SESSION BI01.01: Groundwork for Discovery: Democratizing the Future of Materials Science
Session Chairs: Christopher Kuenneth and Milica Todorović
Monday Morning, December 2, 2024
Sheraton, Second Floor, Constitution B

10:30 AM +BI01.01.01
The Materials Genome Initiative and the Democratization of Materials R&D James A. Warren; National Institute of Standards and Technology, United States

The US Materials Genome Initiative (MGI) is a multi-agency effort to accelerate the discovery, design, development, and deployment of new materials into manufactured products. The means to achieve this overarching goal is the Materials Innovation Infrastructure, a federated, yet tightly knit, interplay of computational, experimental and data resources. The creation of this infrastructure can be viewed as a means to lower the barrier to the application of state-of-the-art materials R&D approaches. The lower these barriers are made, the more the MGI will have successfully democratized these methods. Of course, to acheive this goal, any number of challenges must be overcome, and many of these challenges are of a more social and/or economic character. Here we will explore some of these issues within the broader context of MGI's goals, and delve into the strategies we are employing to overcome these barriers.

11:00 AM BI01.01.02
Harnessing Large Language Models for Metal-Organic Framework Discovery Zhiling Zheng[1,2], Christian Borgs[1,1], Jennifer T. Chayes[1,1] and Omar Yaghi[1,1]; [1]University of California, Berkeley, United States; [2]Massachusetts Institute of Technology, United States

In the rapidly evolving landscape of material research, the integration of large language models (LLMs) such as ChatGPT, Claude, and Llama has opened new frontiers for efficient and innovative scientific exploration. This work presents a study demonstrating the multifaceted applications of LLMs in the field of metal-organic frameworks (MOFs), showcasing their capabilities in text mining, image mining, synthesis planning, hypothesis generation, coding, robotic platform operation, and multi-agent collaboration for autonomous experiments.

First, we develop a text mining agent based on either the GPT-3.5 or GPT-4 model that leverages prompt engineering to enable accurate retrieval of MOF synthesis conditions from the scientific literature. By employing ChemPrompt Engineering strategies, we demonstrate its exceptional performance in text mining tasks, achieving precision, recall, and F1 scores exceeding 90%. The agent's ability to convert unstructured text into tabulated synthesis data, autonomously classify synthesizing paragraphs, and utilize text embeddings for efficient information retrieval significantly streamlines the data mining process. We showcase the extraction of a dataset containing over 26,000 unique synthesis parameters for approximately 800 MOFs from selected research articles. Furthermore, we highlight the development of a chatbot grounded in this comprehensive dataset, enabling interactive engagement with the collected empirical data. The comprehensive dataset was then utilized to train a binary classification machine learning model, which achieved 87% accuracy in predicting MOF crystallization outcomes based on synthesis conditions. This predictive modeling assists chemists in understanding the factors that govern MOF synthesis, enhancing experimental planning and success rates.

Building upon the success of text mining, we explore the capabilities of GPT-4V, an LLM equipped with vision capabilities, in navigating complex graphical data from MOF literature. By converting scholarly articles into images and deploying GPT-4V to categorize and analyze them using natural language prompts, we demonstrate its proficiency in identifying and interpreting key plots integral to MOF characterization, such as nitrogen isotherms, PXRD patterns, and TGA curves, with accuracy and recall above 93%. This methodology underscores GPT-4V's potential to aid in the digitalization of experimental data and the creation of datasets for porous framework materials.

Finally, we introduce the ChatGPT Research Group, a multi-agent system powered by seven LLM-based assistants, which seamlessly orchestrates diverse aspects of MOF research in the laboratory. In essence, each agent is assigned a specific aspect of a task, such as literature review, code writing, robotic platform operation, and so on, and the agents can talk to each other and pass the information. By leveraging this multi-agentic collaboration system, we accelerate the discovery of optimal microwave synthesis conditions for water-harvesting MOFs, namely MOF-321 and MOF-322, achieving desired porosity and water capacity. It is demonstrated that this approach enables a single researcher working with AI to achieve productivity levels comparable to those of an entire traditional scientific team. The incorporated Bayesian search approach, using Python code developed by LLM agents, efficiently identifies optimal synthesis conditions from a pool of large number of possibilities and reduces the reliance on empirical knowledge in the screening process. In summary, this study provides a blueprint for future material research where the synergy between human expertise and artificial intelligence propels us toward accelerated material discovery.

11:15 AM BI01.01.03

Leveraging Large Language Models for Automated Materials Database Curation Maciej Polak[1,2], Tyler Sours[1], Omar Allam[1], Shivang Agarwal[1], Steffen Ridderbusch[1], Dane Morgan[2] and Ang Xiao[1]; [1]SandboxAQ, United States; [2]University of Wisconsin–Madison, United States

The advancement of machine learning (ML) models in materials science heavily relies on the availability of large, high-quality datasets. While open-access datasets exist, they often suffer from limitations such as incomplete data, lack of standardization, and insufficient coverage of diverse material properties. Therefore, harnessing the comprehensive and detailed information available in scientific literature becomes highly appealing. By leveraging

Large Language Models (LLMs) for data extraction and programmatically querying extensive databases of scientific literature, we can create robust, standardized datasets that address these limitations. This automated process significantly reduces the time and effort required for data collection, allowing computational researchers to focus on data analysis and model development using real data that is representative of the scientific community at large. While these methodologies are domain agnostic, we demonstrate their application to several areas of interest in materials science, with a focus on alloy mechanical properties and battery stability data. We illustrate the utility of these comprehensive datasets by training ML models to perform downstream predictive tasks and guide material design, thereby accelerating discovery and innovation. By integrating diverse data sources, our approach ensures a rich and holistic representation of the current state of knowledge, enhancing the predictive capabilities of ML models and leading to faster development of better materials.

11:30 AM BI01.01.04
Question Answering Models for Information Extraction from Perovskite Materials Science Literature Matilda M. Sipilä, Farrokh Mehryary, Sampo Pyysalo, Filip Ginter and Milica Todorović; University of Turku, Finland

Scientific text is a promising source of data in materials science, and there is ongoing research on how to utilize textual data in materials discovery. The recent success of transformer-based language models has led to the development of new machine learning tools. These tools, such as question answering (QA), are now available for information extraction (IE) from scientific literature. The QA models are large language (BERT) models tuned towards an IE task, conducted by asking a comprehensible question. The potential of the QA method lies in its versatility, accessibility and scalability. Human language queries make it easy to use even for researchers with no previous knowledge of language technology. Also, no re-training of QA model is needed to extract information about different materials and properties.

We explored the IE performance of the QA method on the task of extracting bandgap values of halide perovskite materials from scientific literature. We tested five different BERT models and found that MatBERT model produced the best results. Compared to the more established IE tool ChemDataExtractor2, the QA method performed well, and we were able to collect correct bandgap values from text. Extracted information will next be used to map the space of materials properties and find promising new materials solutions. We implemented this method into a web application to make the QA tool more widely available. Through this work, we seek to lower the barriers for non-experts to use large language models for IE and help democratize use of language technology in materials research.

11:45 AM BI01.01.05
Prediction of Inorganic Crystal Synthesis Pathway by Large Language Model Ryotaro Okabe, Zack West and Mingda Li; Massachusetts Institute of Technology, United States

Inorganic crystal synthesis methods involve combining solutes with different compounds through techniques often involving heating to dissolve the solute in the compound, followed by cooling to precipitate crystalline structures. Synthesizing materials with properties optimized for computation presents a significant challenge; the conventional dependence on human intuition to navigate the uncharted state space of synthesis parameters is marked by inefficiencies, becoming more evident as the duration for crystal growth extends from weeks to years. Our work analyzes the efficacy of large language models (LLMs) on inorganic material synthesis prediction. We can observe accurate recreations of known chemical equations and synthesis operations by fine-tuning the GPT-based model on the text-mined inorganic crystal synthesis dataset. Our models are trained on partitions of the data, enabling predictions from incomplete inputs, such as reactants to products, products to reactants, target compound to the chemical equation, and chemical equation to synthesis operations, to guide experimental crystal synthesis. We evaluate the performance of each model using the Tanimoto index relative to ground truth values and analyze prediction trends as both prompts and outputs vary in complexity. By leveraging transformers' attention mechanisms to capture long-range dependencies in increasingly complex chemical equations, our approach can provide researchers with valuable insights and predictions that are not immediately intuitive, showing promise for more efficient and informed experimental designs in crystal synthesis.

SESSION BI01.02: Building and Utilizing Digital Frameworks: From Data Management to Computational Discovery

Session Chairs: Matthew Evans and Pascal Friederich
Monday Afternoon, December 2, 2024
Sheraton, Second Floor, Constitution B

1:30 PM *BI01.02.01

Digital Infrastructures for 21st Century Science—Opportunities, Benefits and Needs Nicola Marzari[1,2]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Paul Scherrer Institute, Switzerland

The scientific community has long established the need for major national and international long-term efforts to support ambitious and unique capabilities - from synchrotrons and colliders to telescopes, from computing and sequencing to fusion. Intriguingly, it's computational science and especially computational condensed-matter physics, chemistry, and materials science that have led across fields the indicators for publications and impact - one might even surmise relevance. Crucially, these computational capabilities are most often available under open-source and open-access models, meaning that they can be replicated effortlessly and at a flick of a switch worldwide, with scaling costs that are profoundly different from those of physical infrastructures, and with a most democratic model of dissemination. And they are supported by IC technologies where throughput capacity still doubles every 18 months; where unexpected accelerators - from machine learning to big data to large-language models - have appeared; and where novel paradigms - from memcomputing to quantum computing - might emerge. I'll present my own vision of an ecosystem and a digital infrastructure of open-source simulation codes and open-access data, of automated workflows, of externalizable capabilities driven by universal APIs that can be integrated by human or non-human orchestrators, and that can be dedicated to the most pressing societal needs addressed by materials innovations. Most notably, I'll underscore that what is most needed for these digital infrastructures are software scientists and engineers and long-term career opportunities, at a cost that is negligible with respect to the traditional investments of big science, and with multipliers that no physical infrastructure can match. Disclaimer: No artificial intelligence was employed in the preparation of this abstract.

2:00 PM ^BI01.02.02

opXRD—Open Experimental Powder X-Ray Diffraction Database Daniel Hollarek, Henrik Schopmans, Jona Östreicher and Pascal Friederich; Karlsruhe Institute of Technology, Germany

Powder X-ray diffraction (pXRD) experiments are a cornerstone for materials structure characterization. Despite their widespread application, the analysis of pXRD diffractograms still presents a significant challenge to automation and thus a bottleneck in high-throughput experimentation automated materials discovery in self-driving labs. Machine learning has emerged as a promising research direction to resolve this bottleneck by enabling automated powder diffraction data analysis. A notable difficulty in applying machine learning to this domain is the lack of sufficiently sized experimental datasets, which has relegated machine learning researchers to train primarily on simulated data. Since simulations largely fail to accurately reflect the experiment, the performance of models trained on only simulated data often lacks transferability to experimental data and thus fails to provide value in practice. With the Open Experimental Powder X-Ray Diffraction Database (opXRD, https://xrd.aimat.science), we aim to remedy this by providing an openly available and easily accessible dataset of partially labeled experimental powder diffractograms, providing machine learning researchers with a large quantity of real experimental diffractograms collected from a broad range of samples. We provide almost barrier-free software tools that allow experimental researchers to find their data and make it accessible - in virtually any widely used format. We collected multiple thousand mostly unlabeled diffractograms from a wide spectrum of materials classes, which establishes the first version of the opXRD database. We hope that this ongoing effort can guide machine learning research toward domain transfer from simulation to experiment and eventually fully automated analysis of pXRD data and thus enable future self-driving materials labs.

2:15 PM BI01.02.03

Machine Learning Potentials Unveils Rare Events During Diffusion of Organic Compounds in Metal-Organic Frameworks Sudheesh Kumar Ethirajan and Ambarish Kulkarni; University of California, Davis, United States

Machine learning potentials (MLPs) bridge the gap between high-fidelity, short-time ab initio Density Functional Theory (DFT) simulations and long-time classical Molecular Dynamics (MD) simulations for functional nanoporous materials [1]. A key challenge is developing accurate MLPs, often achieved with active learning based on model ensemble uncertainty. However, traditional exploration strategies using MD simulations primarily sample configurations near local minima on the potential energy surface, limiting the MLP's ability to predict high-energy configurations (rare events). To overcome this limitation, we introduce an active learning framework utilizing the "On-the-fly-Probability-Enhanced-Sampling" (OPES) method for systematic exploration of high-energy configurations [2].

This work showcases the effectiveness of the OPES-based active learning framework by modeling imidazole diffusion in functionalized ZIF-8 Metal-Organic Frameworks (MOFs) as a prototypical example. We employ a time-dependent OPES bias along expanded collective variables (ECVs) for temperature and distance-based CVs during model development. This enables extended MD simulations (up to 10 ns) with ab initio accuracy in large supercells using the trained MLPs, allowing detailed observation of the diffusion process. Intriguingly, our simulations reveal a previously unconsidered phenomenon: ring-opening events within the MOF structure during imidazole diffusion across four-membered rings. Classical potentials (e.g., UFF), lack the flexibility to represent these complex, large-scale structural rearrangements that involve breaking and reforming bonds within the MOF framework and hence cannot capture this emergent behavior even at long-time simulations. This discovery unlocks exciting possibilities for designing MOFs with novel functionalities by strategically modifying linkers to exploit this ring-opening process. Additionally, we investigate the impact of OPES on optimal training set selection and its transferability across diverse structures and chemistries.

Reinforcement Learning for Transferable Force Fields in Binary Nano-Alloy Synthesis and Soft Landing Sukriti Manna, Troy Loeffler and Subramanian Sankaranarayanan; Argonne National Laboratory, United States

Traditional molecular dynamics (MD) simulations often struggle to accurately model binary nano-alloy clusters due to the limitations of force fields based on bulk crystalline data, which fail to account for the unique sizes and compositions of nanoclusters. To address this challenge, we present a novel reinforcement learning approach for developing adaptable force fields specifically tailored to the size and composition of binary nano-alloy clusters. By utilizing a comprehensive dataset derived from first-principles nanocluster data, our method optimizes a Tersoff Bond Order Potential, covering a wide range of cluster sizes and compositions. This advanced force field enhances the accuracy of dynamic and structural predictions compared to density functional theory (DFT) results while significantly improving computational efficiency.
We validate the practical application of our approach through MD simulations of the gas-phase synthesis and soft landing of AuxAgy nanoclusters on graphite surfaces. These simulations explore the detailed formation mechanisms of nanoclusters from atomic vapors, demonstrating that cluster formation proceeds via sequential formations of dimers and trimers, which grow through agglomeration and coalescence. Additionally, our findings reveal that the morphology and deposition dynamics of clusters during soft landing are profoundly influenced by the strength of cluster-substrate interactions, deposition velocities, composition, and substrate temperature. These insights into cluster formation, stability, and interaction dynamics are vital for advancing technological applications in fields such as catalysis and materials science. Our tailored force fields thus offer significant potential for enhancing the predictive power and efficiency of molecular simulations.

