SiC by concentration, VC, and VC with 4% SiC by concentration) and three W-Ti-Cr specimens (W–Ti–Cr with 10% Ti by concentration and 5%, 10%, and 15% Cr by concentration) were sintered. To prepare for microstructural characterization, the samples were sequentially polished with SiC polishing paper of grits P800, P1200, and P2400, then fine polished with diamond suspension solutions of sizes 15 microns, 9 microns, 3 microns, and 1 micron. The samples were then ultrasonicated in isopropanol for 5 minutes and analyzed using X-ray diffraction (XRD) with a Copper K-α source, and atomic force microscopy (AFM) at a 5 μm by 5 μm field of view. XRD results were further examined using TOPAS (Bruker) Rietveld refinements for quantitative phase analysis, while AFM images were segmented using Trainable Weka Segmentation in FIJI and Watershed Segmentation in Gwyddion to determine mean grain size.

XRD analysis revealed the UHTC specimens were primarily single-phase, while the W-Ti-Cr samples were multi-phase. Both specimen sets contained minor surface contamination from the SiC polishing. TOPAS refinements indicated two trends: in the UHTC specimens, similar lattice parameters and coherent mean crystallite sizes were *found between the WC and VC and their SiC-containing counterparts, while in the W-Ti-Cr specimens, increased chromium concentration corresponded with systematic lattice contraction with decreased mean crystallite sizes. Within the W-Ti-Cr specimens, diffraction peaks from a chromium phase were not observed, indicating that the chromium was effectively incorporated within the tungsten host matrix as a substitutional dopant and potentially concentrated at grain boundaries. AFM segmentation revealed consistent mean grain sizes across the UHTC samples, while lateral force imaging showed the segregation of chromium at W-Ti-Cr grain boundaries with clear depressions in force traces across.*

Our results indicate the stability of the UHTC microstructure and the incorporation of chromium within the W-Ti-Cr host matrix. In future studies, the stability of the grain size and chemical alloying distribution of our samples after neutron irradiation and high-temperature exposures will be investigated, electrical properties of the W-Ti-Cr specimens will be measured using kelvin probe force microscopy, and XRD and AFM methods will be utilized to quantify changes post-exposure.

We acknowledge the Louis Morin Charitable Trust for funding.

SF04.15.24

Monitoring the Recovery of Crystalline Phase in Irradiated $Gd_2Ti_{2-y}Zr_yO_7$ Pyrochlore

Yogendar Singh, Vivek Kumar and Pawan K. Kulriya; Jawaharlal Nehru Technological University, India

Recently, significant efforts have been made to understand the radiation effects in nuclear materials in order to improve their performance under extreme conditions of the nuclear reactor system, including waste management. The ability to retain the crystalline phases in irradiated materials demonstrates how the complex microstructure of these ceramics influences the kinetics of temperature-induced structural transition.
This study reports the thermal annealing-induced recovery of crystalline phases in ion-irradiated $Gd_2Ti_{2-y}Zr_yO_7$ (y=0.4,1.2,1.6) pyrochlore (120 MeV Au^{9+} ions) using in-situ synchrotron x-ray diffraction (SR-XRD), micro-Raman spectroscopy, and scanning electron microscopy (SEM). The results of the SR-XRD analysis show that the pre-irradiated pyrochlore structure is recovered at 1000 °C for Ti-rich composition. However, beyond 500 °C, Zr-rich compositions show recrystallization to an intermediate defect-fluorite phase, and even after annealing at a high temperature of 1000 °C, the pre-irradiated pyrochlore superstructure does not recover. These results reveal that recrystallization temperature strongly depends on the accumulated radiation damage, which is generally described with the cationic radius ratio (r_A/r_B).

SF04.15.25

Effects of Non-Schmid Stresses on 〈a〉-Type Screw Dislocation Cores in α-Ti

David Jany and Daryl Chrzan; University of California, Berkeley, United States

〈a〉-type dislocations are a major carrier of plasticity in HCP metals. Their mobility is known to be limited by their screw component. In α-Ti, 〈a〉-type screw dislocations have been observed to have a jerky glide: gliding at high velocity over long distances on the prism plane, but occasionally getting locked in position, and sometimes gliding slowly on the pyramidal plane over short distances. The motion is controlled by the dislocation core morphology which impacts the energy barriers of the prism-, pyramidal-, and cross-slip. Density functional theory computations have shown that the difference between these energy barriers is small, within tens of meV per burgers vector. From a metallurgical standpoint, this is of particular interest. If one can tune the magnitudes of these barriers, one can enhance pyramidal or prism slip, and one can thus tune the material's mechanical properties.
Non-Schmid stresses, i.e., stresses that do not drive the motion of dislocations, are known to impact the core

morphology of 〈a〉-type screw dislocations in α-Ti. We have developed a model to quantitively assess the interaction of the dislocation core with non-Schmid stresses. We show that non-Schmid effects are caused by an interaction of the dislocation core displacement field with non-Schmid stresses and that this displacement field is accurately characterized by an elastic dipole tensor. Density functional theory was used to compute the elastic dipole tensor of screw dislocations during a pyramidal and prism slip and a cross-slip from a pyramidal to a prism plane. We illustrate the effects of non-Schmid stresses on the mobility of dislocations through the case of an oriented single crystal undergoing tensile stress. We predict a change in the dislocation pattern (planar to wavy) depending on the crystal orientation.

The model allows one to assess the effect of complex stress fields on dislocation mobility. One could use it to understand how to leverage non-Schmid effects to engineer dislocation cores through alloying. Indeed, point defects generate a stress field that will interact with the core field and change the energy barriers of slip events. This problem can now be tackled with a quantitative approach.

The authors gratefully acknowledge funding from the U.S. Office of Naval Research under grants N00014-17-1-2283 and N00014-19-1-2376. The final portions of this work were completed with funding from the National Science Foundation under contract 2324022.

Novel Electrochemical Approaches for Plating of In-Sn Alloys *Abdullah Faisal Pasha, Peter Borgesen and Nikolay G. Dimitrov; Binghamton University, The State University of New York, United States*

In the era of Artificial Intelligence (AI), our society needs processors that offer high computing power while maintaining a compact chip configuration without sacrificing reliability. The current development in chip configuration is 3D stacking technology, which is a vertical arrangement of chips to make integrated circuits (ICs) more compact. A hierarchy of solder joints according to the melting point is essential for 3D IC boards to achieve this vertical arrangement. So, the first layer of solder joints should have a higher melting temperature than the second layer to prevent the melting of the first layer during the chip packaging process. The European Union legislation has banned the application of tin-lead (Sn-Pb) solder alloy, the most widely used low-melting alloy to date. A vigorous search for alternatives to Sn-Pb identified the alloy with a composition of Sn–3.0Ag–0.5Cu (SAC305) as a good substitute for the Sn-Pb solder. However, a key drawback of that alloy in 3D configurations is associated with its relatively high melting temperature. Therefore, eutectic tin-bismuth (Sn-Bi) and tin-indium (Sn-In) alloys may be a viable alternative due to their low melting solderability. However, mechanical assessments show that Sn-Bi alloys are brittle, thus rendering the Sn-In alternative a more feasible option for next-generation interconnections. The electrochemical approach is the most conventional method for creating micron interconnections. However, the electroplating of Sn-In in aqueous solution is largely unexplored.

In the present work, two different electrochemical methods have been studied to generate Sn-In alloys. The first approach involves bulk plating of plain Sn and In metals as successive layers, followed by a high-temperature reflow. In the latter approach, we developed a unique technique for co-depositing Sn-In alloys by simply adjusting the pH in a joint plating bath containing $SnSO_4$ and $In_2(SO_4)_3$, respectively. The pH was set at 2.2, 2.5, 2.9, and 3.5 while keeping other experimental parameters constant. This led to the formation of Sn-In alloys with different compositions. Overall, this research emphasizes the latter approach as a new pathway for co-depositing Sn-In alloys. Differential Scanning Calorimetry (DSC) and Scanning Electron Microscopy (SEM) were utilized to determine the composition and projected solderability of the accordingly synthesized alloys.

SF04.15.27

Ball-Milling Technique to Produce Massive Boride Nanoparticles *Grace Farrell[1], Zhe Chen[2], Willie Rockward[1], Hertanto Adidharma[2], Maohong Fan[2] and Yucheng Lan[1]; [1]Morgan State University, United States; [2]University of*

Wyoming, United States

Diborides are ultra-high temperature ceramics with exceptional mechanical strength / hardness, thermal conductivity, and chemical stability. These properties make them highly valuable in applications such as refractory materials, renewable energy, hypersonic industries, and fusion reactors. Therefore, it is essential to produce large quantities of nanoparticles of these compounds. In this study, we employed ball-milling, a conventional top-down method, to fabricate nanoparticles of zirconium diboride, a representative diboride. The effects of milling time and the ball-to-material ratio were systematically investigated. X-ray diffraction analysis revealed that the raw compound transformed into nanomaterials after eight hours of milling and became amorphous after sixteen hours. The underlying mechanism was also discussed and materials with different crystallinity were produced by tuning experimental conditions.

SESSION SF04.16: Machine Learning and Modeling for 2D and WBG Materials

8:45 AM *SF04.16.01
Data-Driven and Machine Learning-Assisted Design of Functional Defects in Two-Dimensional Materials
Qimin Yan; Northeastern University, United States

Being atomically thin and amenable to external controls, two-dimensional (2D) materials offer a new paradigm for many technologies such as (opto)electronics, energy conversion, and quantum information. In this talk, as an example of functional defect design, I will discuss how data-driven material science can be combined with symmetry-based physical principles to guide the search for spin defects in 2D materials for quantum information technologies and beyond. In our initial work, the use of local bonding symmetry as a material design hypothesis enables the identification of anion antisite defects as promising spin qubits and quantum emitters in six monolayer transition metal dichalcogenides. To enable high-throughput search of functional defects in a vast material space, we propose two machine learning (ML) models that are specially designed for learning localized defect properties, taking advantage of topological objects (Betti numbers) as node features and the Siamese equivariant network architecture. Trained by 5,000~20,000 diverse defected material systems, our models outperform the state-of-the-art models in predicting the formation energies of point defects. This ML capability enables the fast screening of functional defects in 2D materials, and the high-throughput search in all known binary 2D materials led to the identification of more than 45 quantum defect candidates that can be utilized as qubits and/or quantum emitters. At the end of the talk, I will discuss future directions to accelerate the discovery of "defect genome" in a vast space of material systems.

9:15 AM SF04.16.03
Inverse Design of Thermal Transport with Auxiliary Physics-Informed Neural Networks for Ultra-Wide-Bandgap Semiconductor Materials *Roberto Riganti and Luca Dal Negro; Boston University, United States*

The traditional formulation for the inverse design of complex electronic devices consists of determining desired material properties and device geometrical and doping characteristics from a limited set of measured data. The rigorous solution of this problem based on the inversion of the Boltzmann transport equation would enable the *predictive design of desired novel functionalities in a large frequency range. However, such inverse problems are notoriously high dimensional, intrinsically ill-posed, and strongly nonlinear. Under these circumstances, traditionally numerical techniques fail to predict the desired systems' parameters to a reasonable degree of precision. Motivated by these limitations, a new class of mesh-free numerical solvers based on artificial neural networks (ANNs), known as physics-informed neural networks (PINNs), have recently gained popularity due to their inherent ability to regularize and efficiently handle the solution of inverse problems. In particular, using only a single training dataset, PINNs leverage both the physical constraints and the desired engineered output to restrict the space of potential solutions and inversely solve for a realistic set of parameters for a desired structure. We have already successfully employed this methodology for the inverse design of scattering nanostructures and photonic metamaterials based on the inversion of the dynamic Maxwell's equations. Here, we describe our recent advances in developing auxiliary physics-informed neural networks (APINNs) for the forward and inverse solution of the phonon Boltzmann transport equation (BTE) applied to a class of ultra-wide-bandgap (UWBG) semiconductor alloys. Specifically, we focus on* $Al_xGa_{1-x}N$*, materials at different Al concentrations and obtain APINN solutions for arbitrary temperature gradients in different relevant device geometries. The APINN framework avoids discretization errors due to the quadrature evaluations of integral terms, mapping an integro-differential transport problem into an equivalent differential one. Our work provides a new path to efficiently design UWBG materials with desired thermal transport properties for applications to high-frequency and high-power microelectronics devices.*

9:30 AM SF04.16.04

Accelerated Discovery of Perovskite Solid Solutions Through Automated Materials Synthesis and Characterization *Mojan Omidvar[1], Hangfeng Zhang[1], Achintha A. Ihalage[1], Theo Saunders[1], Henry Giddens[1], Michael Forrester[2], Sajad Haq[2] and Yang Hao[1]; [1]Queen Mary University of London, United Kingdom; [2]QinetiQ, United Kingdom*

The emergence of laboratory automation has significantly accelerated the materials discovery process. Advances in machine learning (ML) have been applied in various areas, including discovering novel perovskite compositions for photovoltaics, optimizing electronic properties of thin films, and generating databases. Perovskite materials are extensively researched due to their broad functional properties, applicable in wireless communications, tunable antennas, and biosensors. However, traditional discovery and optimization of perovskite solid solutions are hindered by extensive chemical diversity and complex processes of solid state reaction influencing their micro-structure and properties.

Most current ML models rely on computational samples due to the challenge of obtaining substantial experimental data, limiting their accuracy. There is a scarcity of studies that experimentally synthesize and validate ML-predicted materials, highlighting a significant research gap. With the maturation of artificial intelligence (AI) and collaborative robots, more "self-driving laboratories" (SDLs) for material discovery are being developed. However, SDLs are predominantly in their early stages, particularly within the realm of solid solutions due to intricate workflows and the complexities involved in dielectric measurements for 3D materials.

We present a customizable SDL loop concept for the synthesis and characterization of perovskites, combining AI and expert scientific input. Our automated platform for rapid sintering processes and high-throughput dielectric property measurements facilitates fast material screening and characterization. The platform features a central hub on MATLAB for orchestrating lab instruments and data management. The sequence initiates with ML models recommending sample library compositions, followed by automated pellet sintering, synthesizability validation via XRD, temperature tuning, real-time dielectric property measurements, and analysis linking dielectric attributes to the synthesis process. The cycle concludes with the updating of archives.This advancement significantly reduces the time and labor required for generating validation datasets, improving ML models by rapidly revealing correlations between processes and structures. Continuous learning from experimental outcomes allows ML *models to propose modifications in composition or processing factors to attain desired dielectric properties.*

Monday Morning, December 2, 2024
Hynes, Level 2, Room 203

10:30 AM *SF05.01.01
Theory-Guided Defect Engineering in Magnetic Materials *Martin Friak; The Czech Academy of Sciences, Czechia*

Defects are omnipresent and defect-free states exist only as approximative idealizations of complex reality around us. Specifically in materials science, defects can be not only tolerated (as nearly unavoidable) but also exploited within various defect-engineering approaches. Indeed, defects offer potentially unlimited playground for fine-tuning materials properties in contrast to the defect-free state which is only one. Quantum-mechanical calculations have proved to be an excellent guide in this uncharted territory, in particular, in the case of magnetic materials. Both point defects and extended defects may profoundly impact various properties, including structural, elastic or thermodynamic ones. Importantly, the impact can be, in fact, positive and welcome when defect-containing systems outperform their perfect counterparts. The talk will exemplify these facts in the case of our recent projects focused on defects in magnetic intermetallic compounds and disordered alloys. The former will be represented by Fe_3Al-based intermetallics, the latter by Fe-based intermetallics-containing superalloys.

Special attention will be paid to mutual interactions of defects with different spatial dimensions, such as point-defect impurities interacting with planar grain (antiphase) boundaries, or extended defects existing in materials exhibiting different levels of chemical disorder.

11:00 AM SF05.01.02

High-Pressure Discovery of Co–Bi Compounds *Catherine K. Badding[1], Eric Riesel[1], Danilo Puggioni[2], Yingwei Fei[3], Yue Meng[4], James M. Rondinelli[2] and Danna E. Freedman[1]; [1]Massachusetts Institute of Technology, United States; [2]Northwestern University, United States; [3]Carnegie Institution for Science, United States; [4]Argonne National Laboratory, United States*

Many transition metal (TM) and Bi compounds exhibit emergent properties, such as superconductivity and permanent magnetism, driving interest in TM and Bi bond formation. However, there is a paucity of TM–Bi materials due to the limited reactivity between TMs and Bi at ambient pressure. We can use high-pressure conditions to overcome this to synthesize novel TM–Bi compounds. High pressure yielded the first Co–Bi compound, superconducting CoBi_3*, at 10 GPa. We aimed to study the Co–Bi system above 10 GPa. Using ab initio random structure searching (AIRSS), we found 5 new predicted Co–Bi structures. In conjunction with our calculations, we performed laser-heated diamond anvil cell experiments and realized 3 of the predicted structures:* $\alpha\text{-CoBi}_2$*, ß-CoBi, and* ß-CoBi_2*. Additionally, by using a high-pressure multi-anvil press, we synthesized a 4th compound not predicted by AIRSS, α-CoBi, that forms in a novel structure type not reported in the ICSD. Through examination of these structures, we determine trends in TM and Bi bond formation, such as higher dimensionality and higher bismuth content at higher pressure. Further, these higher-pressure phases are isostructural to other TM–Bi structures. Density of states calculations suggest these materials are non-magnetic, unlike ferromagnetic MnBi and* $\text{Mn}_{1.05}\text{Bi}$*. These results illustrate how computational methods can enhance the discovery of experimental materials and understanding of the structure-property relationship.*

11:15 AM SF05.01.03

Improving the $(BH)_{max}$ ***of*** $L1_0$***-Structured t-MnAl by Processing*** *Ian Baker[1], Thomas Keller[1], Wuxian Yang[2], Wen Chen[2] and Gheorghe Gurau[3]; [1]Dartmouth College, United States; [2]University of Massachusetts Amherst, United States; [3]Dunarea de Jos University of Galati, Romania*

$L1_0$ *structured, near-stoichiometric t-MnAl has great potential as a permanent magnet for applications to fill the gap between high-performance rare-earth magnets with an energy product,* $(BH)_{max}$*, up to 470* kJ/m^3 *and inexpensive low performance ferrites with a* $(BH)_{max}$ *of ~32* kJ/m^3*. The metastable t-phase can display a saturation magnetization,* M_S *of ~161* Am^2/kg*, a coercivity,* H_C*, of 430 KA/m, and has a theoretical* $(BH)_{max}$ *of 101* kJ/m^3*. Unfortunately, simultaneously obtaining a high* M_S *and a high* H_C *has been problematic. Here we present the results of processing by three different methods: high strain rate high-pressure torsion at elevated temperature, back-pressure-assisted equal channel angular extrusion also at elevated temperature of cast billets, and laser powder bed fusion using pre-alloyed powder. The microstructures of the resulting materials were characterized using x-ray diffraction and electron backscattered diffraction imaging in a scanning electron microscope. The latter was used to identify the phases present and their orientations, the grain size and to determine the dislocation density. The extent of cracking was also characterized. The magnetic properties were measured in different directions using a vibrating sample magnetometer and related to the microstructures. This work was supported by the National Science Foundation under awards 1852529 and 2238204.*

11:30 AM SF05.01.04

Advanced Processing Methods for CeFe_{12}***-Based Permanent Magnets Phases with Narrow Stability Regimes***
Alfred Amon, Eunjeong Kim, Alex Wilson-Heid and Alex Baker; Lawrence Livermore National Laboratory, United

States

Projections expect the demand for permanent magnets to double by 2030 when it will exceed the supply of neodymium-based magnets by far. The fastest market growth is foreseen in wind energy and electric vehicles. Economies preparing for a green energy transition are therefore looking for alternative technologies such as permanent magnets based on the cheap and abundant rare earth metal cerium. Promising performance has been demonstrated in thin films and powders of the intermetallic phase $CeFe_{12-x}Ti_xN$ with $ThMn_{12}$ structure, but manufacturing of bulk magnets, essential for commercialization, remains a major obstacle. Besides the realization of fully dense material and microstructure optimization, the thermodynamic instability of these materials results in a narrow window of processing conditions and has hitherto prevented the realization of optimum performance. Hitherto, the majority of works have focused on the influence of substituting Fe for Co, Mo, Ga, Ti or V on the phase stability and magnetic properties in cast material or thin films.
We have investigated the suitability of advanced powder processing methods such as laser powder bed fusion and spark plasma sintering for the preparation of bulk magnets from powders of the $CeFe_{12-x}Ti_xN$ phase. The rapid solidification rates of the former and the mild sintering conditions of the latter method are ideally suited for the consolidation of powder materials that defy conventional processing methods. After establishing process-structure-property relationships for the material, we have investigated the processing regimes for obtaining suitable microstructures for permanent magnet performance while retaining the targeted chemical composition of the intermetallic phase. Work performed at LLNL under contract DE-AC52-07NA27344.

11:45 AM SF05.01.05
Topotactic Denitriding of Antiperovskite Compounds to Synthesize Novel Magnetic Intermetallics *Shaun O'Donnell[1], Rebecca Smaha[1], James R. Neilson[2] and Sage Bauers[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado State University, United States*

Atomic disorder can be detrimental to the functional properties of intermetallic compounds. For example, in Heusler half metals, anti-site defects decrease the fraction of mobile polarized electron spins. Unfortunately, disorder can be difficult to avoid in materials with metallic bonding, where there is often only a small energetic difference between many atomic configurations. On the other hand, in ternary compounds with two metals and an anion, such as antiperovskite nitrides, it can be much more energetically costly to adopt metal site disorder. If order on the metallic sublattice is maintained during anion removal, antiperovskite nitrides could serve as precursors to new ordered intermetallic phases that can, (1) not be made using conventional approaches, and/or (2) be difficult to prepare without atomic disorder.
Inspired by this idea, we have prepared several antiperovskite nitrides using conventional solid-state chemistry techniques, then topotactically removed the N to transform the antiperovskites into magnetic intermetallic phases. We focus on the transformation of Mn_3GeN to Mn_3Ge, which is achieved by reducing the precursor powder in flowing Ar gas (800 °C for 12 hours). Using synchrotron and neutron scattering, we track the effects of denitriding. Subtle structural distortions related to rotations of NMn_6 octahedra disappear when partially denitrided. The fully denitrited Mn_3Ge phase then undergoes an additional slight structural rearrangement but overall, the metal positions are almost entirely “locked” into their antiperovskite positions. While structural distortions are subtle a change in magnetic order is observed by emergent magnetic Bragg peaks in neutron diffraction and further confirmed by SQUID magnetometry which shows that while Mn_3GeN is magnetically soft, Mn_3Ge has a wide magnetic hysteresis loop and coercive field of ~1T at 300 K. In addition to the $Mn_3GeN \rightarrow Mn_3Ge$ transformation, we discuss the generality of topotactically denitriding antiperoskites using precursors of Mn_3GaN and Mn_3CuN powders, as well as thin films of Mn_3GeN and Co_3PdN. Overall, this work highlights an exciting approach for the synthesis of many novel ordered intermetallic phases.

SESSION SF05.02: Shape Memory Alloys
Session Chairs: David Holec and Yonghoon Lee
Monday Afternoon, December 2, 2024
Hynes, Level 2, Room 203

1:30 PM *SF05.02.01
Shape Memory Alloys—Industrial Needs and Trend *Koichi Tsuchiya; National Institute for Materials Science, Japan*

Shape memory alloy (SMA) exhibits two very unique properties, known as shape memory effect (SME) and superelasticity(SE), both are closely related to thermoelastic martensitic transformation. In SME, when SMA is deformed in martensitic state, it recovers the original shape by heating above Af temperature, where the austenite phase is stable. In SE, when the load is applied to SMA in the austenitic state, the strain is produced by stress-induced martensitic transformation and it vanishes by the reverse transformation on unloading.
Most widely used SMA is TiNi. They are used widely in various areas of applications, such as, medical devices, aerospace, micro-actuators, constructions, etc. There is also an increasing interest in the elastocaloric effect of the alloy.
However, the TiNi has several drawbacks, such as, 1) shape recovery temperature (Af temperature) is limited to about 100 degC. 2) Poor plastic formability. 3) functional/structural fatigue, etc. To overcome these drawbacks, extensive effort has been made to develop new alloys, new processing method, and to gain further insight into the transformation mechanism.
This talk will review the recent trend in SMA research and introduce some of the emerging applications.

2:00 PM SF05.02.02
Enhancing Recovery Characteristics of FeMnSi-Based Shape Memory Alloys Through Complex Defect Engineering *Ji Young Kim, Minseok Kim, Wook Ha Ryu, Hyun Gi Min and Eun Soo Park; Seoul National University, Korea (the Republic of)*

Iron-based shape memory alloys (SMAs), especially FeMnSi-based alloys, have great potential in civil engineering because of their low cost and shape memory properties based on stress-induced epsilon martensitic transformation (SIEM). In FeMnSi-based SMAs, austenite phase strengthening was aimed to enlarging the elastic deformation strain range, thereby enhancing recovery characteristics such as recovery strain and recovery stress. Thus, previous researchers have tried to strengthen the parent austenite phase by adding interstitial atoms or the precipitation of secondary phases. As a new paradigm for enhancing the recovery characteristics of FeMnSi-based SMAs, in this study, we suggested FeMnSi-based SMAs with high grain boundary density to strengthen the austenite phase based on the understanding of the intrinsic grain size effect. However, based on the in-situ high-energy diffraction experiments during uniaxial tensile testing and ex-situ electron microscope analysis, we found that the reduction in grain size simultaneously leads to an increase in annealing twin boundaries and the suppression of forward martensitic transformation, which are undesirable outcomes in terms of recovery strain. Herein, to overcome the limitation of high annealing twin boundary density and suppressed forward martensitic transformation, which is known as an obstacle to enhancing recovery characteristics, we developed a novel subsequent thermomechanical treatment that can control the annealing twin boundary density and stacking fault probability. We optimized the pre-strain value and heat treatment condition based on the understanding of the *generation and annihilation mechanisms of each defect. As a result, we have successfully developed ultra-fine grain-sized FeMnSi-based SMAs with an improved recovery strain. Moreover, we also investigated the recovery stress depending on the grain size and developed a thermomechanical treatment. Finally, we successfully developed a FeMnSi-based SMA exhibiting both excellent recovery strain and recovery stress via grain size control and complex defect engineering. This study is the first to improve recovery characteristics through grain refinement, especially with a low density of annealing twin boundary density and increased stacking fault probability. Therefore, we expect that this study has the scientific significance of revealing the effect of grain boundary, annealing twin boundaries, and stacking faults on non-thermoelastic martensitic transformation and the engineering significance of offering a guideline for designing shape memory alloys with enhanced recovery characteristics through defect control.*

X-Ray Absorption Spectroscopy Study of the Local Atomic Structure in a Ductile Cu-Al-Mn Shape Memory Alloy

Kakeru Ninomiya[1,1,1], Zheyuan Liang[1], Hiroshi Akamine[2], Ryotaro Arai[2], Sumio Kise[3], Minoru Nishida[2] and Maiko Nishibori[1,1,1]; [1]Tohoku University, Japan; [2]Kyushu University, Japan; [3]Furukawa Techno Material Co., Ltd., Japan

Cu-Al-Mn-based superelastic alloys (CAM) are expected to be used in fields where Ni-Ti alloys, such as seismic-resistant materials, are difficult to apply due to their low cost and excellent workability [1]. Although it has been reported that the shape memory properties change significantly with low-temperature heat treatment, it is necessary to identify the degree of order that contributes to improving these properties and understand the mechanisms of structure changes. We believe that the atomic arrangement is highly disordered after quenching and changes into a short-range ordered state during low-temperature heat treatment, leading to a variation in phase equilibrium between the parent and martensite phases [2]. While it is known that the β phase undergoes A2/B2/$D0_3$/$L2_1$ order-disorder transformations, a quantitative evaluation of the structural changes induced by the ordering heat treatment has not yet been conducted. In the previous study, we attempted to track the average local structure of Cu, which represents the highest content in CAM, using X-ray absorption spectroscopy (XAS) [3]. This time, we used XAS to analyze the changes in the average structure of the additive elements Al and Mn, which determine the shape memory effect [4] during low-temperature heat treatment, to clarify the impact of the degree of order on the martensitic transformation in the Cu-16.5Al-10.6Mn (at%).

The As-quenched Cu-16.5Al-10.6Mn (at%) alloys exhibit non-homogenous, in which the average local Mn exhibits an $L2_1$-like structure, and the local Al displays an intermediate state between $D0_3$ and $L2_1$. Conversely, the local structure of Cu is composed of a $D0_3$-like structure in the present work [3]. During the 100°C heat treatment, the average local structure of Mn atoms tends to form an $L2_1$ structure. The arrangement of Mn atoms changes in two stages: the formation of Mn-rich structures and reduction during 150°C heat treatment, while no significant change was observed for Al. These results show that the ratio of $D0_3$-like to $L2_1$-like is 3:2 in As-quenched alloy. During the heat treatment, the degree of order in the local structure of Mn and Al increased.

Stress-Induced Martensitic Transformation of Niti Shape Memory Alloy Thin Films at Elevated Temperatures

Ji-Young Kim, Yuhyun Park, Zhuo Feng Lee and Gi-Dong Sim; Korea Advanced Institute of Science and Technology,

Korea (the Republic of)

Shape memory alloys (SMAs) exhibit exceptional strength, along with unique mechanical and thermal recovery properties not found in conventional metals. These outstanding properties are preserved even at microscopic scales, offering advancements in micro-scale medical devices and electronic components that require both high strength and flexibility. In particular, shape memory alloy thin films can be directly deposited onto semiconductor chips and patterned into specific shapes, making them ideal for the development of various miniature devices.
The unique properties of SMAs arise from the martensitic phase transformation process in response to heat and stress. While phase transformation characteristics persist even at small scales, it is known that these characteristics change as the size of the structure decreases. Additionally, since phase transformation is highly sensitive to the chemical composition and operating temperature, both factors must be considered to tailor the phase transformation behavior of small-scale SMAs. However, there are only limited studies on the phase transformation of SMAs under mechanical loading in micro/nano-scale.
Therefore, we fabricated nickel-titanium (NiTi) SMA thin films and observed their temperature-dependent mechanical response. Using microelectromechanical systems (MEMS) processes, we produced 500 to 600 nm-thick freestanding thin film specimens along with Joule-heating tungsten microheaters. A custom-built micro-scale tensile testing equipment was installed inside a scanning electron microscope (SEM) to observe stress-induced martensitic transition of thin films at elevated temperatures. Interestingly, all thin films across the composition range from Ti-rich (47.4 at. % Ni) to Ni-rich (52.7 at. % Ni) exhibited martensite start temperatures (M_s) below 0 °C, approximately 50 °C lower than their bulk counterparts. Because of the low M_s, Ti-rich and equiatomic NiTi thin films show superelastic behavior around 40 °C, which is near the human body temperature. Moreover, Ti-rich thin films exhibit better mechanical stability than equiatomic thin films. The change in mechanical behavior with chemical composition could be attributed to different type of precipitates that can either expedite or suppress forward and reverse transformation processes.

Performance of Thermoelectric Generation Module Using $Mg_2(Si,Sn)$ Based Thermoelectric Materials

Yonghoon Lee[1] and Yoshisato Kimura[2]; [1]KELK Ltd., Japan; [2]Tokyo Institute of Technology, Japan

Thermoelectric conversion is an energy conversion technology that has been around for a long time, which includes thermoelectric power generation that can directly convert heat energy into electrical energy in principle without emitting CO_2, and thermoelectric cooling and temperature control that can directly convert electrical energy into heat energy. Thermoelectric conversion technology is expected to help address environmental issues believed to be caused by global warming, as well as the increasing energy demand issue. In the concept of a rapidly expanding smart society in recent years, there are many challenges that need to be addressed, and stable energy supply is one of them. In addition to the use of natural energy sources such as wind power and solar power, effective utilization of renewable energy sources like waste heat utilization for thermoelectric power generation is *also considered as one of the solutions to the energy supply problem. Furthermore, there is a growing demand for energy harvesting as a power source for driving various sensors that are widespread in modern society. Thermoelectric power generation is a versatile technology that can be applied regardless of the scale, from powering mW-level wireless sensor drives to MW-level large power generation.*

While there have been many research efforts to develop and improve the performance of thermoelectric materials, the practical thermoelectric conversion materials currently in use are mainly Bi_2Te_3-based and PbTe-based, which contain heavy metals, and are still relatively few compared to the long history and extensive research on materials. When selecting thermoelectric materials, it is important to consider not only having high thermoelectric performance but also factors related to safety (non-toxicity), thermal stability, and peripheral technologies related to module development such as device technology for modularization. In addition, for the practical implementation of thermoelectric conversion technology, further enhancement of material performance, scaling up of modules, establishing mass production processes, confirming the durability (reliability) of modules and systems, reducing costs, and providing numerous examples of successful applications are necessary.

KELK Ltd. and Komatsu Ltd. have been focusing on $Mg_2(Si,Sn)$ compounds that demonstrate relatively high thermoelectric characteristics in the temperature range from around 300°C to 600°C, and have been consistently conducting research from material performance improvement to module development over the years. The figure of merit ZT of the materials obtained so far were 1.2 for N-type materials and 0.5 for P-type materials at around 400°C, where Z is given as $S^2/(\rho\kappa)$, S is the Seebeck coefficient (Thermopower) [V/K], ρ is the electrical resistivity [Ωm], and κ is the thermal conductivity [$Wm^{-1}K^{-1}$]. Note that a ZT value exceeding 1 is considered as required potential for practical applications. Furthermore, from the power generation test of modules using these materials, a maximum output of 7.8 W and an output density of 1.2 W/cm^2 were obtained at the temperature difference ΔT of 470°C ($\Delta T = T_h500°C/T_c30°C$, where T_h and T_c are hot-side and cold-side temperature), with a maximum thermoelectric conversion efficiency of 7.5%. The presentation will introduce the results in material research, the current status and challenges of module development.

Thermal Conductivity Reduction of Fe2VAl Thermoelectric Alloys Through Atomotic Disorder Engineering

Apoorva P. Joshi, Russell Taylor, Tao Fang, Cory T. Cline, Weiling Dong, Jifeng Liu, Ian Baker and Geoffroy Hautier;
Dartmouth College, United States

Understanding the fundamental thermal transport is crucial to tuning thermal conductivity, an important factor in high efficiency of a thermoelectric material. Fe2VAl has emerged as a promising thermoelectric material due to its non-toxicity, narrow bandgap, and cost-effectiveness, making it suitable for high-efficiency energy conversion applications. This study investigates the impact of both n-type(Germanium) and p-type(Aluminum) dopants on the thermal conductivity of Fe2VAl, aiming to optimize its thermoelectric performance. Through engineering disorder in the compound in particular by doping with germanium we demonstrate a significant reduction in thermal conductivity. The base alloy Fe2VAl has thermal conductivity of ~25W/K-m at 300K, while the doped Fe2VAl0.9Ge0.1 has a thermal conductivity of less than 5W/K-m at 300K. Furthermore, the temperature-dependent thermal conductivity shows a behavior similar to amorphous materials such as fused silica .This reduction is attributed to enhanced atomic disorder within the material. Furthermore, we explore the fundamental mechanisms of thermal conductivity and atomic disordering and its impact on lattice dynamics by fitting temperature-dependent thermal conductivity measurements from 10K to 600K. By analyzing the combined effects of off-stoichiometric composition and heat treatments, we elucidate how factors such as alloying and disorder lead to a drastic reduction in thermal conductivity. This is achieved by considering diagonal and off-diagonal transport mechanisms and incorporating electron-phonon scattering enhanced by band structure modification upon atomic disordering into the Callaway Model, in addition to point defect scattering and boundary scattering. Our findings provide insights into the pathways for achieving low thermal conductivity in Fe2VAl and highlight the

potential of tailoring thermal properties through a strategic combination doping and heat treatments, advancing the development of high-performance and economically viable thermoelectric materials.