2:45 PM BI01.02.05
Designing Datasets for Next-Generation Machine-Learning Potentials Zakariya El-Machachi and Volker L. Deringer; University of Oxford, United Kingdom

The relationship between atomic structure and physical properties remains a challenging but crucial research task in materials chemistry. To tackle the challenges in describing materials with complex structures, machine learning (ML) based interatomic potentials are now a widely used approach for predicting material properties based on the atomic positions. This is typically achieved by “training” an ML potential on quantum-mechanical reference data, keeping the quality of the training data whilst unlocking simulation sizes and times that are many orders of magnitude larger.

In this contribution, I will present three emerging ideas which underpin current developments in ML-driven atomistic materials modeling: (1) Data in the age of ML potentials are becoming increasingly important with advancing computing power, growing model complexity and novel approaches to data curation – for example, large synthetic datasets for pre-training neural-network potentials [1]; (2) Synergies exist between ML potential fitting and *ab initio* molecular dynamics for on-the-fly fitting and evaluation, resulting in considerable acceleration – thereby highlighting the shift to automated generation of rich and diverse datasets, in turn enabling the easier construction of specialized ML potentials [2]; (3) Foundation models can contribute to democratizing materials research by providing a starting point for new researchers in the field – with a specific focus on a recent open-access foundation model trained using very large datasets from the Materials Project [3].

I will argue that these three ideas will play a central role in the further development of materials modeling. For example, unlocking device-scale size simulations faithfully resembling the real material have remained elusive – here, I will showcase recent studies on ten-nanometer-scale models of graphene oxide [4] and chalcogenide phase-change materials [5] that have both built on carefully constructed datasets. This recent paradigm shift in ML-driven atomistic modelling reinforces the need for open data, open collaboration and transparency as ML-based approaches are becoming a mainstay in the field.

3:30 PM *BI01.02.06
Data Visualization and Democratizing AI in Materials Science Krishna Rajan; University at Buffalo, The State University of New York, United States

This presentation discusses role of data visualization methods in material science as an effective means for lowering the barriers for interpretation. Examples are given on how one can use such data visualization methods, especially those derived from data dimensionality reduction techniques, to impact our understanding of complex phenomena in materials science. We also discuss how we have adopted such approaches to not only speak to domain experts but also use it as a pedagogical tool in education, a data driven tool for guiding policy makers and as science communication tool to empower public understanding of science

4:00 PM BI01.02.07
A Dynamic Multi-Modal Fusion Model for Material Discovery Indra Priyadarsini S, Seiji Takeda, Lisa Hamada and Hajime Shinohara; IBM Research-Tokyo, Japan

Recent advancements in Artificial Intelligence (AI) and Machine Learning (ML) have created vast opportunities in the field of material discovery, with models trained across various data forms or modalities such as SMILES, SELFIES, molecular graphs, spectrum, properties, etc. spanning across different domains (such as polymers, drugs, crystals). Though these unimodal models are capable of effectively capturing the representations of their respective data modalities or domains, it is further possible for models to gain a more comprehensive understanding of materials from representations learnt from different modalities.

Multimodal models learn to integrate and process information from diverse sources, thus enhancing model robustness and providing deeper insights compared to unimodal models. By leveraging insights from each modality, multimodal models have significantly higher representation power by uncovering patterns that may remain hidden in unimodal models.
Previous attempts at multimodal fusion methods often combined unimodal models through basic concatenation or simple strategies, which rely on paired representations and may overlook challenges due to data scarcity or missing modalities. In this work, we propose a dynamic multimodal fusion model that efficiently combines unimodal representations, adapting dynamically to capture a comprehensive representation as needed.

The core objective of our proposed dynamic multimodal fusion model is to elevate both the robustness and performance of the multimodal model by adaptively tailoring the fusion process to the inputs from distinct unimodal models. The key benefits of our proposed approach include:

1. Dynamic Selection: It allows for the dynamic selection of unimodal inputs that are most likely to enhance the performance of the fused model, effectively filtering out noise or less impactful input modalities.
2. Handling Missing Modalities: Our method adeptly manages scenarios where paired data for different modalities is scarce or unavailable.

To illustrate our method, we demonstrate its efficacy in combining three modalities—namely SMILES, SELFIES, and Molecular Graphs— and benchmark its performance against conventional fusion techniques such as simple concatenation. Our findings reveal that the representation generated through our proposed dynamic fusion strategy significantly surpasses the outcomes achieved by traditional fusion methods on various downstream prediction tasks.

This research presents a flexible and revolutionary way to combine representations from various modalities, paving the way for a more profound comprehension of materials and their properties.

Running Python Simulations in the Browser—The Case of Thermal Metamaterial Optimization Giuseppe Romano; Massachusetts Institute of Technology, United States

Scientific WebApps are gaining popularity both in the classroom and for research. Notable examples include Apps from the NanoHub ecosystem and the Material Project. Current mainstream platforms, however, require a backend that sends Javascript code to the front end, which in turn presents the WebApp to the end user. In this talk, we will outline a paradigm-shifting approach where Python code is executed in the browser, and the resulting WebApp can even run without an Internet connection. We show an example, based on PyScript [1], where a thermal metamaterial is optimized via a Graphical User Interface (GUI); the GUI allows the user to specify the prescribed full effective thermal conductivity tensor. The code executes topology optimization of a periodic 2D domain in the browser and visualizes the optimized structure. Finally, the corresponding STL file can be downloaded for 3D printing. The WebApp, dubbed HeatOpt, can run locally or be deployed via GitHub. Because of their cost-effective (in most cases, free) deployment and ability to use mainstream languages (e.g. Python), we anticipate this approach will challenge current server-based.

4:30 PM *BI01.02.09

Assessing Quality of Machine-Learning Models and Underlying Data Claudia Draxl; Humboldt-Universität zu Berlin, Germany

The power of artificial intelligence has allowed us to reach a new level of scientific approaches with predictive power. On the one hand, machine learning is used to explore trends in material properties. On the other hand, one may aim at highly accurate modeling. How accurate finally predictions are for a given problem at hand, depends on various factors. With a range of very different examples, we assess what Big Data means in the context of typical machine-learning problems in materials science [1]. This concerns data volume, data quality and veracity, but also infrastructure issues. We also show how machine learning, in turn, can be used for error quantification and data augmentation [2,3].

8:30 AM *BI01.03.01
Open Metrology for Materials Science Neil Gershenfeld; Massachusetts Institute of Technology, United States

For AI to have an impact in materials science it's necessary to close a feedback loop from measurement to modeling to training to prediction to validation. Each of these steps can introduce barriers to access. I will survey work on lowering them, including open designs of materials science instrumentation, merging offline measurements with online processing, machine architectures for rapid-prototyping of rapid-prototyping, and computational metrology to effectively measure predictive models.

9:00 AM BI01.03.02
Enhancing Precision in Laser Coloring—Deep Learning for Accurate Spectrum-Based Laser-Induced Color Prediction Yun-Jie Jhang[1], Chia-Hung Chou[1], Tsung-Ming Tai[2] and Hung-Wen Chen[1,1]; [1]National Tsing Hua University, Taiwan; [2]NVIDIA AI Technology Center, Taiwan

Laser coloring technology uses laser beams to irradiate metal surfaces, revolutionizing the creation of microstructures that display colors through light interference. This method offers a variety of eco-friendly coloration options and provides a sustainable and pollution-free alternative to conventional coloring techniques. However, despite these advantages, current laser coloring technology faces significant challenges. A major challenge is the reliance on a trial-and-error approach to achieve the desired colors, requiring finely tuned laser machining parameters and multiple rounds of adjustments, which consumes a significant amount of time and resources, making it difficult to meet industrial demands efficiently. Consequently, there is a call for innovative methods to ensure accurate and efficient forecasting. Deep learning offers a promising solution by extracting the information from laser machining parameters in laser-induced coloring. However, existing deep learning methods typically predict color values such as L*a*b*, RGB, xyY, and HSV. This conversion from spectral data to color values can result in a loss of color information, reducing data quality and making the color prediction less accurate. In this study, we utilize deep learning to achieve accurate color prediction in laser coloring methods by using spectrum-based data rather than relying on conventional color values. Our method enhances color precision and can predict laser-colored spectra with high accuracy. In simulated data, the model achieved an average $\Delta E < 1$, indicating it can predict colors that are indistinguishable to the human eye. In real-world experiments, by inputting machining parameters into the model, it accurately predicted the color spectrum, achieving a ΔE of 4.95, which is below the industrial standard of $\Delta E = 7$. Additionally, our method demonstrated an inference time of less than 1 millisecond, greatly enhancing the speed of the laser coloring prediction.

9:15 AM BI01.03.03

Analysis of the Impact of Integrating Neural Networks into Ensemble Learning for Band Gap Prediction from the Perspectives of Bias, Variance and Shapley Values Taichi Masuda and Katsuaki Tanabe; Kyoto University, Japan

The band gap is a critical parameter for characterizing the electronic structure of a wide range of materials, including semiconductors and insulators. Consequently, accurate calculation of the band gap is highly sought. However, standard density functional theory calculations tend to underestimate the band gap by more than 30% compared to experimental values. To achieve more accurate band gap calculations, methods such as the GW approximation and hybrid functionals have been employed. While these methods are precise, their computational costs are high, rendering them impractical for high-throughput calculations of numerous materials. To predict band gaps with high accuracy and speed, research on machine learning-based band gap prediction has been advancing. This study analyzes various machine learning models, including neural networks, for predicting experimental band gap values. Additionally, it evaluates the utility of ensemble learning, which combines neural networks with classical machine learning, from perspectives beyond performance alone, including bias, variance, and Shapley values. In our research, the ensemble learning approach that combines message passing neural network (MPNN) and conditional adversarial generative network with classical machine learning achieved the highest prediction accuracy among machine learning models for experimental band gap prediction. To the best of our knowledge, this ensemble approach outperformed other methods in terms of prediction accuracy. Furthermore, from the perspectives of bias, variance, and shapley values, it was found that MPNN played a crucial role in the ensemble learning predictions. These findings not only indicate the potential for discovering novel semiconductor materials through ensemble learning combined with neural networks but also provide important guidelines for designing new ensemble learnings for band gap prediction.

Advancing Open-Source AI in Chemistry and Materials—From Foundation Models to Integrated Frameworks to Solve Global Challenges Kristin Schmidt, Eduardo Almeida Soares, Victor Shirasuna, Emilio Vital Brazil, Renato Cerqueira, Dmitry Zubarev, Seiji Takeda, Tim Erdmann, Stefan Zecevic, Sarathkrishna Swaminathan and Brandi Ransom; IBM Research, United States

This presentation highlights AI advancements in chemistry and material science, emphasizing open-source tools and applications. We will introduce the AI Alliance, a community dedicated to open innovation in AI technology, fostering responsible innovation while ensuring scientific rigor, trust, safety, security, diversity, and economic competitiveness. Particularly, the AI for Chemistry and Materials focuses on developing open-source foundation models for materials. We will highlight the first large structured state space sequence models (SSMs) for molecules, pre-trained on 91 million SMILES samples from PubChem, equating to 4 trillion molecular tokens. This model excels in molecular property prediction, classification, and reconstruction. However, despite advances in computational chemistry and machine learning, many tools remain underutilized due to their complexity and the need for programming skills. We will show how LLM-based AI agents can bridge this gap by orchestrating workflows and multi-step tasks and by integrating a large variety of cheminformatics tools and available foundation models. Finally, we will showcase how these AI technologies can help solve urgent global challenges we are facing, such as the widespread efforts to replace PFAS compounds, or so-called forever chemicals.

Decentralized Materials Research Data Management, Curation and Dissemination for Accelerated Discovery Matthew Evans[1,2,3]; [1]Université Catholique de Louvain, Belgium; [2]Matgenix SRL, Belgium; [3]Datalab Industries, United Kingdom

The primary barrier to widespread adoption of AI-accelerated materials science is the availability and quality of data. Researchers lack frictionless tooling and have limited incentive to record their data in such a way that is immediately amenable for machine learning, whether by them or by others. This talk introduces two data projects in the materials space that aim to lower the barrier to data access and curation by both humans and machines: the OPTIMADE federation of materials databases, and the open-source *datalab* materials data management platform.

OPTIMADE consists of an international consortium of databases that have designed, over many years, a common application programming interface (API) format, which now allows for 30+ databases across 20+ providers to be seamlessly queried. Such federated data unification enables decentralized data-driven workflows in materials informatics and beyond, from materials selection up to materials discovery. OPTIMADE is supported by several community-oriented tools that allow others to easily contribute their data to this growing ecosystem. This talk will introduce the OPTIMADE ecosystem, discuss the process of consensus-forming amongst provideres, and outline how OPTIMADE could be extended to other domains.

The second project primarily concerns experimental data; *datalab* is a open-source data management platform that can be customized and adopted by materials research groups to allow for straightforward provenance tracking of samples, devices and raw data. It integrates with the broad open-source community of file format parsers (from the datatractor initiative and other popular packages) to allow for data normalization and simple analysis in the browser for many characterisation techniques (XRD, NMR, Raman, electrochemistry, etc). This platform provides the traditional benefits of having a digital system of record (e.g., an electronic lab notebook), whlilst also enabling programmatic re-use of data across a research group via its API, with the aim to allow end user programming. By providing labs with control over their data platform, they can develop their own AI-driven developments, as well as selectively sharing and collaborating with others on shared workflows and samples. This talk will summarize the ongoing developments of *datalab,* including the integration of AI-based agents, and motivate future use cases of a federation of such *datalab* deployments.