4:00 PM SF05.03.03

Atomic Disorder Engineering of Thermoelectric P-Type Fe_2VAl Doubling Previously Reported ZT *Russell Taylor[1], Tao Fang[1], Cory Cline[2,1], Weiling Dong[1], Apoorva P. Joshi[1], Geoffroy Hautier[1], Wei Chen[3], Ian Baker[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Exponent, Inc., United States; [3]Université Catholique de Louvain, Belgium*

The $L2_1$ intermetallic compound Fe_2VAl is an ecofriendly, low cost, and easy to process potential replacement for conventional low temperature (250 - 500 K) thermoelectric materials used for waste-heat energy harvesting, such as Bi_2Te_3, which is brittle and uses toxic and expensive elements. The main issue with Fe_2VAl is its high thermal conductivity (~25 W/mK at 300 K) which leads to a low figure of merit, ZT. The aim of this project is to investigate off-stoichiometric compositions and engineer atomic disorder to enhance both the thermal and electrical properties of bulk p-type Fe_2VAl.

While the highly ordered $L2_1$ phase is the ground state, the higher temperature B2 (Al-V site swapping) and A2 (fully disordered) phases, whose transition temperatures are identified using DSC, can be retained through quenching. Notably, by replacing V with Al the B2 phase transformation temperature is lowered causing more retained disorder after quenching. The effect is a thermal conductivity reduction >60% to 9 W/mK. Al-rich compositions also demonstrate a flattening of the conduction band and widening of the bandgap resulting in an increased effective carrier mass and lower mobility. The flattened conduction band edge, however, converges with a second band increasing the carrier density and enhancing conductivity while maintaining the Seebeck coefficient. The net result is a far off-stoichiometry composition, namely $Fe_2V_{0.7}Al_{1.3}$, that exhibits a ZT >0.3 at temperatures above 400K which is nearly a 2x improvement compared to existing p-type Fe_2VAl.

4:15 PM SF05.03.04

Atomic Disorder Engineering of N-Type Thermoelectric Fe_2VAl Approaching the ZT of Bi_2Te_3 *Russell Taylor[1], Cory Cline[1], Tao Fang[1], Weiling Dong[1], Apoorva P. Joshi[1], Geoffroy Hautier[1], Wei Chen[2], Ian Baker[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Université Catholique de Louvain, Belgium*

The $L2_1$ intermetallic compound Fe_2VAl is an ecofriendly, low cost, and easy to process potential replacement for conventional low temperature (250 - 500 K) thermoelectric materials used for waste-heat energy harvesting, such as Bi_2Te_3, which is brittle and uses toxic and expensive elements. The main issue with Fe_2VAl is its high thermal conductivity (~25 W/mK at 300 K). The aim of this project is to identify dopants and engineer atomic disorder to enhance both the thermal and electrical properties of bulk n-type Fe_2VAl.

While the highly ordered $L2_1$ phase is the ground state, the higher temperature B2 (Al-V site swapping) and A2 (fully disordered) phases, whose transition temperatures are identified using DSC, can be retained through quenching. With the addition of Ge, these meta-stable phases, which are quantified using XRD, can be further stabilized. The band structures of the disordered phases show a flattening of the conduction band and therefore an increased effective carrier mass and reduced mobility which is compensated for by the increased carrier density. The result is a high Seebeck coefficient approaching 200 μV/k at 350 K. With reduced lattice periodicity from large element doping and disordered phases, the temperature dependent thermal conductivity shows "glass-behavior" and is reduced by >80% to below 5 W/mK. The net result is a figure of merit, ZT, >0.7 at 400 K, twice the value previously reported and rivaling the performance of Bi_2Te_3 (maximal ZT ~0.9).

4:30 PM SF05.03.05

Properties Control by Solid Solution Substitution for Vacancy-Site in Half-Heusler ZrNiSn-Based

Thermoelectric Materials *Yoshisato Kimura[1], Yu An Chen[1], Yusuke Tsubono[1] and Yaw Wang Chai[1,2]; [1]Tokyo Institute of Technology, Japan; [2]Metal Technology Co. Ltd., Japan*

Thermoelectric power generation is an appealing approach for conserving energy and preserving the global environment. We are focusing on the half-Heusler compound ZrNiSn, a well-known excellent n-type thermoelectric material, which can be used at around 1000 K to directly convert high temperature waste heat into clean electrical energy. Recently, thermoelectric power generation is expected to use as battery-free IoT applications such as data sensing and transmission system aiming to utilize waste heat lower than 500 K. The present Author's group found that thermoelectric properties of ZrNiSn can be converted from n-type to p-type by the solid solution substitution of Co and Ir for the vacancy-site, one fourth of all the lattice points, which is a characteristic of Half-Heusler. The understanding for this important finding remains phenomenological, and it is necessary to elucidate mechanistically, for achieving the new thermoelectric materials design concept. For a given amount of substitution for the vacancy-site, Ir is more effective than Co in enhancing p-type values of Seebeck coefficient. Additionally, it was elucidated that lattice thermal conductivity can effectively be reduced according to the solid solution effect substituting for the vacancy-site, owing to the enhancement of phonon scattering. Here, we have noticed of the chance that solid solution formation should affect mechanical properties through solid solution hardening or softening depending on the situation of the vacancy-site substitution. Objective of the present work is to understand the effects of solid solution substitution for the vacancy-site on thermoelectric properties, and as well as on mechanical properties, for the half-Heusler ZrNiSn. For the desirable thermoelectric module design, it is beneficial to design both n- and p-type materials based on the same compound since physical and chemical properties are expected to be similar each other in n- and p-type materials, which may reduce efforts of complicated care against damages due to such as thermal stress and oxidation. Nearly single-phase Half-Heusler $Zr(Ni,M_x)_{1+x}Sn$ alloys (M = Co, Ir) were fabricated by the directional solidification using optical floating zone melting. In our previous research, the amount of Ir substitution fraction x was higher than 0.20 up to 0.43 in the chemical formula $Zr(Ni,Ir_x)_{1+x}Sn$, and a peak temperature range showing the maximum of Seebeck coefficient was at around 1000 K. In the present work, for example, we decreased Ir substation amount ranging from x is 0.04 to 0.10, with a prediction that peak temperature of Seebeck coefficient could be shifted toward the low temperature direction based on the previous observation. Consequently, the peak temperature of Seebeck coefficient shows the tendency to be shifted from 1000 K down to about 380 K as the Ir substitution decreases from 0.20 to 0.04, while the maximum value of Seebeck coefficient slightly decrease from 115 to 95 μV/K. This result should be attributed to the change of electronic structure regarding narrow band gap and the Fermi level. On the other hand, regarding mechanical properties, it was found that Half-Heusler ZrNiSn shows higher hardness in nano-indentation measurement at 300 K and higher 0.2% proof stress at 1273 K in compression test than Heusler $ZrNi_2Sn$. In the case of Co substitution for the vacancy-site, propensity of the solid solution softening has been observed while the amount of Co substitution increases from Half-Heusler to Heusler compositions.

SESSION SF05.04: TiAl I

TiAl-Based Intermetallics for Turbine Applications—Status, Development Opportunities and Challenges

Pierre Sallot; Safran Tech, France

Titanium-based intermetallic alloys have been for years identified as a solution for weight reduction in turbo-engine. The improved specific mechanical properties of these alloys, when compared to Ni-based superalloys, have pushed Safran and other major aero-turbine producers to develop and to introduce them in their newest generations of turbines. Nevertheless, despite clear advantages, not all of them are a reality for mass production. In the present study, the case of TiAl intermetallic systems will be used to exemplify actual developments, applications and remaining challenges for a widespread industrial usage of such alloys.
The industrialization steps for TiAl alloys in actual aircraft engines will clarify the importance of choosing adapted processing routes for complex parts production, and its strong interlinking with final properties and design. A specific section will focus on new Powder Metallurgy routes and their application to industrial parts.
In particular, the latest development of the Spark Plasma Sintering process to produce complex part out of TiAl powders will be detailed. The impact of the process parameters on final properties, as well as composition of alloys on microstructure will be discussed and compared to actual mechanical properties. An analysis of energy consumption will be presented with the comparison of such new processed with regard to conventional ones.
A discussion will be open as well to specifically address the issue of impact tolerance for such alloys, and particularly when targeting the next generation of engines.

9:00 AM *SF05.04.02
Mechanical Properties and Deformation Mechanisms at High Temperatures in TiAl Alloys *Alain Couret[1], Michael Musi[2], Guy Molénat[1] and Jean-Philippe Monchoux[1]; [1]Centre d'Élaboration des Matériaux et d'Etudes Structurales, France; [2]Montanuniversität Leoben, Austria*

Following the successful implementation of TiAl blades in aero-engines produced by GENERAL ELECTRIC and SAFRAN companies, the aim is now to increase the operating temperature of TiAl alloys, up to 800°C if possible. This requires optimization of the microstructures and chemical compositions of this family of alloys. In this context, the aim of the present work is to provide an in-depth understanding of the mechanical properties and deformation mechanisms of TiAl alloys in the temperature range above 700°C.
Tensile tests were carried out over the entire temperature range, as well as creep tests at 800°C and 200 MPa. The microstructures of the samples were studied using scanning and transmission electron microscopy, as well as X-ray diffraction. The deformation mechanisms were studied by means of in situ deformation experiments and post-mortem analyses of deformed samples, both using transmission electron microscopy. In addition, atom probe tomography analyses were carried out to assess the influence of additive elements.
Deformation is mainly due to ordinary dislocations. Several populations of dislocations are identified. Their Burgers vectors, the plane in which they move and the corresponding deformation mechanisms are determined. It will be shown that these dislocations are capable of gliding or climbing as a function of temperature and stress conditions. Next, the influence of the addition of elements such as tungsten, molybdenum, niobium, carbon and silicon will be studied. Finally, a controlled microstructure will be proposed to obtain optimum mechanical properties.

9:30 AM SF05.04.03
Three-Dimensional High Temperature Deformation Mechanisms in Tial Intermetallics Determined by Electron Tomography *Jean-Philippe Monchoux[1], Alain Couret[1], Guy Molénat[1], Michael Musi[2] and Daniel Ferry[3]; [1]Université de Toulouse, France; [2]Montanuniversität Leoben, Austria; [3]CINaM, CNRS, Université Aix-Marseille, France*

To identify the controlling mechanisms of alloys deformed at high temperatures, it is necessary to determine in

three dimensions (3D) the relative orientation of the dislocation motion planes with respect to the Burgers vector. Hence, glide, climb and/or mixed climb mechanisms can be deduced. While conventional tilting experiments have allowed such determination for a long time [1], the development of electron tomography techniques has recently opened new perspectives for a more accurate and systematic determination of the 3D dislocation structures, from which the mechanisms can be more easily derived [2-11]. Here, we present an electron tomography approach based on the accurate alignment of tilt series, using landmark tracking methods originally developed for the life sciences in the bibliography. In particular, it will be shown that complex dislocation sub-structures in TiAl alloys deformed at 800°C can be resolved in 3D with a typical spatial resolution of 10 nm. We will also present atom probe tomography studies, which aim was to identify the interaction mechanisms of the dislocations with substitutional (tungsten) and interstitial (carbon) solutes, added to increase the specific strength of TiAl alloys. We will then show that the morphological information provided by electron tomography, coupled with the chemical information provided by atom probe tomography, leads to unique insights into the interactions between gliding and climbing dislocations with solute atoms at the atomic scale, inspiring thus new TiAl alloy designs.

Strain Measurements within Lamellar (α_2+γ) Colonies of a γ-TiAlNb Alloy *Heike Gabrisch, Henry Ovri, Marcus Rackel, Florian Pyczak and Andreas Stark; Helmholtz-Zentrum Hereon, Germany*

It is well established that in γ-titanium aluminides that are alloyed with niobium the orthorhombic O-phase may form. In the present alloy, Ti-42Al-8.5Nb (at.-%), it was observed that at annealing temperatures between 450-680 °C or during slow cooling the hexagonal α_2 phase becomes distorted along three equivalent <11-20> directions and transforms to a disordered O-phase of identical chemical composition. The orientation relationship between the parent α_2 phase and O-phase is $(0001)_{\alpha 2}$ $//(001)_{O\text{-}phase}$ and $[11\text{-}20]_{\alpha 2}//[100]_{O\text{-}phase}$. During further annealing at 550 °C the initially formed O-phase separates into a two-phase mixture of α_2-phase and niobium rich O-phase with the respective compositions Ti-37Al-6Nb and Ti-36Al-12Nb [1].
High resolution imaging of α_2/O-phase lamellae shows that the crystal lattice that is continuous across the α_2-O-phase boundaries is highly strained. These strains likely alter the mismatch stresses between (α_2/O)-phase lamellae and γ lamellae and thereby affect the deformation behavior of the alloy.
Internal stresses resulting from small differences in lattice parameters can be measured conveniently by high-energy X-ray diffraction (HEXRD), giving average results over a large volume. Our measurements have shown that in Ti-42Al-8.5Nb annealed at 550 °C the lattice parameter of γ is constant after different annealing times. On the other hand, the lattice spacings in the O-phase vary with annealing time. The spacing along the a-direction becomes larger while the b-lattice parameter shrinks. Due to peak overlap in the HEXRD patterns it is not possible to measure the difference between lattice parameters of the O-phase and the α_2 phase.

In the TEM, microstructural characteristics can be traced on a more localized scale. We monitor the relative strains between (α_2/O)-phase lamellae and γ-lamellae in different annealing states of the alloy. The strain measurements show an increase in the mismatch between (α_2/O)-phase lamellae and γ-lamellae with annealing time. The effect of the O-phase on the mechanical properties of the alloy, along with insights into the underlying deformation mechanisms, is being investigated by comparing the stress-strain behavior and dislocation/twinning activities in deformed micropillars.
The alloy of the composition Ti-42Al-8.5Nb (at.-%) has been produced by hot isostatic pressing of pre-alloyed powders as described in literature. Two annealing states are produced: the α_2-annealing state with all of the α_2 phase in hexagonal shape (DO_{19}) and the O-phase-state, where the α_2 phase has transformed to a mixture of α_2 and O-phase. The α_2-annealing-state is produced by heating to 1235°C for 2h followed by furnace cooling and a second heat treatment at 700°C for 72 h followed by water quenching. The O-phase-state is produced by a further heat treatment of 5000h at 550°C followed by furnace cooling. For the strain measurements, TEM foils are prepared electrolytically. The relative strain between (a_2/O)-phase lamellae and γ-lamellae is obtained from precession diffraction using the Nanomegas© system in a Talos F200i Transmission Electron Microscope. Micro-pillars of lamellar colonies in selected orientations were milled in an FEI Nova 200 dualbeam FIB/SEM microscope and were deformed at room temperature under constant strain rate in a Hysitron TI 980 Nanoindenter. Cross-sections were also excised from the deformed micropillars by focused ion beam milling for observation of dislocations in the (α_2/O)-phase lamellae and γ-lamellae or the interface between both.

10:30 AM *SF05.04.05
Engineering and Science Required for the Development of Advanced Heat-Resistant Materials—Learning from the Practical Application of Tial Alloys *Sadao Nishikiori[1,2], Akihiro Okita[1], Satoshi Takahashi[1] and Koji Nezaki[1]; [1]IHI Corporation, Japan; [2]Osaka University, Japan*

To enhance the appeal of TiAl alloys as lightweight, high-strength materials, alloy design guidelines and metallurgical structure control technologies that surpass the high-temperature creep, oxidation resistance, and other properties of existing Ni-based superalloys, such as Alloy 718 and Alloy 713C, have been proposed. To date, research programs have been carried out in various countries around the world, leading to today's activities. While watching these R&D trends with a keen interest, IHI is also conducting R&D from various perspectives. An additional point worth noting is, when the specific application areas of the target equipment are narrowed down and the aim is to mass-produce TiAl alloy parts for those components, to avoid product recalls during market sales extensive prototype development is required. Highly skilled experts from the fields of design, production, and quality assurance, as well as material application engineers (MAE), are involved from an early stage of prototype development to engage in advanced discussions aimed at improving performance and reliability. IHI has learned a lot from studying the application of HIP-TiAl alloy to low pressure blades (LPT) of aircraft engines in the 1990s, achieving the development of component technologies to high Technology Readiness Levels (TRL) after ground engine tests. Based on this experience, we further deepened our knowledge of TiAl alloys, and in the early 2000s, due to high market demand, began evaluating the applicability of TiAl alloy wheels to vehicle superchargers. In 2008, with our systematic understanding of alloy design, metallurgical structure control, casting, machining and joining, and, with the cooperation of material manufacturers, IHI began mass-producing and supplying turbochargers equipped with as-cast TiAl wheels for domestic commercial vehicles. After that, IHI advanced to mass-producing and supplying high-performance European cars as well as improving efficiency with the latest *design technology. The cumulative production volume has reached approximately 200,000 units.*

In the process of overcoming issues toward commercialization through new technological development, it is essential to narrow down the various conditions of each production technology to be applied based on the theory of TiAl alloys, and the efficiency and progress of R&D will change significantly depending on the level of understanding. In particular, with TiAl alloys, for which there are very few examples of practical application, it is extremely important to provide scientific evidence for phenomenon of each engineering result and to enhance the scientific evidence that supports optimization of the entire process. For example, in the case of vehicle turbochargers, technological development is diverse, including the development of TiAl alloys with high creep strength ratios/oxidation resistance, the application of thin-walled multi-blade shapes that ensure high aerodynamic characteristics, the understanding of microstructural control to give a full lamellar structure to an as-cast impeller, and the establishment of welding/joint interface control between the impeller and heat-resistant steel. IHI believes that academic theory has made a significant contribution to achieving mass production and ensuring high reliability.

In this presentation, we will introduce examples of solving scientific and engineering problems common to practical applications and share approaches to deepening our understanding of the engineering and science required for the development of future advanced materials.

Microstructural Effects on the Mechanical Response of a γ-TiAl Based Alloy Studied with In Situ High-Energy X-Ray Diffraction and Finite Element Simulations *Benjamin Seligmann[1], Michael Musi[1], Emad Maawad[2], Petra Spörk-Erdely[3], Helmut Clemens[1] and Thomas Antretter[1]; [1]Montanuniversität Leoben, Austria; [2]Helmholtz-Zentrum Hereon, Germany; [3]Graz University of Technology, Austria*

Intermetallic γ-titanium aluminide (TiAl) based alloys are of great interest to the aviation industry, i.e. for use in turbine engines, as this material class has excellent creep properties, high oxidation resistance at elevated temperatures and outstanding specific mechanical properties due to its low density. In service, temperatures up to 750°C are reached and especially tensile properties are of utmost concern. Therefore, a novel setup combining high-temperature tensile testing with in-situ high-energy X-ray diffraction (HEXRD) is utilized in this work. It allows to investigate the evolution of lattice strains up to macroscopic plastic deformation and subsequent failure of the specimen. Furthermore, the experimental observations are compared with the outcome of finite element simulations (FEM) to verify the ongoing deformation mechanisms.

The alloy of interest is the so-called TNM alloy (Ti-43.5Al-4Nb-1Mo-0.1B, at.%). Tailored heat treatments allow to adjust different microstructures comprising the ordered phases γ (L1$_0$ structure), α_2 (D0$_{19}$ structure) and β_o (B2 structure). The different crystal lattices, combined with the phase-specific morphologies within the prevailing microstructure, result in varying mechanical responses, which are also naturally dependent on the testing temperature. Therefore, a nearly lamellar β microstructure, comprising γ/α_2 lamellar colonies and a β_o seam at the colony boundaries, as well as a microstructure with additional globular γ grains are investigated at temperatures ranging from room temperature to 800°C to highlight differences in the macroscopic as well as microscopic mechanical behavior.

The experiments are conducted at the beamline P07B at Deutsches Elektronen-Synchrotron (DESY) in Hamburg, Germany. The setup is based on a tensile testing rig with a 20 kN load cell. The measurements at elevated temperatures are achieved by induction heating of the sample. By analyzing the positional change of the individual peaks in the diffractogram during the in-situ tensile HEXRD experiments it is possible to determine the lattice strain of individual sets of lattice planes and furthermore the phase strain of the microstructural phases. Comparing the plastic onset of the lattice strain - macroscopic stress curves, one can gain insights into the apparent load partitioning between the phases and the different deformation mechanisms depending on the testing temperature. Additional finite element analysis of the samples investigated by HEXRD is conducted using ABAQUS. The *necessary microstructures are simulated using a software called Neper, as well as an in-house routine to derive random 3D periodic lamellar structures, conforming to the experimentally observed microstructural characteristics, e.g. α_2/γ colonies with varying lamellar spacings obeying the Blackburn orientation relationship as well as the subdivision of single lamellae into domains. Since the HEXRD experiments at the synchrotron only provide part of the strain tensor, as the information gained from one diffractogram is just two-dimensional, the missing information can be filled with these FEM investigations. Ultimately, the connection between experiment and simulation can be drawn via the present phase strain, which can be calculated from both methods.*

Microstructure Control of TiAl Alloys via Metal Additive Manufacturing *Ken Cho[1], Hiroyuki Y. Yasuda[1], Masao Takeyama[2] and Takayoshi Nakano[1]; [1]Osaka University, Japan; [2]Tokyo Institute of Technology, Japan*

Metal additive manufacturing (AM) techniques, such as electron beam-powder bed fusion (EB-PBF), have attracted much attention as a novel fabrication technology for difficult-to-machine materials in the aerospace and medical implant industries because it is possible to build 3D objects with complex shapes directly from 3D-CAD data. Another important feature of AM techniques is unique microstructures induced by unusual solidification conditions and thermal history during the process. The alloys with a unique microstructure prepared by the AM techniques exhibit better mechanical and/or functional properties than conventional cast or forged materials. In this study, we developed new microstructure control techniques for TiAl alloys using the EB-PBF process by focusing on the repeated thermal effects from the melt pool and the ultra-rapid cooling which are important features of the process.

We found that the thermal effects from the melt pool have a significant influence on the microstructural evolution of practical Ti-48Al-2Cr-2Nb (4822) alloys. Owing to the repeated thermal effects, 4822 alloys with a unique layered microstructure consisting of equiaxed γ grain regions (γ bands) and duplex regions perpendicular to the building direction can be obtain. Moreover, in β phase-containing TiAl alloys fabricated by the EB-PBF process, a unique microstructure is formed due to a peculiar phase transformation induced by ultra-rapid cooling rate that reaches up to 10^6 K/s. The α_2/γ nano lamellar grains with lamellar spacing of a dozen nm are formed via massive α transformation caused by ultra-rapid cooling. In addition, we also found that the strength-ductility balances and fatigue properties of these TiAl alloys are improved significantly by each unique microstructure.

How Rapid Heating and Quenching Cycles Affect Phase Evolution in Advanced γ-TiAl Alloys—An In Situ Synchrotron Radiation Study *Andreas Stark, Marcus Rackel, Jan Rosigkeit and Florian Pyczak; Helmholtz-Zentrum Hereon, Germany*

Additive manufacturing (AM) processes are increasingly considered as an alternative manufacturing route to investment casting and conventional forging to produce complex aircraft components out of γ-TiAl based alloys. Due to their extremely fast heating and cooling rates, AM processes are very dynamic and often take place under thermodynamic and chemical disequilibrium conditions. While with conventional research methods, AM parts can only be studied after processing and all interpretations are based on the final microstructures and properties, in situ high-energy X-ray diffraction (HEXRD) experiments in a synchrotron radiation source enable a highly time-resolved and direct observation of the evolution of phases, strains, and texture during the dynamic process.

We simulated and studied the intrinsic heating cycles, which occur below the top layer during an AM process using a quenching dilatometer DIL 805 A/D that has been slightly modified to operate in the Hereon run HEMS beamline of the Petra III synchrotron radiation source at DESY. An advanced γ-TiAl based alloy was exposed to several cycles with cooling rates up to 500 K/s and the diffraction patterns were continuously recorded with a frame rate of 10 Hz. These in situ experiments allow to determine the influence of the cooling rate and a chosen powder bed *temperature on lattice parameters and phase fractions, and to observe changes in the crystal structure and atom site occupancy for all phases present, namely α/α_2, β/β_o and γ/γ_m. Based on the results, e.g. a powder bed temperature above 700 °C can be recommended for AM processes in order to allow chemical equilibration in the produced γ-TiAl parts.*

Phase Equilibria of TiAl-Based Alloys Containing Ternary and Quaternary Additions of the Refractory Metals Nb, Mo and W *Frank Stein[1] and Benedikt Distl[1,2]; [1]Max Planck Institute for Iron Research, Germany; [2]Plansee, Austria*

TiAl-based alloys have proven to be capable to replace Ni-based superalloys at temperatures up to about 800°C in applications such as, e.g., turbine blades in aero-engines. The effect of this 50% decrease in weight is a significant reduction in fuel consumption and with that a decrease in greenhouse gas emissions. However, to achieve the ambitious goals of climate-neutral aviation set by the ACARE council (Advisory Council for Aviation Research and Innovation in Europe) of the European Commission for the year 2050, the TiAl-based alloys currently in use and under development still need to be significantly improved, especially with regard to aspects such as their high-temperature formability and their phase and microstructural stability at application temperature above 800°C, i.e., in particular their creep resistance in the critical temperature region.
Nb is the most important alloying element for Ti-Al alloys. In addition to its beneficial effects on the high-temperature oxidation and creep resistance, it is also a β-phase stabilizer, i.e. it stabilizes the cubic (β-Ti) high-temperature phase and thus enables processing (e.g. hot forging of the blades) at very high temperatures. However, above a certain limiting alloying content, further Nb addition results in the formation of the ternary ω_o phase (which often but wrongly is described with the formula Ti_4Al_3Nb). This hexagonal phase has an embrittling effect and is therefore very detrimental for the mechanical properties and should be avoided. Alternative β-stabilizers are Mo and W both having the advantage that in the respective ternary systems no ω_o phase exists. Thus, it is also of particular importance to investigate and understand the combined effect of Nb and Mo or W on the stability and phase fraction of ω_o phase and on the phase relations, microstructure and properties of such TiAl-based alloys.
In this presentation, the results of our experimental phase diagram studies of the three ternary systems Ti-Al-Nb, Ti-Al-Mo, and Ti-Al-W in the temperature range between 700 and 1300°C will be summarized and compared. A focus then will also be on the effect of quaternary additions. Although it can be expected that the addition of Mo or W to Ti-Al-Nb alloys will reduce the amount and/or stability of the ω_o phase, there are no systematic studies on this issue. Therefore, some results obtained from two series of quaternary alloys containing 1-5 at.% Mo or W will be discussed.

2:00 PM SF05.05.02

New Insights into the $\beta_o \rightarrow \gamma$ Phase Transformation in an Intermetallic Ti-44Al-7Mo Alloy *Petra Spörk-Erdely[1,2], Gloria Graf[3,2], Christoph Gammer[4], Simon Fellner[4], Peter Presoly[2], Johanna Byloff[5,2], Helmut Clemens[2], Andreas Stark[6] and Peter Staron[6]; [1]Graz University of Technology, Austria; [2]Montanuniversität Leoben, Austria; [3]KTH Royal

Institute of Technology, Sweden; [4]Austrian Academy of Sciences, Austria; [5]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [6]Helmholtz-Zentrum Hereon, Germany

Intermetallic γ-TiAl based alloys are innovative structural materials for lightweight high-temperature applications. While previous generations of these alloys were notoriously difficult to deform, some of the latest generation β-stabilized γ-TiAl based alloys have demonstrated significantly improved hot workability, which nowadays even enables conventional forging. In this work, ternary Ti-Al-Mo model alloys are investigated with regard to the influence of β-stabilizing elements, such as Mo, on the phase transformation behavior of this group of γ-TiAl based alloys. Here, in particular, the transformation of a strongly supersaturated, ordered body-centered cubic β_o phase into the ordered tetragonal γ phase is addressed.

Previous studies on the $\beta_o \rightarrow \gamma$ phase transformation in a Ti-44Al-7Mo (at.%) alloy have combined in-situ high-energy X-ray diffraction (HEXRD), high-energy small-angle X-ray scattering (SAXS), and atom probe tomography as a direct imaging technique to study early stages of the γ growth sequence. Specimens were homogenized in the β single phase region at 1450 °C, water-quenched, and subsequently continuously re-heated in a dilatometer setup at beamline P07 at the Deutsches Elektronen-Synchrotron (DESY) in Hamburg, Germany. Tracing the diffusional processes and growth kinetics of the γ particles within the supersaturated β_o matrix during these in-situ HEXRD/SAXS experiments, it was found that the growth sequence is controlled by elemental redistribution. Based on the diffraction data, it was suggested that coherent γ precipitates are formed initially, which may lose coherency upon further heating.

Here, we provide first experimental proof of this previous assumption as to the coherency of the precipitates formed. Transmission electron microscopy (TEM) was used to characterize γ precipitates in selected heat-treated conditions in terms of their relationship with the β_o matrix. Combining the TEM results with those gained by means of differential scanning calorimetry, it is shown that, in fact, two competing populations of γ precipitates are involved in the phase transformation. Finally, all experimental results are summarized in a consistent and comprehensive description of the $\beta_o \rightarrow \gamma$ phase transformation.

2:15 PM SF05.05.03

Quantitative Evaluation of Solute Oxygen Effect on the Young's Modulus and Hardness of β-Ti, α_2-Ti_3Al, and γ-TiAl Phases in Ti-Al-Cr-O Alloys

Yotaro Okada[1], Ryosuke Yamagata[2], Hirotoyo Nakashima[1,3] and Masao Takeyama[1]; [1]Tokyo Institute of Technology, Japan; [2]Chiba University, Japan; [3]NIPPON STEEL CORPORATION, Japan

Introducing the bcc β-Ti phase has been found to be effective in improving the strength and toughness of conventionally processed TiAl alloys. In recent years, powder processed fabrication technologies such as additive manufacturing and metal injection molding have been focused for TiAl alloys. In such processes, a certain amount of oxygen contamination is inevitable in comparison to conventional ingot metallurgy. It is believed that the solute oxygen makes the alloys less ductile and more brittle, so that the oxygen was avoided for alloy design. However, from the microstructure viewpoint, the following information is needed how the oxygen affects the phase equilibria among the constituent phases and affects the mechanical properties of the phases, but no information is available. In this study, thus, we have investigated the effect of oxygen on the Young's modulus, E, and hardness, H, of the constituent phases of β-Ti, α_2-Ti_3Al and γ-TiAl phases in Ti-Al-Cr-O quaternary alloys quantitatively in terms of the chemical composition analysis and nano-indentation method. The alloys used are Ti-43Al-3Cr and Ti-44Al-4Cr-1.0O (at.%). These alloys consist of the three phases after the equilibration at 1373 K. The equilibrium compositions of each phase were analyzed by EPMA and the oxygen content in each phase was analyzed by soft X-ray emission spectroscopy.

Regardless of the oxygen levels in the alloys, oxygen does not dissolve in the γ phase, and its concentration is nearly the same of less than 0.2 at.%. Most of the oxygen are partitioned into the α_2 phase with partition coefficients of $k_O(\alpha_2/\gamma) = 18$ and $k_O(\beta/\gamma) = 2.3$ against γ phase in the O-doped alloy. In addition, the oxygen addition *also changes the Cr concentration of each phase, especially in the β phase, although Al concentration of each phase remains almost unchanged; the Cr concentration in the β phase was changed by 8 at.%, whereas those in the* α_2 *and γ phases was changed by only about 2 at.%. These composition changes result in a significant increase in E of the β phase from 135 GPa to 160 GPa, whereas it does not affect the E of* α_2 *(185 GPa) and γ (178 GPa) phases. On the other hand, the composition changes harden the β and* α_2 *phases from 6.1 to 7.1 GPa and 7.2 to 8.1 GPa, respectively. However, the H of the γ phase remains almost the same of 4.3 GPa. Based on these results, the dependency of E and H on oxygen was separately evaluated and found that the mechanical properties of the β phase are extremely sensitive to the oxygen in solution, and those in* α_2 *phase are less but somehow sensitive than those of the β phase. Surprisingly, however, the oxygen does not affect the mechanical properties of the γ phase at all, since solubility of oxygen is very limited.*

From these results it is suggested that the oxygen should be treated as one of the alloying elements, rather than contamination element, and that one can design the appropriate microstructures to meet the required properties in TiAl alloys even with the high amount of oxygen.

2:30 PM SF05.05.04

Effects of Temperature and Environment on Fatigue Crack Growth Behavior in TiAl Alloys *Ryosuke Yamagata*[1]*, Ryuichi Isomura*[2]*, Hirotoyo Nakashima*[2]*, Takaomi Itoi*[1] *and Masao Takeyama*[2]*;* [1]*Chiba University, Japan;* [2]*Tokyo Institute of Technology, Japan*

Understanding the fatigue crack growth (FCG) mechanism from room to service temperature is essential for airplane engine materials. Recently, we successfully developed the "design principle" for wrought TiAl alloys based on thermodynamics and kinetics. Our model wrought alloys with controlled α_2*-*Ti_3Al*/γ-TiAl lamellar microstructure with ordered bcc structure β-Ti phase at the grain boundaries show excellent room temperature FCG (initiation/propagation) resistance, superior to that of the cast GE 4822 with the fully lamellar microstructure. However, it has not yet been done at high temperatures. In addition, very limited information is available on the FCG behavior of the alloys at elevated temperatures at around 1073 K. In addition, at such temperatures, environmental effects might not be negligible. Therefore, in this study, the effect of temperature and atmosphere on the FCG behavior was investigated using an alloy with microstructure controlled to have β phase at the grain boundaries.*

The microstructure of the specimens is similar to the previous ones with β phase along the lamellar boundaries. The β phase was introduced using the cellular reaction ($\alpha_2+\gamma\rightarrow\beta+\alpha_2+\gamma$) *through multi-step heat treatments. A pre-crack was first introduced to each CT specimen, and FCG tests were done at RT, 873 K, and 1073 K under 20 Hz and R (a tension/tension load ratio) of 0.1. The elevated-temperature tests were conducted in a uniquely designed, environmentally controllable chamber with heating elements. In the case of the test in Ar, the chamber was evacuated and backfilled with Ar flowing. The crack length was measured using the DCPD (direct current potential drop) method.*

The stress intensity factor range threshold for fatigue crack growth (ΔK_{th}) *obviously decreased at 873 K in both atmospheres compared to the room temperature. However, it increased to the same value or even better at 1073 K in the air, whereas it remained low in the case of the Ar atmosphere. The Paris slope value (m) was nearly the same regardless of the test conditions. However, the crack growth rate value (da/dN) value became apparently low by an order of magnitude at the same ΔK value in the Ar atmosphere compared to the value tested in the air. Almost no oxide formation in the cracks was confirmed in the sample tested in Ar, whereas a thick oxide layer was formed in the sample tested in air. From these results, it should be suggested that the FCG behavior obtained in the Ar atmosphere is the nature of the alloys, and the behavior highly affects the oxide formation. The underlying* *mechanism of FCG will be presented in conjunction with the microstructure analyses.*

2:45 PM SF05.05.05

Effect of High Temperature Exposure in Air on the Deformation Mechanisms of Intermetallic γ-TiAl Alloys

Frederic Habiyaremye[1], Daniel Monceau[2], Kamal Nayan Goswami[2], Damien Connétable[2], Michal Kuris[3], Thomas Vaubois[4], Pierre Sallot[4], Maria Tsoutsouva[3], Marc Thomas[3], Damien Texier[2] and Jean-Philippe Monchoux[1]; [1]Centre d’Élaboration des Matériaux et d’Etudes Structurales, France; [2]Université de Toulouse, France; [3]Université Paris-Saclay, France; [4]Safran Tech, France

Intermetallic γ-TiAl-based alloys are promising lightweight alternatives to nickel superalloys for aircraft engine components that operate at temperatures up to 900°C. This due to their low density, high specific strength/moduli and good creep properties. However, exposure to air at these elevated temperatures results in a significant in yield stress and a drop in ductility. The underlying mechanisms that are responsible for this embrittlement remain poorly understood. One hypothesis is that this embrittlement is a direct consequence of the bulk and/or interfacial oxygen (O) diffusion. The first objective of this study is to determine the extent to which oxygen can penetrate into the material. To this end, samples heat treated in a controlled environment of 83% Ar-17%$^{16}O_2$ were first observed using SEM-based BSE and EBSD to analyze the microstructure of the surface layer. Nanoindentation was then used to monitor the change in hardness from the surface layer to the matrix. To accurately determine the depth of O penetration, Secondary Ion Mass spectrometry (SIMS) profiling was carried out on samples that had been heat-treated in a controlled environment of 99% Ar-1%$^{18}O_2$. The second objective was to investigate the mechanisms of plastic deformation (pinning of dislocations on oxygen-rich precipitates) within the O-diffused surface layer by using transmission electron microscopy (TEM), for comparison with the O-free regions far from the surface. Lamellae were obtained in these distinct regions by site-specific lift-out using a FIB-SEM. Comparative analysis of microstructure and deformation mechanisms in the O-diffused surface layer and O-free regions far from the surface is expected to provide new insights that may offer a way to eliminate embrittlement in intermetallic γ-TiAl alloys.