Expanding Materials Embeddings for More Expressive Machine Learning Models Anthony Onwuli[1], Keith Butler[2] and Aron Walsh[1]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom

High-dimensional representations of the elements have become common within the field of materials informatics to build useful, structure-agnostic models for the chemistry of materials. (1,2) These representations are often pooled to form composition-based feature vectors to represent materials. Beyond their utility for property prediction, element representations also have applications for defining the chemical similarity of compounds for structure substitution approaches. (3,4) However, the characteristics of elements change when they adopt a given oxidation state, with distinct structural preferences and physical properties.
Here, we propose SkipSpecies, a method of learning distributed representations of ions, which is an adaptation of SkipAtom, a method for learning distributed representations of atoms. (5) Clustering these learned representations of ionic species in low-dimensional space reproduces expected chemical heuristics, in particular the separation of cations from anions. We show that these representations have enhanced expressive power for property prediction tasks involving inorganic compounds. We expect that ionic representations, necessary for the description of mixed valence and complex magnetic systems, will support more powerful machine learning models for materials.

Molecular Descriptor for Global Relationship of Intra-Molecular Substructures Lisa Hamada[1], Akihiro Kishimoto[1], Masataka Hirose[2], Junta Fuchiwaki[2], Kohei Miyaguchi[1], Indra Priyadarsini S[1], Hajime Shinohara[1] and Seiji Takeda[1]; [1]IBM, Japan; [2]JSR Corporation, Japan

Fluorescent organic dyes are widely applied in diverse fields, such as OLEDs, sensors, solar cell, medicine, and drug delivery. Extensive research efforts have been dedicated to develop new dyes with desired photophysical and photochemical properties. Photophysical and photochemical properties depend on intra-molecular interactions resulting from global relationships of substructures, e.g., distance of Donor-Acceptor and/or conjugated systems, within the molecule, especially for large-scale molecular structures.
Machine learning (ML) has played a significant role in accelerating material discovery aiming to reduce the time/cost and increase variability. ML models, specifically designed for predicting properties, are trained using features that encapsulate the characteristics of molecules, including molecular descriptors which capture different facets of these molecules. Consequently, the efficiency with which structural features are extracted plays a crucial role. Various molecular descriptors have been developed, ranging from Quantitative Structure-Property Relationships (QSPR) based descriptors, which basically enumerate constituent elements, to neural-network-based descriptors. However, they still have limitations in accurately capturing global relationship of intra-molecular substructures.
Herein, we introduce a new molecular descriptor - Topological Distance of intra-Molecular Substructures (TDiMS), which can extract topological distance between each pair of substructures within a molecule. A topological distance between a substructure pair is approximately defined as the total mean of the shortest bond distances between atoms constituting each substructure. We aim to capture the distance with spread in order to be independent of the shape of particular substructures. Additionally, using this calculation method enables to freely target any desired fragment. In this study, we targeted heavy atoms, circular substructures derived from Morgan

Fingerprint, and fragments related to organic solar cells. The feature vector derived by the proposed TDiMS approach includes values that are directly linked to the topological distance between pairs of substructures. More precisely, this study utilized either the inverse square or the inverse of the topological distance, considering factors like Coulomb's law and conjugated systems.
Our evaluations reveal that TDiMS outperformed six representative descriptors based on both QSPR and neural networks in prediction model for several tasks on dye-related datasets. Across all tasks, TDiMS achieved an average enhancement rate of 17% over other benchmark descriptors. Moreover, further analysis indicates that TDiMS actually captured the crucial features that significantly contributed towards accurate target property prediction. These features collectively offered chemical insights into substructure pairs, emphasizing the importance of topological distance in molecular design. This study also provides an important direction for neural network development that combining topological distance of intra-molecular substructures information can lead to further improvement.

2:30 PM BI01.05.05
Structural Motif-Based Material Network for Material Discovery and Property Prediction Anoj Aryal, Weiyi Gong and Qimin Yan; Northeastern University, United States

The effectiveness of machine learning (ML) algorithms in material science depends on the precise and accurate representation of material systems. Structure motifs are considered structure descriptors of solid-state materials and are strong predictors of material properties. This work introduces a novel approach for constructing a network of 145,249 solid-state materials within the Materials Project database connected by common structure motifs. Network analysis shows that the most shared motifs act as hubs, effectively linking several materials within the network. We utilize a bipartite network embedding technique to obtain high-dimensional vector representation of both material and motif nodes, capturing both direct and transitive links in the network. The t-SNE-transformed embeddings exhibited distinct clustering patterns for motifs of different types and for materials sharing most common motifs in the network. This clustering behavior highlights the repetitive nature of structural motifs and their critical role as indicators of specific material properties. The learned embeddings, when used in a neural network model, can effectively predict material properties such as formation energies and band gaps and classify metals and non-metals. The combination of t-SNE visualization, property prediction, and classification shows the crucial role of structural motifs in understanding material behavior, predicting properties, and classifying materials. Our approach provides a robust framework that integrates ML techniques with structural motif information to explore and categorize vast material spaces, accelerating discovery and design of novel functional materials.

Editors-in-the-Loop—A Publisher’s Role in the AI-Driven Science Era Steven W. Cranford; Cell Press, United States

Computational methods such as machine learning, artificial intelligence, and big data in physical sciences, particularly materials science, have been exponentially growing in terms of progress, method development, and number of studies and related publications. This aggregate momentum of the community is palpable, and many exciting discoveries are likely on the horizon. At the same time, the *de facto* standard to disseminate scientific output is the traditional peer-reviewed manuscript via established journals. Here, some of the challenges of handling, assessing, and distributing the idiosyncrasies of data-heavy studies are discussed from the perspective of the editor and journal, with some proposed initiatives and opportunities.

Synthesizing Multimodal Experimental Datasets from Scientific Literature of Materials Science Vipul Gupta[1,2], Florian Pyczak[1,2] and Ingo Schmitt[2]; [1]Helmholtz-Zentrum Hereon, Germany; [2]Brandenburgische Technische Universität Cottbus-Senftenberg, Germany

Recent developments in the field of data mining have received significant attention across scientific communities for their potential to advance research. Experimental datasets of research findings are usually published in scientific literature. Mining such literature thus enables the discovery of synergistic effects and meaningful insights by virtue of evaluating the combined experimental datasets. The availability of machine-readable collections containing experimental datasets from relevant literature is therefore essential for knowledge discovery in scientific literature. Unfortunately, such collections are not provided by any existing tool or digital library. The creation of these collections demands: i) highly specific searches to identify relevant literature, and ii) non-trivial extraction of experimental datasets due to complex patterns and multimodal representations, such as text, table, and scatter plot. For example, within the field of materials science, creating a collection that has exclusively experimental datasets on a specific mechanical property of a particular alloy system is not possible.

This work introduces a scientific literature data mining platform designed to address these challenges. It facilitates federated search-based automatic ingestion of literature from digital libraries, followed by retrieving relevant literature. Besides phrase, faceted, full-text, and conjunctive and disjunctive search capabilities, the implemented information retrieval system allows dataset-aware literature retrieval based on the metadata of visual elements. This metadata includes a visual element type depending on its content and characteristics, along with the caption text. Moreover, the platform enables semi-automatic extraction of experimental datasets from the identified relevant literature. In particular, it employs plot digitisation and deep learning-based techniques to extract named entities (e.g., temperature, stress, and microstructure) and events (e.g., thermal history of specimen) from both text corpus and visual elements. Furthermore, the platform aids in creating curated datasets that can be utilized for exploratory data analysis and predictive modelling. This presentation emphasizes features and applicability of the platform within the materials science field, exemplified by the use case to create the minimum creep rate dataset for a gamma titanium aluminide system.

Promises and Perils of Big Data—Philosophical Constraints on Chemical Ontologies Rebekah A. Duke-Crockett[1,2], Ryan McCoy[1], Julia Bursten[1] and Chad Risko[1,2]; [1]University of Kentucky, United States; [2]Center for Applied Energy Research, United States

Materials research is experiencing a paradigm shift in the way it interacts with data. So-called “big data” is collected and used at unprecedented scales with the idea that algorithms can be designed to aid in chemical discovery. As data-enabled practices become ever more ubiquitous, researchers must consider the organization and curation of their data, especially as it is presented both to humans and increasingly intelligent algorithms. One of the most promising organizational schemes for big data is an ontology, a system for representing relations among objects and properties in a domain of discourse. The future of materials research will be shaped by the choices made in developing big data chemical ontologies. How such ontologies will work should, therefore, be a subject of significant attention in the chemical community. We recommend answering these questions with an interdisciplinary approach that draws on the long history of philosophers of science asking questions about the organization of scientific concepts, constructs, models, and theories. We present insights from these long-standing studies and initiate new conversations between chemists and philosophers. We illustrate how the "blooming, buzzing confusion" of chemical ontologies is merely a feature of advanced chemical thought, and an often desirable one at that. Ultimately, we advocate for a shift in time and energy away from a quest for a universal chemical ontology and towards developing context-sensitive pluralistic ontologies in collaboration with philosophers.

Machine-Learning Based Virtual Screening for Sustainable Polyesters Navya Nori; Milton High School, United States

Current biodegradation timelines show that polyesters take 200+ years to break down. A crucial component of several industries, polyesters are relied upon for materials development and thus require sustainable alternatives. Over the past few years, artificial intelligence has transformed the landscape of molecular generation. In 2020, a method of molecular generation specifically tuned to large polymer generation, the Junction Tree Variational Auto-Encoder, was developed. Prior approaches focused on atom-by-atom construction of small molecules, with significant declines in performance for large polymers. Jin et al. developed a scalable method that incorporates structural motifs, a hallmark feature of large polymers, into the generation process. However, these molecules are still completely general and have several unknown properties.

This work designs a new method for virtual screening of these polymers to specifically filter for sustainable polyesters. A biodegradability classifier trained on HTS polyesters and polycarbonates scores each generated molecule, capturing the biochemical complexity of biodegradability. In conjunction, chemical rules adapted to sustainability are used to evaluate the top molecules, and their correlations with biodegradability are used in molecular design. Specifically, this work investigates the effect of structure, bond types, and interactions with water. These three properties were chosen in particular to evaluate the structures from an atom, bonding, and environmental lens. For molecular structure, it was hypothesized that aromatic rings will reduce biodegradability because of their high rigidity. The predicted bond type to increase biodegradability was an ester linkage due to its high susceptibility to hydrolysis. Lastly, hydrophobicity was predicted to decrease biodegradability due to low solubility in polar solvents.

The methods of this work can be split into two components: biodegradable polyester filtering and synthesizability analysis. For polymer generation, structures from Jin's work were filtered from polymers to polyesters. Several chemical properties were then computed using the cheminformatics library RDKit, including LogP, molecular weight, and bonding information. These captured the general characteristics of the polyesters before applying sustainability-specific criteria. However, one property not easily computable from the structures is biodegradability, due to a host of extraneous contributing features. A separate tree-based classifier was trained and tuned to score this property. A gradient-boosted machine (GBM) model was chosen because of its complexity, interpretable output, and bias-variance tradeoffs. The top 10 scoring molecules were further analyzed. Gao et al's SynNet was used to create synthesis pathways consisting of safe reactions and purchasable ingredients for each top molecule.

The biodegradability predictor performed with a test AUC of 85%, indicating that it captured the property well. The presence of aromatic rings had a weak negative correlation on biodegradability due to high rigidity from its alternating single and double bonds. For results on bond types, ester linkages were significantly positively correlated with biodegradability due to a substantial electronegativity difference, resulting in polar structures that are dissolvable in polar solvents and cleavable by hydrolytic enzymes. Finally, there was a weak positive correlation between hydrophobicity and biodegradation. Additionally, the neural network SynNet showed that the top-ten high-scoring molecules are completely chemically synthesizable. The final molecules comply with the American Society for Testing and Materials' guidelines for sustainable polymers to begin breakdown within 180 days, a significant improvement from the current timeline. This combined screening approach of chemical rules and prediction is comprehensive and can capture the necessary biochemical complexity.

BI01.07.02

Unveiling the Knowledge of a Parallel Synthesizer Generated Database of RAFT Polymerizations Michael Ringleb[1,1], Yannik Köster[1,1], Stefan Zechel[1,1] and Ulrich S. Schubert[1,1,2]; [1]Friedrich-Schiller-Universität Jena, Germany; [2]Helmholtz Institute for Polymers in Energy Applications Jena, Germany

Combinatorial chemistry and high-throughput testing have been indispensable tools in the materials sciences since their introduction in the 1970s. Several configurations, including automated parallel synthesizers, flow-chemistry setups, and pipetting robots, have been used to produce experimental data automatically.
Since there are so many combinations of useable monomers, solvents, initiators, and other reaction conditions that can be combined with different methods of polymerization to turn a monomer into a polymer, the topic of polymer sciences has attracted a lot of attention. In the past, human intuition was usually utilized to gather the knowledge produced by campaigns to sample a particular subset of polymerizations. The conclusions of the experimental work were then published, and with any luck, the original and primary data supporting those conclusions were also made available to the public as part of the publication's supporting documentation. As the community strives to implement machine learning models, some of which are data-hungry, to further explain certain trends in the data collected, it is of utmost importance to simplify access to the data generated.
Hence, in this work, a synthesis robot has been utilized to perform more than 450 polymerizations in an automated approach in batches of 15 reactions. During the reaction time of 15 hours, 14 samples per polymerization – either for size-exclusion chromatography or NMR spectroscopy – were collected automatically to generate a dataset consisting of more than 4600 data points. The polymerization parameters were varied between 15 different monomers, seven RAFT-agents and three solvents. The subset of monomers consisted of five monomers each, from the group of acrylates and methacrylates with differing substituents at the ester moiety. Additionally, five styrenic monomers with differing *para*-position substituents were examined. Dimethylsulfoxide, dimethylformamide, and toluene were the investigated solvents utilized to collect data on contrasting polarity regimes. All of the radical polymerizations utilized azobis(isobutyronitril) as initiator, and were carried out at 70 °C. The collected data points were curated into several hundred kinetics and fitted with suitable growth functions so that data points could be extrapolated and interpolated from one another. The resulting knowledge was made

accessible through an online interface, enabling a rapid search for the ideal reaction conditions to synthesize a polymer with desired characteristics, like molar mass.
This work cannot only be seen as a presentation of a high-throughput generated database of homopolymers. It also illustrates the possibilities and restrictions of using such a database and provides insights into data curation and augmentation.
In the future, an extension of the dataset seems to be possible with, e.g., further RAFT-agents, different temperatures, additional initiators or further monomers as test points. Furthermore, the data provided could be utilized to examine trends regarding the polymerization behavior of certain monomer groups with different substituents at the relevant moiety in combination with specific RAFT-agents.