Data to Aid Materials Design and Process Optimization of Intermetallics Based Materials

Anders Engström, Yang Yang, Johan Jeppsson, Magnus Anderson and Qing Chen; Thermo-Calc Software, Sweden

Alloys are complex systems where microstructure and properties depend on both processing conditions and chemical composition. Such variations are not typically reflected in handbook data and repositories that tend to be limited in the scope of materials covered (their compositions) or the temperature ranges (processing

conditions) or lack of time dependence. As such, the engineering simulations which depend on these data are limited, especially for cases involving novel materials or new processes and often it becomes necessary to go and measure the needed data or live with the uncertainty.

The CALPHAD approach captures the composition and temperature dependence of properties, as well as their temporal evolution, for industrial multicomponent alloys. As a result, data can be calculated for materials or conditions where there are gaps in the measured data. Additionally, location specific properties can be predicted and optimized for a part, which means that manufacturers will no longer be restricted to design minimums.

CALPHAD simulations can be used to complement compilations or repositories of measured data, improve machine learning models, and can also be used as input into engineering codes that require more reliable materials property data. This applies to alloys in general, including alloys that contain intermetallic phases. In this presentation we introduce the CALPHAD approach and exemplify how CALPHAD based tools can be efficiently used to aid materials design and process optimization of intermetallics based materials. We will focus on Additive Manufacturing (AM) of intermetallics based materials, such as Titanium Aluminides and Ni-base superalloys. It will be demonstrated that in order to successfully be able to simulate this process and make predictions, for examples in the form of printability maps, it's necessary to not only include sufficient physics in the simulations, but also to input accurate composition and temperature dependent thermochemical and thermophysical data.

4:00 PM SF05.06.02

Advanced Characterization of Cu- and Si-Containing Intermetallic Phases in a Novel Ti-Based Superalloy for Additive Manufacturing *David Obersteiner[1], Michael Musi[1], Andreas Landefeld[1], Helmut Clemens[1], Ehsan Farabi[2], Sophie Primig[2], Peter Staron[3], Andreas Stark[3], José Neves[4] and Thomas Klein[4]; [1]Montanuniversität Leoben, Austria; [2]University of New South Wales Sydney, Australia; [3]Helmholtz-Zentrum Hereon, Germany; [4]AIT Austrian Institute of Technology, Austria*

Near-α Ti alloys are widely employed in high-temperature applications within the aerospace and automotive industries due to their high strength, low density as well as excellent resistance against oxidation and creep deformation. While conventional manufacturing processes remain prevalent, additive manufacturing (AM) has gained a lot of interest in recent years due to its ability to produce components exhibiting complex geometries with a high level of efficiency. Current research has shown that conventional alloys like Ti-6Al-4V (wt.%) or Ti-6Al-2Sn-4Zr-2Mo (wt.%) present significant challenges in AM due to their response to the unique process conditions. Especially, high cooling rates, high temperature gradients and the layer-wise build-up yield a complicated, position-dependent thermal history and, eventually, lead to complex and unique microstructures. In Ti alloys, the formation of large columnar β grains oriented along the build direction results in anisotropic mechanical properties. To mitigate these microstructure-related challenges in AM, the development of new alloying concepts is essential. Recent research has shown that eutectoid-forming elements, such as Cu, can have a beneficial effect on the solidification behavior in Ti alloys. Together with the possible formation of intermetallic phases, leading to an increased number of nucleation sites, this can induce a columnar to equiaxed transition (CET) during solidification in the AM process.

This study presents a fundamental investigation of a novel Ti-based superalloy with additions of Cu and Si suitable for high-temperature service and optimized for the wire-arc direct energy deposition (waDED) process. This work primarily focuses on the detailed analysis of the precipitation of intermetallic phases at the nm-scale, employing advanced characterization techniques such as in-situ small-angle (SAXS) and wide-angle X-ray scattering (WAXS), transmission electron microscopy (TEM), and atom probe tomography (APT). While WAXS provides insights into crystallographic information of the constituent phases as a function of temperature, the morphology and size distribution of nm-sized intermetallic precipitates can be observed simultaneously by SAXS. In particular, *continuous heating experiments revealed the formation of a Cu-enriched phase between 580-760°C and a silicide phase between 660-930°C, which correspond to temperatures below this alloy's β-transus temperature. The results of complementary high-resolution TEM measurements classified these intermetallic phases as* $Ti_{2-3}Cu$ *and* Ti_6Si_3 *(S2-type) with slightly off stoichiometric chemical compositions. Furthermore, the combination of TEM and APT investigations revealed the morphology and chemical composition of these two phases. These results allowed a detailed interpretation of the SAXS data in a complex multiphase Ti-based system. Thus, this study includes the comprehensive characterization of phase fraction, size distribution and shape of the forming precipitates with high statistics in a time-resolved manner.*

By employing advanced complementary characterization techniques, this research enhances the fundamental understanding of a novel near-α Ti-based superalloy optimized for AM processes. A profound knowledge of phase transformations and microstructure control is crucial for the practical application of these alloys. These findings not only provide a solid foundation for future research but also highlight the critical role played by innovative alloying concepts in overcoming the limitations of conventional Ti-alloys and advancing their use in manufacturing technologies such as waDED.

4:15 PM SF05.06.03

Homogenization of Porous, Intermetallic Ni_3Al ***by Additive Manufacturing and In Situ Alloying*** *Marlene Eichlseder[1], Petra Spörk-Erdely[1], Siegfried Arneitz[1], Andreas Stark[2] and Christof Sommitsch[1]; [1]Technische Universität Graz, Austria; [2]Helmholtz-Zentrum Geesthacht, Germany*

Nickel is a common and well-researched catalyst material with a wide variety of industrial applications. However, pure Ni also comes with limitations such as poisoning and sintering at the elevated temperatures required for some catalytic processes. Intermetallic Ni_3Al*, by contrast, has been found to exhibit catalytic properties comparable to Ni, while being less prone to both poisoning and sintering. Therefore, we have started to investigate potential approaches to fabricate a porous* Ni_3Al *catalyst.*

To obtain a large surface area as required for catalysis, samples were produced through additive manufacturing. In particular, laser powder bed fusion (LPBF) was used, whereby the printing parameters were optimized for maximum bulk porosity. Furthermore, in order to keep the fabrication route economically competitive, so-called in-situ alloying was used to print the samples. In-situ alloying refers to the procedure of mixing two elemental powders mechanically and creating the alloy during the printing process.

In the case of a nominal chemical composition of 76 at.% Ni and 24 at.% Al, the printing parameters optimized for a porous structure were found to cause an inhomogeneous microstructure with pronounced local variations in the chemical composition. Although the powder particles were fully melted during the printing process, the melt solidified before complete mixing and equilibrium could be reached. Using X-ray diffraction, the phases Ni(Al), Ni_3Al*, NiAl,* Al_3Ni_5*, and* Al_3Ni *were detected in these as-printed samples. To homogenize the microstructure and increase the phase fraction of* Ni_3Al*, heat treatments have been conducted. Due to the relatively low melting points of the Al-rich phases, a stepwise heat treatment was designed. At 600 °C, the dissolution of Al-rich phases was investigated, before increasing the temperature to 1000 °C in a second step. To obtain further information about the phase fractions and to trace the phase evolution during different heat treatments, in-situ heating experiments were conducted in a dilatometer setup at the Hereon-run beamline P07B at the Deutsches Elektronen-Synchrotron in Hamburg, Germany. The data collected by means of high-energy X-ray diffraction offer valuable insights into the effect of the various heat treatments on the as-printed samples and allow to draw conclusions as to their final catalytic properties.*

4:30 PM SF05.06.04

Unique High-Temperature Mechanical Behavior of CuCrZr Alloy Additive-Manufactured by Laser Powder Bed Fusion *Dasom Kim[1], Naoki Takata[1], Junji Umeda[2], Toshihiko Shimizu[3] and Makoto Kobashi[1]; [1]Nagoya University,*

Japan; [2]Aichi Center for Industry and Science Technology, Japan; [3]TKE Co., Ltd., Japan

It is generally known that the Cu-Cr-Zr (CuCrZr) alloy series strengthened by various intermetallic phases exhibits superior thermal/electrical conductivity and high strength in terms of industrial applications such as electric devices, thermal management in automobiles, and aerospace. It is necessary to understand the precipitation behavior in the CuCrZr alloys. The precipitation morphologies and the strengthening phenomenon by Cr-rich or Cu-Zr intermetallic phases have been studied in conventional wrought-type CuCrZr alloys. Recently, laser powder bed fusion (L-PBF), which is one of the most representative metal additive manufacturing processes, enables the manufacture of metallic components. The L-PBF process is being applied to manufacture induction-heating coils of Cu alloys with complex shapes. In terms of applications to induction-heating coils, a sufficient strength level is required at elevated temperatures in service, whereas there are few reports of the high-temperature mechanical performance of L-PBF processed CuCrZr alloys. In particular, The L-PBF process using a scanning laser beam to selectively melt consecutive bedded powder layers is characterized by a high solidification rate. The effect of microstructural features formed in the rapid solidification on mechanical behavior remains unclear. In this study, we systemically investigated the effect of microstructural features on the high-temperature strength of L-PBF processed CuCrZr alloys using tensile tests at elevated temperatures.

Rectangular alloy samples with a size of 15~60 × 60 × 70 mm^3 were fabricated using the gas-atomized CuCrZr ternary alloy powder and SLM280PS machine (SLM Solutions GmbH, Germany) under a laser scan speed of 0.6 m/s and laser power of 400 W. The applied laser-scanning hatch distance, powder-bed thickness, and beam focus size were 0.07 mm, 0.03 mm, and 0.08 mm, respectively. The L-PBF processed CuCrZr alloys exhibited microstructure consisting of a number of melt pools (a depth of approximately 100 μm) that were formed by local melting and rapid solidification using scanning laser irradiation. A much higher content of Cr (1.0 mass %) is soluted in the Cu matrix than the solubility of Cr in Cu (approximately 0.3 mass%) due to the non-equilibrium solidification state. As a result of the tensile test of L-PBF processed CuCrZr alloy at room temperature (RT) and elevated temperatures, the 0.2% proof stress was increased to 350 MPa at a testing temperature of 500 °C. This is a unique temperature-dependent strength when compared to that of cast pure Cu and conventional CuCrZr alloy, as reported in previous studies. Transmission electron microscopy revealed that the dislocations interacted with nano-sized Cr-rich precipitates formed inside the supersaturated solid solution of the Cu matrix during the tensile test at 500 °C. The Cr-rich precipitates would be metastable fcc-(Cu, Cr) phase that was often observed in annealed samples at 400 to 500 °C. That is, the unique microstructural characteristics (i.e., such as supersaturation of Cr in Cu matrix) of L-PBF processed CuCrZr alloy contributed to the unique temperature-dependent mechanical behavior. This study demonstrates the possibility of the L-PBF process to realize superior high-temperature strength of CuCrZr alloy.

In Situ Alloyed NiTiCu by Laser Powder-Bed Fusion for Biomedical Applications

Xipeng Tan; National University of Singapore, Singapore

In-situ alloying by additive manufacturing (AM) or three-dimensional (3D) printing of pre-mixed powders has been recognised as a promising low-cost method for creating complex-shaped intermetallic parts. This work preliminarily addresses several technical concerns with the laser powder-bed fusion (L-PBF) in-situ alloyed NiTiCu for biomedical applications. The influences of heat treatment temperature and duration on the microstructural homogeneity, phase transformation temperatures and sequences of the NiTiCu alloy are studied. Heat treatments with elevated temperatures and long duration cause a significant increase in porosity. To achieve sufficiently good microstructural homogeneity with low porosity, an optimum post homogenization heat treatment scheme is determined. All heat treatments lead to the formation of secondary phase $Ti_2(Ni,Cu)$, along with precipitates dispersed throughout the matrix, which induces two-step phase transformations to occur. Moreover, the Cu *addition into NiTi shape memory alloy is found to increase the wear resistance of the alloy under lubrication conditions. Conversely, under dry conditions it had an adverse effect on the tribological properties. Overall, AM is shown to have a positive impact on the wear behaviour of the alloy under both testing environment.*

Tuning Ferrimagnetic Response in Compositionally Spread Gd-Fe-B Amorphous Thin Films

Mayuko Okada, Takahiro Yamazaki, Alexandre Lira Foggiatto, Kentaro Fuku and Masato Kotsugi; Tokyo University of Science, Japan

As global electric power consumption rises, reducing energy loss in power usage has become a crucial environmental challenge. Soft magnetic materials account for about 30% of total energy loss in electrical devices, underscoring the need for high-performance materials. Nanocrystalline amorphous alloys are the best soft magnetic materials available now, but there is still room for development. In this study, we propose a novel soft magnetic composite alloy consisting of an amorphous Fe-based nanocrystalline material doped with the rare earth element Gd. The combination aims to leverage the high saturation magnetization from ferromagnetic Fe nanocrystals and antiferromagnetic exchange coupling from ferrimagnetic residual amorphous Gd-Fe-B matrix. This unique structure is expected to result in a ferrimagnetic material with a rapid response to external magnetic fields. Our objective is to identify the optimal conditions for achieving superior soft magnetic properties in the proposed Gd-doped Fe-based amorphous/nanocrystalline alloys. To achieve this, we employ combinatorial synthesis and high-throughput measurements to analyze the ferrimagnetic properties and underlying mechanisms.
$Gd_xFe_{85-x}B_{13}Nb_1Cu_1$ *(x = 0-25 at%) were deposited as composition-graded thin film on Si (100) substrate via RF magnetron sputtering. A 2 nm Ta layer was applied to prevent diffusion and oxidation. Post-annealing for nanocrystallization was performed at various temperatures ranging from 250°C to 650°C using an infrared lamp heating system. The fabricated samples were characterized by out-of-plane X-ray diffraction (XRD) analysis magneto-optical Kerr effect (MOKE) loop measurement. Additionally, X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) measurements were conducted at the BL25SU beamline of SPring-8, Japan, to analyze chemical bonding state magnetic moments.*
Crystal structure analysis revealed that samples with low Gd concentration exhibited a nanocrystallization/amorphous composite structure after annealing at 250-650°C, while those with 25 at% Gd showed an impurity peak of the Gd-Fe-B compound after annealing at 650°C. The XAS spectrum confirmed the presence of Fe^{+2}/Fe^{+3} *peaks alongside Fe metal peaks, attributed to the B-bonding following Gd addition. Magnetic moment analysis using XMCD revealed the sublattice magnetic structure unique to ferrimagnetism in the proposed material. MOKE measurements of pre-annealed samples (amorphous precursors) with varying Gd concentrations revealed that the MOKE signal decreased with increasing Gd content, ultimately resulting in a reversal of the magnetic hysteresis, which is characteristic of ferrimagnetism. This indicates that a Gd concentration of ~25 at% represents the magnetic compensation point at room temperature. Additionally, the slope of hysteresis (magnetic susceptibility) improved with the addition of small amounts of Gd, suggesting an enhancement in rapid magnetic response due to ferrimagnetic exchange coupling between Fe and Gd.*

SF05.07.02

Effect of Si Addition on Formation of Intermetallic Phases at the Interface Between Solid Fe and Liquid Al-Zn Alloy *Yasuo Omi, Dasom Kim, Naoki Takata, Asuka Suzuki and Makoto Kobashi; Nagoya University, Japan*

Hot-dip Zn-55mass%Al alloy galvanized steel sheets are generally called "galvalume" steel sheets and are widely used in structural materials because of their good corrosion resistance, durability, and heat resistance. The commercial Zn-55%Al alloy coating exhibits a composition of Al-25Zn-2Si (at%). In the hot-dip galvanized process for steel sheets, diffusional interfacial reactions occur on the steel surface in the Al-Zn-Si alloy melt, resulting in the formation of various intermetallic compounds in the coating of the hot-dip galvanized steels. In order to achieve good formability and workability of hot-dip galvanized steels, it is necessary to ensure high adhesion of the coating with steel components. The adhesion properties depend on the distribution, morphology, and deformability of the intermetallic compounds in the galvanized coating and its interface with steel substrates. It is generally known that the Si addition to the Al-Zn alloy melt is required to reduce the interfacial reaction between the Al-Zn alloy melt and the steel sheets for controlling the coating thickness. However, there are few studies investigating the formation process of intermetallic compounds in the hot-dip galvanizing process for the production of "galvalume" steel sheets., whereby the details of the role of added Si in the interfacial reaction and its related formation of intermetallic phases remains unclear. In this study, we have systematically characterized microstructures of pure Fe sheets hot-dipped in Al-25Zn binary alloy and Al-25Zn-2Si ternary alloy at an elevated temperature of 600 °C for different dipping times of 2~3600 s. These results were utilized to discuss the effect of the added Si element on the interfacial reaction and its related formation of intermetallic phases.

Significantly thick coatings were formed on Fe sheets hot-dipped in the Al-25Zn binary alloy melt for a longer time than 10 s. The coating thickness became several millimeters after 30 s, resulting in a delamination of the coating. The microstructural characterizations revealed that a significant Fe dissolution occurred in the Al-Zn binary alloy melt, accompanied by the growth of η-Fe_2Al_5 phase toward the solid Fe. The Zn enrichment was found on the surface of the pure Fe sheet, which was indicative of the diffusion of Zn into the solid Fe. Such a Zn enrichment was often localized inside/around the growing η phase in the solid Fe. The measured total compositions of Fe-Al intermetallic phases containing the Zn-rich regions corresponded to two-phase regions of the Zn-rich liquid phase with η-Fe_2Al_5 or θ-Fe_4Al_{13} phases in the calculated isothermal section at 600 °C of the Al-Fe-Zn ternary phase diagram, indicating the significant growth of η phase promoted by the Zn-rich liquid phase with a lower melting temperature. In the case of hot-dipping in the Al-25Zn-2Si ternary alloy melt, uniform coatings were formed on the Fe sheets regardless of the Fe dissolution and growth of Fe-Al intermetallic phases. A continuous layer of Si-rich T_5 ($Fe_2Al_{7.4}Si$) phase was formed at the interface of solid Fe with the Al-25Zn-2Si alloy melt. The continuous T_5 phase layer would play a role in a diffusion barrier at the interface of solid Fe with liquid Al-Zn alloy, resulting in the suppressed interfacial reaction.

SF05.07.03

Isothermal ω and α" Phase Evolution and Mechanical Behavior of Aged Ti–Al–Mo Shape Memory Alloys *Naoki Nohira, Masaki Tahara and Hideki Hosoda; Tokyo Institute of Technology, Japan*

To utilize β-Ti based high-temperature shape memory alloys (HTSMA), a high Al concentration of 14 mol% was designed to suppress the ω phase. Conventional NiTi alloys are unsuitable for high-temperature aerospace applications due to their limit of 373 K. β-Ti HTSMA are considered for these applications because of their lightweight and corrosion resistance but suffer from embrittlement from ω phase formation during high-temperature holding. This study aims to enhance the shape memory effect (SME) and mechanical properties of β-Ti HTSMA by exploring high Al concentrations. The alloys used were Ti–14Al–4.5Mo and Ti–7Al–6Mo, both with an identical reverse martensitic transformation start temperature (A_s) of approximately 407 K. These alloys were

isothermally held at 393 K for up to 360 ks to investigate their deformation behaviors and microstructures. High-purity titanium, aluminum, and molybdenum were used as raw materials. Ingots were prepared by arc melting in argon, homogenized at 1273 K, and quenched in water. The ingots were hot-rolled and cold-rolled into sheets, followed by solution treatment at 1273 K and quenching in iced water. Differential scanning calorimetry (DSC) evaluated transformation temperatures. X-ray diffraction (XRD) identified phase constituents at room temperature (RT). Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) provided microstructural observations. Tensile tests assess mechanical properties and shape memory behavior.
DSC curves indicated both alloys had an A_s of approximately 407 K. XRD profiles revealed both alloys consisted of β phase and α" phase at RT, suggesting M_s is above RT and M_f below RT. SEM images showed equiaxed β phase grains and acicular martensitic α" phase near grain boundaries. The Ti–14Al–4.5Mo alloy had a lower β phase and higher α" phase fraction compared to the Ti–7Al–6Mo alloy. Tensile tests showed both alloys exhibited shape memory properties with residual strains of about 2.5% entirely recovered upon heating. Stress–strain curves showed distinct two-stage yielding behavior in the Ti–14Al–4.5Mo alloy, remaining almost unchanged after isothermal holding. In contrast, the Ti–7Al–6Mo alloy displayed significant changes in deformation behavior and increased yield stress after isothermal holding, with two-stage yielding behavior disappearing in the 36 ks and 360 ks specimens. TEM observations revealed the isothermal ω phase (ω_{iso}) was suppressed in the Ti–14Al–4.5Mo alloy but grew significantly in the Ti–7Al–6Mo alloy. The α''_{iso} phase presence in the Ti–14Al–4.5Mo alloy indicated high Al concentration suppressed ω_{iso} phase formation and growth. The yield stress of the Ti–14Al–4.5Mo alloy increased slightly with isothermal holding time, while the Ti–7Al–6Mo alloy showed a significant increase in yield stress early in isothermal holding. Microstructural analysis using high-resolution TEM indicated in the Ti–14Al–4.5Mo alloy, both ωiso and α"iso phases were complementarily dispersed at a nanometric scale, leading to minor changes in mechanical properties. Conversely, in the Ti–7Al–6Mo alloy, ω_{iso} phase growth significantly increased yield stress and altered deformation behavior. High Al content in Ti–14Al–4.5Mo alloy not only suppresses ω_{iso} phase but also ensures α''_{iso} phase stability, maintaining favorable mechanical properties. High Al concentration is crucial for suppressing ω phase and maintaining mechanical properties in β-Ti HTSMA. The Ti–14Al–4.5Mo alloy, with its stable microstructure and consistent deformation behavior even after prolonged high-temperature exposure, is particularly promising for HTSMA applications. Further research on β-Ti alloys with varying Mo and Al contents is recommended to optimize their performance for high-temperature shape memory and superelastic applications.

SF05.07.04

First Principles Evaluation of Temperature Effects on the Stability and Further Properties of Ti_2AlM-Type O-Phases with V-VIB Group Element Additions

Zeinab Heidari Pebdani[1,2], Rebecca Janisch[3] and Florian Pyczak[1,2]; [1]Helmholtz-Zentrum Hereon, Germany; [2]Brandenburgische Technische Universität Cottbus-Senftenberg, Germany; [3]Ruhr-Universität Bochum, Germany

TiAl alloys have established themselves as materials for aero-engine turbine blades. These TiAl alloys predominantly consist of the tetragonal γ-TiAl and the hexagonal α_2-Ti_3Al phase. However, to improve the damage tolerance and processability additional alloying elements like Nb or Mo are frequently added. It was found in the Ti-Al-Nb system that certain alloy compositions tend to precipitate an orthorhombic so-called O-phase with Ti_2AlNb stoichiometry. Two aspects make this phase interesting. Firstly, small amounts of it were found in some γ-TiAl-based alloys with Nb contents exceeding 8 at.%. In those systems, the O-phase could be an unwanted constituent and its content should be controlled. Secondly, the O-phase proved to be a ductile constituent in more Nb-rich and Al-leaner alloy variants, which show an attractive combination of strength and ductility in the 500 to 600 °C range. In the present work, we investigate the stability of this phase depending on temperature and variation of the ternary alloying element by first-principles methods. In addition to Nb, other elements from the groups V and VI of the periodic table like V, Ta, Mo, and W were investigated. To determine the 0 K properties of the Ti_2AlM compounds

the plane wave density functional approach as implemented in the VASP software package with projector-augmented waves was used. To determine the lattice constants and energies at 0K, the energies of formation vs. volume are fitted using the Birch-Murnaghan and Morse equation of state (EOS). Two techniques describe the vibrational contribution to Helmholtz free energy: (i) the Debye model with the Debye–Grüneisen approach; and (ii) the calculation of the complete phonon spectra via the supercell method. Through a comparison of the available data from experiments with those from thermodynamic modeling, it is found that the phonon calculations, as well as the Debye model, accurately depict the thermodynamic properties of the Ti_2AlM compounds under study. The quasi-harmonic approximation (QHA) was used to calculate the lattice expansion at raised temperature for the phonon-based modeling of temperature effects. The calculated lattice parameters compare well with experimental ones from neutron scattering experiments [1,2].
The main results are that (i) the equilibrium volume increases roughly linearly as a function of temperature for all ternary additions M, (ii) the bulk modulus decreases dependent on the ternary element addition in the order Mo>W>Ta>Nb>V, (iii) the bond strength follows the trend of Ti–M> Ti–Al> Al–M irrespective, if M is V, Nb, Ta, Mo or W, and the hybridization of Ti-d states, M-d states and Al-p states contributes to the bonding, and (iv) the vibrational contribution to entropy, and in turn to Gibbs energy, increases with increasing mass of the ternary addition M in the different TiAl–M compounds. The predicted thermodynamic properties provide helpful insights into the stability of different types of O-phases, especially for systems where the experimental information is lacking or less reliable.

Finite Element Analysis for the Effect of Microstructure Morphology on Microcracks and Deformability of MoSiBTiC Alloy at Room Temperature *Junfeng Du[1], Chihana Kudo[1], Shuntaro Ida[1], Eri Nakagawa[2], Takahito Ohmura[2] and Kyosuke Yoshimi[1]; [1]Tohoku University, Japan; [2]National Institute of Materials Science, Japan*

The first−generation MoSiBTiC alloy, 65Mo-5Si-10B-10TiC (at%), consists of Mo solid solutions (Mo_{ss}), Mo_5SiB_2, TiC, and Mo_2C phases. The fracture toughness of this alloy has always been a concern that needs to be enhanced in this alloy to reduce the risk of brittle fracture failure. In the present study, the effect of constituent-phase morphology on the micro-crack initiation and propagation was investigated by finite element method (FEM). The FEM model was established based on the back-scattered electron image of the MoSiBTiC alloy. Continuum elements were used to model the constituent phases, while the cohesive elements were used to model debonding at the interfaces of the constituent phases, and the cleavage fracture within the brittle phases, Mo_5SiB_2, TiC, and Mo_2C. It was found that the brittle phase particles with higher roundness, lower aspect ratio, and smaller size contribute to a more uniform deformation of the microstructure under loading and maintaining the stability of the alloy. Additionally, the ductile Mo_{ss} phase isolating the brittle phases played a key role in improving the toughness of the alloy.

SF05.07.06

Relationship Between Morphology of Hierarchical Structure and Mechanical Properties of Ni-Based Superalloy Printed via Metal Additive Manufacturing *Kippei Yamashita[1], Ken Cho[1,2], Hiroyuki Y. Yasuda[1,2], Takuma Saito[3], Taisuke Sasaki[3], Katsuhiko Sawaizumi[1], Masayuki Okugawa[1,2], Yuichiro Koizumi[1,2] and Takayoshi Nakano[1,2]; [1]Osaka University, Japan; [2]Graduate School of Engineering, Osaka University, Japan; [3]National Institute for Materials Science, Japan*

Ni-based superalloys with excellent high temperature strength and oxidation resistance are used for turbine blades in aircraft engines. A recent study reported the formation of a unique hierarchical structure in Ni-based superalloys fabricated by laser beam-powder bed fusion (LB-PBF). This unique structure is composed of a meso-scale crystallographic lamellar microstructure (CLM) and a nanoscale cellular structure. While such a unique microstructure leads to excellent mechanical properties, the influence of process parameters on the morphology of the hierarchical structure has not yet been clarified in detail, nor has the relationship between the morphology of the hierarchical structure and mechanical properties been established.
This study examined the influence of input energy density on the morphology of the hierarchical structure in Inconel 718 alloys fabricated by LB-PBF, focusing on the cell spacing. The effect of cell spacing on the room temperature strength was also examined by tensile tests and in-situ neutron diffraction analyses. We found for the first time that the cell spacing increases with increasing input energy density. Furthermore, it was revealed that the tensile strength strongly depends on the cell spacing.

SF05.07.07
Relationship Between Microstructure and Fatigue Behavior of β-Phase Containing TiAl Alloys Prepared by Metal 3D Printing *Haruki Konishi[1], Ken Cho[1,2], Hiroyuki Y. Yasuda[1,2], Masao Takeyama[3] and Takayoshi Nakano[1,2]; [1]Osaka University, Japan; [2]Graduate School of Engineering, Osaka University, Japan; [3]Tokyo Institute of Technology, Japan*

TiAl alloys are expected to be used for low-pressure turbine blades in aircraft jet engines because of their light weight and excellent high-temperature strength, which contributes to improved fuel efficiency through weight reduction. In recent years, β-containing TiAl alloys that contain an ordered β phase (B2 structure) at service temperatures have been developed and have attracted attention as next-generation heat-resistant materials. In our previous study, we have reported that it is possible to obtain β-containing TiAl alloys with a nano α_2/γ lamellar structure in which grain boundaries are covered with a fine α_2/γ cellular structure using the electron beam powder bed fusion (EB-PBF), one of the metal additive manufacturing techniques. Furthermore, we also found that the alloys with this unique microstructure have excellent high-temperature strength-ductility balance. However, the fatigue properties of this alloy and the effects of each microstructure on the fatigue behavior have not yet been investigated. In this study, the morphologies of the nano-lamellar and cellular structures were controlled by post heat treatment, and the effects of each microstructure on the fatigue behavior were investigated, focusing particularly on the crack initiation and propagation behaviors. As a result, we found that the fatigue strength of the alloys at 750°C was superior to that of the cast Ti-48Al-2Cr-2Nb alloy even without a hot isostatic pressing process. This is considered to be attributed to the suppression of fatigue crack propagation by the α_2 phase in the fine cellular structure. In addition, ductile γ phase in the fine cellular structure suppresses crack initiation, resulting in excellent fatigue properties.

SF05.07.08
Impact of Excess Vacancies on Antiphase Domain Growth in Laser Irradiated and Single Crystal Like Fe_3Al Fabricated by Laser Powder Bed Fusion *Tsubasa Sato, Yuheng Liu, Masayuki Okugawa, Kazuhisa Sato, Hiroyuki Y. Yasuda, Takayoshi Nakano and Yuichiro Koizumi; Osaka University, Japan*

Fe_3Al intermetallic single crystals show superelasticity due to the interaction between antiphase domain boundaries (APBs) and dislocations [1,2]. Optimizing heat treatment conditions to regulate antiphase domain (APD) structure is important to enhance the superelasticity of Fe_3Al. Previous study derived accurate ordering mobility for forming APD structure by the combination of phase-field (PF) simulations and transmission electron microscopy (TEM) observation [3]. Recently, additive manufacturing (AM) processes have attracted much attention

because of their degrees of freedom in shapes. In addition, the laser powder-bed fusion (L-PBF) type AM process can fabricate single crystal parts by applying an optimum scanning strategy [4]. If Fe_3Al single crystals are fabricated by the L-PBF process, they will be useful in practical applications. However, the excess vacancies introduced by rapid cooling in the L-PBF process would affect the growth of APD, which is closely related to the mechanical properties of the fabricated single crystals. Fabricating Fe_3Al by L-PBF process is difficult due to cracks and defects [5]. Fe_3Al single crystals have not yet been fabricated by L-PBF process. In this study, we investigated the growth of APD in the laser-irradiated regions of the Fe-28at.%Al bulk by transmission electron microscopy (TEM) to reveal the effect of excess vacancies on APD growth. Also, we fabricated Fe_3Al block samples under various laser irradiation conditions and evaluated crystal orientation, solute segregation and the formation of defect, aiming to achieve superelasticity in Fe_3Al fabricated by L-PBF process. It was found that APD growth during ordering heat treatment is faster in the laser-irradiated and rapidly cooled than in water-quenched regions. Excess vacancies introduced by the rapid cooling are suggested to promote the APD growth of the Fe_3Al intermetallic phase. The ordering mobility calculated by phase-field simulations was smaller than that predicted using the amount of the excess vacancies induced in the laser-irradiation process, i.e., quenching from the solidus temperature. In the laser-irradiated region, a lot of dislocations were observed by TEM. It is implied that dislocations act as a sink for vacancies and reduce the effect of supersaturated vacancies. Block samples were fabricated by laser metal additive manufacturing equipment under a total of 110 conditions with various laser power, scanning speed, scan pitch, substrate temperature and scanning strategy. Crystal orientation analysis was performed by electron backscatter diffraction (SEM-EBSD). Elemental analysis was performed by energy-dispersive X-ray spectroscopy (SEM-EDS). EBSD orientation maps have revealed that the single crystal-like texture with <100> oriented in the X, Y and Z directions was fabricated. However, partial cracks originating from thermal stress were observed in the sample. EDS maps have shown that solute segregation did not occur, in accordance with the results of laser irradiation to bulk material [6], suggesting the occurrence of absolute stability.

Effect of Cooling Rate on Fe-rich Intermetallic Phases in Solidification Microstructure of Al-Si-Fe-Mn Alloys

Shunta Kita[1], Naoki Takata[1], Asuka Suzuki[1], Makoto Kobashi[1], Takashi Tomita[2] and Yuichi Furukawa[2]; [1]Nagoya University, Japan; [2]Toyota Motor Corporation, Japan

Al-Si cast alloys are widely used in automotive industrial applications as structural casting, wheels, and powertrain components. Recently, the recycling of Al-Si alloys has received specific interest in terms of circular economy. However, a major impurity element of Fe during the recycling process promotes the formation of the Fe-rich intermetallic phases (β-Al_5FeSi phase with a coarse needle-shaped morphology), which negatively affects the mechanical properties of the alloy. Therefore, Mn, which is also another major impurity element, is often added to avoid the formation of the β-Al_5FeSi phase. The Mn addition enhances the α-$Al_{15}(Fe,Mn)_3Si_2$ phase (script or polygonal morphologies) in Al-Si alloys. The α-$Al_{15}(Fe,Mn)_3Si_2$ phase is expected to improve high-temperature mechanical performance due to its high thermal stability. However, few studies have systematically investigated the solidification sequence of the α-$Al_{15}(Fe,Mn)_3Si_2$ phase in Al-Si-Fe-Mn quaternary alloys, and the effects of *cooling rate on the solidification microstructure are still unclear. This study systematically investigated the solidification microstructure of Al-Si-Fe, Al-Si-Mn ternary alloys and Al-Si-Fe-Mn quaternary alloys solidified at different cooling rates. Based on thermodynamic calculations, we designed the alloy compositions of the Al-Si-Fe and Al-Si-Mn ternary alloys utilizing the eutectic reaction of the α-Al/Fe-intermetallic (β-Al_5FeSi or α-$Al_{15}(Fe,Mn)_3Si_2$) phases. The alloy compositions are Al-5%Si-1.5%Fe, Al-8%Si-1%Fe, and Al-5%Si-1.5%Mn (all wt% thereafter, unless otherwise stated). Also, since the addition of Fe to the Al-5%Si-1.5%Mn alloy was assessed to increase the volume fraction of the α-$Al_{15}(Fe,Mn)_3Si_2$ phase based on thermodynamic calculations, we designed quaternary alloys with 2.0%, 4.0%, and 6.0% Fe added to the Al-5%Si-1.5%Mn alloy.*

In this study, alloys designed based on thermodynamic calculations were prepared by solidification at two different cooling conditions. The metal raw materials were melted in a high-frequency induction furnace in the temperature range of 800-900 °C for 1800 s in an Ar atmosphere. Some were cooled by switching off the power source to the furnace (cooling rate: 0.3 $°C \times s^{-1}$). The others were cast into an iron mold to form rod-shaped ingots at a higher cooling rate (145 $°C \times s^{-1}$).