BI01.07.03

Advanced Machine Learning-Driven Multi-Objective Optimization for Peak Performance in Ultra-Thin a-IGZO Thin-Film Transistors Hyunkyu Yang, Jiho Lee, Minho Jin, Haeyeon Lee, Jiyeon Kim, Chan Lee, Jong Chan Shin and Youn Sang Kim; Seoul National University, Korea (the Republic of)

The relentless pursuit of miniaturization, in accordance with Moore's Law, has driven memory devices such as DRAM and NAND to unprecedented performance levels. However, this trend has encountered fundamental physical limitations, impeding further scaling of conventional silicon (Si)-based transistors and restricting potential performance gains. To address this challenge, novel materials and innovative device architectures are being actively explored. Within the realm of emerging semiconductor technologies, the Indium Gallium Zinc Oxide (IGZO) channel transistor has garnered significant attention due to its inherently low leakage current characteristics. While IGZO offers promising prospects for low-power memory applications, a key challenge lies in simultaneously achieving high field-effect mobility, a crucial factor for enabling fast operation speeds, without compromising its intrinsic electrical properties.
To address this inherent challenge, a novel machine learning (ML)-based approach is proposed for fabricating ultra-thin IGZO thin-film transistors (TFTs) with exceptional performance using the sputtering process for the transistor channel. This approach employs ML algorithms to optimize multiple sputtering parameters, acting as a powerful tool to overcome the limitations of conventional techniques. Notably, this approach addresses the key challenge of simultaneously achieving multiple competing electrical properties in IGZO TFTs. Consequently, this ML-driven method enables the fabrication of TFTs exhibiting outstanding characteristics, including a high field-effect mobility of 36.5 cm^2/V s, a near-zero threshold voltage of -0.08 V, and an impressively thin channel below 7 nm. The fabricated TFTs exhibit performance metrics on par with those achieved using Atomic Layer Deposition (ALD), a well-established technique known for producing high-quality, ultra-thin films. This accomplishment suggests the potential for the ML-optimized sputtering process to address the inherent throughput limitations associated with ALD.
Harnessing the power of machine learning, the proposed method revolutionizes the optimization of the sputtering process, effectively eliminating the need for traditional labor-intensive and time-consuming trial-and-error approaches. This transformative approach holds immense promise for accelerating the development of next-generation memory devices with groundbreaking efficiency and speed.

BI01.07.04

Can Machine Learning Predict the Liquidus Temperature of Binary Alloys? Yifei He and Jan Schroers; Yale University, United States

Despite significant efforts in developing model descriptions of alloys mixing behavior, the liquidus temperature of an alloy is generally not predictable through theoretical models but instead determined experimentally. Here we explore if machine learning strategies can be used to predict them. We use random forest and consider various

representations of the alloy through features vectors based on a prior known information. We found that when features based on physical insights into alloys' mixing are used, an average prediction with 8% error can be achieved compare to 13% when only using the properties of A and B elements as features. Such error is essentially identically to a linear extrapolation of known melting temperatures of A and B to predict the alloy's liquidus temperature. The poor predictability even under the best circumstances is most dramatically reflected in the fact that even when over 99.8% of all data considered for training of the algorithm, the error of prediction into the remaining 0.2% is only 8%. Our analysis reveals that the major challenges in predicting the liquidus temperature through ML algorithms originates from the challenge to represent the relevant characteristics of an alloy through which we argue is a common challenge in complex materials science problems. Further, the discrete nature of atoms and their corresponding features, constitutes the most fundamental challenge in applying machine learning strategies for complex materials science problems.

BI01.07.05

Improvement of Dual-Stacked Oxide Thin Film Transistor Using Bayesian Optimization Jiho Lee, Haeyeon Lee, Jiyeon Kim, Chan Lee, Jong Chan Shin, Hyunkyu Yang and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Oxide semiconductor Thin Film Transistors (OS TFTs) have shown outstanding characteristics such as a low leakage current and a threshold voltage near 0 V, making them a promising technology. However, their field-effect mobility is lower compared to Si-based TFTs, which is considered a weakness. To overcome this challenge, extensive research has been conducted, leading to the development of OS TFTs. Among various study, Dual-stacked OS TFTs are characterized by layered structures composed of various oxide semiconductors, forming an active layer. The use of multiple materials in the active layer allows the advantages of various materials, but leads to complex physical and electrical interactions, complicating the fabrication process and the operational mechanism of these transistors. Optimizing the performance of dual stacked TFTs is, therefore, a substantial challenge. Recently, the application of machine learning in material science, especially in complex design spaces, has gained significant attention as an efficient approach. Among various algorithms, Gaussian process (GP)-based Bayesian optimization (BO) is recognized as a promising optimization algorithm that reduces trial-and-error. In this study, we aimed to optimize the performance of dual-stacked (IZO/IGZO) TFTs using BO. We simultaneously considered three key sputtering variables: Argon/Oxygen gas flow ratio (%), DC power (W), and working pressure (mTorr), all of which influence the overall performance of the TFTs. Since the performance of TFT cannot be defined by a single parameter, we employed a Figure of Merit (FoM), combining three representative output parameters: field-effect mobility, threshold voltage (V_{th}), and subthreshold swing (S.S.), to train the machine learning algorithm. Despite the complex experimental design, we successfully optimized the performance of the dual stacked (IZO/IGZO) TFTs using BO. By leveraging the active learning characteristics of BO, the sputtering conditions were optimized with the guidance of ML. The optimized TFT exhibited high performance, showing a mobility of 46.71 $cm^2V^{-1}s^{-1}$, V_{th} of -0.10 V, and S.S. of 0.19 $Vdec^{-1}$. This resulted in a significantly improved field-effect mobility, more than twice that of conventional IGZO TFTs (20.1 $cm^2V^{-1}s^{-1}$), without any degradation in other characteristics. This study demonstrates the feasibility of utilizing BO to fabricate high-performance TFTs under complex experimental conditions, involving numerous input variables (sputtering process variables) and output variables (performance parameters of TFTs). By leveraging the capabilities of ML, researchers can explore complex design spaces more efficiently, leading to the development of advanced materials and devices with improved performance. This study serves as a valuable example of how the integration of machine learning and materials science can drive innovation and progress in various technological domains.

Large-Scale Atomistic Simulations of Proton Transport in Perfluorinated Ionomer Membranes Using a Neural

Network Interatomic Potential Yuta Yoshimoto, Naoki Matsumura, Yuto Iwasaki, Hiroshi Nakao and Yasufumi Sakai; Fujitsu Limited, Japan

The rapid advancement of machine learning technology in recent years has led to the development of materials discovery and materials simulation techniques utilizing machine learning in the field of materials science. Specifically, machine learning interatomic potentials (MLIPs) constructed using density functional theory (DFT) calculation results as training data have attracted significant attention because they enable molecular dynamics (MD) simulations at time and spatial scales that are not possible with ab initio simulations while maintaining accuracy comparable to DFT calculations. The construction of MLIPs requires a series of steps, including the generation of labeled data (energy and/or forces) using DFT calculations, the training of MLIP models, and the accuracy evaluation of MLIP models. We are developing a software called Generator of Neural Network Interatomic Potential for Molecular Dynamics (GeNNIP4MD) to automate this MLIP construction workflow. In GeNNIP4MD, by just providing the initial structure(s) for DFT calculations, it is possible to automatically perform data generation using active learning, training of neural network potential (NNP) models, and accuracy evaluation of NNP models. In each cycle of active learning, structure sampling is performed using MD simulations with the NNP model constructed in the previous cycle, and a two-stage screening based on the uncertainty of the force prediction and structural features is performed to efficiently sample structural data that is not present in the dataset. This two-stage screening allows for the construction of highly accurate NNP models while reducing the number of computationally expensive DFT calculations required. In this study, we employ GeNNIP4MD to create an NNP model capable of analyzing the proton transport in Nafion (perfluorinated ionomer) membranes, which are widely used as polymer electrolyte membranes. As initial structures, we prepare multiple systems consisting of Nafion monomers and water molecules with different water contents (<300 atoms) and use them as inputs to GeNNIP4MD. We employ Deep Potential (DP) as the NNP model and construct the DP model using GeNNIP4MD. At the end of all active learning cycles, the root mean squared error (RMSE) of energy is approximately 1 meV/atom and the force RMSE is below 80 meV/Å on the validation set, indicating successful construction of a highly accurate DP model. Using the constructed DP model, we perform MD simulations of large systems (>10000 atoms) composed of Nafion polymers and water molecules and find that the water-content dependence of densities and proton diffusion coefficients is successfully reproduced.

Unraveling the Historical Roots and Thematic Dynamics of Perovskite Solar Cell Research—A Bibliometric Analysis of Highly Cited Papers and the Role of AI in Materials Science Jun-Seok Yeo and A-Ram Kim; Korea Institute of Science & Technology Evaluation and Planning, Korea (the Republic of)

From 2009 to 2023, over 20,000 papers have been published on perovskite solar cells (PeSCs), reflecting a notable level of academic interest and research activity within this field. This increase in research activity is driven by the integration of various pre-existing research areas. Moreover, advancements in PeSCs have had a reciprocal impact on other technologies. It is therefore essential to undertake a comprehensive analysis of the inflows and outflows of research within the PeSC field in order to gain a full understanding of its intellectual structures. Despite this necessity, no systematic and bibliometric methodologies have been utilized to address these issues in a comprehensive manner. In this study, we conducted a comprehensive examination of the development and thematic evolution of PeSC research through extensive bibliometric analyses, with a particular focus on leveraging AI techniques to enhance our understanding. Our methodology included the analysis of citation relationships, the tracking of publication trends in PeSC-related fields, the identification of highly cited papers (HCPs), and the mapping of keywords and collaboration networks. A significant aspect of our study involved an in-depth analysis of researchers who have had a substantial impact on the PeSC research community. We initially identified those who published 10 or more HCPs between 2009 and 2021, designating them as PeSC highly cited researchers

(PeSC-HCRs). Subsequently, a social network analysis (SNA) was conducted on their research activities from 2005 to 2022, based on author keywords. To guarantee a comprehensive and systematic analysis, all publications were classified according to their respective publication years and InCites citation topics. This classification enabled the identification of shifts in research priorities and the emergence of new sub-disciplines over time.

Information Extraction from Fermi Surfaces Using Unsupervised Machine Learning Daichi Ishikawa[1], Kentaro Fuku[1], Yoshio Miura[2,3], Yasuhiko Igarashi[4], Yuma Iwasaki[2], Yuya Sakuraba[2], Koichiro Yaji[2], Alexandre Lira Foggiatto[1], Arpita Varadwaj[1], Naoka Nagamura[2] and Masato Kotsugi[1]; [1]Tokyo University of Science, Japan; [2]National Institute for Materials Science, Japan; [3]Kyoto Institute of Technology, Japan; [4]University of Tsukuba, Japan

Fermi surface is crucial information for the designing various functions in spintronics devices. Particularly, electron states such as Weyl point and nodal line on Fermi surface contribute to spin polarization and anomalous Nernstian effects. However, a great deal of expertise and effort is required to analyze Fermi surfaces and discuss their mechanisms. Moreover, the volume of Fermi surface data has been rapidly increasing due to recent advancements in high-throughput angle-resolved photoelectron spectroscopy（ARPES） measurements at next-generation synchrotrons. Accordingly, there is a significant demand for extracting information on physical properties through the automated analysis of Fermi surfaces. In this study, we applied machine learning to the Fermi surface of Heusler alloy $Co_2MnGa_xGe_{1-x}$ (CMGG) and visualized the regions contributing to physical properties.
The band structures of CMGG were calculated with 1 at% increments using the first-principles calculation program VASP. The Fermi surface was prepared on the k_x-k_y plane from the calculated band structures, similar to ARPES data. Spin polarization at the Fermi level for each composition was calculated from the density of states (DOS). We performed dimensionality reduction using principal component analysis (PCA), which has high explanatory power and enables anomaly detection, to visualize data changes and extract features in high-dimensional datasets.
Composition-dependent Fermi surface changes were visualized in two-dimensional space using PCA. The distances between data points correspond to changes in the Fermi surface. We could confirm significant “jumps” in certain compositions in the reduced two-dimensional space. The data jumps at Ga=15, 24, and 38 at% corresponded to the compositions where there were local maximum or local minimum in the spin polarization changes. Additionally, the jump around Ga=77-79 at% corresponded to a composition where the majority band changed significantly, greatly affecting the spin polarization. By dimensional reduction of the Fermi surface data, we were able to automatically extract compositions related to the spin polarization. Furthermore, for compositions around Ga=94-95%, not only were data jumps observed, but there were also regions that deviated from the data trend. Detailed analysis of the band structure revealed that these compositions had gapped Weyl points at the Fermi level. These results demonstrate the success of using unsupervised machine learning to reduce the dimensionality of the complex Fermi surface and visualize it in data space, allowing for the automatic extraction of noteworthy compositions and features. To verify the robustness of this analysis method against noise data, we tested it by adding noise. Although the contribution rate of dimensionality reduction decreased with increased Gaussian and Poisson noise, the shape in data space was preserved to some extent. By performing the previously analysis, we were still able to automatically extract noteworthy compositions and features despite the noise.
In this study, we applied unsupervised machine learning to the Fermi surface of CMGG, successfully constructing a relationship between changes in the Fermi surface shape and spin polarization in data space. This enabled us to automatically visualize features that explain the spin polarization and identify notable regions on the Fermi surface. Additionally, we successfully extracted compositions where special electronic states, such as Weyl

points, appear on Fermi level. We expected that this developed automated analysis method can be applied to actual ARPES measurement data to extract buried information in band structures and handle data with high noise levels.

BI01.07.09

From AI to Application—Generative AI for Rapid and Efficient Mechanical Design of Composites Milad Masrouri and Zhao Qin; Syracuse University, United States

The distribution of material phases is crucial to determine the composite's mechanical properties. Studying the complete structure-mechanics correlation of meticulously ordered material distributions is feasible within a finite number of cases. However, this relationship becomes challenging to discern for complex irregular distributions, hindering the design of material structures that meet specific mechanical requirements. Generative artificial intelligence (AI) is shown to be a useful tool to automatically learn from the existing information and generate new information based on their connections, but its usage for quantitative mechanical research is less understood.

In this work, we aim to combine the cutting edge generative artificial intelligence (GenAI), specifically Stable Diffusion, with Molecular Dynamics simulations and insightful mechanical analysis to design the material distribution within a composite material for optimal mechanical functions. We develop a fine-tuned SD model that generates the matrix-reinforcement material distributions within a rectangular composite sample and provides its corresponding stress fields in uniaxial deformation with accuracy. We use mechanical analysis to extract the composite mechanical properties from the material distribution and stress fields and use variational auto-encoder to reveal the latent space of the mechanical functions for the composite design, enabling its function-based optimization and design. Our findings demonstrate that GenAI can effectively learn critical features from a relatively small training dataset and, by exploring the design space, can accurately and extensively generate composite material distributions along with their corresponding stress fields under load. We also emphasize that this technique is efficient in generating extensive composite designs with valuable mechanical information that determines the stiffness, toughness, and robustness of the material using a single model, a process that would typically require multiple experimental or simulation tests.
We extend this framework by enabling the understanding of the natural language descriptions of the sample geometry, boundary conditions, and loading conditions and validate the prediction of the optimal material distribution with practical experiments using a multi-material 3D printer

Our research framework will enable the efficient design of complex composites with natural language description instead of complex numerical modeling, data-hungry learning, and sophisticated optimization. It will significantly reduce the modeling effort, and the predicted outcome can be directly applied to composite synthesis for validation or application to broad engineering fields that heavily depend on composite materials.

BI01.07.11

Data-Driven Prediction of Battery Cycle Life Using (Dis)Charge Cell Temperature Joonyoung Kee[1] and Duho Kim[1,2,3]; [1]Kyung Hee University, Korea (the Republic of); [2]Department of KHU-KIST Convergence Science and Technology, Korea (the Republic of); [3]Prediction Co. Ltd., Korea (the Republic of)

As many researchers in academic and industry fields made great improvements in Li-ion battery (LIB), they have accumulated a lot of data on LIB and consequently made big data. Since the data are the result of battery components, (dis)charge method, and many other conditions, they include many important key factors of the batteries and have the meaning of the battery cycle life. Many researchers have focused on these properties of the battery big data and made a great prediction of battery cycle life utilizing the data itself, especially discharge capacity and internal resistance data. To measure these important properties during the (dis)charge process, researchers need some expensive machine or special technique. On the other hand, the cell temperature is cheap and easy to measure and does not need special techniques. The cell temperature is closely related to the increase of internal resistance during (dis)charge, therefore cell temperature can replace the role of internal resistance. As the charging/discharging process proceeds, which is the movement of the Li-ion in LIB, the Li-ion must overcome some small energy barrier. Lots of Li-ion can overcome this energy barrier during the early cycle, but as the cycle continues, the number of Li-ion that fail to overcome the energy barrier increases. These remaining Li-ion contribute to the resistance of battery cells and consequently make irreversible charge and discharge processes. Since the cell temperature is closely related and can be substitution for the resistance of the battery, cell temperature will be an important data to predict battery cycle life.

In this research, I have used open data of fast-charged lithium iron phosphate (LFP). The charge and discharge process were performed at a constant temperature of 30°C in an environmental chamber. The cell temperature was recorded by stripping a small section of the plastic insulation and contacting the thermocouple to a bare metal casing. The battery cells were charged from 0% to 80% state-of-charge (SOC) using one of 72 different single-step and two-step charging methods. Subsequently, all cells were charged from 80% to 100% SOC using a 1C constant current-constant voltage (CC-CV) charging step, up to 3.6V, with a current cutoff at C/50. The discharge process is same in all cells by CC-CV discharge at 4C to 2.0V with a current cutoff of C/50. By using Machine Learning Interatomic Potential (MLIP), I have found the energy barrier that Li-ion must overcome in LFP. The remaining Li-ion on the cathode makes resistance and affects the cell temperature. Therefore, temperature will be related to the battery cycle life.

Discharge capacity data shows a relation with cycle life by Pearson coefficient. The value of the Pearson coefficient is low during the early cycle, but as the cycle increases, the Pearson coefficient increases and converges to about 0.7, which means that discharge capacity and cycle life are related. However, temperature data shows a low value of the Pearson coefficient during the early cycle, and it decreases as the cycle increases. From these different tendencies of Pearson coefficient value, it is easy to think that the temperature data is useless to predict cycle life. However, through many trials and errors of the statistical data processing, I have made a variance of charge and discharge temperature difference between two cycles, and it showed a great relationship with cycle life. These two features I have found are used to predict cycle life by making a linear regression machine learning model and result in good prediction with high accuracy. This research shows that statistical data processed from temperature can be a promising machine-learning feature even when the temperature data itself are not closely related to battery cycle life.

ChemChat—Recent Advances in Democratizing and Facilitating Access to Domain-Specific AI/ML Through LLM-Powered Conversational Assistants

Tim Erdmann, Stefan Zecevic, Nathan Park, Brandi Ransom, Holt Bui, Krystelle Lionti, James Hedrick and Kristin Schmidt; IBM Research, United States

In recent years, computational chemistry and machine learning have undergone transformative advancements, yielding powerful tools and AI models. Despite this progress, these resources remain underutilized due to high technical barriers and their tendency to operate in silos. The necessity for programming and ML expertise further restricts access for many domain experts, particularly experimentalists. Meanwhile, large language models (LLMs) from companies like OpenAI (GPT), Google (Gemini), Meta (Llama), xAI (Grok), and Anthropic (Claude) have revolutionized various sectors over the past 24 months. However, their application in chemistry—even with the recent GPT-o1—remains limited due to deficiencies in understanding scientific workflows, domain-specific tasks (e.g., drug discovery), access to current data sources, skill-based reasoning, and accurate referencing, often leading to incorrect and hallucinated responses that undermine trust and reliability.

This critical gap between AI and scientific disciplines can be bridged by equipping LLM-powered conversational assistants with specialized cheminformatics tools and AI models. By providing tailored instructions on their capabilities and usage, such an assistant can intelligently plan and execute workflows to fulfill user requests. This approach promises to (I) increase the adoption of cheminformatics tools and AI models, (II) democratize AI/ML accessibility within the field, and (III) ultimately enhance scientific discovery and education.

In this talk, we introduce *ChemChat*, a proof-of-concept fully functional and cloud-deployed conversational assistant for material science and data visualization, and our advancements towards agentic systems. It features a chatbot-driven web application interface and is powered by non-OpenAI LLMs. By integrating existing cheminformatics tools and advanced AI models—including PubChem, CIRCA, RDKit, GT4SD, RXN, MolFormer, DeepSearch, and other knowledge sources—*ChemChat* aids chemists with tasks such as property calculations, molecule design, retrosynthesis, data visualization, and literature research. Our presentation will detail *ChemChat*'s workflow architecture, its use of retrieval-augmented generation (RAG)-based in-context learning, and its specific use cases. A comparison with popular applications and recent developments like ChatGPT-o1, ChemCrow, and SynAsk will also be provided.

We hope that our work can serve as a blueprint for accelerating the development of similar systems within the scientific community, particularly in material science, to further enhance collaboration, discovery, and innovation.

BI01.07.13

SpectraScope—A Toolkit for Materials Characterization from Spectral Data Amalya C. Johnson[1,2], Chris Fajardo[2], Leena Sansguiri[2], Weike Ye[2] and Steven Torrisi[2]; [1]Stanford University, United States; [2]Toyota Research Institute, United States

SpectraScope is a toolkit for materials characterizaiton from spectral data using interpretable machine learning models. It is both a python package and a web app, allowing for its easy accessibility by both experimental and computational materials researchers. The software provides a framework for feature generation, feature selection, and model training. It can currently be used with spectra from experiments such as Raman, x-ray diffraction, x-ray absorption, pair distribution functions, infrared spectra, and optical absorption spectra, and will be expanded to work with two-dimensional microscopy data as well. Additionally, SpectraScope can be applied to time-series data. It has been used to predict coordination number and bond length from x-ray absorption spectra of transition metal oxide structures. Through feature selection, SpectraScope identifies regions of spectra that are important for prediction. This helps shed light on the physical relationships between spectra and the characterization. Additionally, SpectraScope can use multiple datatypes at once for prediction, which can help identify the relationships between different spectra and how they may impact model performance. This talk will outline the software's technical details and accessibility.

BI01.07.14

A Discovery Platform for Developing Stable Layered Oxide Cathodes for Potassium-Ion Batteries Muhamad Kurniawan and Jaekook Kim; Chonnam National University, Korea (the Republic of)

The search for advanced electrode materials for potassium-ion batteries (KIBs) presents a significant challenge due to the absence of efficient high-throughput screening methods in modern battery technology. Layered oxide cathodes, such as KxMnO2, have been widely explored for KIB applications due to their high energy and power density. However, KxMnO2 faces challenges with structural instability and its highly hygroscopic nature. To tackle these issues, we introduce, for the first time, a combined machine learning (ML) and first-principles approach based on density functional theory (DFT) for screening and experimental validation. This method enables the design of stable KxMnO2 cathodes with enhanced structural and environmental stability alongside superior electrochemical performance. Among the numerous candidates, the ML and DFT-driven strategies highlight P3-type K0.3Mn0.9Cu0.1O2 (KMCO) as a promising high-performance KIB cathode. Experimental validation confirms

that the KMCO cathode significantly improves K-storage properties, exhibiting high-power density and cycling stability even after four weeks of air exposure. This study opens new pathways for discovering and developing suitable electrode materials for next-generation battery applications.

BI01.07.15
Evaluating the Performance and Robustness of LLMs in Materials Science Q&A and Property Predictions
Hongchen Wang, Kangming Li, Scott Ramsay, Yao Fehlis, Edward Kim and Jason R. Hattrick-Simpers; University of Toronto, Canada

Large Language Models (LLMs) have the potential to revolutionize scientific research, yet their robustness and reliability in domain-specific applications remain insufficiently explored. This study conducts a comprehensive evaluation and robustness analysis of LLMs within the field of materials science, focusing on domain-specific question answering and materials property prediction. Three distinct datasets are used in this study: 1) a set of multiple-choice questions from undergraduate-level materials science courses, 2) a dataset including various steel compositions and yield strengths, and 3) a band gap dataset, containing textual descriptions of material crystal structures and band gap values. The performance of LLMs is assessed using various prompting strategies, including zero-shot chain-of-thought, expert prompting, and few-shot in-context learning. The robustness of these models is tested against various forms of 'noise', ranging from realistic disturbances to intentionally adversarial manipulations, to evaluate their resilience and reliability under real-world conditions. Additionally, the study uncovers unique phenomena of LLMs during predictive tasks, such as mode collapse behavior when the proximity of prompt examples is altered and performance enhancement from train/test mismatch. The findings aim to provide informed skepticism for the broad use of LLMs in materials science and to inspire advancements that enhance their robustness and reliability for practical applications.

BI01.07.16
Transforming Engineering Education—Leveraging Molecular Dynamics Simulations, Artificial Intelligence and Guided Inquiry to Enhance Community-Based Problem-Solving Skills in College Students Lexi Hwang[1], Arpit Vaishya[1], Priyanshu Luhar[2] and Sungwook (Leo) Hong[2]; [1]California State University, Los Angeles, United States; [2]California State University, Bakersfield, United States

In this study, we set out to boost the computational modeling and simulation skills of undergraduate students, especially in tackling real-world engineering problems. Our focus was on complex nano-scale systems like hydrocarbons and solid nanoparticles. To achieve this, we created a semester-long training program with 10 sessions. These sessions covered everything from software setup and tutorials to hands-on activities and a final project. We used molecular dynamics (MD) simulations to help students model and design chemical reactions at the atomic level. The program featured Artificial intelligence (AI)-assisted simulation modules and a guided inquiry-based approach. This method encouraged students to ask questions based on their own experiences and explore scientific concepts in a meaningful way. We also included explicit instructional supports at each stage to make the inquiry process more effective. Throughout the program, students got to work with dynamic representations of abstract phenomena, like chemical reactions at the molecular and atomic levels. They built molecular structures, ran MD simulations, and analyzed the results. We measured the outcomes of this training both qualitatively and quantitatively to see how effective it was. Our work will make a unique contribution to diversifying computational materials research which incorporate compuer simulations, AI technology, and science pedagogy at minority-serving institutions.

BI01.07.17
ALCHIMIA—Advanced Learning for Chemistry Interpretation and Integrated Molecule Analysis Emilio Vital

Brazil, Eduardo Almeida Soares, Breno Carvalho, Victor Shirasuna and Renato Cerqueira; IBM Research, Brazil

The current application of foundation models (FMs) in industrial chemical problems, such as the generation and prediction of properties of small molecules, has shown promising results [1]. A key advantage of FM technology is the ability to create a single model using a large amount of pre-training data, which can then be adapted for various downstream tasks using smaller datasets [2]. However, the complexity of working with FM technology, which requires specialized knowledge in AI and expensive hardware, makes it difficult for experts in the chemical domain to access and utilize these models [3]. Moreover, the lack of uncertainty characterization in most models limits their practical use [4].

To address these challenges, we propose a comprehensive pipeline that enables material discovery experts to create machine-learning models based on advanced FM technology. Our pipeline and software stack, built using Python, encapsulate FM technology and provide experts with the ability to fine-tune models using state-of-the-art techniques such as adapters [5] and mixture of experts (MoE) [6]. For example, our pipeline allows experts to choose from four different models based on SMILES mixing and fine-tune them using low rank approximation techniques. The entire process is recorded, and uncertainty characterization is calculated for the fine-tuned models.

Our proposed pipeline and software stack aim to make FM technology more accessible to experts in the chemical domain, enabling them to leverage the power of these models for material discovery and other applications. By providing a user-friendly interface and advanced fine-tuning techniques, we hope to democratize the use of FM technology and drive innovation in the field of chemistry.

Toward AI-Ready Microscopy and Spectroscopy Data Maria K. Chan; Argonne National Laboratory, United States

The explosive growth of AI/ML in materials science has largely been fueled by computational data which are abundant, diverse, and consistent. In contrast, AI training based on experimental data has been extremely challenging due to numerous fundamental challenges in obtaining, preparing, or sharing AI-ready data. In this talk, we will discuss how we may resolve such difficulties. Strategies include creating experimentally-realistic computational data, extracting labeled microscopy [1] and digitized spectroscopy [2] data from scientific literature (now with LLM!), and establishing metadata standards in experimental microscopy and spectroscopy data, and corresponding data infrastructure. We will also discuss intricacies involved in linking computational and experimental data. The importance of both types of data in AI/ML workflows will also be discussed [3].

Sustainable Materials Acceleration Platforms—A Pathway to Democratizing AI in Materials Science Tonghui Wang[1], Lucia Serrano Lujan[2], Jacob Mauthe[1], Dovletgeldi Seyitliyev[1], Ruipeng Li[3], Milad Abolhasani[1], Kenan Gundogdu[1] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]Rey Juan Carlos University, Spain; [3]Brookhaven National Laboratory, United States

Materials scientists are called upon to solve grand societal challenges, such as climate change, by developing sustainable materials and technologies. To do so, they are rapidly adopting AI methods that may cause a severe crisis in sustainability in our research institutions. To support this shift, we have seen the emergence of materials acceleration platforms (MAPs), which automate data generation tasks and facilitate digitization of materials laboratory data by emulating human research workflows. However, while automation is proven to reduce labor, simply repeating existing costly, wasteful and environmentally harmful tasks to generate bigger datasets will exacerbate budgets and environmental sustainability problems in the short to medium terms, causing a challenge to mass adoption. A recent report by the Royal Society of Chemistry (RSC) has highlighted the need to design and adopt Sustainable Laboratory Practices that reduce the environmental impact of research by implementation of Life Cycle Assessment (LCA). Use of such design tools can also help reduce the overall cost of data generation.