The microstructural characterization revealed that needle-shaped β-Al_5FeSi phase and fine α-$Al_{15}Fe_3Si_2$ phase were formed as the Fe-rich intermetallic phases in the solidified Al-Si-Fe ternary alloys. The α-$Al_{15}Mn_3Si_2$ phase with Chinese-script morphology was formed in Al-5%Si-1.5%Mn ternary alloy. In the Al-Si-Fe ternary alloys, the volume fraction of the needle-shaped β-Al_5FeSi phase decreased with increasing cooling rate, and the fine α-$Al_{15}Fe_3Si_2$ phase was dominantly formed in solidification microstructures. Such Fe-rich intermetallic phases were dominantly formed as the primary solidified phase in a low cooling rate of 0.3 $°C \times s^{-1}$, whereas the primary solidified α-Al phase was often observed in samples solidified at a high cooling rate of 145 $°C \times s^{-1}$. Therefore, two-phase eutectic microstructures of the α-Al phase with Fe-rich intermetallic phases, which were predicted by calculated liquidus projections, were scarcely observed in the experimental alloys. Such a trend was found by differential scanning calorimetry (DSC) measurements of the solidification reactions at controlled cooling rates. These results suggest the reaction sequence in solidification may not follow the liquidus projections, likely due to the limited temperature range of liquid equilibrium with Fe-rich intermetallic phases. In this presentation, the solidification microstructure of the Al-Si-Fe-Mn quaternary alloy will be shown to discuss the influence of Fe and Mn combined addition to Al-Si alloys.

SF05.07.10

Systematic Investigation of Ordered B2 Structure Ru-Al-Ni Alloys Property

Tatsuya Nakazawa, Fumihiko Saito and Shuichi Kubota; TANAKA Kikinzoku Kogyo K.K., Japan

Materials used in gas turbines and jet engines require numerous properties such as thermal and chemical stability, oxidation and corrosion resistance, and creep strength. Turbine blades are typically coated with a bond coat layer and a ceramic topcoat on a superalloy substrate. To prevent delamination caused by the mismatch in the coefficient of thermal expansion between the substrate and the coating, as well as the formation of oxides at the interface, platinum (Pt) and other platinum group metals (PGMs) are added to the bond coat materials, typically represented by NiAl. The NiAl layer containing Pt improves the adhesion between the top ceramic coating and the substrate. However, Pt is rapidly sublimated when exposed to a high-temperature oxidizing atmosphere due to the volatility of Pt oxide. Another issue is the manufacturing cost due to the high price of PGMs, especially Pt, rhodium, and iridium.

Ruthenium (Ru) is not only relatively inexpensive among PGMs, but also has a high melting point and a lower vapor pressure of the oxide compared to other noble metal oxides, which prevents volatilization. RuAl has already attracted interest as a bond coat material for Ni-based superalloys because of its strength and plasticity at room temperature and its ability to maintain these properties even at high temperatures. The Ru-Al-Ni ternary alloy, which is Ru added to the well-known bond coat material NiAl, an ordered B2 intermetallic compound, is regarded as a candidate bond coat material. However, the potential of Ru-Al-Ni alloys for the aerospace industry has not

been fully explored because systematic characterization of Ru-Al-Ni alloys has not been well conducted.
In this presentation, Ru-Al-Ni alloys with compositions varying to the extent that ordered B2 intermetallic compounds were prepared by the arc melting method. After homogenization heat treatment, the phases were identified by X-ray diffraction (XRD). Vickers hardness at room temperature and high temperature, thermal expansion, and high-temperature oxidation wear tests were conducted.
XRD patterns and microstructural observations by FE-SEM (field emission scanning electron microscopy) and EDX (energy dispersive X-ray spectroscopy) showed that the Al 50 at% alloys were a single ordered B2 structure, while the alloys with Al below 50 at% were a mix of Ni_3Al *and a Ru-rich phase. Vickers hardness at room temperature increased with Ni content. Furthermore, Ru-Ni-Al alloys were harder than the NiAl and RuAl binary alloys due to the size effect of Ru and Ni substitution. Particularly in the* Ni_3Al *phase precipitation region, the hardness exceeded 800 HV because of the B2+γ' duplex phase.*
Linear expansion coefficient measurements from room temperature to 1100°C demonstrated that the coefficient of thermal expansion decreased with increasing Ru concentration. High-temperature oxidation tests at 1100°C for 24 to 120 hours indicated that compositions with higher Ru content and lower Ni content exhibited significantly more depletion over a long period of time. The formation of a dense Al_2O_3 *layer was observed on the alloy surface after the oxidation test, and an Al-depleted phase existed in the underlying layer. The Ru-depleted phase was also present on the surface, indicating that the formation of* Al_2O_3 *and volatilization of Ru oxide were occurring simultaneously.*
Ru-Ni-Al alloys exhibit superior high-temperature oxidation properties compatible with the Ni-based superalloy substrate. It is important to obtain systematic property data to utilize these alloys in the aerospace industry as bond coat materials.

SF05.07.11

Room-Temperature Deformation Behavior and Dislocation Fine-Structures of β-$Mg_{17}Al_{12}$ Micropillar Single Crystal—The Strengthening Phase in AZ-Series Low-Density High-Strength Mg Alloys *Shinga Yamashita[1], Zhenghao Chen[1], Koji Hagihara[2], Kyosuke Kishida[1] and Haruyuki Inui[1]; [1]Kyoto University, Japan; [2]Nagoya Institute of Technology, Japan*

Magnesium alloys are attracting increasing interest because of their low density, high strength, and good corrosion resistance. Among them, the Aluminum-zinc alloyed Magnesium alloys, known as the AZ series Mg alloys (such as AZ91 alloy containing Mg-9 wt.% Al-1 wt.%Zn-0.3 wt.%Mn), are the most popular as-cast Mg alloys and have been widely used in automotive and aerospace fields owing to their excellent mechanical properties. It has been generally accepted that the β-$Mg_{17}Al_{12}$ *intermetallic phase precipitated in the α-Mg matrix with continuous or discontinuous morphology caused by the high Al addition is highly influential on the performance of the AZ-series alloys. Because of that, a great deal of effort, both experimental and computational, has been devoted to investigating this β-*$Mg_{17}Al_{12}$ *phase of its thermal stability, its formation during solidifications, and its effect on room- and elevated-temperature strength, corrosion resistance performance, castability performance, and so on. However, surprisingly, very little study has been focused on the plastic deformation properties of the β-*$Mg_{17}Al_{12}$ *itself, and none of them has ever revealed the operative slip system, the most fundamental information of the plastic deformation property, at room- or high-temperature. The β-*$Mg_{17}Al_{12}$ *phase has an α-Mn-like cryptographic structure, which is a complex crystal structure of the A12 type in the Strukturbericht symbol in the space group of* $I\underline{4}3m$*. Although the crystal structure is based on the body-centered cubic lattice and shares the BCC type symmetry, for example, the shortest Burgers vector is the same as the BCC structure as **b**= 1/2[111], the unit cell (containing 58 atoms) is much larger than a normal BCC cell and the operative slip systems are totally deferent to those in normal BCC alloys, as revealed in our previous study on the deformation behavior of α-Manganese. Hence, it is not only of great importance in industry but also of great interest in material science to know whether the β-*$Mg_{17}Al_{12}$ *exhibits plastic deformability at ambient temperature, which slip system will be activated during the*

deformation, and what the dislocation structure looks like in these slip systems.
In the present study, we investigate the deformation behavior of single crystal of the β-$Mg_{17}Al_{12}$ by micropillar compression at room temperature as a function of crystal orientation and specimen size. In spite of the repeated reported brightness in bulk deformation, plastic deformation is observed in micropillar single crystal specimens at room temperature for all loading axis orientations. Three slip systems, {110}<-110>, {110}<-111>, and {110}<001> are identified to be operative at room temperature depending on the loading axis. The CRSS values for all the identified slip systems are very high (~1 GPa) and decrease slightly with increasing pillar size, following the well-known 'smaller is stronger' size effect in the micropillar compression test. We also make an in-depth investigation of the dislocation structure with the 'weak-beam dark field' transmission electron microscopy (TEM) photography technique accompanied by the atomic-resolution scanning transmission electron microscopy (STEM) technique focusing on the dislocation core structure. Dislocations for all three slip systems are confirmed to dissociate into partial dislocations. The experimentally determined dissociation scheme agrees well with our simulation based on the generalized stacking fault energy calculation. These new findings on the room-temperature deformation behavior and the dislocation structure of the β-$Mg_{17}Al_{12}$ will contribute to the understanding of the mechanical properties and can be applied to get useful strategy to further improve the performance of the AZ-series Mg alloys strengthened by this intermetallic phase.

SF05.07.12
Digital Twin Analysis of Solidification Process in Powder-Bed Fusion of Inconel 718 Ni-Based Superalloys

Katsuhiko Sawaizumi[1], Masayuki Okugawa[1,2], Yuichiro Koizumi[1,2] and Takayoshi Nakano[1,2]; [1]Osaka University, Japan; [2]Anisotropic Design & Additive Manufacturing Research Center, Osaka University, Japan

Solute segregation in the powder-bed fusion (PBF) additive manufacturing (AM) process significantly affects material properties1). Therefore, a comprehensive understanding of solute segregation is essential for controlling the mechanical properties of PBF fabricated parts. We have investigated the segregation behavior of Ni-based superalloys under solidification conditions in the PBF process using phase field (PF) simulations weakly coupled with computational thermal-fluid dynamics (CtFD) simulations, suggesting that solute segregation at the interface affects material properties such as strength and toughness 2,3). In this study, the effect of temperature change on segregation behavior under solidification conditions in the PBF process is investigated by PF simulations weakly coupled with CtFD calculations.
The subject of this study is IN718, a precipitation hardening Ni-based superalloy that has been frequently applied to the PBF pr beam irradiation experiments were performed on the IN718 cubic samples fabricated by PBF-LB machine (EOSINT M290, EOS). The beam power, scanning speed, and scanning line spacing were set to 360 W, 1000 mm s^{-1}, and 80 μm, respectively, and the laser was scanned in 10 reciprocating scans parallel to the X direction (left-right direction, directly facing the device).The solute distributions in the laser-irradiated region were analyzed using a scanning electron microscope (SEM) equipped with the energy dispersive X-ray spectroscopy (EDS). Corresponding CtFD simulations were also carried out using a commercial 3D thermal-fluid analysis software (Flow Science FLOW-3D® with Flow-3D Weld module) to obtain the temperature distributions during the laser-beam irradiation. Beam power, scanning speed, and scanning line spacing were the same as in the experiment. The number of lasers was set to six. Two-dimensional MPF simulations weakly coupled with CtFD simulation were performed to analyze the microstructure formation and the solute segregations using the Microstructure Evolution Simulation Software (MICRESS). The Gibbs free energy and diffusion coefficient of the system were calculated using the Thermo-Calc TCNI10 thermodynamic database and the MOBNI5 mobility database. The solidus temperature and the equilibrium phases using the compositions of each local region were calculated to reveal the effects of the solute segregations on the properties of the parts.
Cross sectional observation of the laser-irradiated part showed a dendritic cellular structure formed by directional solidification. The primary dendrite arm spacing (PDAS) increased in the cross section formed by the 10th laser

irradiation compared to the 1st laser irradiation, and the Nb segregation at the cell interface became more pronounced. CtFD-coupled PF simulations were similar to the experimental results, with an increase in PDAS and more pronounced Nb segregation in the solidification microstructure formed at the 6th laser compared to the 1st laser. This is considered to be because repeated laser irradiation increased the substrate temperature and decreased the temperature gradient and solidification rate in the melt region. Thermal equilibrium calculation suggests that the precipitation of the γ” phase at the cell interface formed by the 6th laser increased compared to that in the 1st laser scan track, resulting in a stronger susceptibility to ductility lowering cracking.

This work was partly supported by CREST Nanomechanics: Elucidation of macroscale mechanical properties based on understanding nanoscale dynamics for innovative mechanical materials (Grant Number: JPMJCR2194) from the Japan Science and Technology Agency (JST) and JSPS KAKENHI (21H05192, 21H05193)

Optimizing Mechanical Properties of A205 Aluminum-Copper Alloy in Additive Manufacturing *Niall Pastuszek[1,2], Tara Mitra[2], Maximillian L. Adams[2,1], Kester Clarke[2] and Amy Clarke[2]; [1]Fort Lewis College, United States; [2]Colorado School of Mines, United States*

This project targets the enhancement of mechanical properties in additively-manufactured aluminum alloy through accurate microstructural control. A multi-stage heat treatment process that includes solution heat treatment, aging, and quenching is being developed to control the formation of strengthening particles precisely. This method is designed to enhance the performance of the alloy, which will be assessed using microscopy, x-ray diffraction (XRD), hardness testing, and tensile testing. By analyzing how the process, structure, and properties interact, the A205 alloy will be optimized to ensure it has sufficient mechanical properties for advanced applications. This research could significantly impact industries that rely on cutting-edge materials by enhancing material performance and efficiency.

SF05.07.14

A Dilatometer High-Energy X-Ray Study—Quenching from the α Phase Field in a Niobium Rich Titanium Aluminide Alloy *Tim Lengler, Andreas Stark, Dieter Lott and Florian Pyczak; Helmholtz-Zentrum Hereon, Germany*

Intermetallic γ-TiAl based alloys have been successfully introduced as structural materials for low-pressure turbine blades in civil aero engines during the last decade. A possibility to expand the range of their use is the introduction of novel production methods like additive manufacturing (AM). The manufacturing process of TiAl alloys with a subsequent heat treatment has a large impact on the properties of the material. A challenge of AM processes are the very fast cooling and heating rates that enforce phase transformations far away from thermodynamic equilibrium. These transformation pathways are difficult to understand using conventional characterisation and analysis methods solely based on the resulting microstructures.

In this study, in situ high-energy synchrotron X-ray diffraction was used to investigate the phase transformation pathway of a niobium rich TiAl alloy which was quenched from the α phase field and subsequently reheated. The alloy had a nominal composition of Ti-46Al–9Nb (in atomic %). First, the sample was heated to 1350 °C and quenched. In the subsequent reheating process the sample was slowly heated to 1250 °C with 10 °C per minute and cooled at the same rate. During these processes the X-ray diffraction patterns were continuously measured with frame rates up to 10 Hz.

The quenched sample showed an incomplete massive transformation, with large remaining α grains. During reheating the analysis of the collected data showed two significant changings in the diffraction patterns starting at 425 °C and 750 °C. The width and intensity of the diffraction peaks of both the γ and α_2 phase started changing at these temperatures. We suggest that at the temperatures of about 425 °C and 750 °C short- and long-range diffusion start to occur, respectively, leading to an equalizing of the chemical disequilibrium in the sample. For the reheating process, the c/a ratio of the γ and α_2 phase was analyzed. The c/a ratio at room temperature of the γ phase increased from 1.005 before the reheating process to 1.011 at the end. For the α_2 phase, the ratio decreased from 0.803 to 0.797 at the end. The different room temperature c/a ratios indicate a chemical disequilibrium in the material introduced during the quenching process, which is not the case during slow cooling.

SF05.07.15

Stabilization of the Metastable $Sn_XTi_{1-X}O_2$ Alloy and Suppression of Its Spinodal Decomposition *Pritha Biswas, Tamara Koledin, Melissa K. Santala and Janet Tate; Oregon State University, United States*

Among the bimetallic oxide alloys, spinodal decomposition of the SnO_2-TiO_2 phase has garnered much attention due to its applications in gas sensors, photo anodes, and electron transport layers. The tin titanium oxide alloy usually undergoes spinodal decomposition at a critical temperature, exhibiting a characteristic lamellar microstructure upon decomposition. Unlike classical nucleation and growth, spinodal decomposition is a homogeneous phase transformation with no associated activation energy barrier. In this work, a non-decomposed, metastable $Sn_XTi_{1-X}O_2$ thin film alloy with the Sn:Ti atomic ratio in the range of 62:38 to 78:22 was deposited from a mixed oxide target by controlling the partial pressure of oxygen, sputter power, and deposition time in a radio frequency sputter chamber. The crystalline phase of the oxide film was obtained upon subsequent annealing at 500°C. While the thermodynamic equilibrium solubility limit of TiO_2 in SnO_2 at 500°C is of the order of 10%, this thin film alloy demonstrated a substantially higher cationic substitution of Sn by Ti, approximately 38%, in $Sn_{1-X}Ti_XO_2$, highlighting its metastability. These $Sn_{1-X}Ti_XO_2$ thin film samples were annealed from 500°C to 1200°C in steps of 100°C, but there was no observable decomposition. According to the (SnO_2-TiO_2) phase diagram, a metastable $(Sn,Ti)O_2$ alloy with Sn:Ti in the range of 62:38 to 78:22 should decompose at a critical temperature in the range 1100°C – 1200°C. Stacking faults and other planar defects observed in cross-sectional TEM analysis point toward a complex intergrowth of SnO_2 and TiO_2 which may suppress the decomposition and enhance the metastability window of the alloy to the temperature as high as1200°C.

Oxygen Diffusion Coefficient in the γ Phase of a Tial GE Alloy Determined by SIMS *Camille Thenot[1], Daniel Monceau[1], Damien Connétable[1], Pierre Sallot[2], Marie-Amandine Pinault-Thaury[3] and Jean-Philippe Monchoux[1]; [1]Université de Toulouse, France; [2]Safran Tech, France; [3]GEMaC, CNRS, Université Paris-Saclay, France*

First reliable experimental oxygen diffusion coefficient data have been obtained in a $Ti_{48.3}Al_{47.7}Cr_{1.9}Nb_{2.1}$ near-γ GE alloy through secondary ion mass spectrometry (SIMS) depth profiling measurements of ^{18}O isotopes between 500°C and 700°C. The following expression of diffusion coefficient D has thus been derived: $D(m^2/s) = 10^{-10.6 \pm 1} \exp(-107 \pm 10\ kJ.mol^{-1}/RT)$. These data have been compared with theoretical calculations from literature, showing reasonable agreement concerning the activation energy, but significant discrepancy regarding the D values.

SF05.07.17

Tailoring NiTi-Based Shape Memory Alloy Characteristics Based on the Extrinsic Size Effect *Ji Young Kim[1], So Yeon Kim[1], Jinwoo Kim[1], Kook Noh Yoon[1], Wook Ha Ryu[1], Won-Seok Ko[2] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)*

Nanoscale shape memory alloys (SMAs) have recently attracted special attention because of their unique shape recovery characteristics. In particular, previous studies have focused on the phenomenon of the signal of shape memory behavior disappearing below the critical size. However, examining the deformation and phase transformation behaviors of SMAs at a small scale, considering the extrinsic size effect, has been challenging due to issues such as ion damage formed during focused ion beam sampling. Thus, in this study, we tried to investigate the extrinsic size effect of polycrystalline NiTi-based SMAs by overcoming the limitations of the conventional experimental method. In particular, we suggest a novel fabrication method of NiTi-based free-standing SMA nanoparticles based on a liquid-to-liquid phase separation and selective leaching in Ni-Ti-Gd system, which is inspired by reported processing techniques of the bulk metallic glass. We utilized the melt-spinning technique to obtain liquid-to-liquid phase-separated microstructure. Due to the gradient in the cooling rate across the entire specimen, a droplet structure with various sizes was formed, ultimately producing particles in the size range of 100-1600 nm after selective leaching. The extrinsic size effect of obtained particles is then examined by conducting in-situ mechanical tests on individual particles within an electron microscope. Then, we carefully compared the experimental results with the results of molecular dynamics simulation to analyze the mechanical behavior of the nanoparticles. Interestingly, the isotropic polycrystalline NiTi-based shape memory alloy particles show size dependence on recoverable strain, which shows decreasing recoverable strain as the particle size increases until the critical size. The origin was a size-dependent transition temperature studied by molecular dynamics simulation. This study provides a theoretical basis for fabricating isotropic polycrystalline shape memory alloy nanoparticles and novel guidelines for studying the size effect of shape memory alloys, excluding any unintended effects such as ion beam damage. We also expect that the results will provide an effective guideline for tailoring shape memory alloy characteristics based on the extrinsic size effect, especially the constructed size-stress-temperature phase diagram. Finally, we expect the study to accelerate the design and practical uses of shape memory alloys not only through composition but also through size.

SF05.07.18
AI-Driven SMA Design—Feature Extraction Metrics for Generative Model *Jack Shannon and Caroline Desgranges; University of Massachusetts Lowell, United States*

Shape Memory Alloys (SMA) have become critical in next-generation robotic systems with applications in aerospace, construction, and other industries. The development of more advanced SMAs is contingent on having generative models that can predict the actuation forces produced by its movement. More conventional methods of determining these properties are time consuming. However, by implementing generative machine learning models to predict these forces, superior control of SMA actuation is possible. When developing such models it is advantageous to pre-process raw high dimensional data into a set of independent features for training. The inclusion of this step provides benefits for both model accuracy and in the interpretability of the training data. A particular model that excels in extracting features from this class of datasets is the Restricted Boltzmann Machine (RBM). Historically, RBMs utilized contrastive divergence algorithms that minimized the Kullback-Leibler divergence to determine the learning rule. This work will compare extracted features of high framerate video depicting SMA actuation from methods that minimize the Kullback-Leibler divergence to a newer approach where the model minimizes the Wasserstein distance.

SF05.07.19
Characterization of Core-Shell-Structured NiCo-Pt Nanoparticles Using H_2-Temperature-Programmed Reduction *Seyed Danial Mousavi, Dominic Caracciolo, Merry N. Madiou, Isaac Kolisch, Guojun Shang, Zeqi Li and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States*

Alloys and intermetallic compounds derived from nickel, cobalt, and platinum are extensively used as catalysts in *various industrial processes, ranging from petroleum refining to the synthesis of fine chemicals. These catalysts are particularly studied for processing various types of plant materials, including bio-oil, vegetable oils, microalgae lipids, and numerous model organic compounds. The significant interest in such systems is due to the availability of nickel and cobalt and the relatively high activity of Ni-Co alloy-based catalytic systems in hydrogenolysis-based reactions. Modifying nickel-cobalt alloy-based catalysts with different metals greatly affects their catalytic activity and selectivity in processing biomass-derived feedstocks. We have been developing various nanoalloys and intermetallic nanoparticles for the catalytic and electrocatalytic reactions. In this presentation, recent results from the investigation of the synthesis of nickel-cobalt alloy decorated with platinum in a core-shell type of structure by wet-chemical and seeded growth methods will be described. H_2-temperature-programmed reduction (H_2-TPR) is used to obtain qualitative information on the reducibility of metal oxide species. Catalysts are reduced in a hydrogen stream at a fixed temperature immediately before testing in a target process. The reduction conditions can crucially impact the dispersion and activity of the catalysts. By different heating rates, the activation energy was determined, showing strong dependence on the core-shell composition and structure. Implications of the results for the design of the catalysts in different catalytic or electrocatalytic reactions will be discussed.*

SF05.07.20

Nanomolding Single-Crystalline $CoIn_3$ and $RhIn_3$ Nanowires *Nghiep Khoan Duong[1], Mehrdad T. Kiani[1], Quynh Sam[1], James L. Hart[1], Thomas Whoriskey[2], Christian D. Multunas[3], Shanta R. Saha[4], Satya Kushwaha[2], Ravishankar Sundararaman[3], Johnpierre Paglione[4] and Judy Cha[1]; [1]Cornell University, United States; [2]Johns Hopkins University, United States; [3]Rensselaer Polytechnic Institute, United States; [4]University of Maryland, United States*

Intermetallic nanostructures are desirable for catalysis applications and the study of topological materials, owing to the maximization of active catalytic sites as well as the enhanced contributions of topological surface states at the nanoscale, respectively. Fabricating such nanostructures is often challenging, especially for compounds comprised of elements with large differences in melting points, vapor pressures, or diffusivities, due to the complicated reaction pathways and potentially uncontrolled stoichiometries that may entail. To address this challenge, we have employed thermomechanical nanomolding – i.e. hot-pressing of bulk materials into nanoporous molds – to fabricate $CoIn_3$ and $RhIn_3$ nanowires with diameters down to ~ 20 nm and lengths exceeding 10 microns. Using scanning transmission electron microscopy (STEM) and STEM electron energy-loss spectroscopy (EELS), we demonstrate the single-crystalline nature of the wires and the diffusion of Co and In from the bulk crystal into the nanopores, thus elucidating the nanowire formation mechanism therein. Temperature-dependent resistivity measurements demonstrate the metallicity of the wires, and their room-temperature resistivities are measured to be 140 and 275 μΩ.cm for $CoIn_3$ and $RhIn_3$, respectively, which is about 3-4 times the calculated bulk value in the case of $CoIn_3$. DFT calculations indicate that Co and In vacancies can shift the Fermi level and introduce substantial scattering that could explain the increased resistivity in $CoIn_3$ nanowires. Our study demonstrates the scalable synthesis of single-crystalline intermetallic nanowires combining elements with large differences in melting points and vapor pressures (such as Co, Rh versus In). The nanowire diameters and aspect ratios are well-controlled, making them exceptionally suitable for potential applications in catalysis and further studies on the structural and electronic properties at the nanoscale.

SF05.07.21

Ni-Based Superalloy Strengthened by In-situ Alumina Formation During Laser Powder Bed Fusion with Recycled Powder *Hyungsoo Lee, Joong Eun Jung, Hi Won Jeong, Dae Won Yun, Young Soo Yoo and Seong-Moon Seo; Korea Institute of Materials Science, Korea (the Republic of)*

Considering the high material costs, economics, and sustainability of the additive manufacturing (AM) industry, powder reuse is essential for the Laser Powder Bed Fusion (LPBF) AM process. Given that powder quality is a *critical determinant of the mechanical performance of LPBF-fabricated parts, it is crucial to investigate the effects of powder reuse on powder characteristics and the properties of the final LPBF parts. This study examines the microstructure and mechanical properties of LPBF specimens fabricated by reusing IN718 powder up to 10 times, employing a virgin powder supplementation approach. The average particle size of the reused powder progressively increased as the number of powder reuse cycles was increased. Additionally, repeated reuse caused the powder to oxidize and form alumina spots on the powder surface. LPBF specimens manufactured with reused powder contain fine alumina of less than 100 nm in an austenite matrix. The presence of alumina influenced the recrystallization behavior during the 1065°C homogenization heat treatment. Additionally, the oxide dispersion strengthening effect imparted by the alumina led to simultaneous enhancements in both tensile strength and elongation of the LPBF specimens tested at 25°C and 650°C.*

SF05.07.22

Studies on Thermal and Nanoindentation Properties of Spark Plasma Sintered Ti-48Al-2Cr-2Nb Alloy

Mahlatse R. Mphahlele[1], Peter A. Olubambi[2] and Eugene Olevsky[3]; [1]Durban University of Technology, South Africa; [2]University of Johannesburg, South Africa; [3]San Diego State University, United States

The enhancement of thermal properties of Ti-48Al-2Cr-2Nb intermetallic alloy by spark plasma sintering (SPS) technique was investigated by laser flash analyser (LFA) and dilatometry scanning calorimeter (DSC) at a temperature range of 25-900 °C and 25-1200 °C, respectively. Investigation on thermal properties showed that the thermal capacity and conductivity of the SPSed TiAl material decrease with an increase in temperature up to 300 °C, and then rise with an increase in temperature. DSC results showed that at 1200 °C, phase transformation associated with the phase transition from $\alpha_2 + \gamma$ *à* $\alpha + \gamma$ *was observed. Quantitative analysis of the SEM-BS images showed that in the temperature range 25 – 600 °C no structural changes were observed, only microstructure texture changed with residual γ-phase increasing with an increase in temperature. Nanoindentation load-displacement curves showed that the sample that was subjected to a temperature of 600 °C prior to testing displayed low penetration depths under varied loads, relatively high H and E, and exceptional H/Er and* H^3/Er^2 *ratios which indicates improved anti-wear properties. The observed enhancement is attributed to the duplex microstructure and the presence of minor hard phases (i.e. TiN, NbC, and CrOOH) of the TiAl intermetallic alloys. This study established that spark plasma sintering is an effective technology to fabricate well-densified Ti-48Al-2Cr-2Nb with a tailored microstructure that yields improved mechanical properties and wear resistance, especially at high temperatures, thus, is recommended for high-temperature wear applications.*

SF05.07.23

Structural Characterisation of Nanoporous Copper *Prabhu P. Biswal, Samuel Graf, Marlene Eichlseder, Fernando Gustavo Warchomicka, Fabio Blaschke, Maximilian Fuchs, Eduardo Machado Charry, Karin Zojer, Roland Resel and Eva-Maria Steyskal; Graz University of Technology, Austria*

Nanoporous metals are generally defined as metals with features in the pore structure in the range of 100 nm or less and are of significant interest due to their high surface areas and unique properties, which make them valuable for applications in catalysis, energy storage, and sensing. Nanoporous copper (np-Cu) has recently emerged as a promising alternative to more expensive nanoporous metals such as gold and platinum. In this study, np-Cu was prepared using a three-step process: (i) in-situ alloying of aluminium and copper by laser powder bed fusion (LPBF), commonly known as 3D laser printing, (ii) annealing the alloy at 530°C to promote phase stability and atomic diffusion, and (iii) de-alloying to selectively remove aluminium from the bulk alloy, leaving behind a porous copper structure. Despite changes in the composition during the de-alloying process, the domains within the alloy retained their spatial positioning and extent, preserving the structural integrity of the material. The properties of np-Cu were systematically characterized using various techniques. X-ray diffraction

(XRD) was employed to examine the crystal structures, confirming the retention of the copper crystal lattice post-de-alloying, while X-ray fluorescence (XRF) spectroscopy provided an analysis of the chemical composition, verifying the effective removal of aluminium and purity of the copper. Surface topography and morphology were investigated using scanning electron microscopy (SEM), revealing a well-distributed network of nanopores. The pore size distribution and internal surface area were quantified using advanced techniques such as microcomputed tomography (μ-CT) and mercury intrusion porosimetry. These methods provided detailed insights into the material's internal structure, confirming an internal surface area and a controlled pore size distribution. Overall, the three-step process used to synthesize np-Cu, involving in-situ alloying, annealing, and de-alloying, offers a versatile and scalable approach to producing nanoporous metals with controlled properties. The retention of the spatial arrangement of alloy domains throughout the de-alloying process ensures the stability of the nanoporous structure, making np-Cu a promising material for a variety of advanced applications. The comprehensive characterization of its morphology, crystal structure, and surface properties provides valuable insights into its potential use in fields such as catalysis, energy storage, and sensing technologies.

SESSION SF05.08: Intermetallics and Multicomponent Alloys

Comparing and Contrasting High-Entropy and Intermetallic Alloys *Easo P. George[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Ruhr-Universität Bochum, Germany*

Not unlike high-entropy alloys (HEAs), which are having a moment now (beginning two decades ago), intermetallics had a flowering starting in the late nineteen-seventies that bloomed for three decades or so. With the benefit of hindsight, and having worked on both classes of materials, I will attempt in this presentation to compare and contrast them. Both started off targeting properties of interest for structural applications; over time, though, other physical and chemical properties piqued researchers' interest. Similarly, like the justification offered for the investigation of HEAs, namely that there are countless possible candidates at least some of which will possess useful properties, Laves-phase compounds were once expected to be the most promising intermetallic candidates because of their sheer abundance. In retrospect, that did not quite pan out and it remains to be seen whether the abundance of HEA candidates will yield better prospects. Initially, research on intermetallics focused on ordered compounds close to their stoichiometric compositions. With time, however, it became clear that such compounds lacked the balance of properties required for high-temperature structural applications (e.g., strength, ductility/toughness, and oxidation resistance) and focus shifted first to off-stoichiometric compositions and then to two-phase microstructures consisting of ordered precipitates in a solid solution matrix. A similar evolution has occurred in the HEA field, to off-equiatomic compositions and two-phase microstructures comprising ordered intermetallic compounds in a HEA matrix. Thirty years apart, intermetallics and HEAs have in other words converged on a much earlier microstructure, namely, that of the highly optimized Ni-base superalloys. Given the current state, where are the opportunities for HEAs? I will make some speculations based on our recent research results, confining my comments to mechanical behavior.

9:00 AM SF05.08.02

Unraveling the Structure and Thermodynamics of Intermetallic Precipitates in Multicomponent Refractory

Alloys from First-Principles *Anirudh Raju Natarajan and Yann Müller; École Polytechnique Fédérale de Lausanne, Switzerland*

Precipitation hardened refractory alloys are attractive candidates for high-temperature applications. Although multicomponent refractory alloys made of elements in groups 4, 5 and 6 of the periodic table are attractive candidates for aerospace applications, they often lack sufficient mechanical strength. Precipitation hardening is a promising route that could enhance the strength of these alloys. The addition of alloying elements, such as aluminum, can induce the formation of a microstructure comprised of ordered precipitates embedded within a disordered matrix phase. In this talk, we will utilize first-principles electronic structure calculations and statistical mechanics techniques to discern precipitate crystal structures and precipitation mechanisms in aluminum-containing multicomponent refractory alloys. High-throughput computations and rigorous Monte-Carlo simulations will be employed together with machine-learning techniques to elucidate the thermodynamics of precipitate formation in this class of materials. We will also highlight some promising alloy chemistries and processing conditions that could have improved mechanical strength and thermal stability.