Here, we discuss a sustainable MAP, known as RoboMapper, designed to generate data with an order of magnitude less cost, environmental impact and time compared to existing MAPs. The sustainable MAP is designed in conjunction with an evironmental economist using comparative LCA analysis of data generated using traditional workflows, traditional automation and alternative approaches, to identify the main bottleneck for sustainability. To our surprise, we find that materials characterization is the primary bottleneck and source of environmental impact with material waste and single use plastics following in distant second. We demonstrate how RoboMapper workflow can be implemented collaboratively in a multi-institutional setting through examples in perovskite and polymer research.

Variational Autoencoders for Multi-Objective Design of Fluorescent DNA-Stabilized Nanoclusters Peter M. Mastracco[1], Elham Sadeghi[2], Anna Gonzalez Rosell[1], Petko Bogdanov[2] and Stacy Copp[1]; [1]University of California, Irvine, United States; [2]University at Albany, State University of New York, United States

DNA-stabilized silver nanoclusters (Ag_N-DNAs) have sequence-tuned compositions and fluorescence colors.

High-throughput experiments together with supervised machine learning models have recently enabled design of DNA templates that select for Ag_N-DNAs properties, including near-infrared (NIR) emission that holds promise for deep tissue bioimaging. However, these existing models do not enable simultaneous selection of multiple Ag_N-DNA properties, and require significant expert input for feature engineering and class definitions. Moreover, NIR-emitting Ag_N-DNAs remain significantly rarer that Ag_N-DNAs with visible emission, posing additional challenges for machine learning-guided discovery. Here, we present a model for multi-objective, continuous-property design of Ag_N-DNAs with automatic feature extraction, based on variational autoencoders (VAEs). This model is generative, *i.e.*, it learns both the forward mapping from DNA sequence to Ag_N-DNA properties and the inverse mapping from properties to sequence. The VAE is trained on an experimental dataset of DNA sequences paired with Ag_N-DNAs fluorescence properties. Batch stratification is implemented to improve the model's ability to capture trends for the NIR spectral window, where training data is especially limited. Experimental testing shows that the model enables effective design of Ag_N-DNAs emission, including bright NIR Ag_N-DNAs with four-fold greater abundance compared to training data. In addition, Shapley analysis is employed to discern learned nucleobase patterns that correspond to fluorescence color and brightness. This generative model can be adapted for a range of biomolecular systems with sequence-dependent properties, enabling precise design of emerging biomolecular nanomaterials

9:15 AM *BI01.08.05

Pycroscopy and AECroscopy—Reproducible and Open-Source Workflows for Automated Microscopy Experiments Rama K. Vasudevan[1], Gerd Duscher[2] and Yongtao Liu[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Microscopy workflows are becoming incresingly complex, at times necessitating coordination between simulations, experiments, and computational resources. When attempting to automate microscopy workflows, most application programming interfaces (APIs) available from vendors are sui generis, creating yet more barriers for users who need to couple multiple instruments together for true autonomous workflows. Additionally, with increasing automation, maintaining a record of every step conducted becomes a challenge, and ensuring metadata is stored for full reproducibility is a must.

To tackle these challenges, we developed a python-based package termed 'AEcroscopy', short for AutomatedExperiments for microscopy, that consists of a hardware and software component that can be utilized to automate many different microscopes, including scanning tunneling microscopes, scanning transmission electron microscopes, and atomic force microscopes. Users can call specific functions to quickly code up their experiments in python, without need to change code for different microscopes. Moreover, the software auotmatically logs every function call made and every parameter set, to ensure reproducibility. All datasets are stored in an open source dataset object termed a sidpy dataset, which are objects built on top of dask arrays. These objects contain information relevant to the dimensionality of each variable, automatically include all the metadata, and offer features such as easy visualization, parallelization, and can be written to HDF5 files. We show examples of reproducible workflows for different systems, including sparse scanning measurements, Bayesian optimization and reinforcement learning workflows for optimized materials manipulation and physics discovery.

AI/ML in Additive Manufacturing and Polymer Synthesis for New Data and Discovery Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

Creating and curating new data appends the way we approach materials science. In additive manufacturing (AM), the fabrication of parts and objects with high complexity and high performance is advantageous over other methods. Using nanocomposites enables highly improved properties even with “commodity polymers” that do not need to undergo high-temperature processes or extensive reformulation. With artificial intelligence and machine learning (AI/ML), optimizing the formulation and manufacturing methods is possible. Using sensors capable of a feedback loop mechanism and the ability to use simulation to create digital twins, optimizing properties in record time is possible. Statistical and logic-derived design, including regression analysis, are starting points for designing experiments (DOE) or principal component analysis (PCA) in optimization and analysis vs trial-and-error approaches when working with polymer materials. In this talk, we demonstrate the approaches toward understanding nanostructuring in composites and hierarchical approaches in optimization via AI/ML and other training/learning sets for specific properties and applications, such as 3D printing and flow chemistry reactions. Introducing more sensors (monitoring instruments) in AM processes and real-time ML with online monitoring allows a feedback loop and deep learning (DL) for autonomous fabrication and data analytics.

10:30 AM BI01.08.07

Design Optimization of Additively Manufactured Anisotropic Piezoelectric Lattice Structures by Gaussian Process Modeling Aaron Rodriguez[1,1], Abdiel Cruz[1,1], Yanwen Xu[2], Sara Kohtz[3] and Anabel Renteria[1,1]; [1]The University of Texas at El Paso, United States; [2]The University of Texas at Dallas, United States; [3]Binghamton University, The State University of New York, United States

Piezoelectric materials have gained significant attention for numerous energy applications due to their ability to convert mechanical stress into an electrical response. Polyvinyl fluoride (PVDF) is a piezoelectric polymer known for its high flexibility and excellent piezoelectric properties, making it suitable for various fields including robotics, healthcare, and aerospace. However, conventional manufacturing methods have limitations in fabricating complex geometrical designs, leading to lower piezoelectric coefficients. Additive Manufacturing (AM) has emerged as an alternative for producing complex shapes with good mechanical properties. By leveraging AM, it becomes feasible to optimize designs and structures tailored to specific applications. Cellular structures represent a clear example of complex manufacturing designs achievable only through AM. Additionally, cellular structures offer a promising solution for optimizing the strength-to-weight ratio and increase directional piezoelectricity. This paper presents an optimization approach for gradient unit-cell of PVDF structures fabricated using fused deposition modeling (FDM). We propose a multiphysics finite element (FE) simulation to predict the output voltage response. Furthermore, we developed a Gaussian Process (GP)-based surrogate model using the simulation results as the training dataset with adaptive sampling techniques. The proposed surrogate model effectively predicts the output voltage of piezoelectric materials, enabling an optimum search over the design space, where we are aiming to minimize the volume while maintaining a high voltage output. The optimal results from the GP model were validated with experimental work, showing an accuracy above 90%.

10:45 AM BI01.08.08

Automating Materials Design and Scientific Discovery Through Multi-Modal Multi-Agent Artificial Intelligence
Alireza Ghafarollahi and Markus J. Buehler; Massachusetts Institute of Technology, United States

Recent advances in AI, particularly Large Language Models (LLMs), have transformed research methodologies and accelerated discoveries in materials science. Moreover, LLMs have been instrumental in powering multi-agent systems, facilitating the automation of complex problem-solving processes and integrating knowledge from external sources such as new physics from first principles. This talk presents case studies on the design of *de novo* materials, from proteins to metallic alloys, using LLM-driven multi-agent systems, demonstrating how complex multi-model materials modeling, design, and analysis problems can be solved through various examples.

A special focus will be on the use of multi-agent systems to automate advancing scientific understanding and discovery. We introduce **SciAgents**, an approach leveraging (1) large-scale ontological knowledge graphs, (2) LLMs and data retrieval tools, and (3) multi-agent systems with in-situ learning. The framework autonomously generates and refines research hypotheses, elucidates mechanisms and design principles, and discovers unexpected material properties. By integrating these capabilities, our system accelerates materials discovery by harnessing a "swarm of intelligence" akin to biological systems, unlocking nature's design principles.

11:00 AM BI01.08.09

NOMAD CAMELS—An Open-Source Solution for Creating FAIR Data from Experiments Johannes A. Lehmeyer[1,2], Alexander D. Fuchs[1,2], Michael Krieger[1] and Heiko B. Weber[1,3]; [1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]FAIRmat, Germany

In materials science and solid-state physics, a significant fraction of our science relies on highly specific self-written software for driving experiments, resulting in extremely heterogeneous data output. For facilitating homogeneous and metadata-rich research data, an easy-to use lab control software with a standardized output would be a crucial factor for data interoperability.

NOMAD CAMELS (short: CAMELS)[1] is a configurable open-source measurement software created within Germany's national research-data consortium FAIRmat. It is suited to control smaller or complex experiments and records fully self-describing experimental data. It has its origins in the field of experimental physics where a wide variety of measurement instruments are used in frequently changing experimental setups and measurement protocols. CAMELS provides a graphical user interface (GUI) which allows the user to configure experiments without the need of programming skills or deep understanding of instrument communication. CAMELS translates user-defined measurement protocols into stand-alone executable Python code for full transparency of the actual measurement sequences. Existing large-scale, distributed control systems, such as EPICS can be natively implemented. Metadata inflow from Electronic Lab Notebooks (ELNs) and data output into such is well supported for a seamless workflow. CAMELS is designed with a focus on full recording of data and metadata aligned with the NeXus ontology. Because CAMELS is open source, the community is welcome to contribute instrument drivers and alternative output data formats.

When shared with others, data produced with CAMELS allow full understanding of the measurement and the resulting data in accordance with the FAIR (Findable, Accessible, Interoperable and Re-usable) principles.

[1] A.D. Fuchs, J.A.F. Lehmeyer, H. Junkes, H.B. Weber, M. Krieger, NOMAD CAMELS: Configurable Application for Measurements, Experiments and Laboratory Systems, Journal of Open Source Software, 9 (2024).

11:15 AM BI01.08.10

Multi-Sigma—An Easy-to-Use AI Analysis Platform for Prediction and Optimization Navin Rajapriya and Kotaro Kawajiri; AIZOTH America, Inc., United States

This abstract introduces Multi-Sigma, a proprietary no-code AI analysis tool designed for multi-objective prediction and optimization. As part of our efforts to make AI more accessible to a broader research community, we have developed a free web application based on Multi-Sigma for screening molecules based on their global warming potential (GWP), an essential parameter in the development of environmentally friendly refrigerants.

The development of AI in science and engineering has progressed rapidly, but its increasing complexity often hinders its adoption in research and development (R&D). To bridge the gap between AI specialists and non-experts, we developed Multi-Sigma: a cloud-based, user-friendly software with a full graphical user interface (GUI), designed to democratize the use of machine learning for R&D.

Multi-Sigma features three core modules: Bayesian analysis, neural network analysis, and chain analysis. Researchers can train AI models with up to 200 explanatory variables and 100 target variables. Multi-Sigma's patented auto-tuning feature performs hands-free hyperparameter optimization. For experiments or processes with multiple stages, the chain analysis module allows users to link multiple AI models, where the output from one model can serve as the input for the next, facilitating complex multi-stage predictions and optimizations. We leveraged Multi-Sigma's capabilities to develop a model predicting the 100-year GWP values of greenhouse gases (GHG) and refrigerants using molecular descriptors.

The primary challenge in predicting GWP values lies in the limited availability of experimental data and the continuously evolving nature of GWP values due to varying atmospheric conditions and GHG lifetimes. The 6th assessment report (AR6) from the United Nations' Intergovernmental Panel on Climate Change (IPCC) reports GWP values ranging from zero to 25,200 over a 100-year period, reflecting the wide range and skewed distribution of data. This massive scale and skewed data distribution complicate the development of accurate models. Additionally, the small dataset of 207 samples introduces a significant risk of overfitting during hyperparameter optimization.

To address these challenges, we sought to answer several key questions essential for developing a GWP100 prediction model based on molecular structure:
○ Given the heavy skewness of the data, is log transformation appropriate, or are alternative transformations such as Box-Cox, Yeo-Johnson, or quantile transformations more suitable?
○ Would up-sampling the data help mitigate overfitting in the context of the limited dataset?
○ With multiple available molecular descriptor packages, which numerical representations (e.g., RDKit, Mordred, Alvadesc) are most appropriate for modeling GWP100?

We will leverage the statistical transformations available in Multi-Sigma's preprocessing module to evaluate and identify the most suitable methods for improving model performance. Multi-Sigma also includes functions for imbalanced data adjustment function, automatically up-sampling minority classes, and a balanced validation extraction function to ensure equal representation during model validation. We compared the performance of AI models using molecular descriptors from RDKit, Mordred, and Alvadesc.

The most accurate model resulted from a combination of Mordred molecular descriptors, quantile transformation, and Multi-Sigma's balanced validation and imbalanced adjustment functions. The resulting model achieved high accuracy, with an R^2 score of 0.913 on the original scale, outperforming previous scientific reports on GWP prediction.

This highly accurate model is now available through a free web application, allowing users to input individual molecules or lists of molecules in SMILES format to predict their GWP100 values. This tool can facilitate the identification and screening of low-GWP refrigerant candidates, contributing to the development of sustainable, ozone-friendly refrigerants.

An Open Multi-Modal Foundation Model for Materials and Chemistry Seiji Takeda[1], Indra Priyadarsini S[1], Lisa Hamada[1], Hajime Shinohara[1], Onur Boyar[1], Emilio Vital Brazil[2], Eduardo Almeida Soares[2], Flaviu Cipcigan[3] and David Braines[3]; [1]IBM Research-Tokyo, Japan; [2]IBM Research - Brazil, Brazil; [3]IBM Research - UK, United Kingdom

Short Summary:

Up-to-date as of November 14, 2024

In this talk, we present the latest status of our multi-modal foundation model (FM) for material discovery, along with our open innovation efforts in model development and community building. Our FM integrates over five modalities, including SMILES and SELFIES, providing two key functions: (1) robust feature representations for high-accuracy downstream prediction tasks, and (2) cross-modal inferences. Additionally, we are fostering an open community in the framework of the AI Alliance, bringing together industries and academia to collaboratively advance model development.