Effect of Ordered B2 Phase on Deformation Behavior of Al-Nb-Ta-Ti-Zr High Entropy Superalloys *Hiroyuki Y. Yasuda, Ryohei Haruna and Ken Cho; Osaka University, Japan*

Refractory high entropy alloys composed of group 4-6 transition metal elements are expected to be a potential candidate for high temperature structural materials. However, there are some phase transformations such as phase separation of bcc phase into two bcc phases and formation of hcp phase, which is not suitable for high temperature applications. In contrast, $Al_{0.25}NbTaTiZr$ *high entropy alloys have the (bcc+B2) two-phase structure stable at high temperatures, similar to Ni-based superalloys. Al-doping results in the formation of the B2-*$(Ti,Zr)_2AlNb$ *phase, while the bcc phase is mainly composed of Nb and Ta. The two-phase structure is formed by the spinodal decomposition and is effective in improving high temperature strength. It is also noted that dislocations after deformation at 1073 K are distributed in both the bcc and B2 phases. This suggests that not only the bcc phase but the B2 phase deforms plastically. In* $Al_{0.25}NbTaTiZr$ *alloys, the misfit strain between the bcc and B2 phases is +2.7% and the volume fraction of the B2 phase is nearly 50%. The volume fraction of the B2 phase can be systematically changed from 28% to 74% by changing the chemical composition of the alloys. The yield stress at 873 K increases almost linearly with increasing the volume fraction of the B2 phase. This means that the B2 phase is effective in increasing high temperature strength in Al-doped refractory high entropy alloys. It is also noted that refinement of the two-phase structure leads to an increase in high temperature strength.*

Thermodynamics and Phase Transformations in BCC-B2 Refractory Superalloys *Eric A. Lass; The University of Tennessee, Knoxville, United States*

Since being reported by Senkov et al. in 2014, two-phase, body-centered cubic (BCC) plus ordered B2, refractory-based compositionally complex alloys (R-CCAs), also known as high-entropy alloys, have received significant research attention as potential next generation materials for extreme environments beyond Ni-based superalloys. These recent efforts are predated by a comprehensive investigation by Naka and Khan in the late 1990s searching for refractory alloy systems strengthened by intermetallic phases, or so-called "refractory superalloys" (RSAs). In their study, Naka and Khan identified the AlMoNbTaTiZr system as containing a two-phase BCC+B2 microstructure, coincidentally the same system first reported by Senkov et al. Of the outstanding issues currently facing BCC+B2 RSAs, microstructural evolution and stability is one of the more prominent. Most often, an inverted "BCC-precipitate in B2 matrix" microstructure manifests in these materials, while other times a spinodal-like *microstructure is observed. This is a result of the higher-order thermodynamic phase transformation between BCC and B2, which had been largely overlooked until recently. The present work details the underlying thermodynamics governing the BCC-B2 phase transition in multicomponent alloys, specifically RSAs, and the multitude of pathways available for the BCC→BCC+B2 transformation. Microstructural evolution in BCC-B2 RSAs parallels that in binary alloys such as Fe-Al, but the added compositional complexity opens new transformation pathways and may improve B2 phase stability. Previously reported RSAs are discussed in the context of concurrent ordering and phase separation involving higher order phase transitions in multicomponent alloys, including those utilizing both the TiAl- and RuX-based (where X is Ti, Zr, or Hf) B2 phases. The ideas and discussion herein offer insight into the thermodynamics of microstructure development in RSAs and provide tools and guidance for future research in this promising class of materials.*

In Situ Assessment of the Complex Microstructural Evolution of Refractory Metal Superalloys *Nicholas Jones, Howard Stone, George Wise, Nicole Church, S-T Yang, Rosie Mellor and Robert Thompson; University of Cambridge, United Kingdom*

Global energy consumption has tripled in the last fifty years and our usage is predicted to increase. The high power to weight ratio and flexibility of gas turbine engines means that they will continue to see use across all areas of energy generation. As such, it is desirable that their efficiency is improved by enabling operation at higher temperatures, thereby reducing emissions. However, Ni-base superalloys, are reaching the limit of their capability, meaning that new materials are required to achieve enhanced performance.

One promising class of materials are refractory metal superalloys (RSA), which aim to combine the high melting temperatures and low intrinsic diffusivities of the refractory metal elements, with intermetallic reinforcement analogous to those of Ni-based superalloys. However, the majority of RSA compositions typically produce ordered matrices and solid solution precipitates, raising concerns about ductility and toughness, particularly at lower temperatures. Consequently, it has become critical to understand the microstructural formation pathway as this is key to establishing strategies by which the phase configuration can be controlled.

Gaining a deep understanding of the microstructural evolution in these systems requires the use of in situtechniques. In this presentation, data acquired using high energy synchrotron radiation during heating and cooling of a number of RSA will be discussed alongside key observations made via high resolution electron microscopy. These data not only provide direct evidence of the microstructural formation pathway and the critical temperatures at which key transitions occur but also highlight how the evolution of interphase misfit can lead to the formation of novel nanometric assemblies that reduce the interfacial stresses.

11:00 AM SF05.08.06
Additively Manufacturing of Eutectic Multicomponent Alloys with Nanolamellar FCC and B2 Phases *Yu Zou; University of Toronto, Canada*

Laser-based directed energy deposition (DED) technique provides new opportunities for fabricating eutectic eutectic multicomponent alloys or high entropy alloys (EHEAs) with directional nanolamellar structures that exhibit superior mechanical properties. The mechanisms of co-deformation, strengthening, fracture of the two constituent phases, and their resulting anisotropic mechanical properties, have not yet been systematically studied. Here we employ in situ synchrotron-based high-energy X-ray diffraction and X-ray tomography to study a

DED-fabricated nanolamellar AlCoCrFeNi$_{2.1}$ that is comprised of face-centered cubic (fcc) and ordered body-centered cubic (B2) phases. This study demonstrates that the DED-produced EHEAs exhibit the optimal strength-ductility synergy along the lamellar direction and provides a fundamental understanding of the co-deformation behavior of dual phases in directional nanolamellar structures.

11:15 AM SF05.08.07

Synthesis and Characterization of Random and Intermetallic Types of Ternary Alloys *Merry N. Madiou, Connor Kanyuk, Julia Zottola, Shan Wang, Shiyao Shan, Dominic Caracciolo, Guojun Shang and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States*

The ability to control the phase structures of alloy nanoparticle-structured catalysts, including random alloys and intermetallic compounds, is critical for tuning the catalytic activity for various oxidation reactions under oxygen, which are important for auto emission control systems to combat air pollution. We have been developing synthesis and processing protocols for the preparation of various nanoalloy catalysts for controlling the size, composition, structure, and morphology. A key challenge is understanding the role of the nanoscale phase structure in the catalytic reaction. In this presentation, we will discuss recent findings of an investigation of Pt-based ternary nanoalloys with random alloy and intermetallic structures for lower temperature catalytic oxidation of CO and hydrocarbons. We seek to understand the relationship between composition, structure, and catalytic activity of the two different types of nanocatalysts. X-Ray Diffraction (XRD) and Transmission Electron Microscopy (TEM) techniques are used for characterization of the phase structures, whereas H_2-Temperature Programmed Reduction (H_2-TPR) and online Fourier Transform Infrared Spectroscopy (FTIR) are used for monitoring the oxygenation degree and CO oxidation activity of the nanocatalysts. Results serval a strong correlation between the phase structure and the catalytic properties, the implication of which for the design and optimization of the nanocatalysts will be discussed.

Thermophysical and Mechanical Properties of α'/α"-Strengthened Ferritic Superalloys *Christopher H. Zenk, Luis A. Morales and Carolin Körner; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany*

Ferritic superalloys are an emerging group of materials that are based on the Fe-Al-Ni ternary system. In these materials, a coherent bcc-derived α/α' (A2/B2) microstructure can be established, analogous to the fcc-based γ/γ' (A1/$L1_2$) phases in Ni-base superalloys. With Fe as their base element (~ 50 at.%) and a high Al content (~ 18 at.%) these materials have a major cost advantage over Ni-base superalloys. A relatively high Cr content (~ 10 at.%) provides corrosion resistance. It has recently been reported that the addition of Ti facilitates the partial transformation of α' into an $L2_1$ Heusler phase (based on Ni_2AlTi, henceforth referred to as α"). One of the first reports on these α/α'/α" alloys coins the term Hierarchical Precipitate Strengthened Ferritic Alloys (HPSFA) due to the fact that smaller precipitates form within larger ones. The introduction of these precipitates was shown to improve the creep resistance of these alloys at 700 °C by four orders of magnitude.
We will present our own alloy development in which Ni/Co and Cr contents were carefully balanced to avoid an α → γ phase transformation. Cu was added to stabilize α" further and improve the room temperature toughness. The efforts led to the alloy FSA2, which was subsequently processed successfully via Laser Metal Deposition. High-energy X-ray diffraction reveals a complex phase transformation pathway, which allows the design of a large variety of different microstructures. TEM and APT investigations confirm the presence of the α" and reveal Cu-rich nanoparticles co-precipitating with α'. Segregation of Co and Ti to interfacial dislocation networks is observed and the linear alignment of Cu-rich particles in proximity to the interface indicates that they also preferentially nucleate there. Initial compressive creep and strain rate jump tests at 750 °C reveal that the homogenized (HST) and air-cooled state exhibits a much higher strength than an aged condition. This is presumably mainly caused by the

topological and morphological changes that takes place during aging: in the HST state, α forms a fine interpenetrating basket-weave network with the much harder α' phase, which is a result of spinodal decomposition. After aging, the α' re-aligns into equiaxed, cube-shaped precipitates while the low-strength but more ductile α phase forms the matrix. High-temperature tensile and tensile creep tests reveal that various embrittlement phenomena are occuring between RT and 950°C. Some of these seem to involve environmental effects, even though the high-temperature oxidation resistance of FSA2 is significantly better than that of common Ni-base superalloys.

1:30 PM *SF05.09.01
Modelling of Structural Phase Transformations in Intermetallic and Related Alloys *David Holec;*
Montanuniversität Leoben, Austria

Atomistic quantum mechanical calculations provide insights into the functioning of materials beyond experimental resolution and can be used as an unbiased tool for the design of novel alloys. In this talk, I will use our recent activities to demonstrate their application to the study of phase transformations in several Ti-containing systems.

NiTi is a class of shape memory alloys. The transformation temperature can be effectively shifted by exposing the material to hydrogen-rich environments. Through a combination of transmission electron microscopy and synchrotron diffraction experiments, we have been able to demonstrate the uptake of hydrogen into the material in the B2 austenite phase. The changes in lattice constant measured in this way were compared with DFT predictions, allowing the H content in the material to be quantified. The experimental work led to a proposal for the existence of a hydride phase. We then used Monte Carlo simulations to demonstrate that there is a thermodynamic driving force for hydride formation, rather than uniformly distributed H interstitials.

In another case study, we used Monte Carlo to study the effect of Mo alloying in an intermetallic TiAl alloy on its ordering temperature. While the low-temperature variant consists of an ordered cubic B2 or hexagonal B19 phase, increasing the temperature leads to disordering of the system to a bcc or hcp alloy, respectively. Using DFT and MC calculations, we have shown that alloying Mo at the expense of Al (Ti-rich compositions) dramatically increases the ordering temperature by almost 1000 K for 15 at.% Mo, whereas replacing Ti (Ti-lean compositions) has a negligible effect.

The B2-TiAl phase is unstable with respect to spontaneous transformation into both gamma-TiAl (Bain's transformation pathway) and B19 phase. By calculating the potential energy surfaces for increasing Mo content, we show that a small barrier appears between the two phases before the B2 phase finally becomes the most stable. Thus, Mo acts as a stabiliser for both structural and ordering transformations in the model TiAl+Mo intermetallic alloy.

As a final example, I will discuss the influence of several alloying elements on transformation barriers for TWIP *(twinning-induced plasticity) and TRIP (transformation-induced plasticity) effects in binary beta-Ti alloys. Here Mo and Cr are proposed to stabilise the system with respect to the TRIP effect, while Mo and Al show stabilisation with respect to {331}<11-3> twinning.*

Chemical Interactions in Cu-Al-Mn Shape Memory Alloy During Low-Temperature Heat Treatment—XAS and DFT Study *Zheyuan Liang[1], Kakeru Ninomiya[1,1,1], Hiroshi Akamine[2], Ryotaro Arai[2], Sumio Kise[3], Minoru Nishida[2] and Maiko Nishibori[1,1,1]; [1]Tohoku University, Japan; [2]Kyushu University, Japan; [3]Furukawa Techno Material Co., Ltd., Japan*

Cu-Al-Mn-based superelastic alloys (CAM) are expected to be used in fields where Ni-Ti alloys, such as seismic-resistant materials, are difficult to apply due to their low cost and excellent workability [1]. Although it has been reported that the shape memory properties change significantly with low-temperature heat treatment, to design shape memory alloys, it is necessary to identify the degree of order that contributes to improving these properties and understand the mechanisms of structure changes. We believe that the atomic arrangement is highly disordered after quenching and changes into a short-range ordered state during low-temperature heat treatment, leading to a variation in phase equilibrium between the parent and martensite phases [2]. While it is known that the β phase undergoes A2/B2/D0$_3$/L2$_1$ order-disorder transformations, a quantitative evaluation of the structural changes induced by the ordering heat treatment has not yet been conducted. In the previous study, we attempted to track the average local structure of Cu, which represents the highest content in CAM, using X-ray absorption spectroscopy (XAS) [3]. In this study, we used XAS and Density Functional Theory (DFT) calculation to analyze the changes in the average structure of the additive elements Al and Mn, which determine the shape memory effect [4] during low-temperature heat treatment, to investigate the diffusion behavior of Cu-16.5Al-10.6Mn (at%). We elucidate the underlying mechanisms driving the observed diffusion phenomena by analyzing structural energy variations and atomic interactions.
The as-quenched Cu-16.5Al-10.6Mn alloys exhibit inhomogeneous [2] , in which the average local Mn exhibits an L2$_1$-like structure, and the Al atoms indicate an intermediate state between D0$_3$ and L2$_1$. While the local structure of Cu is composed of a D0$_3$-like structure in the present work [3]. During the 100°C heat treatment, the average local structure of Mn atoms tends to form L2$_1$, and the arrangement of Mn atoms changes in two stages. Mn-rich structures formed and reduced during 150°C heat treatment, while no significant change was observed for Al. The DFT calculation provided insights into the XAS detection results, elucidating the fact that diffusion of Al atoms hardly occurs due to a higher potential barrier, while the formation of Mn-rich local structures can be promoted with the aid of magnetic stabilization between neighboring Mn atoms. However, as the aging treatment duration increased, the local structure of Mn transitioned toward the stable ferromagnetic L2$_1$ phase. During low-temperature heat treatment, the spin moment change of Mn atoms in the CAM may be the critical factor.

Stacking Fault Energy in Co and Dilute Co Alloys *Yingchun Tang[1,2], Song Lu[3], Wei Li[4], Levente Vitos[4,5,6] and Florian Pyczak[1,2]; [1]Helmholtz-Zentrum Hereon, Germany; [2]Brandenburgisch Technische Universität Cottbus-Senftenberg, Konrad-Wachsmann-Allee 17, Germany; [3]VTT Technical Research Centre of Finland Ltd., Finland; [4]KTH Royal Institute of Technology, Sweden; [5]Uppsala University, Sweden; [6]Wigner Research Center for Physics, Hungary*

In the present work, generalized stacking fault energies (GSFE) of Co-base alloys at different magnetic states are investigated using ab initio calculations. The energy difference between the hcp and fcc structure for pure Co is reasonably well predicted and is in good agreement with the available theoretical data. Theoretical calculations show that the SFEs of dilute Co alloys are sensitive to their chemical composition and magnetic state. The stacking fault energies (SFE) of binary dilute $Co_{1-x}M_x$ *(M represents W, Al, and Ni, respectively) systems and ternary* $CoAl_{18.3-y}W_y$ $(0 \leq y \leq 18)$ *alloys are calculated to study their dependence from chemical composition. The calculated results agree well with available experimental and theoretical data in the literature. We further study the temperature dependence of the SFE for pure Co and ternary Co9.3Al9W alloy calculated by using the corresponding experimental lattice parameter at each temperature. It reveals that the SFE increases as temperature increases in the ferromagnetic (FM) state while it shows an opposite trend in the paramagnetic (PM) state for pure Co. For the ternary Co9.3Al9W alloy, the FM SFE shows similar trends as the FM SFE of pure Co. The PM SFE decreases with increasing temperature in the range from 700 K to 1173 K, but the PM SFE increases with increasing temperature at higher temperatures due to the magnetic entropy contribution. The negative SFE of the dilute Co alloys hints to the possibility of twin formation according to empirical relationships between the value of SFE and the deformation mode. The predicted SFE of CoCrNi base alloys indicates the formation of twinning at room temperature, which is confirmed by experimental observations [Acta Materialia, 252 (2023) 118928, Acta Materialia, 128 (2017) 292-303]. The present study identifies potential plastic deformation mechanisms of metastable dilute Co alloys at elevated temperatures using the same empirical relationship between SFE and twin formation validated by experimental and theoretical investigations [Materials Science and Engineering, 26 (1976) 123-132, PNAS Nexus, 2022, 2,1-11]. This is of special interest as it gives insights into the favorable plastic deformation mechanisms of typical matrix compositions in superalloys at typical service temperatures and could support the design of advanced alloys.*

Room-Temperature Plastic Deformation Behavior of Hard and Brittle Intermetallic Compounds Investigated by Micropillar Compression *Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan*

Hard materials including carbides, borides, oxides, and intermetallic compounds with complicated crystal structures, have been considered as important strengthening phases in improving mechanical properties of various conventional structural materials by utilizing mainly their extremely high strength. In order to make the best use of the attractive mechanical properties of these hard materials, it is essential to clarify fundamental mechanical properties such as operative deformation modes and their critical resolved shear stress. However, detailed deformation mechanisms of these hard materials are largely unknown mainly because of their extreme brittleness at low temperatures.
Recently, micropillar compression method has been found to be useful in investigating deformation behavior of brittle materials such as Si, GaAs at temperatures far below their ductile to brittle transition temperatures

observed for bulk-sized specimens. In our research group, the micropillar compression method has been applied systematically to various hard and brittle materials including transition-metal silicides, Laves phase, mu-phase, sigma phase, transition-metal carbides and so on. We have successfully confirmed that most of them are plastically deformable by the activation of dislocation slip even at room temperature in the micropillar form. In addition to conventional dislocations, atomic-scale scanning transmission electron microscopy (STEM) investigation of dislocation structures developed in plastically deformed micropillar specimens confirmed that non-conventional dislocations of zonal-type and synchroshear-type are activated in sigma-phase and mu-phase at room temperature, respectively. These results clearly indicate the great advantages of the micropillar compression method in investigating inherent deformation behavior of hard and brittle materials with lesser ambiguity.

In the presentation, recent results on plastic deformation mechanisms of various hard and brittle materials including sigma-phase, mu-phase and some carbides investigated by the micropillar compression tests together with the atomic resolution STEM analysis and first-principles calculations of generalized stacking fault energy will be reviewed.

4:00 PM SF05.10.02

In Situ Micro-Hardness Tests on Brittle Intermetallics for Determining Their Slip Systems *Seiji Miura[1], Hiroki Kawashima[1], Takuya Semboku[1,2] and Ken-ichi Ikeda[1]; [1]Hokkaido University, Japan; [2]Furukawa Electric Co., Ltd., Japan*

Compression testing has been used to investigate the mechanical properties of brittle intermetallic compounds rather than tensile testing due to their brittleness, but some of the more brittle materials exhibit collapse or crushing during compression testing. This phenomenon can be attributed to defects such as voids or cracks introduced into the specimen during preparation. Micropillar compression testing has been used to reduce specimen volume. Plastic deformation without collapse or crushing was observed using this method. Based on these results, it is believed that plastic deformation occurs when the specimen is small enough to reduce the probability of the presence of internal defects. However, this method is not easy to apply.

Hardness measurements are effective in introducing plastic deformation in small regions. The authors attempted to apply the micro-indentation test to the study of brittle intermetallic compounds such as the Ce_2YNi_9-hR36 compound, and analyzed the slip traces introduced during indentation in comparison with EBSD analysis results. This method allowed us to confirm the slip plane of brittle compounds. The results of crack initiation and propagation observation using a newly developed “in-situ” indenter apparatus are also presented.

This study was financially supported by Iketani Science and Technology Foundation (Grant Numbers 0351211-A and 0363010-C), and JSPS KAKENHI for Scientific Research on Innovative Areas “MFS Materials Science (Grant Number JP18H05482). Parts of this work were also conducted at the Laboratory of Nano-Micro Materials Analysis, Hokkaido University, supported by “Nanotechnology Platform Program” and “Advanced Research Infrastructure for Materials and Nanotechnology in Japan (ARIM)” of the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

On the Determination of Operative Slip Systems of η-Fe_2Al_5 via Room-Temperature Single Crystal Micropillar Compression Investigation *Zhenghao Chen and Haruyuki Inui; Kyoto University, Japan*

Hot-dip aluminized steels have extensively been used for sheet materials for automotive applications such as exhaust systems and heat shields and have recently received increasing attention as a possible candidate for the replacement of Zn-coated steels used in large quantities in the automotive industries. Some Fe-Al intermetallic phases are reported to form in the reaction layer on the substrate steel during the subsequent heat treatment *process. Among them, η-Fe_2Al_5 is revealed to be the major phase to occupy a large volume fraction in the reaction layer and is thus expected to play a decisive role in determining the mechanical properties of the hot-dip aluminized steels. However, almost nothing is known about the mechanical properties of η-Fe_2Al_5, in spite of the importance of getting some useful strategy to mitigate the extent of cracking and peeling of the coating layer from the substrate steel in press forming. In the present study, we, for the first time, identified room-temperature plastic flow of η-Fe_2Al_5 occurring by the operation of six different slip systems at very high critical resolved shear stresses (CRSSs) above 1 GPa through micropillar compression. The operation of slip systems depends on crystal orientation; the (001)<010>, (001)<110>, (001)<130> and {23}[110] slip systems operate in the middle of the stereographic triangle with the similar CRSS values in the range of 1.1~1.23 GPa, while in orientations close to [001], the {311}<03> slip system as well as the {301}<03> slip system operate with a much higher CRSS values around 1.5 GPa. On the other hand, premature failure occurs without the operation of any slip systems in orientations close to the [100]-[110]-[010] symmetry line. We also make a discussion on the selection of slip systems, their CRSS values, and the possible dislocation dissociation modes with the use of the overlapped atom volume that occurs during the shear deformation by taking the partial occupancies of Al atoms in the c-axis chain into account. A smaller overlapped atom volume is proved to play a decisive role in determining the operative slip system as it leads to the lower CRSS. These new findings on the operative slip systems and their CRSS values in η-Fe_2Al_5 definitely contribute to the understanding of the mechanical properties of this intermetallic phase, which can successfully be applied to get useful strategy to mitigate the extent of cracking and peeling of the coating layer from the substrate steel in press forming.*

4:30 PM SF05.10.04

Mechanical Behavior of Superelastic $ThCr_2Si_2$-Structured Intermetallic Compounds and Their Derivatives

Seok-Woo Lee and Alexander J. Horvath; University of Connecticut, United States

$ThCr_2Si_2$-structured intermetallic compounds and their derivatives are of interest in the field of solid-state physics due to their unique electronic and magnetic properties, including high-temperature superconductivity and pressure-dependent magnetism. Recently, micro-mechanical studies have revealed that they exhibit superelasticity through a lattice collapse-expansion mechanism. Under c-axis compression, Si-Si type bonds are formed, leading to the sudden reduction of c lattice parameter. Then, if the applied stress is relaxed, the crystal restores the original c lattice parameter by breaking Si-Si type bonds. This lattice collapse-expansion mechanism produces recoverable strain higher than 10%. Thus, $ThCr_2Si_2$-structured intermetallic compounds and their derivatives are considered as a new class of superelastic materials.

This presentation will discuss the mechanical behavior of various $ThCr_2Si_2$-structured intermetallic compounds and their derivatives ($CaFe_2As_2$, (CaK)Fe_4As_4, $LaRu_2P_2$, and $SrNi_2P_2$) and their dependence on temperature and loading orientation. These crystals exhibit superelasticity via making and breaking As-As and P-P bonds. The corresponding stress-strain response with hysteresis loops resembles that of shape memory alloys. Due to the significant change in the c lattice parameter under compression, the extremely high recoverable strain (10~17%) are achieved. As a result, the modulus of resilience is orders of magnitude higher than that of most engineering materials. Unlike $CaFe_2As_2$, (CaK)Fe_4As_4, and $LaRu_2P_2$ that show superelasticity only under compression, $SrNi_2P_2$ exhibits superelasticity under both compression and tension because P atoms in $SrNi_2P_2$ are partially bonded at the stress-free state. C-axis compression forms a bond between unbonded P atoms and causes lattice collapse while c-axis tension breaks a bond between bonded P atoms and causes lattice expansion. As a result, $SrNi_2P_2$ exhibits tension-compression asymmetry in mechanical response, and this asymmetry leads to the elastocaloric effect comparable with conventional shape memory alloys such as Nitinol. For all four crystals, as the temperature decreases, the lattice collapse occurs more easily because thermal contraction makes bond formation easier while the lattice expansion becomes more difficult.

In addition, we recently discovered that $CaFe_2As_2$ exhibits a unique hysteresis behavior in the load-depth curve for

a-axis nanoindentation, which does not cause lattice collapse-expansion. Transmission electron microscopy revealed that many new grain boundaries are created through multiple instances of atomic layer buckling and the nucleated dislocations are piled-up near these grain boundaries. These piled-up dislocations cause a reversed plastic flow due to the back stress (the Bauschinger effect), leading to a large hysteresis loop in the nanoindentation load-depth curve. Density Functional Theory calculation confirmed that $CaFe_2As_2$ *has an anisotropic layered structure, where atomic layer buckling and dislocation nucleation can occur easily.*
All results in this study provide an important insight into the fundamental understanding of the mechanical properties of $ThCr_2Si_2$*-structured intermetallic compounds and their derivatives under different loading conditions and at different temperatures. Considering the existence of more than ~1000 possible* $ThCr_2Si_2$*-structured intermetallic compounds, our results will be greatly useful in identifying those with superelastic properties.*

4:45 PM SF05.10.05
Deformed Microstructure in Room Temperature Ductile Nb_2Co_7 ***Intermetallic Compound*** *Daisuke Egusa[1], Konatsu Yamada[2], Toshiaki Horiuchi[2], Frank Stein[3] and Eiji Abe[1,4]; [1]The University of Tokyo, Japan; [2]Hokkaido University, Japan; [3]Max Planck Institute, Germany; [4]NIMS, Japan*

Intermetallic compounds exhibit superior strength at elevated temperatures, but they are generally brittle at room temperature, leading to widespread efforts to improve their plasticity for practical applications. Recently, Nb_2Co_7*, an intermetallic compound with a layered structure, has attracted attention because of its plastic deformability even at room temperature [1]. In this work, we have investigated a microscopic deformation mechanism of layered* Nb_2Co_7 *compounds based on electron microscopy observations and first-principles calculations. Transmission electron microscopy (TEM) observations revealed that the deformation of* Nb_2Co_7 *is mainly carried out by basal dislocations localized between the close-packed (CP) layer. In addition, dislocations with the same signs are aligned to form boundaries with small angle misorientations, termed kink boundaries. A combination of atomic-resolution observations and theoretical calculations demonstrates that the microscopic deformation process is accompanied by partial dislocations with stacking faults and that partial dislocations with specific variants significantly reduce the activation energy of shear deformation.*

Reversibility of Martensitic Transformation Using B2-NiAl Nanoprecipitates *Toshihiro Omori and Ryosuke Kainuma; Tohoku University, Japan*

Martensitic transformation can be classified into two types: thermoelastic, characterized by glissile interfaces and small hysteresis, and non-thermoelastic. In the thermoelastic martensitic transformation, the transformation is reversible and good shape memory properties can be obtained. In this type of transformation, the strain due to lattice deformation associated with martensitic transformation is elastically accommodated. The elastic

accommodation occurs when lattice deformation is small, when local shape strain is reduced by refining twinning, or when the strength of the parent phase is sufficiently high. These conditions have often been satisfied in ordered structures.
The present authors found that Fe-Mn-Al alloy exhibits non-thermoelastic martensitic transformation from the BCC phase to the FCC phase and that the transformation mode changes to thermoelastic by precipitation of the B2-NiAl in the A2 matrix. The NiAl particles with about 10 nm are coherent with the martensite matrix, and the NiAl lattice is distorted by the martensitic transformation. On the other hand, the martensite has a cubic structure (FCC) but nano-twins are frequently introduced, which play a key role for strain accommodation and reversible transformation in Fe-Mn-Al.
Another example is Cu-Al-Mn-Ni alloy with high functional fatigue resistance. Functional fatigue is one of the most significant problems to be solved for applications of superelastic alloys. Highly ordered alloys tend to show less degradation of superelasticity by cycling, but it is not easy to achieve both ductility and functional fatigue resistance. Cu-Al-Mn superelastic alloys show good ductility and good superelasticity until about 100 cycles. Cu-Al-Mn-Ni alloy has the B2-NiAl nanoprecipitates in the A2 matrix. The Cu-Al-Mn-Ni single crystal exhibits better functional fatigue resistance (over 1000 cycles) compared to Cu-Al-Mn single crystal without NiAl precipitates. This improvement of the reversibility of martensitic transformation for mechanical cycles can be attributed to the particle dispersion strengthening due to the NiAl precipitation.

8:45 AM SF05.11.02
Advancing Solid State Synthesis to Enable Nonexistent Intermetallics *Kirill Kovnir; Iowa State University of Science and Technology, United States*

Synthesis of complex intermetallics is often a bottleneck of the materials by design concept. The limitations of conventional synthetic approaches resulted in inability to synthesize predicted materials in ternary and quaternary systems with drastically different reactivities of the constituent elements. Several strategies to advance synthesis and produce challenging phases will be discussed, such as averaging precursor reactivity by atomic mixing of refractory components; and prebuilding chemical bonds in the precursor. In-situ studies are crucial for the development of effective synthesis, especially when backed-up with ex-situ synthetic explorations and DSC results.

9:00 AM SF05.11.03
Decagonal and Icosahedral Quasicrystals Under Femtosecond Laser Ablation—Nanoparticle Synthesis and Phase Analysis. *Bibek K. Singh and Ajay Tripathi; Sikkim University, India*

Femtosecond laser ablation of Al-Co-Ni and Al-Co-Cu-Ni decagonal quasicrystals (DQCs) in deionized water (DI) was conducted to investigate the optical and structural properties of the generated nanoparticles (NPs). Structural analysis revealed the retention of phases from the target materials in the NPs. For $Al_{70}Co_{20}Ni_{10}$, Al_3Ni_2 phase formation was identified through SAED patterns and HRTEM micrographs. In contrast, $Al_{70}Co_{15}Cu_{10}Ni_5$ did not show Al-Ni phase formation, this is attributted to the presence of Cu, which inhibited the mixing of Ni with Al. Further, HRTEM micrographs revealed the presence of Al_2O_3 at the edges of the NPs in both samples. The presence of Al_2O_3, at the edges is attributted to its low enthalpy of melting, due to which it stays in its melted form for the longest and it gets pushed toward the edges as crystalization of the NPs progresses. HRTEM microgrphs also reveled the presence of CuO along with Al_2O_3 at the edges. Optical analysis confirmed Al_2O_3 formation, with weak CuO signals detected in $Al_{70}Co_{15}Cu_{10}Ni_5$, this is attributed to Cu diffusion in Al_2O_3, during the solidification process and getting further oxidized and form CuO.
In parallel, AlCuFe icosahedral quasicrystal (IQC) targets, prepared via vacuum induction melting and spray forming, were subjected to femtosecond laser pulses in DI water. The target prepared via vacuum induction

melting showed presence of IQC phases along with the presence of $Al_{13}Fe_4$ and β-Al(Fe,Cu) phases, where as the other target prepared via spray forming showed only the IQC phases. HRTEM and SAED analysis of the synthesized NPs revealed the presence of IQC phases in both preparation methods. NPs from induction-melted IQC targets exhibited $Al_{13}Fe_4$ and β-Al(Fe,Cu) phases alongside the IQC phase, similar to their bulk counterparts, whereas spray-formed IQC targets exhibited only IQC phases. Consistent detection of CuO and amorphous Al_2O_3 was observed in both the samples. The ablated surfaces displayed laser-induced periodic surface structures (LIPSS) and evidence of liquid vortices during ablation, indicated by the presence of macropores. The results obtained highlights the significance of target preparation method and the importance of the synergy between the elements during the nucleation of the NPs.

9:15 AM *SF05.11.04

Design and Characterization of Silicide-Strengthened Nb-Si-Cr-(Mo) Alloys for Additive Manufacturing *Alice Perrin, Patxi Patxi Fernandez-Zelaia, Chris Ledford, Yan-Ru Lin, Ellen Berry, Ryan Dehoff, Michael Kirkab and Ying Yang; Oak Ridge National Laboratory, United States*

Three high intermetallic volume Nb-Si-Cr-(Mo) alloys have been designed using CALPHAD modelling with the goal of identifying high specific strength, oxidation resistant alloys which can be additively manufactured using powder bed fusion. Nb_5Si_3 and $Nb_9Si_2Cr_3$ silicides were targeted as the primary strengthening phases while the addition of Cr promoted the $NbCr_2$ phase. These alloys were cast and surface processed with electron beam welding at different speeds to simulate additive manufacturing, and the phases and microstructures of both cast and weld regions were characterized. The weld processing was found to produce fine grained microstructures in each alloy and stabilized the high temperature $NbCr_2$ Laves phase as well as the metastable $Nb_9Si_2Cr_3$ phase, which decomposed in cast samples. Microstructural refinement as well as hardness were found to increase with weld velocity, with one alloy reaching its highest hardness of ~16 GPa before the brittleness at higher velocities became detrimental. The alloy with the lowest intermetallic content was found to be the least brittle while also attaining a hardness of 13GPa and was therefore identified as a good candidate for additive manufacturing.

Design of an Alumina Forming Coating for Nb-Base Refractory Alloys *Tresa Pollock, Collin Holgate, Melina Endsley and Carlos Levi; University of California, Santa Barbara, United States*

Refractory multi-principal element alloys (RMPEAs) promise to significantly enhance operating temperatures in advanced propulsion systems, but their poor oxidation performance inhibits their implementation. Alumina-forming bond coat alloys can provide oxidation protection, but discovering suitable chemistries remains a challenge. We employed a design methodology that screens for alumina-formation capability using Al activity and phase constitution predictions from CalPhaD (Thermo-Calc). Alloy down-selection from approximately 7,800 alloys in the Nb-Si-Ti-Al-Hf system was conducted by visualizing calculated thermodynamic properties through *number-density topology style maps. We validate our approach by creating and testing the composition $Nb_{12}Si_{23}Ti_{24}Al_{36}Hf_5$, which forms protective alumina scales up to 1400°C and resists pesting at 800°C. Further, the alloy has an average coefficient of thermal expansion of ~10.1 ppm/K, making it well matched to refractory alloys.*

10:45 AM *SF05.12.02

The High Temperature Oxidation Behavior of Eutectic High-Temperature Alloy Mo-20Si-52.8Ti in Dry and Wet Atmospheres *Bronislava Gorr[1], Matthias Weber[2], Steven Schellert[2], Hans J. Christ[2], Aditya Tirunilai[1], Alexander Kauffmann[1] and Martin Heilmaier[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Universität Siegen, Germany*

Mo-silicide-based alloys containing high concentrations of Ti are a new class of high-temperature materials which offer a promising combination of properties for structural applications such as gas turbines. These alloys possess high solidus temperatures, high creep resistance, and excellent phase stability. However, they suffer under inadequate oxidation properties as well as the lack of plasticity at room temperature. Recently developed alloys are able to overcome the major obstacle of inadequate oxidation resistance in air and offer reliable oxidation resistance not only at high temperatures up to 1200°C but also at the otherwise critical temperature of 800°C. It is well-known that many high temperature materials that exhibit high oxidation protectiveness in dry oxidation environments fail if water vapor is present in the surrounding. Since water vapor is present in many combustion environments at approximately 10%, it is indespensible to explore the corrosion resistance of new Ti-containing Mo-silicide-based materials in atmospheres containing water vapor. In this contribution, the effect of water vapor on the oxidation resistance of the alloy Mo-20Si-52.8Ti (at. %) at 1200°C will be presented. During exposure to dry air, the typical oxide layer formed on Ti-rich Mo-Ti-Si alloys consists of a duplex oxide scale TiO_2/SiO_2 – which is responsible for the good oxidation resistance – and an outer TiO_2 layer. To explore whether the outer TiO_2 layer can diminish the detrimental effect of water vapor, this scale was removed which causes a dramatic acceleration of the scale growth kinetics in the wet environment. It is discussed that water vapor may increase the concentration of oxygen vacancies in titania leading to faster inward diffusion of oxygen. Though the growth of TiO_2 is accelerated in presence of water vapor, no notable pore formation was observed in titania. Besides, TiO_2 does not form OH groups and thus seems to serve as a moderate barrier against water vapor. On the contrary, substantial pore formation was identified in SiO_2 particularly during exposure to the wet conditions, whereby the highest concentration of pores was observed at the interface oxide/substrate. Further, the diffusion of water in silica is substantially higher than that of oxygen obviously accounting for the higher oxidation rates in wet atmospheres.