Introduction:
Artificial intelligence (AI) has been playing a critical role in materials discovery, however current applications are limited and fragmented. Existing AI models are uni-modal, focusing on specific tasks such as property prediction, molecule generation, etc. These models are often constrained by small parameter sizes (typically under 100 million) and limited datasets. Furthermore, they primarily rely on single-modal data, resulting in suboptimal performance. Redundancies in development efforts further hinder progress, as many models operate in isolation without leveraging potential synergies.
To address these challenges, we're developing a multi-modal foundation model. This model significantly enhances AI capabilities, supporing over a billion parameters and utilizing data from different modalities. By merging these data sources, our model generates richer feature representations, resulting in enhanced accuracy, higher fidelity in material generation, and integrated knowledge across various domains.

Model and Experiments:
Rather than constructing a large monolithic model, we adopted a flexible and extensible architecture by late-fusing modality-specific models, each of which is independently pre-trained. Each uni-modal model, having a transformer architecture, was pre-trained in a self-supervised manner on distinct modality data, such as SMILES, SELFIES, molecular graphs, and 3D atomic structures, extracted from public data sets including PubChem and ZINC. The latent spaces from these independently pre-trained models were subsequently fused using several approaches, including naive concatenation, Mixture-of-Experts, attention-based fusion etc., to create a multi-modal foundation model.
We evaluated the performance of these models using well-established benchmarks such as MoleculeNet and QM9, as well as domain-specific datasets including chromophore molecules. Our experiments demonstrate that the fused multi-modal model consistently outperforms existing models in classification and prediction accuracy across these benchmarks.

Community Building:
In parallel with our technical developments, we are building an open innovation community aimed at fostering collaboration between industry and academia through the AI Alliance, an open consortium. This community brings together AI and chemistry experts to advance foundation model development in an open, collaborative environment. Parts of the foundation model have been released as open-source, and to date, over ten companies and academic institutions have adopted these models. We will expand this community globally, creating the first large-scale open consortium for AI-driven materials science.

SESSION BI01.09: Knowledge Discovery, Conservation and Dissemination I

DAEMON COST Action—A Pan-European Network for Materials Discovery Acceleration Ivor Loncaric[1], Kevin Rossi[2], Milica Todorović[3] and Federico Grasselli[4]; [1]Rudjer Boskovic Institute, Croatia; [2]Delft University of Technology, Netherlands; [3]University of Turku, Finland; [4]Università degli Studi di Modena e Reggio Emilia, Italy

DAEMON (Data-driven Applications towards the Engineering of Functional Materials: an Open Network) COST action [1,2] is a pan-European network consisting of 200+ members from 40+ EU countries, which focuses on capacity-building and research-coordination efforts, with the end goal of to accelerating materials discovery in Europe by means of cutting-edge computational techniques and data-driven methods.

In this presentation, I will discuss ongoing efforts and activities of the network towards this goal. Next, I will focus on the challenges, and unexploited opportunities, that characterize materials acceleration in the specific context of a truly horizontal, inclusive, and pan-European network, together with the top-down and bottom-up level policies we aim to lobby for.

Bridging Global Gaps in AI-Driven Materials Science—Strategies for Inclusive Development Jie Liu[1,2] and Xiao Shen[3]; [1]The University of Hong Kong, China; [2]Hong Kong Quantum AI Lab, China; [3]The Australian National University, Australia

The application of AI in materials science is advancing rapidly, but significant disparities exist between different regions globally. Addressing these disparities is essential for achieving equitable development and leveraging AI's full potential in materials research. This study proposes strategies to ensure inclusive growth in AI-driven materials science:

Decentralized Data Sharing: Establish platforms where data providers can continuously benefit from their contributions. This model encourages the sharing of high-quality data, making it accessible to a broader audience and fostering global collaboration and innovation in materials science.

Equitable Access to Computational Resources: Advocate for policies and initiatives that distribute computational resources fairly. Breaking the monopolies on computational power ensures that researchers from diverse regions can participate in AI-driven materials research, promoting global equity in scientific advancements.

Industry Collaboration and Integration: Foster deep integration between academia and industry to drive practical applications of AI in materials science. Collaborative efforts can bridge the gap between theoretical research and industrial implementation, leading to significant advancements in materials development and sustainability.

We provide a detailed design and analysis of these strategies and present a case study of a digital energy storage project in China. This project illustrates the practical application of our proposed strategies and demonstrates how AI can revolutionize materials research while promoting equitable global development.

Advancing Open Science Through "DFT-ML" Tools for Materials Discovery Arun Kumar Mannodi-Kanakkithodi; Purdue University, United States

Typical materials discovery endeavors involve navigating a combinatorial atom-composition-structure space to efficiently optimize multiple desired properties at once. Today, leading materials researchers regularly utilize high-throughput computations and experiments within an autonomous and automated framework, combined with state-of-the-art data science or artificial intelligence approaches. In the Mannodi research group at Purdue University, we perform data-driven discovery of semiconductors for optoelectronic applications such as photovoltaics and photocatalysis, using high-throughput density functional theory (DFT) computations and machine learning (ML) algorithms [1,2,3]. "DFT-ML" predictive models, rigorously optimized on datasets of 10^3 – 10^4 points, enable prediction and screening over > 10^6 possible materials, orders of magnitude faster than a full computational or experimental approach. Such models are trained in a multi-fidelity manner [2] including many levels of theory and even experimental data, and within an active learning framework such that new computations are systematically performed to reduce prediction uncertainties and obtain the most promising compounds in terms of stability, defect tolerance, and optoelectronic properties.

Given the importance of training the next generation of researchers in the vital skills required for data-driven materials discovery, the aforementioned projects have been converted into multiple user-friendly tools on Github and nanoHUB—an online science gateway housed at Purdue [4]. These tools are powered by Jupyter notebooks that store all the DFT data and enable their easy visualization, contain all code necessary for training and examining ML predictions, and enable easy predictions on new data points. Our goal is to ensure that all our data and models are Findable, Accessible, Interoperable, and Reusable (FAIR) [5], which is critical for advancing research and facilitating collaboration within the scientific community. Specifically, we develop a comprehensive workflow that utilizes nanoHUB's Sim2Ls framework [6] to systematically parse DFT calculations and store them in a universally indexed database. This database is designed to be easily queried via a Python-based API, which simplifies data access and manipulation for researchers. Moreover, by integrating ML predictive models both as scripts and graphical user interfaces (GUIs), our workflow enables rapid and accurate predictions of key material properties.

In this presentation, I will discuss how we utilize the above tools for (a) discovering novel halide perovskites for optoelectronic applications and accelerating prediction of defect properties in technologically-important semiconductors, (b) sharing data and models with the community, welcoming engagement, reducing duplication of efforts, and driving future collaborations, and (c) education purposes, specifically for hands-on tutorials organized on behalf of MRS at spring and fall meetings as well as online via nanoHUB, and as exercise material in graduate courses on materials modeling and informatics. Our workflows are dynamic with new data and capabilities added regularly, and are currently being expanded to multiple materials classes and energy-relevant applications.

Siamese Equivariant Neural Network for Property Predictions of Point Defects in Solids Weiyi Gong, Zhenyao Fang and Qimin Yan; Northeastern University, United States

Computations of point defect properties such as formation energy using density functional theory (DFT) in defected materials is critical for the understanding of defect-property correlations and defected material growth mechanisms, yet the accurate and efficient calculation of defect properties remains a challenge in materials science. In this study, we introduce the Siamese Equivariant Neural Network (SENN) for predicting properties in defected material systems. We leverage E(3) equivariance to construct representations for both defects and their host crystal structures, and use the difference of the learned representations for property predictions, thereby forming a Siamese network structure. Our results demonstrate that the E(3) model surpasses previous invariant graph neural network models, and the proposed SENN further enhances the prediction performance on various defects-in-materials datasets. Our model can be applied for fast prediction of defect properties such as formation energies and beyond, which can be used for fast screening of functional defects and high-throughput computational study of defected material systems at a unprecedented scale.

10:45 AM BI01.11.03

High-Throughput Process Space Exploration Using Mesoscale Model of Microstructure Evolution During Battery Material Drying Process Zirui Mao[1], XinXin Yao[2], Lei Chen[2], Wayne Cai[3] and Shenyang Hu[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Michigan–Dearborn, United States; [3]General Motors Company, United States

Electrode drying is one of the most time and energy consuming processes in Li-ion battery cell manufacturing. As an electric vehicle OEM and Ultium battery cell manufacturer, General Motors seeks to enhance the understanding of the drying mechanisms towards producing high quality battery electrodes with reduced cost and energy usage. In this presentation, we will present an integrated modeling framework to build computational databases for exploring material process space. Coarse-Grained Molecular Dynamics (CGMD) is employed to describe the sedimentation of solid particles and solvent evaporation in the slurry including active materials (AM) particles, conductive carbon solubilized binder and solvent; Smoothed particle hydrodynamics (SPH) is used to describe the multiphase fluid dynamics in porous structures formed by active particles; and Phase-field approach is utilized to describe the species diffusion, convection and pore evolution. With the integrated model, computational database about the effect of initial and operation conditions on the evolution of temperature, drying kinetics, binder distribution and pore structure are built with high-throughput simulations. Then data-driven time-dependent deep learning is applied for the exploration of process space. The results demonstrate the capability of modeling framework for improving the understanding of drying mechanisms and optimizing the drying process parameters to achieve desired microstructures and minimize energy assumption.

11:00 AM BI01.11.04

Sim2Real Multitask Learning for Predicting Polymer and Small-Molecule Miscibility Kazuya Shiratori[1,2], Shunya Minami[3], Stephen Wu[3,2], Yoshihiro Hayashi[3,2], Hiroki Sugisawa[1], Tadamichi Okubo[1] and Ryo Yoshida[3,2,4]; [1]Mitsubishi Chemical Corporation, Japan; [2]The Graduate University for Advanced Studies, Sokendai, Japan; [3]The

Institute of Statistical Mathematics, Japan; [4]National Institute for Materials Science, Japan

The miscibility of polymers and small molecules is a critical property in applications such as plastic recycling, polymer synthesis, and purification. This miscibility is described by the free energy of mixing, derived from Flory-Huggins interaction parameters. Here, we introduces a machine learning approach to predict the Flory-Huggins interaction parameters, aiming to predict the miscibility of polymers and small molecules. The significant challenge is the insufficient and biased data due to the high cost of experiments. This limitation results in low prediction accuracy for structures in extrapolation region, where the structures in that region are dissimilar to those in the training data. To address this problem, we expanded the chemical space coverage by generating the Flory-Huggins interaction parameter data through high-throughput COSMO-RS simulation based on DFT calculations. We trained the experimentally observed and simulated data simultaneously through multitask learning. This successfully enabled predictions for the extrapolation region beyond the chemical space of the training data. Our results surpassed the accuracy of a traditional method based on the Hansen solubility parameter (HSP). Moreover, we observed a scaling law, that is, the accuracy is improved with an increased number of the COSMO-RS simulation data. We anticipate further accuracy improvement with an increased simulation dataset. Our method based on the multitask learning with high-throughput simulation data is not only useful for predicting miscibility, but also has the potential to be a solution to the small data problem that is a challenge in materials informatics.

11:15 AM ^BI01.11.05

Prediction of Aqueous and Non-Aqueous Solubility Using Machine Learning Lihua Chen, Anand Chandrasekaran, Alex Chew, Atif Afzal, Eric M. Collins, Chris Brown and Mathew D. Halls; Schrödinger, Inc., United States

Solubility, the capacity of a solute to dissolve in a solvent, forming a solution, is a crucial design parameter across various materials and life science applications. Due to the high cost of experimental measurements, we have developed quantitative structure-property relationship (QSPR) models to rapidly and accurately predict aqueous solubility in water and non-aqueous solubility in organic solvents. For this purpose, we gathered 14,485 room temperature aqueous solubility data points and 45,313 temperature-dependent non-aqueous solubility data points from literature and open-source databases. Additionally, we incorporated advanced cheminformatics-based, graph-based, and physics-based descriptors computed through classical molecular dynamics to optimize machine learning performance. These models can significantly streamline molecular discovery by providing rapid, accurate solubility predictions, reducing the need for costly experiments, and accelerating the identification and optimization of promising candidates.

11:30 AM BI01.11.06

Using Machine Leaning to Predict Key Solubility Parameters of Polydimethylsiloxane (PDMS) in Solvents Chi-Han Chiu[1], Yu-Chieh Huang[2], Zheng-Kun Yu[3], Sanboh Lee[3] and Chien-Chao Huang[4]; [1]National Applied Research Laboratories, Taiwan; [2]National Taiwan University, Taiwan; [3]National Tsing Hua University, Taiwan; [4]National Tsing-Hua University, Taiwan

Polydimethylsiloxane (PDMS) is commonly used as a key component in microfluidic systems. Given that a significant amount of microfluidic work involves the use of polar liquids, the swelling caused by organic solvent absorption can adversely affect their applications. PDMS material has the ability to absorb both volatile and non-volatile organic compounds. The extent of PDMS swelling in solvents is primarily determined by the solubility of the solvent in PDMS, particularly the solubility parameters of both the solvent and PDMS. Additionally, the hydrophobicity of PDMS is often altered to produce a hydrophilic surface and enhance wettability through surface

energy modification methods. Ultraviolet (UV) irradiation is a widely used method for polymer surface modification. UV light breaks covalent bonds, leading to degradation and the generation of free radicals, which cause changes in the surface structure, further significantly impacting the swelling of PDMS in solvents.
This study proposes a machine learning-based model to predict the solubility parameters of solvents and PDMS. The method uses two machine learning algorithms for testing: Random Forest (RF) and XG Boosting (XGB). Machine learning techniques were applied to the data collected on the swelling degree of UV-irradiated and non-irradiated PDMS materials in six different solvents. The results of the training demonstrated that both machine learning algorithms predicted the same key solubility parameters that the specific function group of solvent will affect the swelling degree of UV-irradiated and non-irradiated PDMS.