11:15 AM SF05.12.03

Improvement of the Strength of Ternary Eutectic V-Si-B Alloys at Ambient and High Temperatures Due to Cr Additions *Georg Hasemann[1], Shuntaro Ida[2], Kyosuke Yoshimi[2] and Manja Krueger[1]; [1]Otto von Guericke Universität Magdeburg, Germany; [2]Tohoku University, Japan*

The V-Si-B system has gained scientific interest as a new low-density, refractory metal-based structural intermetallic alloy system. The alloy design is strongly influenced and driven by the developments in the field of Mo-Si-B alloys and shares some interesting structural and microstructural features. Very recently, the formations of ternary eutectic V_{SS}-V_3Si-V_5SiB_2 microstructure has been reported which contains the same isomorphous phases as the ternary eutectic in the well-studied Mo-Si-B system: a refractory metal-based solid-solution phase (Mo_{SS} or V_{SS}) and the two intermetallic phases with either an A15 (Mo_3Si and V_3Si) or a $D8_l$ (Mo_5SiB_2 and V_5SiB_2) structure. However, while the Mo-Si-B-based ternary eutectic shows some oxidation resistance due to its intermetallic character, oxidation of the V-based eutectic is an even more serious issue. To address this problem, different amounts of Cr were added to a eutectic V-Si-B alloy to study the microstructural influence on the ternary eutectic reaction, the phase stability as well as the mechanical and oxidation properties as a function of Cr concentration. Alloys with Cr additions between 5 - 30 at.% were fabricated by conventionally arc-melting and *were analyzed in the as-cast state or heat-treated at 1400 °C for 100 hrs.*

Prior to the mechanical compression tests the microstructures of the Cr-added ternary eutectic alloys V-9Si-6.5B were investigated. Even at high Cr-additions of 30 at.% the eutectic V_{SS}-V_3Si-V_5SiB_2 *microstructure could be maintained. Thus, Cr has almost no influence on the solidification behavior in this part of the V-Si-B system, which seems to be plausible since Cr stabilizes all three eutectic phases.*

The ternary eutectic alloy V-9Si-6.5B features the ductile V_{SS} *phase as the major phase. Thus, first compression test revealed a deformability even at room temperature. However, the yield strength decreases quickly with increasing test temperatures and is even more pronounces in the heat-treated state. In order to develop a comparably low-density materiel for high temperature structural applications, the high-temperature strength needs to be further improved, i.e. as shown in this study by Cr-additions. Cr dissolves in all the ternary eutectic phases and, as mentioned before, does not influence the eutectic formation. This fact makes Cr an ideal candidate to study the strengthening behavior of the alloys by subsequently increasing it's Cr content. With increasing Cr-additions the compressive yield strength increased, too. Accompanied with the hardening effect, Cr leads to brittle failure during the compression tests. The strengthening effects is mainly attributed to solid-solution strengthening of the* V_{SS} *phase, which forms the major phase (about 50 - 60% phase fraction) in the Cr-free and Cr-added alloys. Since Cr is also dissolved in the intermetallic phase, a strengthening effect may also occur in these phases.*

11:30 AM SF05.12.04

Solid Solution Strengthening of the Body-Centered Cubic Phase in V-9Si-6.5B-xCr Alloys *Weiguang Yang[1], Georg Hasemann[2], Shuntaro Ida[3], Kyosuke Yoshimi[3], Manja Krueger[2] and Ruth Schwaiger[1,4]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Otto von Guericke Universität Magdeburg, Germany; [3]Tohoku University, Japan; [4]RWTH Aachen University, Germany*

Vanadium-silicide-based alloys are promising candidates for high-temperature applications, e.g., for use in turbines. Recently, we have observed that the addition of Cr to the V_{ss}-V_3Si-V_5SiB_2 *ternary eutectic alloy, which might be beneficial for the oxidation resistance, replaced V up to 30 at.% without changing the ternary eutectic microstructure. In addition, the high-temperature compressive strength increased significantly [1], likely caused by solid solution strengthening of the body-centered cubic (bcc) matrix phase due to the Cr addition.*

To better understand the strengthening mechanisms and the effect of the Si and Cr additions, we performed nanoindentation tests in the bcc phase of arc-melted and annealed V-9Si-6.5B-xCr (x = 0, 5, 10, 20, 30 at.%) alloys to determine the hardness. A detailed microstructural analysis was conducted to determine the composition of the phases. Furthermore, the strengthening effect was evaluated using the Maresca-Curtin model of screw dislocation strengthening [2]. The measured variation in hardness showed a significant dependence on the bcc phase composition. Si increased the hardness regardless of the Cr content. Similarly, regardless of the Si content, as the Cr content increased from about 7 at.%, the hardness increased and reached its limit at around 30 at.% Cr, then increased slowly until 40 at.% Cr at least.

Our findings can be well described by the Maresca-Curtin model. Assuming that the solid solution hardening contribution of Si in V is the same as in Cr, we can predict the yield stress of the bcc phase composed of V, Si and Cr elements as a function of strain rate, temperature and composition. This good agreement suggests that both Si and Cr contribute to the solid solution strengthening in a way that is superimposable on each other.

1:30 PM *SF05.13.01

Alloy Design for Control of Al_6Fe Intermetallic Phase by Laser Powder Bed Fusion *Naoki Takata[1], Wenyuan Wang[1], Yue Cheng[1], Takanobu Miyawaki[1], Asuka Suzuki[1], Makoto Kobashi[1] and Masaki Kato[2]; [1]Nagoya University, Japan; [2]Aichi Center for Industry and Science Technology, Japan*

In recent, laser powder bed fusion (L-PBF) has emerged as one of the most representative metal additive manufacturing techniques capable of producing metallic components by using a scanning laser beam to selectively melt consecutive bedded powder layers. The L-PBF process enables not only the manufacturing of complex geometrical forms but also the fabrication of Al alloys with superior mechanical properties. The L-PBF manufactured Al–2.5Fe (mass%) binary alloy exhibits a high tensile strength of approximately 300 MPa due to the fine morphology of the Al_6Fe metastable phase (orthorhombic, oC28). The strength level slightly decreases after long-term exposure at elevated temperatures, indicating the feasibility of employing lightweight, heat-resistant materials. However, increasing Fe alloy content significantly reduces L-PBF processability due to the formation of coarsened $Al_{13}Fe_4$ stable phase. It is, therefore, required to stabilize the refined Al_6Fe phase by third alloy elements for further strengthening without a loss of L-PBF processability for Al–Fe alloys. The present study was undertaken to investigate the effect of selected third elements (Mn and Cu) on the microstructure and mechanical properties of the Al–Fe binary alloy additive manufactured by the L-PBF process.
Attempts of L-PBF processing using the gas-atomized Al–2.5Fe–2Mn or Al–2.5Fe–2Cu (mass%) ternary alloy powder with an average particle size of about 20 mm were made in this study. Rectangular alloy samples were fabricated using a metal AM ProX DMP 200 machine (3D Systems, USA) under a wide range of laser scan speed (0.6 ~ 1.4 m/s) and laser power (102 ~ 204 W). The applied laser-scanning hatch distance, powder-bed thickness, and beam focus size were 0.1 mm, 0.03 mm, and ~0.1 mm, respectively. The results of measuring the sample density provided the optimum laser parameter sets for the manufacturing of both alloy samples with high relative densities above 99 %, indicating high L-PBF processability for the Mn or Cu-added Al–Fe alloy powders. The L-PBF manufactured samples exhibited microstructure consisting of a number of melt pools in which regions locally melted and rapidly solidified due to scanning laser irradiation. The added Mn element was partitioned into the refined Al_6Fe phase, resulting in the formation of the Al_6(Fe, Mn) phase with an orthorhombic structure (oC28). A certain amount of solute Mn (approximately 0.8 mass%) was detected in the a-Al matrix. Numerous nanoscale particles of the Al_6(Fe, Mn) phase were homogeneously dispersed in the α-Al matrix, whereas relatively coarsened Al_6(Fe, Mn) phases with a cellular morphology appeared localized along melt-pool boundaries. Similar microstructures containing the $Al_{23}CuFe_4$ phase (orthorhombic, oC28) were observed in the L-PBF processed Al–2.5Fe–2Cu alloy samples. These results indicate the added third element could stabilize the refined Al_6Fe phase formed in rapid solidification by the L-PBF process. The design concept provides new insights for the combined addition of Mn and Cu to Al–Fe alloys. Both added Mn and Cu elements might stabilize the Al_6Fe phase (corresponding to the formation of $(Al, Cu)_6$(Fe, Mn) phase), providing the larger driving force for the formation of the Al_6Fe phase for strengthening. The design based on the Al–Fe–Cu– Mn quaternary system has the potential to achieve both superior mechanical performance and sufficient L-PBF processability.

2:00 PM SF05.13.02

Development of High Temperature Al-Ce-Mg Alloys—Thermal Stability and Mechanical Properties *Gaurav Singh[1], Humphrey Wara Odhiambo[2], Mohamad Hasan Tasneem[1], Gaoyuan Ouyang[3], Monica A. Soare[4], Jun Cui[2,3], Ralph E. Napolitano[2] and Catalin R. Picu[1]; [1]Rensselaer Polytechnic Institute, United States; [2]Iowa State University of Science and Technology, United States; [3]Ames Laboratory, United States; [4]GE Global Research, United States*

A new generation of temperature resistant Al alloys based on the Al-Ce-Mg system is required for applications in supersonic aircraft fuselage design. This will replace some of the components currently made from Ti with much lighter Al, with subsequent weight savings in both structural and thrust producing aircraft components. The aim is to overcome the present barriers and to develop novel aluminium alloys with superior properties that are stable across the temperature required for aerospace applications. Al alloys are resistant to exposure to elevated temperatures by adding Ce. Ce has low diffusivity in Al, which prevents precipitate coarsening and ensures microstructural stability. It is possible to further improve the strength of as cast binary Al-Ce alloys by alloying with Mg, providing solid-solution or precipitation strengthening.
The cast Al-10Ce-4Mg binary alloy was produced with slab casting and further processed by rolling and extrusion. The mechanical properties and microstructural characterization were carried out on as cast, rolled, and extruded conditions. The as cast, rolled, extruded Al-10Ce-4Mg was used to evaluate property retention after exposure to elevated temperature for various durations and testing at different temperatures. Extruded Al-10Ce-4Mg alloy showed better thermal stability than available high temperature Al alloys like Al-2618. The microstructures generally involve the $Al_{11}Ce_3$ intermetallic phase within the Al-Mg solid solution. To achieve high strength, a uniform dispersion of fine intermetallic is desirable. This work provides a new idea for developing heat-resistant aluminum alloys with a good combination of strength and ductility via thermomechanical processing like rolling and extrusion.

2:15 PM SF05.13.03

Newly Discovered Ultrahigh Strength Solid Solution (Al)—Intermetallic (Al_xGe_y) Metastable Nano-Eutectics
Arkajit Ghosh[1], Wenqian Wu[2], Tao Ma[3], Jian Wang[2] and Amit Misra[1]; [1]University of Michigan–Ann Arbor, United States; [2]University of Nebraska–Lincoln, United States; [3]University of Michigan, United States

Metastability-aided designing, which is either circumstantially induced during synthesis or purposefully engineered, has significant impacts in invigorating the performance of structural materials - mainly metals and alloys. Laser rapid solidification of cast Aluminum (Al) – Germanium (Ge) eutectic alloy is shown to produce ultrafine lamellar eutectics with interlamellar spacing refined up to ~60 nm and composed of FCC Al-rich solid solution and unusual Al_xGe_y intermetallic-rich phases that do not form during near-equilibrium solidification. The crystallographic attributes of the intermetallics are characterized in detail using a combination of selected area electron diffraction (SAED), high-resolution scanning transmission electron microscopy (HR-STEM), energy dispersive X-ray spectroscopy (EDX) to obtain high-resolution elemental maps, and atomistic modeling using density functional theory followed by atomic-scale image simulation. Depending on the undercooling and cooling rate imparted during laser processing, the crystal structure of the Al_xGe_y intermetallic phases was either monoclinic (C 2/c) or monoclinic (P 2_1), with high densities of rapid quenching instigated defects, such as dislocations and planar faults. The phase evolution after laser processing is in sharp contrast to the as-cast alloys that exhibited nominally pure Al and Ge phases with prominent solute partitioning and FCC and diamond cubic crystal structures of those phases, respectively. The mechanism for the formation of these metastable eutectics under rapid solidification have been revealed as greater solidification velocity than atomic diffusion velocity in a complete solute trapping condition that results in significant entrapment of Al atoms in Ge and the corresponding kinetic phase diagrams are proposed to interpret the metastable phase equilibria, to understand the evolution of nano-lamellar eutectic morphologies with equilibrium Al and metastable Al_xGe_y phases, and to explain *compositional metastability in the Al phases manifested by precipitation of ultrafine clusters of Ge. These metastable nano-eutectics when subjected to micromechanical testing exhibit extraordinary compressive strength of up to 1.2 GPa with a stable plastic flow up to 14% plastic strain. Deformed microstructures have been thoroughly investigated to establish the deformation mechanisms in these microstructures. Primary strengthening comes from (i) stacking faults that nucleate in the Al-rich phases in presence of coherent Al(Ge) precipitates and from (ii) arrays of single dislocations that form locally to give rise to confined Al-layer slip owing to the interfaces across soft Al and extremely hard intermetallic phases. The monoclinic intermetallics are hard to deform plastically because of inadequacy of active slip systems and cracked easily beyond a certain strain. However, significant detwinning of the process-induced twins in one of the intermetallic phases contribute to prolonged softening during deformation, unlike the other intermetallic that did not produce solidification instigated twins. The findings of this work help understand how structural and compositional metastability in eutectics with ultrafine length-scale can result in extraordinary mechanical properties with unusual deformation mechanisms.*

2:30 PM SF05.13.04

Precipitation and Dissolution of Intermetallic Phases During Recrystallization in Nanostructured Lightweight Alloys *Klaus-Dieter Liss[1] and Megumi Kawasaki[2]; [1]The University of Tennessee, Knoxville, United States; [2]Oregon State University, United States*

Alloys subjected to severe plastic deformation result in highly distorted nanostructured materials characterized by significant disorder. This disorder is expressed through residual stresses, elevated vacancy concentrations, high dislocation densities, a large grain-boundary to crystallite bulk volume ratio, and substantial crystallographic site disorder in intermetallic compounds, which can even lead to their dissolution. Their heat treatment at increasing temperatures typically leads to recovery, recrystallization, and grain growth. The stored energy driving recrystallization expels significant concentrations of vacancies into the crystal lattices, expediting diffusion and thus the precipitation of intermetallic phases, which may transform or dissolve again at higher temperatures. Here, we present synchrotron micro-beam high-energy X-ray diffraction studies of lightweight alloys, such as Mg-AZ31 and Al-Cu-Li-Mg alloys, revealing in real time the stress relaxation, precipitation kinetics during recrystallization, vacancy concentrations, grain size, and dislocation densities. In particular, the recrystallization process can be employed to tune the microstructure of these materials.

10:30 AM *SF06.01.01
Controlling Autonomously Snapping Soft Matter *Alfred J. Crosby; University of Massachusetts, United States*

Soft materials systems are commonly used by nature to garner energy from the environment to accomplish powerful tasks autonomously. While soft actuators have been widely explored for the past several decades by engineers and materials scientists, the ability to mediate environmental interactions for repeated, high power tasks has only been explored to a limited extent. Here, we describe recent efforts to understand how materials properties and geometry trade-off to control power generated in single and repeated events of an autonomously snapping structure. We experimentally explore the balance of internal transport and elastic energy storage properties of the polymer networks used to define the structures and develop quantitative design guidelines for controlling power output. We extend this understanding and combine it with recent advances in LAtch Mediated Spring Actuation (LAMSA), which is used by many of the most powerful natural organisms, to demonstrate novel multi-latch systems that can amplify performance and control. The strategies and results discussed provide new insight into how materials properties can combine with purposeful structural design to achieve complex, energy-efficient tasks, which can be used in the development of microscale robots.

11:00 AM SF06.01.02
Soft, Responsive Microactuators and Color-Changing Skins Enabled by Networks of Microgels *Stephen A. Morin, Brennan P. Watts and Nengjian Huang; University of Nebraska-Lincoln, United States*

Hierarchical systems can overcome operational constraints by balancing the size, geometry, and connectivity of individual elements across multiple length scales. For example, the macroscopic actuation of skeletal muscle is enabled by the microscopic displacements of thousands of individual myofibrils—coordinated motion is facilitated by a hierarchical structure consisting of bundles of muscle fibers (which house the myofibrils), blood vessels, and connective tissue. This construction enables: 1) rapid delivery/removal of chemical fuels and waste by minimizing diffusion pathlengths, 2) alignment of individual contractile elements for concerted motion, and 3) natural damage tolerance. These characteristics are desired in responsive soft systems but that are difficult to produce, especially with bulk materials. Inspired by this challenge, we are developing strategies that mimic the properties of hierarchical systems, like muscle, using synthetic materials. Specifically, we report the design and fabrication of micro-structured hydrogel (microgel) networks with stimuli-responsive contractile capabilities which, when combined with microfluidic encapsulation, provide chemically controlled actuation under ambient conditions. Like biological muscle, these devices provide for active transport of signaling compounds/fuel, programmable motions, and resilience against damage as each microgel operates independently. We will *describe two applications enabled by microgel networks: 1) free-standing soft actuators featuring thermal/ionic/molecular control and 2) color-changing skins based on thermally responsive synthetic chromatophores. These demonstrations illustrate the broad potential of microgel networks in the design of new, multifunctional/responsive materials supportive of adaptive to autonomous behaviors broadly applicable to the fields of soft robotics, adaptive surfaces and optics, and human-machine interfaces.*

11:15 AM *SF06.01.03

Dynamically Adaptive Metamaterials for Accommodating User Needs *Alexandra Ion; Carnegie Mellon University, United States*

Adaptive user interfaces are understood as an important tool for in digital user interfaces, e.g., to adapt content based on users' screen-sizes (e.g., smartwatch vs TV screen), device types (phone vs augmented reality display), or based on users' context and environment. We argue that adapting not just user interfaces to fit the context, but ***changing the physical affordances****, capabilities, and material properties of objects is the next step in advanced user interface design. Consider the example of a shoe sole that can self-adapt to different weather conditions to provide more grip, or to change its elasticity as a user changes their context from walking to running. We work towards solving several foundational challenges to enable us to create such* ***computationally-adapted materials and objects****. The challenges lie within the small-scale integration of mechanisms that enable repealed configuration, in embedding sensing capabilities to understand users' context, and in embedding actuation to allow the materials react to users and change their affordance correspondingly. We approach this by employing an extended metamaterials approach — the properties of mechanical metamaterials are not determined by the properties of the material they are fabricated from, but are defined by their engineered small-scale geometry which can be designed to achieve desired shapes, damping properties, employ entire mechanisms, simple computation, etc. We build on the idea of metamaterials consisting of simple unit cells that work together to achieve a desired macroscopic behavior. This means that the unit cell building blocks can remain simple and facilitate a small form factor needed for integration into daily objects. We will use computational patterning to embed customized functions in simple materials. We plan to make objects configurable, allowing them to change properties dynamically. To achieve this, we need to configure smaller scale metamaterial cells, add sensing for user interaction and control, and introduce actuation for self-configuration. The* ***research challenges*** *in this area include (1) the experimental development of methods for* ***cell configuration, sensing, and actuation****; (2)* ***computational design*** *techniques as they will play a crucial role in finding optimal configurations; (3) developing new* ***fabrication techniques*** *to streamline the assembly process; and (4) creating demonstrator* ***applications*** *to showcase such dynamic physical interfaces' utility.*

SESSION SF06.02: Embodied Perception

1:30 PM *SF06.02.01

Robotic Materials Using Liquid Metal and Ionogel *Michael Dickey; North Carolina State University, United States*

This talk will discuss recent advances in our group on the use of liquid metals and ionogels within the context of robotics. While there are plenty of differences between these materials, they have some common features such as *conductivity, mechanical extensibility, and facile processing. They are both useful for adding functionality to soft robots.*

Ionogels are polymeric materials swollen with ionic liquids. They are similar to hydrogels, which are polymeric networks swollen with water, yet have advantages relative to hydrogels such as gravimetric stability (due to the ionic liquid not evaporating) and electrochemical stability. These types of gels are useful for making robotic bodies because they can be deformable and easy to fabricate. Yet, gels typically have weak mechanical properties. This talk will discuss efforts in our group to make tougher ionogels using simple one step processing. In one case, we utilize phase separation to create hydrogen bonded domains within a polymer network that result in toughening. In a second case, we use the ionic liquids to crosslink the gels to give them both glassy and gel-like properties.

Liquid metal refers to gallium or gallium-based alloys. These alloys of gallium are liquid below room temperature and are therefore extremely soft and flow in response to stress to retain electrical continuity under extreme deformation. I will discuss the latest efforts in our group to utilize this material within the context of robotics. One example includes printable metallic structures that can grow (get larger) in response to water. We have demonstrated that these can be useful to create circuits that change shape with time while maintaining conductivity. Liquid metals can also be utilized for performing simple tactile logic, in which the response of an elastomeric material will change depending on the way it is touched. This helps break the "sense-compute-respond" model often used to control robots by simplifying it to "sense-respond" based on the movement of elastomeric materials embedded with liquid metal. It is also possible to use liquid metal to actuate soft robots using either surface tension to exert forces on surfaces or electrochemical formation of gas to expand pneumatic chambers. Finally, more recently we have developed a way to separate the native oxide from the surface of liquid metal to print thin oxide films. To our surprise, the films are conductive and metallic-like. Thus, we can print ultra-thin (4 nm thick) transparent conductors over large surface areas at room temperature. Combined, these advances have exciting implications for soft robotic materials.

Stretchable Laser-Induced Graphene Sensors for Soft Grippers Proprioception *Anna Chiara Bressi[1], Giovanna De Luca[1], Radan Pathan[1], Niccolo Pagliarani[1], Martina Maselli[1], Matteo Cianchetti[1] and Francesco Greco[1,2,1]; [1]Scuola Superiore Sant'Anna, Italy; [2]Graz University of Technology, Austria*

In the domain of soft robotics, systems are designed and realized with highly deformable materials and structures, which can be exploited in soft grippers to feature an extended range of motion. This has the potential to replicate and outperform the high dexterity of manipulation of the human hand.[1] Although the intrinsic properties of soft materials already guarantee high safety and adaptability, soft grippers require closed-loop control and continuous feedback during the interaction with the target for precise monitoring and real-time position adjustment. It is therefore crucial to incorporate in these structures sensors that are soft, flexible, and lightweight, to also minimize the physical impact on the host system.

Within this context, we propose the sensorization of a finger-based soft gripper made of silicone actuators. The fingers are equipped with piezoresistive Laser-Induced Graphene (LIG) tracks to exploit their exceptional sensitivity to mechanical deformation for proprioceptive feedback. LIG is a three-dimensional conductive nanomaterial fabricated with single-step local pyrolysis of different polymeric precursors by scribing with commercial Infrared (IR) laser engravers. LIG applications span different fields, including soft and wearable electronics, robotics, and energy storage devices.[2–4]

LIG tracks were scribed on polyimide with a CO_2 IR laser and transferred to silicone to prevent stiffness mismatch during integration. Two piezoresistive strain sensor designs have been investigated, with extensive static, dynamic, and fatigue tensile tests. After the selection of the best design, a finite element method (FEM) study was conducted

as a preliminary evaluation to assess the position of the neutral bending plane of the fingers and therefore determine the best sensor integration position. The sensor was then embedded in the robot's fingers to receive feedback on the fingers' bending angle. The theoretical study has been validated in real working scenarios with experimental static, dynamic, and fatigue results on fingers under relaxed and various bending conditions, and a highlight of the best integration solution is provided.
Our study introduces a novel method for measuring of bending angle in a finger-based pneumatic soft gripper and lays the foundation for future studies on this promising LIG sensor solution for soft robots. Moreover, this sensor, combining lightness and flexibility with a cost-effective, simple, and rapid fabrication process, could be adapted for pressure/contact, temperature, and humidity sensors, leading to fully proprioceptive and exteroceptive soft robots.

Multistage Chemistries for Soft Wearable Technologies *Thomas John (T.J.) Wallin; Massachusetts Institute of Technology, United States*

Recent efforts created the field of soft robotics—highly adaptive machines composed of compliant, polymeric components—that stand to revolutionize bioengineering, human computer interaction, soft wearable technologies and other industries. Despite their mechanical simplicity, these devices can safely interface with humans, imitate animal physiology, operate in harsh environments, and create dynamic physical interfaces. Yet, obstacles in materials and manufacturing prevent such soft machines from obtaining widespread adoption. Namely, the conventional paradigms for manufacturing and assembling rigid components do not translate well to soft, highly extensible polymers. In this talk, I will introduce how multimaterial chemistries overcome this limitation by decoupling the traditional structure-process-property relationship to enable high functional density in soft matter.

Soft Architected Robots—Printing Complex Forms for New Sensorimotor Functions in Robotics *Ryan L. Truby; Northwestern University, United States*

Recent advances in soft robotics motivate the design of multifunctional composites for distributed actuation and perception capabilities. These functionalities are required for addressing long-standing challenges in soft robot control and achieving more sophisticated sensorimotor behaviors. However, continued progress towards this vision is stymied not only by limitations in current materials and manufacturing methods, but also in how to strategically integrate soft and rigid materials in robot bodies. With these challenges in mind, I will present approaches for designing and 3D printing electrically-driven soft robots from architected materials. First, I will introduce a flexible, architected soft actuator unit for motorized extensional motion. I will introduce techniques for sensorizing these architected actuators and assembling them for locomoting soft robots. Finally, I will discuss new strategies for architecting soft ionic conductors for distributed sensing. These efforts aim to embody both physical and computational intelligence into real-world-deployable soft robots with practical task-capabilities.

Materials and Fabrication Techniques to Improve in Stretchability of Transparent Organic Electrochemical Transistors

Takaaki Abe, Teppei Araki, Shohya Matsuda, Hiroko Mori, Naoko Kurihira, Mihoko Akiyama, Takafumi Uemura and Tsuyoshi Sekitani; Osaka University, Japan

Highly transparent and flexible electronics enable multimodal sensing that simultaneously measures electrical, optical, and ionic signals. In this study, fully transparent and intrinsically stretchable organic electrochemical transistors (OECTs) are developed using silver nanowires (AgNWs) and semiconducting polymer-based materials on an elastomer substrate. The OECTs exhibit high durability under 100% strain and an optical transparency exceeding 85%. In addition, the investigation of additives in the channel material shows the potential to improve transistor characteristics under high strain. These devices contribute to the development of next-generation, multimodal, healthcare sensors.

Data obtained from the long-term monitoring of biological signals can be used for the diagnosis, prevention, and treatment of diseases [1]. Flexible electronic devices can measure high-quality biological signals through close contact with biological tissues (such as human skin) and reduce the discomfort of wearing them [2]. OECTs can be used for long-term, biological signals because of their low-voltage operation, mechanical flexibility, and high transconductance [3]. Moreover, highly transparent OECTs have contributed to the advancement of multimodal sensing technologies capable of simultaneous electrical, optical, and ionic measurements. However, conventional OECTs that use materials such as metal thin films lack stretchability and transparency, making them unsuitable for multimodal biosensing.

In this study, transparent and stretchable OECTs are developed using AgNWs and poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS). The nanomaterials are implemented on a transparent elastomer substrate using a printing process to make the device fully transparent and stretchable. Nanomaterials comprising OECTs are protected by lamination techniques, thus reducing potential damage to them. High stretching durability and visible-light transmittance are achieved using AgNWs with controlled orientations as wiring materials [4]. The channel materials are patterned onto the substrate using a printing process similar to that used for AgNWs to construct a transparent and stretchable OECTs. Additives to the channel material are optimized by evaluation of the transmission characteristics and frequency response under high strain. On investigation under high strain, additives in the channel material exhibits potential for transistor-characteristics improvement. Therefore, a fully transparent and stretchable sensor suitable for multimodal sensing using electrical, optical, and ionic methods is expected to address requirement for biosensing.

From Lab to Nature: Soft Material Aerial and Aquatic Robots for Sustainable Ecosystem Interaction and Environmental Sensing

Mirko Kovac[1,2,3]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]Empa–Swiss Federal Institute of Technology Lausanne, Switzerland; [3]Imperial College London, United Kingdom

Aerial, aquatic, and aerial-aquatic soft robots are emerging as adaptable systems for sustainable environmental monitoring, particularly in arboreal and aquatic ecosystems. These robots leverage the flexibility of soft materials

to navigate complex environments, enabling data collection with minimal disruption. Their applications range from long-term monitoring in forest canopies and aquatic habitats.

To address the specific demands of multimodal environments, our team has focused on advancing the development of soft material robots. One such development are robots with a metamorphing body and a tensile perching mechanism, allowing them to anchor to tree branches while conserving energy for data collection. In addition, we have also developed biodegradable soft structures, such as our work on hygroscopically-driven actuators for aerial sensor deployment. Highlighting the placement of biodegradable sensors and actuators in hard-to-reach locations without additional e-waste.

In aquatic environments, our recent work on soft robotic wings for underwater vehicles demonstrates how they can adapt their shape to optimize their lift-to-drag ratio, possibly enabling more efficient long-range missions in deep-sea exploration.

Moreover, combining aerial and aquatic capabilities opens new possibilities. In Blue Carbon ecosystems, for example, aerial-aquatic robots can seamlessly transition between air and water, perching in both terrestrial and aquatic habitats or transporting soft robotic underwater vehicles between locations to efficiently collect data.

Challenges still remain in bringing these robots to real-world applications, particularly in sensing, energy efficiency, and structural robustness. Yet, their potential to collect critical environmental data will make them invaluable tools for assessing ecosystem health and biodiversity in the future.

Multistable Structures for Fluid Manipulation *Zizheng Wang[1], Gabriel Alkuino[2], Sam Avis[3], Teng Zhang[2], Halim Kusumaatmaja[3] and Xueju (Sophie) Wang[1]; [1]University of Connecticut, United States; [2]Syracuse University, United States; [3]Durham University, United Kingdom*

Surface patterning is an effective means to control liquid-solid interactions, particularly for managing droplet motion and interfacial flows. Conventional structures employed in liquid flow operations are often constrained by fixed shapes, limiting their adaptability in fluid obstruction and flow rate control scenarios. In this talk, I will present our recent studies on utilizing a multistable ribbon structure fabricated from magnetic polydimethylsiloxane (PDMS) to manage water flow using rapid, remote magnetic fields. Each ribbon can transition between three stable states: a central peak (buckled arch shape), a left peak, and a right peak state. We investigate the ease of magnetic control over ribbon states under various magnetization conditions. The three states of the ribbon array afford varying degrees of control over water flow, with the right peak state providing the largest critical angle for water flow. Additionally, each individual ribbon's state within the array is independently tunable using a small external magnet, enhancing flexibility in controlling the critical angle of water droplet flow. Furthermore, in practical applications, we employ two groups of ribbon arrays to construct channel structures for controlling droplet flow and facilitating mixing. The manipulation of water droplets using these advanced multistable structures shows promise in applications such as chemical reactions, nanomanufacturing, and drug delivery, thus offering multistable, magnetically controlled structures as a versatile tool.

Versatile Shape-Morphing of Multistable Sructures—A Fluid-Driven Director-Field Design *Yaron Veksler, Ezra Ben-Abu and Amir Gat; Technion–Israel Institute of Technology, Israel*

Shape-morphing structures capable of significantly altering their form and volume play a crucial role in diverse fields, from soft robotics and minimally invasive surgery to deployable structures and environmentally adaptive systems. These materials hold the promise of creating autonomous systems that can adapt to their environment and perform complex tasks without constant human intervention. However, current approaches often face limitations in achieving controllable morphing into various complex shapes while maintaining simplicity in design and actuation.

Our research addresses these challenges by introducing an approach that combines director-field theory with viscous fluid actuation. This method enables the creation of multifunctional, shape-morphing structures capable of controlled transformation into multiple stable, complex 3D surfaces.

The core of our innovation lies in the design of interconnected multistable straw-like deformable tubes, constrained by strategically placed rigid links. This network forms a versatile base structure that can be assembled and connected in numerous configurations. By applying director-field theory, we model and design the links and their assembly process to achieve a diverse range of desired final operational shapes from a single initial structure.

A key feature of our design is the use of viscous fluid actuation, enabling precise control and predictable shape-morphing. This method results in sequential snapping of the bi-stable tube elements, allowing control over the structure’s deployment process. Through carefully sequenced inflation and deflation actuations, all controlled via a single inlet, we can achieve a wide range of stable configurations.

We have successfully demonstrated the ability of our structures to morph from a flat initial shape into multiple complex 3D shapes, including spherical surfaces with positive Gaussian curvature, conical structures with zero Gaussian curvature, and shapes with negative Gaussian curvature. Notably, the final shapes closely match those predicted by director field theory, validating our theoretical framework and showcasing the predictability and reliability of our approach.

The versatility of our method enables potential applications across various fields. In soft robotics, these structures could serve as reconfigurable skeletons or end-effectors that can adapt their shape dynamically to perform delicate tasks. For minimally invasive medical procedures, our technology could improve the design of surgical tools and implants, allowing them to navigate through the body and then morph into patient-specific geometries.

Our work also contributes to the field of programmable matter by demonstrating how materials can be designed to change shape in predictable ways based on fluid input. Furthermore, the shape-morphing capabilities of our structures make them suitable for creating environmentally adaptive surfaces, which could be used in buildings or vehicles to dynamically adjust their shape in response to changing environmental conditions.

In conclusion, this study presents a significant advancement in shape-morphing materials by addressing key limitations in current approaches. By combining director-field theory with viscous fluid actuation, we have created a versatile platform for multistable, controllable, and predictable shape-morphing. This work contributes to the development of autonomous materials and opens new avenues for applications in soft robotics, medical devices, and adaptive structures.

Autonomous Catalytic Motors with Energy Accumulation in Hydrogel Dome Structure for High-Power Intermittent Firing *Shogo Himori, Riku Takahashi, Aya Tanaka and Masumi Yamaguchi; NTT Corporation, Japan*

Autonomous motors that move freely in liquid space enable local stimulation and sensing in natural and in vivo environments, and are expected to have applications such as improving water quality and treating disease. Catalytic motors derive their propulsion from the catalytic reaction of molecules in solution, such as hydrogen peroxide (H_2O_2); thus, they continue to move in solution as long as the fuel chemicals are present [1]. However, the catalytic propulsion power is limited in the real environment due to the low concentration of the fuels. In this study, we propose a high-power motor system which accumulates catalytic driving energy in the body. Our motor accumulated a catalytically produced bubble, followed by instantaneous release of the bubble with high-speed travel.

To fabricate the motor, a hydrogel film was anchored to a disk glass substrate with silane coupling. The silane pattern was removed from a part of the hydrogel/glass interface to create a dome structure by hydrogel buckling [2]. The buckling structure was composed of two parts, a large hemisphere to accumulate the bubble and a narrow tunnel to release the bubble to the outside. A platinum (Pt) layer was deposited on the inside of the hydrogel dome to catalyze the reaction of environmental H_2O_2 to oxygen bubble. The hydrogel/Pt/glass device was placed in H_2O_2 solution, and its behavior was observed under a microscope.

After the motor was placed in the H_2O_2 solution, small bubbles formed around the Pt layer and gradually coalesced into a large bubble in the hydrogel dome because the H_2O_2 fuel continued to access the internal Pt catalyst through the polymer network of the hydrogels. However, the hydrogel and glass walls prevented the bubble products from exiting. The internal bubble was expanded to a critical amount of accumulation and then released all at once to the outside. At the release of the accumulated bubble, the mm-sized motors showed significant horizontal movement, in contrast to the immobility of the motors with normal bubble release without accumulation. The direction of the horizontal movement was controlled by the buckling tunnel of the hydrogel. The cycle of bubble accumulation and release was observed repeatedly because sufficient H_2O_2 was present. In addition, the motor started to float during bubble accumulation due to the increased buoyancy and showed instantaneous diving to the bottom upon bubble release; thus, our motor showed three-dimensional motion in solution. The system enables mm-scale motors to move in the inner liquid space, which requires more driving force compared to the movement at the liquid surface. Furthermore, fluorescence observation of the hydrogel showed a stable deformation cycle during bubble accumulation and release, indicating that the device is sufficiently robust to tolerate the high-power intermittent firing.

In conclusion, we have developed a high-power autonomous motor that accumulates catalytic driving energy in the hydrogel body. The system will pave the way for motors with low energy production efficiency. We will explore applications that take advantage of the instantaneous high-power firing and the accumulation of small environmental energy.

Energy Embeded Soft Robot with Advanced Flow Battery *Duhan Zhang; Massachusetts Institute of Technology, United States*

The multifunctionality of energy components in biology allows for both versatility and compactness. For instance, fat in many animals serves as energy storage, insulation, and a structural element. Similarly, multifunctional energy storage can extend the operating time of robots. In this work, we present a liquid energy source that can create a controllable stiff "hydroskeleton" structure for robots. This hydroskeleton can be paired with tendon actuation to achieve fast and efficient motion. We characterize this stiffening method for a generalizable structure and demonstrate its application in a soft robot inspired by marine creatures. We utilize a flow battery in this setup, where the battery electrolyte serves as the fluid in the hydroskeleton, optimizing materials and methods for integrating a flow battery into a soft robot to enhance its lifespan and performance. The power system and actuation work symbiotically: the flow battery powers the motors, which circulate the electrolyte within the robot, providing controllable stiffness to aid in swimming. At the same time, the electrolytic hydraulic fluid increases energy density and reduces system resistance. We demonstrate that flow battery soft robots are particularly competitive in swimming applications and explore further possibilities for multifunctional fluid energy storage in soft robots.

10:30 AM SF06.04.03
Multistable Structures for Embedded Energy Storage *Sofia Kuperman, Sefi Givli and Amir Gat; Technion-Israel Institute of Technology, Israel*

In traditional robotic systems, batteries are fixed-volume components, limited to a singular function and requiring dedicated space and weight. Exploring new strategies involves distributing energy storage across system components, drawing inspiration from biological systems where energy reserves are seamlessly integrated into the overall system, similar to blood circulation in living organisms. One promising approach is the use of metafluids, enabling embedded energy storage resembling an energetic vascular system, or 'robotic blood'. These metafluids are composed of multistable building blocks sealed with gas, with magnets attached to their ends. By aligning these components with integrated electromagnetic actuators, induced motion or thermal changes can facilitate charging, enabling extensive long-term energy storage in local minima energy configurations. Moreover, energy can be harvested during rapid magnet transition in the vicinity of coils during snap-through events between stable states of the structures.

In this work, we investigate both theoretically and experimentally the equilibrium states of externally actuated multistable structures, identifying regions where nonlinear electromagnetic actuation allows for energy charging and discharging. Furthermore, we examine the transient non-equilibrium states of these structures under external electromagnetic and thermal actuation. Our findings highlight the critical role of balancing the effects of sealed gas and the structure's elasticity for achieving efficient energy storage and release cycles, while considering the harvesting of induced energy during transitions between stable states. Additionally, our simulations capture the multi-timescale dynamics of the structure and its stored energy, identifying thermodynamic processes across cycling stages through a general thermodynamic analysis, free from imposed assumptions on these processes. These insights suggest a promising pathway for advancing embedded energy technologies using metafluids, offering a potential advancement beyond conventional robotic energy storage solutions.

Soft Robotic Artificial Muscle Materials and Design *Erin Rutledge; Toyota, United States*

The desire surrounding soft robotic artificial muscle technology stems from muscles found in the natural world. These electrostatically based soft actuators are prime candidates for the lightweighting of equipment, therefore, also contributing to the creation of a more carbon neutral environment. Electrically driven artificial muscles have not previously approached the performance level of an electric motor, but our research is centered on increasing actuator performance to an advantageous level for competition. Artificial muscles are flexible parallel plate capacitors that yield a hydraulic response after a voltage is applied to the electrodes. The applied voltage causes the attractive forces between the electrodes to move the internal dielectric fluid resulting in flexing of the muscle. The capacitance and attractive force of the artificial muscle is dictated by the dielectric constant of the polymeric insulating material used between the muscle's two electrodes. This relationship directly translates as output force in these soft robotic actuators. Previous results in our research have demonstrated how manipulation of capacitive effects and muscle output force can be achieved through compositing different high dielectric polymeric materials in the artificial muscle fabrication process; these materials included P(VDF)-TrFE-CTFE and PVDF-HFP (with dielectric constants of 50 and 10, respectively). Compositing these polymers in specific ratios allowed us to increase muscle stroke by almost 250% compared to a muscle only using PVDF-HFP. This stroke increase was a major improvement in overall muscle performance. The next steps in our research included utilizing the improved compositing fabrication techniques while simultaneously altering electrode design and size, dielectric fluid fill volume, and muscle stiffness to determine the best combination for a stronger muscle that maintains high stroke. Changes were not only limited to the aforementioned parameters, but measures were also taken to increase the stiffness of the muscle to better obtain the benefits from the larger muscle size and dielectric fluid fill volume. This allowed for the generated force to be able to push the higher dielectric fluid volume for a complete muscle actuation. These minor, yet advantageous changes to the artificial muscle fabrication, resulted in muscles lifting 1.5 kg with over a 300% stroke increase. These muscles operate at a slightly higher voltage of 3.5 kV compared to our prior examples which operated around 2.0 kV. From this stage, high dielectric nanoparticle materials are additionally being incorporated in the polymer composite electrode insulation to further improve artificial muscle performance.

11:00 AM SF06.04.05

3m Long Electrohydrodynamic Fiber Pumps for Powering Soft Fluidic Actuators *Martijn Schouten, Yichi Luo, Jean-Baptiste Chossat and Herbert R. Shea; École Polytechnique Fédérale de Lausanne, Switzerland*

Electrohydrodynamic (EHD) fiber pumps consist of a soft tube in which two helical copper wires are embedded, such that the wires are in electrical contact with the dielectric liquid (e.g. Novec 7100). When a voltage of several kV is applied between the two wires, charge injection EHDs lead to fluid flow. In prior work [1], we achieved flow rates of 0.9 mL/s and pressures of 100 kPa/m for pumps 20 to 80 cm long with a 1.5 mm inner diameter. Those pumps generated pressures between 20 and 80kPa. However, fully inflating a typical McKibben muscle requires pressures in the order of 600 kPa. Using such EHD fiber pumps to drive such fluidic actuators therefore calls for a) longer fibers, and b) higher performance. We report here 3 m long pumps, generating pressures up to 380 kPa/m, with 10-fold higher fluidic output per meter than our earlier work. We lift 2 kg loads using such pumps.

We developed a manufacturing tool to fabricate multi-meter long EHD fibers. Our previous methods involved winding copper and thermoplastic polyurethane (TPU) threads on a metal rod and then fusing the TPU filaments in an oven, a process limited by the oven's size. Our new machine works in a reel-to-reel manner, winding the copper wires and TPU filaments around a 20 m long flexible Teflon tube, using an inline heater to fuse the TPU in a continuous process. The Teflon tube is easily removed from the final fiber pump.

After fabrication, to remove an oxide layer that likely formed on the copper during the heating process, we fill the pumps with glacial acetic acid, wait 10 minutes, rinse with DI water, and dry the pump. The 1 m to 3 m long pumps made with the reel-to-reel process had performance in line with our earlier work.

Pump performance was then improved by reducing the spacing between the copper wires from 0.8 mm to 0.4 mm. This modification increased the electric field strength and enabled the generation of pressures of 380 kPa/m and flowrates of 2.5 mL/s—a tenfold increase in power output per meter. The efficiency at maximum power increased to 4%, doubling the previous result.

We use a 1.3 meter-long EHD pump to drive a 68 cm long, 5 mm diameter McKibben actuator. This EHD-powered actuator could lift a 2.1 kg load by 15 cm in 15 seconds. Our EHD fibers now generate sufficient pressure to fully contract standard McKibben actuators, allowing us to. replace traditional compressors with soft pumps. In the future, both the EHD fibers and McKibben actuators will be integrated into a textile so that they can be easily incorporated into a wearable exo-suit.

11:15 AM SF06.04.06

Bias Pressure Enables Untethered, Power-Dense Fluidic Muscles Driven by Integrated Soft Pumps *Ozgun Kilic Afsar[1], Vito Cacucciolo[2,1], Gabriele Pupillo[2,1], Gennaro Vitucci[2], Wedyan Babatain[1] and Hiorshi Ishii[1]; [1]Massachusetts Institute of Technology, United States; [2]Politecnico di Bari, Italy*

Fiber pumps are mm-sized flexible tubes that create their own pressure and flow rate without the need of an external pump. Soft and solid-state, these pumps solve the long-standing problem of integrating pressure generation in portable systems, such as robots and wearables.

We developed untethered fluidic muscles made of fiber-form fluidic actuators (i.e., thin McKibben muscles) in antagonistic configuration, connected by internal fiber pumps. We discovered that when using an internal pump instead of an external pressure source fluidic actuators need to be operated with a well-defined bias pressure. We studied both analytically and experimentally the effects of bias pressure on closed fluidic systems and discovered that it is not only required, but also increases their global power density by a factor of 5 to 10.

Fiber pumps are made of two materials: a thermoplastic polymer tubing with two metal wire electrodes arranged in a spiral inside the tube. They work based on ion-drag EHD (ElectroHydroDynamics): dielectric liquid molecules get ionised at one electrode, accelerated by Coulomb force in between the electrodes, and de-ionised at the opposite electrode. During their motion from one electrode to the other, they exchange momentum with the rest of the liquid, putting it in motion.

We connected fiber pumps with thin McKibben muscles (OD=1-2 mm) to develop for the first time all-fiber fluidic actuators with integrated pressure generation. These actuators convert electrical energy from a power supply into fluid pressure in the pumps, and then fluid pressure into mechanical work in the thin McKibben muscles. The result is an electro-fluidic muscle fiber that contracts when voltage is applied to it. We designed an antagonistic configuration, where one McKibben muscle acts as a reservoir for its antagonist. When voltage is applied to the fiber pump one muscle contracts and the antagonistic one relaxes.

Our study demonstrates that such systems cannot be operated by filling them with liquid at atmospheric pressure. An extra volume of liquid and a bias pressure is required for closed electro-fluidic muscles to work. We studied the effect of bias pressure and report the following findings:

- Optimal bias pressure increases the contraction by >100% and reduces the response time by >50% by leveraging nonlinearities in elastomer-based fluidic actuators.
-It prevents liquid cavitation, which would make closed fluidic actuators not viable (liquid on the low-pressure side would reach its vapor pressure and evaporate locally).
-It increases the pressure generated by the fiber pumps enabling them to reach higher operating electric fields: from 4 bar/m at 7 V/µm with no bias pressure to 8 bar/m at 10 V/µm with 1 bar of bias pressure.

Integrated all-fiber artificial muscles open wide opportunities for robots and wearables. To fully leverage their performance, these coupled systems need to be carefully designed to maximize the muscles' output given the finite pressure and flow that fiber pumps can generate. Bias pressure is an essential element in the design of these systems.

We developed an analytical model that describes the behavior of the coupled pump-actuator system and provide a design tool to select pumps, actuators and bias pressure for a given robotic task, for example a muscle bundle for lifting 1 kg of weight or a glove for hand rehabilitation.

The combined muscle-pump-muscle ensemble with an optimized bias pressure showed impressive performance in our preliminary tests. Two individual McKibben muscles with one pump lift a 200 g load over 40 mm of stroke in less than 1 second. A bundle of 8 muscles with an overall weight of 40 g can lift over 1 kg with a stroke of 7 cm and in 2 seconds.

Such performance is comparable with skeletal muscles. Using our findings and analytical design tools researchers will be able to deepen the optimization of these novel artificial muscles and achieve a wide adaptation to different form factors and robotic tasks.

11:30 AM *SF06.04.07
Compact Electrohydraulic Actuators Generating over 90 N *Herbert R. Shea, Amir Firouzeh, Fabio Caruso and Florian Hartmann; École Polytechnique Fédérale de Lausanne, Switzerland*

Soft electrohydraulic actuators are electrostatically-driven transducers in which a high voltage is used to zip together two electrodes patterned on thin polymer films, thus displacing a dielectric fluid that can perform mechanical work. Peano-HASELs are the best-known implementation of this class of actuators. Electro-ribbon actuators use dielectrophoretic liquid zipping to pull together two beams, directly obtaining mechanical work from beam motion, with the dielectric fluid serving to allow operation at higher electric fields than would be possible in air. Increasing the specific energy of both these electrohydraulic configurations can in principle be achieved by making arrays of scaled-down devices. This increase in performance with downscaling has been predicted analytically, but has not been demonstrated experimentally to date.
We report here a monolithic electrostatic actuator that incorporates an array of 240 miniaturized Electro-ribbon actuators in a honeycomb-like structure, operating in a low-viscosity silicone oil bath. At 7.5 kV, the actuator generates over 60 N of force with a 3 mm stroke, and 90 N force with a 0.5 mm stroke, with an actuator volume of only 5 cm x 2 cm x 0.3 cm.
The 240 zipping actuators, configured in 20 rows and 12 columns, are on an 8 mm pitch in the beam direction and a 2 mm pitch in the zipping direction. The beams consist of 50 µm thick aluminized polyimide films bonded with 25 µm thick adhesive. Given the very high forces the device creates, a limiting element is the strength of the adhesive that holds the 40 polyimide layers together.
Packing miniature zipping actuators in dense arrays is a promising path to very high energy and power densities and to high forces. We will discuss the scaling of these high-force electrostatic actuators, address some

limitations and present use cases in wearable robotics.

For readers who do not appreciate kV actuators, the second topic we cover in this talk is lowering the actuation voltage in peano-HASELs to below 500 V, by using 14 µm thick dielectric layer of PVDF-TrFE-CTFE. Operating near or below 500 V is appealing as it allows making very low-mass power supplies that the robot can carry. This enabled us to create untethered autonomous swimming robots, only a few mm thick, with a total mass of about 6g, battery included. The locomotion module consists of two independently controlled HASEL actuators, that generate a travelling wave along the 4.5 cm long elastomer fin on each side of the robot. The 30 Hz undulating motion of the fins allows for efficient motion, and very fast rotation. We achieve fast swimming of the untethered robot (5 cm/s forward motion and 195 °/s rotation).
The onboard PCB includes optical sensors (for infrared and visible light), battery, power conversion outputting two bipolar 500 V channels at 100 Hz, and a microcontroller enabling autonomous navigation or decision making. The undulating swimming robot navigates around obstacles, swims through narrow spaces, and can detect moving or stationary light sources and navigate towards them.

Both devices reported here (high force array and low-voltage device) share common challenges in materials and processing. They both also show promise in making soft robots more widely used in wearable and autonomous scenarios.

SESSION SF06.05: Soft Robotic Materials
Session Chairs: Lucia Beccai and Amir Gat
Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 306

1:30 PM *SF06.05.01
***Soft Medical Robots—Innovation and Translation** Xuanhe Zhao; Massachusetts Institute of Technology, United States*

This talk will discuss the design, fabrication, control, and clinical translations of soft medical robots. We will use a magnetically-steerable soft guidewire robot capable of teleoperated robotic neurointervention as an example. We will first discuss the theory of magnetically-responsive soft materials that enable predictive models for the large deformation and actuation of the soft robot. Then we will discuss how to use the massive simulation data of the models to guide the design, 3D printing, and control of the soft robot. Thereafter, we will demonstrate the soft guidewire robots' applications in remotely treating hemorrhagic and ischemic strokes by robotic aneurysm coiling and clot retrieval, respectively. We will validate the safety and efficacy of the soft guidewire robot in both phantom models and live pig models, and compare its performances with experienced neurointerventionalists carrying out manual operations. I will conclude the talk by discussing the clinical translation and FDA approval process of soft medical robots by Magnendo Inc.

2:00 PM SF06.05.02
Microstructural Foundations for the Quirky Electromechanical Properties of Carbon-Elastomer Composites
Logan T. Ritchie, Iain Anderson and Elke Pahl; The University of Auckland, New Zealand

Carbon-elastomer composites are widely used materials for bioinspired and soft robotics. Embedding carbon *nanomaterials such as carbon black, graphene, or carbon nanotubes within an elastomeric matrix can imbue soft and stretchable materials with electronic conductivity. While percolation theory describes the onset of conductivity in such materials, as the conductive filler forms a continuous conductive network within the elastomeric matrix, it cannot explain the non-linear and time dependent piezoresistivity. Thus, it is not clear how deformation and strain rate alter the structure of the filler network and its electrical properties. This behaviour is challenging to model with typical continuum approaches due to discontinuities at the filler-matrix interface. As the filler network structure is of paramount importance to this effect, approaches relying on an assumption of homogeneity also struggle to capture the complexities at the microstructural level. A model must demonstrate how the complex electromechanical properties of carbon-elastomer composites emerge from the interactions between filler units, mediated by the elastomer matrix. We introduce a network-based computational model capable of reproducing several key features of the piezoresistive effect in carbon black elastomer composites, such as nonlinearity, non-monotonicity and time dependence, and show how these features can emerge from simple interparticle interactions. The composite material is modelled as a mechanical network of viscoelastic bonds between filler units. Energy optimization yields the quasi-static equilibrium of the network during each timestep, enabling the electrical conductivity of the altered network structure to be analysed. As this system consists of discrete elements at the nodes, and individual bonds with varying properties, the discontinuities of the system can be easily resolved. We compare model results with experimental data for carbon-filled silicone. An improved understanding of this effect is essential to allow these composites to be utilised to their full potential as stretchable electrodes and soft, biocompatible strain sensors. Furthermore, this network-based modelling yields insight into the strain-structure-property relationships in complex, many particle systems. It provides a potential approach to better understand and design composite materials with microstructure derived properties that can be varied and complex like biological materials.*

2:15 PM SF06.05.03
Self-Folding 3D/4D Printable Nanocomposites and ML-Guided Piezoelectric Materials *Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States*

Stimuli-responsive polymer and nanocomposite materials are helpful in soft robotics and actuators. From thermoset-elastomers to nanocomposite materials, gradient structures with various transport (ion, electron-transfer, mass transport) behavior can influence actuation and even sensing. A class of shape memory materials based on polymers and nanocomposite have been studied but are often fabricated by formative manufacturing. In this talk, we focus on the materials composition and mechanism of the following: 1) self-folding or actuating non-lithographically patterned bi-layer objects, 2) 3D/4D Printing of nanocomposite materials containing carbon nanotubes (CNT) and graphene oxide (GO), and 3) Use of machine learning (ML) guided protocols to designing non-poled piezoelectric devices based on DIW 3D Printing of PVDF-nanocomposite composition. It is important to emphasize their contribution towards developing new materials for soft robotics and flexible electronics.

2:30 PM *SF06.05.04
Photomechanical Polymers—From Semicrystalline Shape Memory Materials to Solution State Osmotic Actuators *Ryan C. Hayward; University of Colorado Boulder, United States*

Materials capable of directly converting photon energy into mechanical deformation offer promise in a wide variety of contexts including adaptive optics, remotely operated robots and vehicles, and actuators controlled via lightweight optical cables that resist corrosion and electromagnetic interference. Organic photoswitches offer significant potential in this regard, thanks to their ability to undergo large changes in molecular geometry following photochemical reactions, and their highly tailorable absorption spectra. Incorporating such photoswitches into polymeric hosts provides a route to modulate their mechanical properties, processability, solubility, and other *properties. Our group has recently focused on developing semicrystalline polymers containing photoisomerizable units in their backbones as two-way optical shape memory materials. While initial efforts suffered from both inefficient switching at ambient temperature and limited penetration of light, we have recently studied higher mobility chain extenders and modified photochromes that enable efficient room-temperature switching and deep penetration. In a second approach, we have studied solution-and gel-state actuators wherein photoswitches are used to modulate osmotic pressure differences capable of driving mechanical deformation.*

Anisotropic Polydimethylsiloxane Sponge as Bending Actuators in Organic Solvents *Esma Mutlutürk[1], Doğa Özbek[2], Onur Özcan[2], Gokcen Birlik Demirel[1], Hasan Tarik Baytekin[3] and Bilge Baytekin[2]; [1]Ankara Haci Bayram Veli University, Turkey; [2]Bilkent University, Turkey; [3]Middle East Technical University, Turkey*

Soft robotics aims to replicate the flexibility and movement displayed in living organisms. Some organisms, such as plants, have no rigid joints or muscles. However, they can move in ways that are different than organisms with joints, which renders them agile. A common motion in these organisms is continuum bending (CB). So far, attempts to replicate this motion have been accomplished with pneumatic, electroactive, or thermal actuators. In all of these actuators, an active layer cast or attached to a passive layer is used. The active layer contracts or expands upon actuation, causing the entire structure to bend. In continuous operation, the two layers can delaminate over time, impeding the actuator's long-term functionality. A single-material bending actuator through spatial gradient expansion can prevent the problems caused by delamination.

Here, we show that a commonly used material in soft robotics, polydimethylsiloxane (PDMS), can be used to manufacture sponges with different spatial porosities. The required anisotropy for bending can be achieved with these porosity differences. The preparation involves simple molding of PDMS with table sugar as a template for pores. After curing the prepolymer, sugar can be removed by dissolving in water. The size of the sugar particles can be used to design the porosity gradient and the mechanical anisotropy of the sponge, and to tune the bending angle. The spongy materials are actuated by solvent absorption/desorption, and the type of solvent affects and controls the actuation speed.

The straightforward production of this one-material system makes complex architectures made from these spongy materials easily reachable, in addition to the advantages of repetitive and reversible bending. The combinations of such unsymmetrical geometry and swelling anisotropy displayed in these spongy PDMS materials can be further extended to hydrogels and polymers for applications in soft robotics and functional materials.

4:00 PM SF06.06.02
Rapid Deployment of Multistable Meter-Scale Reinforced Concrete Structures *Ezra Ben-Abu[1], Anna Zigelman[1], Hod Lipson[2] and Amir Gat[1]; [1]Technion-Israel Institute of Technology, Israel; [2]Columbia University,*

United States

More than one third of global greenhouse gas (GHG) emissions come from the construction industry. One of its most time-consuming and polluting components is formwork, which uses cross-laminated timber (CLT), accounting for almost 12% of total global GHG emissions and up to 75% of construction time. Thus, reducing the need for CLT in formwork for concrete casting has garnered significant attention in recent years. Here, we present a novel formwork method based on the deployment of a multistable structure for reinforced concrete, capable of rapid full deployment with a single inlet. Our structure exhibits similar tensile resistance in tensile tests as traditional reinforced concrete columns, while allowing complex geometries difficult to standard formwork methods. We demonstrate this concept via the deployment of a meter-scale dome structure with a diameter of 3 meters and a height of 2 meters. The presented concept may lead to more environmentally friendly, rapid, and precise reinforced structures, eliminating the need for complex on-site preparation and reducing GHG emissions.

4:15 PM SF06.06.03
Pure Elongation Flow Behavior of an Electrorheological Fluid as a Model Soft Jammed Material Ishu Chaudhary; *Indian Institute of Technology Kharagpur, India*

Electrorheological (ER) fluid is a type of field-responsive smart fluid composed of nano- or micrometer-sized dielectric particles dispersed in a non-conducting liquid (dispersing medium). The strong dielectric properties of the suspended particles cause them to form dipoles under an external electric field. These dipoles align in a preferred orientation along the electric field, creating a chain or columnar structure that imparts a solid-like character to the fluid. The primary advantage of such fluids is the ability to control the extent of jamming by adjusting the electric field strength at a given particle concentration. This external control over fluidity makes ER fluids suitable for various applications involving automotive, aerospace and robotics, such as shock-absorbing devices, damping and braking systems, clutches and haptic devices. Therefore, a fundamental understanding of the flow behavior of these fluids in various flow modes is crucial. This study delves into the modelling of rheological behavior during pure elongation of an electrorheological (ER) fluid as a model soft jammed system to gain deeper insights on wall slip phenomenon. Wall slip is ubiquitous in many daily life and industrial processes, where a complex fluid slips over a solid surface. Such slip is desired for industrial-scale transport of diverse classes of soft materials, such as concentrated dispersion, pasty material, and polymer melt. Slip is also a crucial aspect in a few modern technologies, such as 3D printing, and screen printing. The knowledge of slip is also important for correct estimation of rheological properties. Hence, slip has been studied extensively over the past many decades. However, the role of jamming towards slip dynamics has not been explored systematically. In this study, we induced pure elongation flow by facilitating significant slip at the interface between the material and rheometer plate, while steadily pulling it at a constant velocity under a consistent external electric field. During the flow, we measured the normal force exerted by the top plate on the material as a function of the inter-plate gap for various combinations of pulling velocity and electric field strength. Intriguingly, the force-gap relationship followed a distinct pattern and displayed a remarkable superposition into a single master curve, suggesting self-similar features of flow curves across the gap, electric field, and velocity. Furthermore, we modeled the flow curves using a slip-layer model, rendering incredible predictions and enabling estimation of slip-layer thickness. It has been found that slip-layer thickness decreases as electric field magnitude increases, for a given pulling velocity, indicating the significant influence of electric field-induced jamming on slip dynamics. Hence, analyzing and modeling pure elongation flow provides valuable insights into wall-slip dynamics. Apart from the deeper understanding of slip dynamics in ER fluids, this study provides a generic understanding on the correlation of wall slip phenomenon with material properties and surface characteristics. The fundamental understanding gained from this study can be applicable to other different class of soft jammed systems irrespective of origin of jamming.

4:30 PM SF06.06.04

Collective Action and Entanglement of Magnetically Active Liquid Crystal Elastomer Ribbons *Asaf Dana[1], Manivannan S. Kalairaj[1], Sasha M. George[1], David Chimene[1], Seelay Tasmim[1], Phillip Kohl[2], Youli Li[2], Mustafa K. Abdelrahman[1] and Taylor H. Ware[1]; [1]Texas A&M University, United States; [2]University of California, Santa Barbara, United States*

Interactions between active individuals in animal collectives lead to emergent responses that remain elusive in synthetic soft matter. Shape-morphing polymers are used to create bio-inspired transient solids that self-assemble, modulate their mechanical properties, and disassemble on demand. The solids are composed of aggregates of many magnetic, heat-responsive liquid crystal elastomer ribbons. Dilute-suspensions of curved and moving ribbons mechanically interlock, inducing reversible aggregation. The degree of bend and twist of the ribbon and the motion of the ribbon in a rotating external field control how ribbons interact with one another. Aggregation was favored for ribbons with moderate curvature at 25C above crosslinking temperature as compared to flat ribbons or higher curvature ribbons at higher temperatures. The ribbon suspensions reversibly transition between fluid- and solid-like states, exhibiting up to 6 orders-of-magnitude increase in the storage moduli of the entangled aggregates compared with the liquid dispersions. Subsequent heating by additional 25C resulted in a 2-fold increase in both stiffness and yield stress. Controlled dissociation is induced by imparting kinetic energy to the individual ribbons at high magnetic field rotation speeds. Ribbon shape and the medium in which dissociation occurs were shown to govern disassembly. Imparting dynamic collective behaviors into synthetic systems may enable a range of potential applications from autonomous bio-inspired soft robotics to injectable biomaterials.

4:45 PM *SF06.06.05

Harnessing Physical Learning Theory to Multiplex Actuation and Sensing in Soft Robots *James H. Pikul and Chris X. Cai; University of Wisconsin-Madison, United States*

There is an emerging desire to embed decision making and learning directly into materials. In soft robotics, it is believed this can improve autonomy without needing electronic control systems or by reducing the computational power needed in a central processor. The most common approaches for achieving this physical learning implement physical logic functions in the robot body or mimic a machine learning approach for achieving optimal weights of connections in a network. In the later, the neurons or weights adjust according to global calculations of a central processor, but in the brain neurons and synapses adjust themselves using only local information. Recent work has demonstrated man-made self-adjusting and distributed systems capable of performing machine-learning problems,[1] which has promising scaling advantages over typical neural networks in power consumption, speed, and robustness to damage. These have been demonstrated in transistor-based self-adjusting analog networks that trains themselves to perform a wide variety of tasks, using a process call coupled learning.

This talk introduces our work on applying coupled learning in fluidic networks instead of the electronic networks of prior work. Our goal is to combine the robust manufacturing approaches for integrating fluid networks in soft robots with coupled learning theory to allow the robots to learn to adjust their physical properties towards a desired goal in response to environmental stimuli. We will introduce the theoretical challenges of applying couple learning networks to fluid networks due to their non-linear relationship between flux and pressure. We will also introduce our fluidic network testbed and model, demonstrate how coupled learning can optimize a flow network to achieve a desired set of steady pressures in the network nodes, which we use to multiplex actuation and design new sensing strategies. This work could enable soft robots to circumvent the limitations of traditional material and fluidic network design choices.

Enhanced Light-Responsive Capabilities in 3D-Printed Liquid Crystal Elastomer Actuators by Leveraging Negative Photochromes *Sophia Paul, Jesus Guillen Campos, Elliot W. Hawkes and Javier Read de Alaniz; University of California, Santa Barbara, United States*

Liquid crystal elastomers (LCEs) are excellent material candidates for soft robotics, including sensors, actuators, and structures. 3D printing of these materials has enabled the field to move beyond thin film architectures, increasing the complexity of the form and motion generated. Furthermore, incorporation of photoresponsive molecules like azobenzene enables spatio-temporal and orthogonal control over the actuation. However, these materials interact with light only at the surface, thus restricting their practical applications to thin films. To address this challenge, we incorporate a visible light-responsive, negative photochromic molecule into 3D printed LCEs, enabling the design, fabrication, and implementation of large-scale photoresponsive soft actuators.

SF06.07.02
Electrostatic Capstan Clutch to Reduce Actuation SWaP *Timothy Amish[1], Jeffrey Auletta[2], Chad Kessens[2] and Joshua Smith[1]; [1]University of Washington, United States; [2]U.S. Army, United States*

Roboticists have demonstrated that large mobile robotic platforms are possible. However, we still lack highly dynamic autonomous mobile systems with reasonable operating times. Reducing actuation size, weight, and power is the most effective way to improve the speed, dexterity, and operating time of current platforms. For example, current legged robots consume considerable power just to stand still. In addition, conventional, fully actuated robots employ one actuator per joint, which tends to be heavy, particularly for high degree-of-freedom (DoF) designs. By using clutches that generate high holding torques with low power consumption, one motor can be used for multiple outputs, known as mechanical multiplexing. Clutches accomplish this by routing mechanical power through a system, letting multiple outputs benefit from sharing resources. Clutches can also act as a braking mechanism, locking joints to block unwanted motion from consuming power. Through the synergistic combination of the capstan effect and electrostatic adhesion, we produced the highest reported braking force per unit area (specific shear stress) for electrostatic clutches at 31.3 N/cm^2. This is a 49% increase compared to the previous highest.

Electrostatic clutches are based on the attractive force from an applied voltage between two electrodes separated by a dielectric. In a typical device, one electrode is adhered to the dielectric, while the other acts as the braking surface between itself and the open face of the dielectric when a voltage is applied. Electrostatic clutches can be implemented in a light, thin, and low power fashion and have the added benefit of electrical rather than mechanical control over the braking force. Our design also utilizes the capstan effect. Capstan-based clutches are especially useful devices that take a small input tension and exponentially scale the output tension by wrapping a *flexible line around a shaft. Generally, the capstan effect is used in marine or industrial applications where a human operator can hold entire ships or large equipment in place with little input tension. The combination of electrostatic and capstan effect is accomplished by adding a dielectric to the shaft and controlling the electrostatic adhesive force between the shaft and line wrapped around the shaft. The addition of electrostatic adhesion produces a second term in the capstan equation that is a function of geometry, material properties, and applied voltage. Our device delivered a holding torque of 7.1 Nm on a 25.4 mm diameter output shaft using only 500 V and consuming 2.5 mW/cm^2. The clutch elements weighted 20.2 g. We found that due to the exponential nature of the capstan effect, such devices improve holding torque and power efficiency as the number of wraps increases.*

In previous work, electrostatic clutches demonstrated mechanical multiplexing by operating a 10 DoF tentacle robot using a single servo. Clutches in the joints rapidly controlled the power and motion between segments. Locked joints transferred power via tendons running alongside the robot. Unlocked joints were then manipulated via these tendons. Even though the robot only had one motor, it was still capable of highly dexterous tasks such as grasping and manipulating two objects.

Electrostatic clutches will allow for novel robot configurations unencumbered by the need for numerous motors that are typically the heaviest and most expensive parts of a robotic platform. Mechanical multiplexing gives an actuator the multi-functionality to provide mechanical power to different elements of a robot. Incorporating electrostatic adhesive clutches into robot platforms will increase control and mobility while also reducing power consumption.

SF06.07.03

Tailoring Stress-Strain Curves of Flexible Snapping Mechanical Metamaterial for On-Demand Mechanical Responses via Data-Driven Inverse Design *Zhiping Chai, Zisheng Zong, Haochen Yong and Zhigang Wu; Huazhong University of Science & Technology, China*

By incorporating soft materials into the architecture, flexible mechanical metamaterials enable promising applications, e.g., energy modulation, and programmable shape morphing, with a well-controllable mechanical response. However, the lack of achievable spatial and temporal programmability hinders the way of flexible mechanical metamaterials towards higher-level mechanical intelligence, such as autonomous sequential behaviors. One feasible solution is to introduce snapping structures that can modulate the absorption and release of mechanical energy and then tune their responses by accurately tailoring the stress-strain curves. However, owing to the strong coupling of non-ideal architecture (the structures that are hard to be simplified as hinges, springs, and beams, etc.), nonlinear structural deformation, and nonlinear material constitutive model, it is difficult to deduce the stress-strain curve of snapping metamaterials using conventional modeling ways. Here, a machine learning pipeline is trained with the finite element analysis data that considers those strongly coupled nonlinearities mentioned above to accurately tailor the stress-strain curves of beam-based snapping mechanical metamaterial sheets for on-demand mechanical response. Such a machine-learning-based data-driven inverse design method shows a good accuracy of 97.41% in the testing dataset, and our prediction, as well as the simulation results, conform to experimental data well. Utilizing the established approach, the energy absorption efficiency of the snapping metamaterial-based device can be tuned within the accessible range to realize different rebound heights of a falling ball. And reconfigurable soft actuators that actuated by a single pneumatic energy input can be spatially and temporally programmed to achieve synchronous and sequential actuation with the flexible snapping metamaterial skins designed through our method. Purely relying on structure designs, the accurately tailored snapping metamaterials increase the tunability of devices. Such an inverse design approach can potentially extend to similar nonlinear scenarios towards more responsive and interactive systems with *embodied mechanical intelligence.*

SF06.07.04

Programmable Fluid Based Controller for Soft Robotics Applications *Anirshu Devroy[1], Georgi Paschew[1], Ingrid M. Graz[2] and Andreas Richter[1]; [1]Technische Universität Dresden, Germany; [2]Johannes Kepler Universität Linz, Austria*

Soft robotics have developed in different frontiers due its versatility in terms of application and dexterity of task that can be accomplished. Control of soft robots has been an important focus area in this regard due to challenges of infinite degree of freedom, weight and the selection soft material. There are several strategies to implement soft robot control such as open loop control, closed loop control, autonomous control. This article investigated a new approach for soft robot control. The principle of logic using conducting and insulating liquids has been demonstrated in the past. Here the conducting and insulating liquid segments are used to control a soft robot by a program consisting of different length and conductance of segments in a tube system. The fluid program is coupled with electronics for readout and to give electrical power supply for movement. All current electronic devices including rigid robots have a microcontroller which generates signals, performs certain tasks and other logical operations. Hence the aim is to achieve some of the functionalities such as switching and signal generation that can be integrated into a soft robot. The switch is built by creating continuous phases of conductive and nonconductive liquid. The conductive liquid used is NaCl (salt water) and nonconductive liquid used is mineral oil. Such segments of two different liquids on passing through an electrode with an external power act as a switch where the voltage is a high when the conductive phase passes through the electrodes and a low when the non-conductive phase is passing. The electrodes are acting as the interface to the electronic readout. Coupling transistors in a Darlington setup with the liquid phases leads to the switching of the applied voltage. The Darlington amplifier is fabricated into a SMD (Surface Mounted Device) circuit that is miniaturised. The changes in the voltage values where recorded using a multi-meter and the voltage switched between 4.7V to 0.7V during the conductive and the non-conductive phases with a supply voltage of 5V. The entire setup works as an on/off switch but can also be viewed as a function generator with PWM (Pulse Width modulation) signal. Such a PWM signal is sufficient to drive any actuator or a soft robot due to the switching between a high and a low state. This method leads to creation of sequential programming and logic circuits for soft robots and actuator control using the properties of liquid phases. The future investigations will be to integrate the fluid programs as a controller setup into wearables, control actuators and modular stand-alone programmable device that can individually control different actuations and movements in a soft robot or target towards minimum use of electronics in the soft robot system. Such devices can be used as an application for extreme environments, fluid flow detection, low energy systems.

SF06.07.05

Probing Interlayer Interactions and Commensurate−Incommensurate Transition in Twisted Bilayer Graphene Through Raman Spectroscopy *Vineet Pandey[1], Vidya Kochat[1], Subhendu Mishra[2] and Abhishek K. Singh[2]; [1]Indian Institute of Technology Kharagpur, India; [2]Indian Institute of Science Bengaluru, India*

Twisted 2D layered materials have garnered much attention recently as a class of 2D materials whose interlayer interactions and electronic properties are dictated by the relative rotation/twist angle between the adjacent layers. In this work, we explore a prototype of such a twisted 2D system, artificially stacked twisted bilayer graphene (TBLG), where we probe, using Raman spectroscopy, the changes in the interlayer interactions and electron−phonon scattering pathways as the twist angle is varied from 0° to 30°. The long range Moiré potential of the superlattice gives rise to additional intravalley and intervalley scattering of the electrons in TBLG, which has been investigated through their Raman signatures. Density functional theory (DFT) calculations of the electronic band structure of the TBLG superlattices were found to be in agreement with the resonant Raman excitations across the *van Hove singularities in the valence and conduction bands predicted for TBLG due to hybridization of bands from the two layers. We also observe that the relative rotation between the graphene layers has a marked influence on the second order overtone and combination Raman modes signalling a commensurate−incommensurate transition in TBLG as the twist angle increases. This serves as a convenient and rapid characterization tool to determine the degree of commensurability in TBLG systems.*

SF06.07.06

Free Standing, Multi-Responsive and Programmable Hydrogel/Elastomer Soft Microactuator *Nengjian Huang, Brennan P. Watts and Stephen A. Morin; University of Nebraska–Lincoln, United States*

Soft actuators have been developed for a wide range of applications, such as medical devices, artificial muscles, human-machine interaction, and manipulation. However, current soft actuators rely on externally controlled stimuli. Specifically, hydrogel-based soft actuators must operate in aqueous environments, which significantly limits their application in ambient conditions. To fabricate free-standing soft actuators that operate independently of aqueous environments, we encapsulated hydrogel/elastomer microactuators within microfluidic chambers that allow the circulation of liquid stimuli. The hydrogel/elastomer microactuator serves as the active component of the device. We covalently attached patterned microscale gel arrays to polydimethylsiloxane using silane chemistry and micro-molding methods. This afforded large surface area hydrogels capable of high-level performance in terms of actuation speed and power density. Moreover, it was possible to tune actuation performance and direction by adjusting the geometry of hydrogel arrays. Encapsulation of these samples was afforded via replica molding and plasma bonding of polydimethylsiloxane. We demonstrate thermal-responsive (Poly N-isopropylacrylamide) and pH-responsive (Poly acrylic acid) actuators by circulating stimuli-specific solutions through the device. The actuator exhibits rapid actuation in response to changes in temperature, pH, and ionic strength, and a bending angle of up to 50°. The combination of different stimuli can further improve the actuation performance. This device enabled the fabrication free standing soft robotics with programmable actuation. By combining actuators with different stimuli-responsive hydrogels, we prepared devices capable of various programmable motions in response to different stimuli.

SF06.07.07

Harnessing Extreme Dynamic Soft Elasticity in Liquid Crystal Elastomers with Slidable Crosslinks for Pressure-Sensitive Adhesives *Subi Choi[1], Jihun Seo[2], Eugene M. Terentjev[3], Mohand O. Saed[3] and Suk-kyun Ahn[1]; [1]Pusan National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]University of Cambridge, United Kingdom*

Liquid crystal elastomers (LCEs) exhibit exceptional energy dissipation compared to amorphous elastomers due to their dynamic soft elasticity. In this study, we develop a new class of LCEs incorporating polyrotaxane (PRx-LCEs) as slidable crosslinkers. Surprisingly, PRx-LCE displays much enhanced energy dissipation, surpassing even glass transition (T_g), as evidenced by the tan delta curve in viscoelastic measurements. Such unprecedented high energy dissipation ability together with enhanced stress-relaxation observed in PRx-LCE leads to superior adhesion in both probe tack and peel tests, outperforming conventional LCEs and commercial adhesives. In addition, PRx-LCE demonstrates temperature responsive adhesion, facilitating residue-free removal at elevated temperatures. The synergy between LCE and slidable crosslinks enables the development of robust and switchable pressure-sensitive adhesives with versatile applications.

SF06.07.08

Hydrogel-Based Autonomously Responsive Synthetic Chromatophores with Pattern Control Capabilities
Brennan P. Watts, Matthew R. Jamison, Nengjian Huang, John Kapitan, Delroy Taylor and Stephen A. Morin;

University of Nebraska-Lincoln, United States

Materials capable of rapid changes in color and appearance are of great interest in several application spaces, such as display technology, wearable devices, encryption, and sensing. However, modern chromogenic materials lack the microscale architecture and compliance needed to cover non-planar areas and undergo deformation, for example in autonomous color-changing skins. In nature, cephalopods can rapidly change their appearance through radial activation of chromatophore cells containing pigment sacs. Our recent work in the fabrication of microscale hydrogel arrays on soft, elastomeric supports is well suited to mimic this process, wherein individual microgels act as a class of stimuli-sensitive synthetic chromatophores. We employed dye-stained thermally responsive hydrogels which undergo radial contraction above a threshold temperature, resulting in a decrease in surface coverage and sample color intensity. The macroscopic absorbance of these synthetic chromatophores decreased by up to four-fold when gels were in a contracted state. We constructed a model which allows prediction of the surface fill fraction of gels in a sample using experimentally measured absorbance or vice-versa. The synthetic chromatophores were rendered air-stable by encapsulation in a UV-curable silicone, allowing them to report temperature changes on different surfaces (e.g., walls, windows, or skin) in ambient conditions. Finally, we investigated pattern control by layering multiple samples, which resulted in dynamic Moiré patterns for gels in a contracted or swollen state.

SF06.07.09

Transfer Printing with Cellulose Nanofibers for Fabrication of 3D Electronics *Junsik Choi and Jinho Hyun; Seoul National University, Korea (the Republic of)*

As an emerging technology, three-dimensional (3D) conformable electronic devices on complex surfaces have received increasing attention in recent years. However, their potential is constrained by the lack of effective fabrication techniques, as traditional printing methods face challenges such as the demanding process for mapping and harsh conditions. To address this, we present a mild-conditioned transfer printing technique using carboxymethylated cellulose nanofibers (CM-CNF) enabled by a water-assisted adhesion switching method. CM-CNF films were produced via a combination of chemical carboxymethylation and mechanical grinding. By optimizing the surface charge and hydrophilicity of CM-CNF, the efficiency of transfer printing was enhanced. The high smoothness of CM-CNF films, achieved through sufficient mechanical grinding, facilitated high-resolution ink deposition and easy delamination. To demonstrate the application of this technique in 3D electronics, we fabricated precise electronic devices with polyvinyl butyral (PVB) and silver nanowire (AgNW) using direct ink writing (DIW) on CM-CNF films and transferred the pre-fabricated devices on 3D surface. Modifying the interfacial bonding strength between CM-CNF and PVB-based ink through hydration of the CM-CNF film enabled efficient transfer printing. This water-assisted adhesion switching method requires only hydration, avoiding damage to the ink or target substrate. This technique shows great potential for fabricating 3D electronics on various target substrates and wearable devices.

SF06.07.10

Towards Flexible Autonomous Robotic Nanowire Synthesis *Ishita Banerjee[1], Sadie Seulal[1], Dibyendu Das[1,2], Fumi Honda[1,2] and Nilanjan Chakraborty[1,2]; [1]Garcia High School, United States; [2]Stony Brook University, The State University of New York, United States*

Our goal is to develop an AI-assisted robotic system to discover, optimize, and scale-up the process of nanowire synthesis for various applications including catalysis, fuel-cells, and other biomedical applications. Although different applications may need different operating procedures, to automate and scale up nanowire synthesis with robots, the robots should have the capability to perform complex manipulation tasks like pouring, scooping, etc.

However, programming these capabilities into robots is hard because these constraints may be hard to write down mathematically (think of scooping). One paradigm of making robots widely useful and adaptable for chemical synthesis is to endow them with abilities such that they can interact with chemists and ask guidance from them, as and when required, to learn to perform tasks like a chemist. Ideally, if a chemist can physically guide the robot, the robot can learn to replicate the task. However, learning efficiently without overburdening the human is a difficult challenge. In this research, we take some preliminary steps towards building an interface that allows the robot to effectively communicate with chemists and ask for demonstrations, one at a time, as needed, until the robot believes that it can perform the task reliably.

This research builds on a key capability that was programmed into the robot, and described in prior work[1]. The robot can take a human demonstration, decompose it into a sequence of constant screw motions, which implicitly encodes the constraints in the manipulation task, and can plan paths for new instances of the same task (e.g., when the objects involved in the task are placed at different orientations)[1]. Thus, the robot has the capability to generalize even from a single example, although the generalization is not complete, i.e., there may be task instances where the robot may fail. A solution approach to this lack of generalization capability was proposed based on a bandit optimization framework[2]. For a given work area (which encodes a subset of all possible task instances that may arise), by using bandit optimization, the robot has the ability to self-evaluate its performance, identify a region where it cannot plan successfully, and then ask for demonstrations there[2]. Thus, by incrementally acquiring examples, the robot can say with high confidence whether it believes it can do a task reliably. Experimental results showed that fewer than 10 examples were enough for the robot to learn complex tasks like pouring and scooping[2], though the uniform sampling in the bandit framework became computationally expensive as the task area grew.

In this paper, we present a more efficient upper confidence bound (UCB) bandit-optimization algorithm to identify areas where the robot needs more examples. This algorithm powers an interface that visually shows the robot's belief about its capabilities and where it needs help. We show the UCB approach requires less sampling than the baseline approach[2] to identify the region where the robot needs the most help. We also implemented a voice interface allowing users to guide the robot through named tasks, teaching it to become competent through interaction and demonstrations. Experiments with the Baxter robot showed that a user could teach it to pour within 15 minutes of interaction and fewer than five examples.

Dynamically Reconfigurable Shape-Morphing and Tactile Display Via Hydraulically Coupled Mergeable and Splittable PVC Gel Actuator *Seung-Yeon Jang[1,2], Minjae Cho[1], Hyunwoo Kim[1], Meejeong Choi[2], Seongcheol Mun[2], Jung-Hwan Youn[3], Jihwan Park[1], Geonwoo Hwang[2], Inwook Hwang[2], Sungryul Yun[2] and Ki-Uk Kyung[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]ETRI, Korea (the Republic of); [3]University of Illinois at Urbana-Champaign, United States*

Shape-morphing displays that modulate their surface geometry to encode information via three-dimensional configurations have significant interdisciplinary applications. Recent advancements have shifted to soft materials that morph into continuous three-dimensional shapes through various types of stimuli-responsive actuation [1,2]. However, these strategies have limitations such as low speed for shape morphing, and absence of multi-modality *to provide tactile sensations with surface geometry. Meanwhile, electrohydraulic actuation has addressed key challenges with high-speed response and significant deformation potential [3,4]. However, the rapid transition into seamless and complex 3D shapes that afford multimodal tactile feedback still presents a considerable technical challenge.*

Addressing this, our research introduces a novel soft shape-morphing and tactile display that utilizes an innovative actuator consisting of a polyvinyl chloride (PVC) gel composite, a dielectric liquid, and an electrode matrix to create programmable pressure patterns. This mechanism enables on-demand manipulation of liquid flow via electrohydraulic actuation, facilitating unimpeded internal fluid dynamics. We designed a multi-layered functional polymer composed of PVC gels and an MWCNT electrode, which acts as an active interface, facilitating electrohydraulic actuation while simultaneously enabling the formation of 3D geometries. Thanks to the charge accumulation properties of the PVC gel, the interface has relatively low actuation voltage compared to conventional dielectric elastomers [4]. We analyzed the mechanical and dielectric properties by varying weight fraction of plasticizer of PVC gel, ultimately determining the optimal ratio by considering high dielectric constant and low hysteresis.

Moreover, the design allows dynamic alteration of liquid channels through localized electrostatic activation of specific areas, resulting in rapid shape morphing (45 ms) and transitions into various seamless 3D configurations while generating a large deformation up to 2.5 mm and an exertion force of 2.0 N, despite its slim (1.5 mm) and lightweight (7 g) structure. This capability provides various haptic feedback modalities, including dynamic tactile patterns and vibrations generating distinguishable surface textures on morphed geometries that are verified through empirical user evaluations. Additionally, the developed shape-morphing display allows dynamic motions of object through morphing surface by leveraging liquid flow-induced inertia. In essence, our soft shape-morphing and tactile display introduces novel interaction paradigms with technology, promoting more immersive and intuitive user experiences.

This work was supported by the National Research Council of Science & Technology (NST) grant by the Korea government (MSIT) (CRC23021-000), Samsung Science and Technology Foundation under Project Number SRFC-IT2102-04, and the internal grant of Electronics and Telecommunications Research Institute (ETRI) (24YB1700, Development of light driven three-dimensional morphing technology for tangible visuo-haptic interaction).

8:30 AM *SF06.08.01
Grant Funding Opportunities in the United States and Europe through the Air Force Office of Scientific Research *David Swanson; Air Force Office of Scientific Research, United States*

This presentation will highlight various opportunities for research grant funding for principal investigators located in Europe, which is available each year through the U.S. Air Force Office of Scientific Research (AFOSR). The European Office of Aerospace Research and Development (EOARD) is one of the international locations of AFOSR, and it is located in London in the United Kingdom. This European grant funding office is made up of scientists and engineers who review research topic ideas and make decisions on the best distribution of grant funding for qualified researchers and professors at any European university. EOARD seeks to financially support innovative basic science that will benefit the aerospace community at large. Dr. David Swanson is responsible for funding programs within the material science and structures topic areas, to include robotic and autonomous material systems, and grant funding is available to support U.S. and European PIs. This presentation will provide an overview of AFOSR and EOARD, as well as give detailed instructions on how professors or post-doctoral researchers from any university throughout the United States and Europe may inquire about and apply for grant funding opportunities. It will also highlight the current status of the grant funding portfolios of AFOSR. This presentation will also describe the type of support that AFOSR can provide, to include grants for in-house university research programs, as well as conference support, and visiting scientist travel costs for international professors to collaborate in the U.S.A. The international offices of AFOSR provide a unique opportunity for U.S. researchers to find funding for their international collaborators who are conducting research in other countries. Through collaboration with the European office, many researchers within universities in nearly every country in Europe are currently supported by the U.S. Air Force.

Squid-Inspired Materials for Healing, Display and Encryption in Soft Robotic Devices *Abdon Pena-Francesch; University of Michigan, United States*

Recent progress in soft robotics has motivated the search for new materials and actuators that can replicate biological functions and behaviors (such as sensing, healing, powering, etc.) with autonomy and complexity. In this talk, we will introduce cephalopod-inspired structural proteins with dynamic supramolecular nanostructures that regulate their physical properties. We demonstrate the dynamic properties of squid-inspired polypeptides in self-healing protein networks with healing strength and kinetics surpassing those typically found in other natural and synthetic soft polymers. This family of cephalopod proteins and their biosynthetic derivatives have opened new opportunities in bioinspired design for adaptive functional materials and soft devices with enhanced autonomy and durability, and we will demonstrate their implementation in self-healing and reconfigurable soft actuators. Furthermore, we will introduce a soft display system inspired in squid skin composed of active particle swarm metamaterial with emergent display, computing, memory, and encryption functions.

Optomechanical Reservoir Computing for Embodied Signal Processing *Steven Kiyabu[1,2], Timothy Vincent[1,2], Amanda Criner[1], Andrew Gillman[1] and Phil Buskohl[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States*

The sense-assess-respond feedback loop is a key building block for intelligent behavior in living and synthetic materials systems. Soft robotics is an ideal testbed for the development and embodiment of sense-assess-respond feedback networks, due to the compatible integration of novel sensing motifs, diverse multi-functional responses, and the prevalence of many interesting material and geometric nonlinearities to exploit for assessing (or computing) their local environment. In addition, soft robotic systems are typically power and size constrained, further motivating the development of alternative strategies for their environmental processing and control. In this study, we investigate the information processing capacity of a coupled optomechanical spring system with tunable nonlinearities using the computing framework of physical reservoir computing. Reservoir computing is a class of recurrent neural networks that trains only a readout layer of the network dynamics in contrast to tuning all the internal parameters of the network. This simplified training regime opens the door to physical implementations (vs on chip) of this neural network mapping behavior, and harnesses the unique, intrinsic nonlinearities and variabilities of a physical system. We introduce a mechanical analog for the rectified linear unit (ReLU) activation function, and tune the stiffness ratio of the bilinear force-displacement curve through geometric design. Elastomeric light guides are mechanically attached to a 1D experimental ReLU spring network and demonstrate a nonlinear optical transmission vs displacement response when mechanically driven. The nonlinearity in optical intensity is a result of leakage when the lightguide deforms in bending, which follows Snell's law of refraction. We further develop a spectral projection method to characterize the relationship between system nonlinearity and reservoir computing performance. The analysis partitions the dimensionality increase of the signal among its frequencies, distinguishing between the strengths of the linear vs various nonlinear classes of frequency content. Collectively, the simulation and experimental results of this work demonstrate the benefit of combining different physical nonlinearities for signal processing, as highlighted in the optomechanical reservoir outperforming the mechanical only system. The study also motivates the identification of coupled physical nonlinearities in more complex materials systems, such as soft robotics, to directly perform embodied signal processing and advance their sense-assess-response feedback toward more intelligent behaviors.

Mechanical Computing with Continuum Morphing of Kirigami Shells *Yi Yang[1], Jin Feng[2] and Douglas Holmes[3]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States; [3]Boston University, United States*

Continuum shape-morphing structures capable of encoding memory and performing logic operations have sparked tremendous interest in developing soft robots with embedded intelligence. Integrating memory and computing in such systems requires building blocks with a range of adjustable, metastable states. Previous efforts *focused on creating mechanical memory and logic by exploiting snap-through instabilities in multistable structures, with each logic gate requiring a distinct structural design. This study introduces an innovative design approach using a single kirigami architecture to execute and switch between multiple fundamental logic operations. By leveraging the kirigami architecture as a foundational element, the study demonstrates mechanical signal transmission and performs half-adder computations. This strategy suggests broad applicability across diverse materials and structures, potentially simplifying the development of intelligent materials systems.*

Multifunctional Materials via Multimaterial Computational Design and Fabrication Robert MacCurdy; *University of Colorado Boulder, United States*

In a 2006 paper titled "The Properties of Foams and Lattices", Michael Ashby articulated the 3 determinants of the properties of cellular solids: base material type, relative density (foaming percent), and cell topology and shape (architecture). The first two determinants have been widely studied over the past century, while the third has been enabled by additive manufacturing (3D printing) methods, leading to the exploration of metamaterial structures during the past decade. The recent development and proliferation of multimaterial 3D printing methods motivates the inclusion of a 4th determinant in Ashby's list: spatially-varying material composition. I will present three recent efforts from my group that leverage all four of these material property determinants, including the development of novel computational design methodologies, with applications in soft robotics and impact mitigation.

Additive manufacturing has made significant advancements in multi-material fabrication techniques that allow for site-specific control of material deposition, but design tools have not kept pace. The intense interest in compliant mechanisms and meta-materials demands a new design method that can support architecting material distributions throughout an object. To address these needs, we present OpenVCAD, an open-source volumetric design compiler with multi-material capabilities. It provides a scriptable suite of geometric and material design methods that enable efficient representation of complex objects with hundreds of materials. Through functional grading and convolutional blending, OpenVCAD allows material distributions to be parameterized on spatial locations to yield complex multi-material distributions that would be impossible to describe using alternative methods.

Traditional methods of mitigating impacts rely on isotropic stochastic foam materials. Plate lattices, an emerging class of architected metamaterials, exhibit superior mechanical properties, but they are challenging to fabricate via conventional means in all but the simplest geometries, such as 2.5D honeycombs. In contrast, we use additive manufacturing to relax these constraints and realize metamaterials with locally varying geometry. We design these lattices using constructive geometry (OpenVCAD), bypassing the constraints of conventional CAD tools. Our software creates a direct mapping between design representations and computational meshes for finite element analysis, allowing us to simulate complex buckling and collapse behavior without a manual meshing step. By validating these computational models against empirical data from impact tests on fabricated samples, we enable inverse design of plate lattice materials optimized to specific geometries and impact scenarios.

Soft robotic structures embed computation in the form of material distributions that yield specific desirable properties such as the ability to conform to objects in the environment or respond to external stimuli. However, achieving the specific required material distributions is a challenging inverse design problem. We have applied multi objective heuristic Pareto-optimization methods to address this design challenge, allowing human designers to choose among a variety of potential solutions, which are realized automatically via multimaterial 3D printing. While these multimaterial distributions form the body of soft robot structures, methods analogous to a nervous system that sense, process, and transmit signals are also required. The soft robotics community has recently *explored pneumatic methods for this purpose, though signal density and energy requirements present challenges. We have recently developed solution-processed materials compatible with multimaterial inkjet 3D printing methods, that enable rapid and automated fabrication of 3D transistor circuits embedded within a robot structure.*

11:15 AM SF06.10.04
An Autonomous Snapper with Physical Intelligence *Duygu Sezen Polat[1], Zihua Chen[2], Sam Weima[1], Dick Broer[1], Satoshi Aya[2] and Danqing Liu[1]; [1]Eindhoven University of Technology, Netherlands; [2]South China Advanced Institute for Soft Matter Science and Technology, China*

Harnessing elastic instabilities enables plants to surpass the constraints of their intrinsically slow and limited movement. Carnivorous plant D. muscipula, for example, can control the spatial variation of osmotic pressure on its leaves to induce snap-through transition and to reset their curvature for subsequent predatory snaps. Nature's use of elastic instability has profoundly influenced the development of many snap-through systems in the soft robotics field. However, majority of these systems cannot perform autonomously under uniform stimulation due to the energy barrier between two states. In our paper, we present a novel strategy to achieve autonomous snapping under uniform stimulation by exploiting the interaction between the snapping device with its environment. We illustrate that the mechanism is rooted in the photothermally induced snap-through and energy transfer of the snapper with the environment, regulated by a negative feedback loop enabling autonomous snapping. We investigate the underlying mechanism through experiments and numerical simulations. The snapper's interaction with its environment facilitates sustained and adaptive motion, attributing physical intelligence to the device and allowing it to function as both an actuator and a sensor. Our findings reveal the snapper's capability to differentiate substrates based on color and texture, leading to its application as a color detector. We finally explore the snapper's ability to adapt to changes in the stimulation and the environment. These results demonstrate an effective approach for developing autonomous and physically intelligent actuators.

11:30 AM +SF06.10.05
How Autonomous Material Systems Enable Embodied Intelligence Robert Shepherd; Cornell University, United States

In embodied intelligence (EI), already, the gravel below a robot's foot may change the shape of the foot–storing energy and adding stability, becoming part of the machine for milliseconds prior to release. A projectile impacting a surface may partially and reversibly imbed itself into the volume, the A chemical spray may change the macromolecular orientation of the surface, changing its optical and mechanical properties, displaying a warning to human teams and changing the trajectory of a robot away or towards the source. The key difference between Physical Intelligence (robots with AI algorithms on board) and EI is how diffuse the Input/Output system of the robot is with the environment; ultimately, an EI robot has no distinguishable interface with the environment it operates in. The key enabler for EI are material systems that operate autonomously, containing sensing, actuation, computation, and energy capabilities. This talk will describe the state of the art in EI and Autonomous Material Systems (AMS's) and what can be done to improve the field.

Closed Loop FDM Printing of Fluidically-Driven Robotic Materials *Markus Nemitz; Tufts University, United States*

FDM printing has traditionally been an open-loop process, where print parameters are adjusted based on machine, filament imperfections, and the print environment. This expert-based calibration is effective for rigid filaments but remains challenging for polyurethanes due to their inherent elasticity. In this talk, we introduce a vision-based, closed-loop printing process that monitors and corrects 3D prints automatically to achieve airtight systems. We present a roadmap of current challenges and future opportunities of closed-loop printing and its importance in the development of fluidically-driven robotic materials.

2:00 PM *SF06.11.02
Additive Fabrication of Soft Robotics *Shlomo Magdassi; The Hebrew University of Jerusalem, Israel*

Additive manufacturing, which is the process of fabrication through printing, brings new opportunities in the field of soft robotics. It enables the fabrication of complex structures that cannot be fabricated without post-assembly, including making objects composed of multi-materials. Here we describe new materials and processes for making soft grippers with embedded sensors, starting from a solution of monomers and oligomers, and dispersion systems. The resulting highly stretchable polymers are utilized to print pneumatic actuators, which are the main component of soft grippers. Furthermore, several responsive materials will be presented, which bring sensing abilities, towards the fabrication of autonomous soft grippers. The sensing is obtained by unique designs of the grippers with embedded electrically conductive materials, or by meta-materials based-design of optical sensors. These grippers can adapt to different shapes, apply holding forces tailored to the object's mechanical properties, and provide feedback to the control system for optimal operation, as will be demonstrated for several practical examples.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

Laser Induced Graphene for Soft Actuators and Sensors *Francesco Greco[1,2,3]; [1]Scuola Superiore Sant’Anna, Italy; [2]Sant'Anna School of Advanced Studies, Italy; [3]Graz University of Technology, Austria*

Laser Induced Graphene (LIG) is a 3D porous conductive carbon material produced by laser-induced pyrolysis of polymer precursors. In recent years it has found applications in soft and wearable electronics, energy storage devices, among others.[1–3] LIG conductive tracks, electrodes, sensors are created through a single synthesis/patterning step by laser scribing with a IR or UV laser onto some polymer precursors. Alternatively, biologically-derived precursors are investigated and employed.[4] LIG technology represents a maskless and

chemical-free alternative to other printing technologies but is also opening unprecedented possibilities for the realization of circuits onto virtually any surface.
In our LAMPSE group, we investigate LIG for the development of soft sensors and actuators, and their use in various Robotics applications.
We create stretchable conductive composites by embedding LIG within elastomeric matrices like polydimethylsiloxane PDMS, various silicone rubbers, or polyurethane PU. Their characteristic piezoresistive behavior can be fine-tuned through laser processing parameters. Strain, bending, pressure, temperature sensors are thus developed for a variety of applications: sensorization of soft pneumatic grippers for enabling proprioception, thin wearable sensors which conform to the human skin for personal monitoring, integration of sensing capabilities in wearable haptic devices.
On the other hand, by coupling those LIG/elastomer stretchable conductors with stimuli responsive polymers, new strategies for soft actuation can be devised. A smart humidity-responsive hydrogel (poly-(N-vinycaprolactam), pNVCL) is used to realize a multi-responsive soft bending actuator, capable of self sensing. Other approaches involve a Liquid Crystal Elastomer (LCE): a thermoresponsive material featuring excellent properties like large actuation strains and reversible linear actuation process. In both cases soft LIG/elastomer circuits served as Joule heating elements to resistively heat the active materials and trigger an actuation.

Finally, I will show some novel developments of LIG from new non-polymer precursors and from bio-sourced materials and how they can enable sustainable approaches to soft robotics and electronics.

Deterministic Spin-Orbit Torque Switching in 2D Dilute Magnetic Semiconductors Above Room Temperature

Siwei Chen[1], Zitao Tang[1], Mengqi Fang[1], Rui Sun[2], Licheng Xiao[1], Xiaotong Zhang[2], Seyed Sepehr Mohajerani[1], Yuze Zhang[1], Dali Sun[2], Stefan Strauf[1] and Eui-Hyeok Yang[1]; [1]Stevens Institute of Technology, United States; [2]North Carolina State University, United States

Two-dimensional (2D) van der Waals (vdW) magnets with perpendicular magnetic anisotropy (PMA) hold great potential for next-generation high-density, energy-efficient spintronics[1–9]. Recent breakthroughs have emerged with the discovery of Fe_3GaTe_2 ,$PtTe_2$ and $CrTe_2$, boasting Tc exceeding 300K, opening possibilities for constructing functional 2D magnetic devices operating at room temperature[10–14]. However, achieving high-efficiency spin-orbit torque (SOT) switching of monolayer vdW magnets at room temperature poses a significant challenge, particularly in the absence of an external magnetic field. Here we demonstrate an ultra-low power, field-free, deterministic, and nonvolatile PMA switching of SOT system up to 370 K using a dilute magnetic semiconductor (DMS), monolayer Fe:MoS_2[15], through interfacial spin-orbit coupling with a Pt Hall bar. A clear anomalous Hall effect (AHE) loop shift is observed at a zero in-plane magnetic field, verifying the existence of z spins in the Fe:MoS_2/Pt heterostructure, which induces a damping-like torque that facilitates field-free SOT switching with the current density of 10^5 A cm^{-2} at 370K. The Fe doping into MoS_2 disintegrates the rotational crystal symmetry, evidenced by the crystal axis dependency of the switching in Fe:MoS_2/Pt heterostructures with PMA. A strong topological Hall effect (THE) was also observed, attributed to interfacial Dzyaloshinskii-Moriya interaction (DMI). This field-free SOT application using a 2D monolayer dilute magnetic semiconductor provides a new pathway for developing highly

power-efficient spintronic devices.

Surface Engineering and Umpolung Chemistry of 2D Transition Metal Carbide MXenes Through Electrochemical Reduction *Di Wang[1], Noah Mason[1], Maia Czaikowski[1], Benjamin Atterberry[2], Yu Han[1], Aaron Rossini[2], Chong Liu[1], John Anderson[1] and Dmitri V. Talapin[1]; [1]The University of Chicago, United States; [2]Iowa State University of Science and Technology, United States*

Two-dimensional (2D) materials show unique properties that have led to their extensive study for diverse applications. 2D materials are mainly dielectrics, semiconductors, or semimetals. MXenes are an emerging family of 2D transition metal carbides and nitrides, most of which are metallic conductors. Thus, they are actively studied for their promising performance in energy storage, electromagnetic interference (EMI) shielding, and catalysis. MXenes follow a generalized formula of $M_{n+1}X_nT_x$ *(n = 1-4), where M stands for early transition metal (such as Ti, V, or Nb), X is C or N, and T is surface terminations (for example, -OH, -F, and -Cl). Their structures can be described as n+1 hexagonally packed M layers interleaved with n layers of X atoms. The M layers are then capped by the surface termination groups. Examples of MXenes include* Ti_2CCl_2 *and* $Ti_3C_2Cl_2$*.*

We show that conductive MXenes can be engineered by controlled electrochemical processes. By tuning the reductive potential applied to a Ti_2CCl_2 MXene electrode soaked in tetrabutylammonium (TBA) chloride acetonitrile electrolyte, MXenes can be intercalated by TBA or get reduced to eliminate terminal Cl atoms. The most interesting observation is the substitution of surface Cl with butyl groups, forming butyl-terminated MXenes. To the best of our knowledge, Alkyl groups have not been covalently grafted to the surface of MXenes. Attempts to substitute Cl with organolithium produced reduced MXene anions, which barely showed affinity towards carbanions. Our reaction was found to be an unconventional Umpolung (polarity inversion) chemistry of MXenes: $Ti(\delta^+)\text{-}Cl(\delta^-)$ bond in MXenes is considered an analogue of $C(\delta^+)\text{-}Cl(\delta^-)$ bond. A cathodic current reduces the electrophilic $Ti(\delta^+)$, and its polarity is inverted to nucleophilicity $Ti(\delta^-)$. Then the butyl carbocation from TBA can be transferred to MXene surfaces, squeezing out tributylamine.

The alkyl surface groups can be swapped into other organic species such as alkoxides and amides. Alkyl-terminated MXenes also show reactivity for the catalysis of acetylene deletion and hydroamination. The discovery of alkyl-functionalized MXenes is a demonstration that 2D MXenes can behave like organometallics, initiating a bunch of new opportunities at the interface of solid-state chemistry and organic chemistry.

Long Afterglow Response of 2D Transistion Metal Dichalcogenides *Assaf Yaakobovitz; Ben-Gurion University of the Negev, Israel*

Two-dimensional materials are attractive materials to be integrated into functional systems due to their excellent physical properties, such as high mechanical strength, thermal stability, and semiconducting behavior. Recent Progress in synthesis methods allowed the realization of two-dimensional materials in the form of a three-dimensional network, also known as nano foam. We focused our work on graphene foam (GF) and hexagonal boron-nitride (BN) nano foam resonators. We developed a process to build suspended GF electrostatic actuators and we investigated vibrations and electrostatic pressure change their atomic structure. In addition, we developed BN nano foam resonators. Since BN is a large bandgap semiconductor, we developed a new approach for exciting them using Kelvin polarization force.

Both GF and BN showed significant dissipation as the quality factor values that we measured, even under high vacuum conditions, were low (below 100). These observations inspired us to study the dissipation mechanisms underlying the dynamics of layered foam materials that showed that atomic friction between the layers is the most dominant dissipation source. We found that modifying the atomic structure mitigated this dissipation source.

We finalize our talk with an applicative example, as we developed GF resonative COVID-19 sensors. We developed a protocol to allow the exposure of the sensors to liquid and our experimental analysis showed that our sensors exhibited very high sensitivity, as their limit of detection is as low as several thousand viruses.