11:45 AM BI01.11.07

To Improve the Accuracy of Quantitative Metrics for Polystyrene (PS) Crack Patterns Using CNN-Based Deep Learning Models Yu-Chieh Huang[1], Chi-Han Chiu[2], Chien-Wei Chang[3], Sanboh Lee[3] and Chien-Chao Huang[3]; [1]National Taiwan University, Taiwan; [2]National Applied Research Laboratories, Taiwan; [3]National Tsing Hua University, Taiwan

Polystyrene (PS) is widely used in medical materials due to its low cost, ease of molding, good transparency, and mechanical properties. PS materials undergo expansion-contraction dynamics due to changes in water content, often forming cracks over sufficient time and stress. Distinguishing characteristic crack patterns and their dynamics, the measured geometric dynamics explain the crack formation process from a physical perspective. Quantifying structural dynamics is a prerequisite for achieving quantitative crack simulation. Studies often extract a large number of possible measurement indices from digitized images to quantify the surface cracks. They propose using fundamental geometric properties to quantify the surface area of cracks (M0), the length of cracks (M1), and the Euler number of the crack network (M2). The dynamics of crack formation are quantified through the time series of Mk, providing information about the crack formation process.
This study proposes an optimization algorithm that uses a deep learning model to reduce background noise in images of dynamic crack growth in polystyrene (PS). The goal is to enhance the accuracy of quantitative metrics for PS crack patterns. The model, based on a CNN segmentation approach, is initially pretrained with Khanhha's dataset and then fine-tuned using PS crack images. The results demonstrate that the deep learning algorithm significantly improves accuracy in measuring surface cracks, specifically crack surface area and length in 2D PS crack patterns.

Broadening Access to Accelerated Experimentation with Open-Source Hardware Brenden Pelkie[1], Maria Politi[1,2], Blair Subbaraman[1], Wm Salt Hale[1], Nadya Peek[1] and Lilo Pozzo[1]; [1]University of Washington, United States; [2]The University of British Columbia, Canada

Autonomous experimentation enables faster optimization of material properties by coupling a machine learning guided experimental design strategy with automated experimental execution workflows. Autonomous

experimentation approaches have shown real advances in developing improved materials. However, implementing the required experimental automation workflows is a barrier to broader adoption of these systems. Traditionally, automated experimentation setups require expensive automation hardware and extensive technical expertise. Community driven open-source experimental automation hardware can lower these access barriers. One example is the Jubilee platform. Jubilee is composed of an open-source motion platform with researcher-developed tools and software to enable experimental workflows. Our lab has been contributing to the development of Jubilee and learning to use it in our research. Here, I will discuss the capabilities and possibilities of integrating Jubilee into automated experimentation. I will showcase these capabilities by discussing the development of an autonomous experimentation system for the optimization of silica nanoparticle morphologies. This system integrates automated sol-gel synthesis of silica nanoparticles with small-angle X-ray scattering characterization to autonomously optimize nanoparticle size distributions. Our work demonstrates that open hardware can make autonomous experimentation accessible to more researchers.

2:00 PM BI01.12.02

AI-Generated Control Software to Democratize Automation of Materials Science Instruments Davi M. Febba, Kingsley Egbo, William Callahan and Andriy Zakutayev; National Renewable Energy Laboratory, United States

Large language models (LLMs) are one of the AI technologies that are transforming the landscape of chemistry and materials science. Recent examples of LLM-accelerated experimental research include virtual assistants for parsing synthesis recipes from the literature, or using the extracted knowledge to guide synthesis and characterization. However, these AI-driven materials advances are limited to a few laboratories with existing automated instruments and control software, whereas the rest of materials science research remains highly manual. AI-crafted control code for automating scientific instruments would democratize and further accelerate materials research advances, but reports of such AI applications remain scarce. In this presentation, we will discuss how we swiftly established a Python-based control module for a scientific measurement instrument solely through interactions with ChatGPT-4. Through a series of test and correction cycles, we achieved successful management of a common Keithley 2400 electrical source measure unit instrument with minimal human-corrected code. Additionally, a user-friendly graphical user interface (GUI) was created by ChatGPT-4, effectively linking many instrument controls to interactive screen elements. Finally, we integrated this AI-crafted instrument control software with a high-performance Differential Evolution algorithm to facilitate rapid and automated extraction of electronic device parameters related to semiconductor charge transport mechanisms from current-voltage (IV) measurement data. This integration resulted in a comprehensive open-source toolkit for semiconductor device characterization and analysis using IV curve measurements. We will also discuss the application of these tools to the analysis of IV data from a $Pt/Cr_2O_3{:}Mg/\beta\text{-}Ga_2O_3$ heterojunction diode, a novel stack for high-power and high-temperature electronic devices. We will present the challenges encountered during our interactions with ChatGPT-4, and how to evolve from this prompt-based conversation approach to an automated workflow using tools such as *LangChain*, where LLMs can effectively take control of the instrument and actively develop control solutions based on real-time tests.

2:15 PM BI01.12.03

Broadening Participation with The Autonomous Formulation Laboratory—An Open Hardware, User-Facility-Based Self-Driving Lab for Formulation Optimization Peter Beaucage, Duncan Sutherland and Tyler Martin; National Institute of Standards and Technology, United States

The Autonomous Formulation Laboratory, developed at NIST, is a flexible, open hardware and software platform for AI-accelerated design, discovery, and optimization of liquid formulations using multimodal characterization and x-ray or neutron scattering. Liquid formulations are ubiquitous, ranging from pharmaceuticals to paints, deicing fluids to dandruff shampoo. These products undergo a continuous need for (re)design driven by new active ingredients, changing regulatory landscapes, consumer demands, ingredient availability in the dynamic supply chain, etc. The platform has demonstrated typical speedups of 3-5 x vs typical human-designed grids in tackling real formulation problems in drug delivery, coatings, personal care products, and other areas, with exceptional cases yielding 25 x speedups.

The project launched in 2020 with a single robot housed at NIST and traveling to other facilities, and has since grown to a fleet of 4 NIST-owned platforms that routinely travel for measurements around the world and 3-5 platforms in existence or in the process of being built by partners. Originally built by nSoft, an industry-government consortium focused on developing neutron-based measurements for US industry, the platform has expanded to other techniques, other user facilities, and academic labs and users. This talk will focus on our experiences and lessons learned in scaling the project, broadening our contributor and user base, and outline our vision for self-driving labs that scale directly and meaningfully from sub-$10k, benchtop-scale hardware to globally unique national user facilities. We believe that the realization of this vision will result in substantially increased access to and uptake of autonomous experimentation in labs across materials science.

Materials for Energy—Quantum Chemistry Informed Data-Driven Discovery Rajeev Surendran Assary; Argonne National Laboratory, United States

A priori and reliable simulations can enable timely and cost-efficient design and discovery of materials for energy. Therefore, '*Let's Start from Computing*' is an optimal approach to initialize modern day R&D processes. In energy storage, *beyond lithium-ion (BLI) research* has the potential to revolutionize consumer electronics including portable and stationary power, transportation, and grid energy storage sectors. Multi-valent (Mg, Ca, Zn) energy storage or economically viable monovalent (Na, K) batteries, high-density metal-air, metal-sulfur batteries, or grid-storage systems are considered in the beyond lithium-ion research and development. *All these R&D efforts require significant fundamental knowledge via a priori computations for materials discovery, property prediction, and optimization*. Atomistic modeling when coupled with reliable Artificial Intelligence (AI) approaches can provide *accurate* insights to *accelerate* discovery of *optimal*electrolytes, electrodes, and membranes for BLI systems to *reduce the cost*. Thus, coupled with AI and multi-scale simulations techniques, atomistic modeling can address prediction of molecular level properties of materials (redox potentials, solvation, spectroscopic, and reactivity) to down-select *optimal materials or material combinations*. In this presentation, I will describe some of our recent efforts in active learning coupled with large scale first principles simulations to down select/optimize desired molecules for *flow battery*technology. This concept can be utilized for design of experiments using autonomous experimentation. Additionally, I will describe some of our quantum chemistry-informed molecular property predictions redoxmers and liquid organic hydrogen carriers. In addition to molecules, I will present. A data driven approach to study longer time scale diffusion of ions for multivalent battery concepts. Finally, I will describe our computational catalysis program development timeline with details of a recent data-driven approach for catalytic property prediction using high performance periodic density functional computing and deep learning .

3:15 PM *BI01.12.05
Human-AI-Machine Collaboration to Accelerate Materials Research with Autonomous Labs Milad Abolhasani; North Carolina State University, United States

Despite significant advancements in artificial intelligence (AI) over the past decade, its trustworthy implementation for materials research remains challenging. In this talk, I will present our recent work on trustworthy AI for materials research by bridging the gap between the digital and physical worlds with autonomous labs. I will discuss the importance of *optimal* human-AI-machine (robot) collaboration to truly accelerate (and not *decelerate*) research in materials science. I will discuss the ideal traits of autonomous labs where novel materials are proposed by human-AI teams and synthesized and refined by robots within a few weeks (or days). I will present how closed-loop integration of *AI co-pilots* with lab automation (robotic material synthesis) can enable human scientists to rapidly navigate the design-make-test-analyze cycle of materials research and accelerate the timeframe for discovering new advanced functional materials by 100x–1000x as compared to the *status quo*.

1:30 PM *BI02.01.01
Standing Up Innovation—Lessons from Academia to Industry Kristy Jost; Meta Reality Labs – Research, United States

Throughout my career, which has spanned fashion design, materials science, industrial manufacturing, and the tech industry, I have had the privilege to invent and innovate within the specialized yet influential field of smart textiles. Each sector has significantly influenced my approach to innovation, introducing unique challenges and opportunities that have expanded my understanding of how science and technology can be applied. I will begin by sharing specific experiences and insights from these varied environments, emphasizing the distinct differences I've encountered. Additionally, I will discuss the importance of continual learning and making unconventional connections, which have been crucial to my success and a key source of innovation.

The process of launching new ideas can vary greatly depending on the business focus and needs. I will explore key lessons learned from both successes and failures in starting new projects. This includes understanding business requirements, navigating funding and collaboration, and leveraging the varied motivations of stakeholders to support unique and significant projects. Specifically, I have led three long-term projects where establishing a strong value proposition early on was vital to managing expectations versus the actual timeline of innovation.

Finally, I will talk about my development into the tech lead and manager I am today. I will share best practices for building effective teams and managing complex projects, focusing on the critical roles of trust and clear communication. These practices have been essential in cultivating successful partnerships in both industry and academia and are invaluable even if you are not directly managing or leading a project.

2:00 PM BI02.01.02
Unlocking Mobility in Materials Science with Granular Labor Market Data Matthew Walsh; Lightcast, United States

Over the last year, materials science skills were requested in more than 220,000 job postings in the U.S. The sectors with the highest demand for materials scientists were semiconductor manufacturing, pharmaceutical manufacturing, and aerospace and defense manufacturing, though many other industries also registered demand. The median salary advertised by employers hiring for materials science skills was $105,000, but this average obscures the range of salaries available for different job titles: VPs of Development earn $400,000, Process Engineers tend to earn around the median $105,000, and sub-bachelor’s roles like Construction Materials Testing Engineers earn closer to $50,000. Additional skills that prospective materials scientists can include on their resume to earn a salary boost are computer engineering, AI/ML, metrology, and new product development. And for early-career materials scientists, a five- or ten-year career plan might begin at Quality Engineer, move through Process Engineer and Reliability Engineer, and end at Principal Engineer.

Equipping early-career scientists with granular labor market data empowers better career decisions and unlocks upward mobility. While no single participant in the labor market can see the full picture, every participant -- and indeed the field overall -- benefits from elucidating labor market trends. Lightcast, a labor market analytics firm, is the world’s leading authority on jobs, skills, talent, and labor market dynamics. Lightcast (formed by the merger of Emsi and Burning Glass) is frequently cited in leading publications such as the New York Times, the Wall Street Journal, and the Economist. **In this symposium session, Lightcast will present early-career materials scientists with the labor market data and trends that will help them navigate the market for their skills.**

Lightcast is an expert in the materials science labor force. In the last year, Lightcast produced regional and national reports on the semiconductor manufacturing workforce (for example, https://lightcast.io/resources/research/rebuilding-our-semiconductor-workforce, https://lightcast.io/resources/blog/semiconductor-workforce-strategies, and https://lightcast.io/resources/blog/specializing-in-semiconductors). Lightcast has also supported cutting-edge materials science organizations, including Manufacturing USA Institutes such as AFFOA (Advanced Functional Fabrics of America), America Makes, ARM (Advanced Robotics for Manufacturing), BioFabUSA, BioMADE, and IACMI (the Institute for Advanced Composites Manufacturing Innovation).

Lightcast is also a champion for the democratization of data. Lightcast is a pioneer in “open taxonomies” -- classification systems for skills, job titles, certifications, and more, which are available online for free. These resources can be very useful to materials scientists in the job market. There are even links to live job postings that job candidates can follow. For example, Lightcast publishes monthly data digests on materials science skills (https://lightcast.io/open-skills/skills/ES32C0E94AFC9C08A0E0/materials-science) including general materials science, polymer chemistry, and semiconductors, among others, and for materials science job titles (https://lightcast.io/open-titles/titles/ETE2630A4FC14B37F4/process-engineers) including process engineers, polymer chemists, and semiconductor engineers, among others.

In this symposium session, Lightcast will share important labor market data and trends for early-career materials scientists. This information includes but is not limited to aggregate supply and demand data, breakdowns on in-demand skills and their associated salary premia, key certifications that materials scientists can earn, possible career pathways, and information on the sectors with the most acute demand for materials scientists and the differentiating skillsets that job candidates can leverage to enter those sectors.

Pitfalls in the Career Path Towards an Establish Researcher Mmantsae M. Diale; University of Pretoria, South Africa

The path to a PhD degree has been bumpy for some, with uncertainty to future employment. In turn many PhD followers end up compromising scientific standards while pursuing the final degree. Postdoc has been a career for many Early Career Researcher (ECR) due to limited spaces in job-offering institutions. There are fellows who have been in senior postdoc positions up to four terms, reaching years of maturity without stable position. Strategies used by successful established researchers are available and requires an ECRs with open minds and initiatives to navigate through potholes. There are many opportunities for research and work to be done, with lots of funding, particularly towards climate mitigation and the ECR should be able to write funded proposal to generate own support to survive pitfall. Material Science is a very broad topic that should be used to address the United Nations Sustainable Development Goals. This talk will give prospects on the value of self-initiative by understanding the research landscape to address societal problems of the day.

From Lab Coats to Marketing Strategies—A Young Chemist's Journey from Academics to Industry Lauren Ostopowicz; Shimadzu Scientific Instruments, United States

I have experience teaching and love to educate, but do those skills translate to increasing U.S. sales numbers? I understand my research project better than anyone, but do I know how to develop marketing strategies? Do I have to forego my passions for cutting edge science when I enter a corporate setting? These are just a few of the many questions I asked myself when transitioning from academia to industry, and the answers may surprise you! In five short years I jumped from High School Chemistry Teacher to Analytical Chemistry Graduate Student and Researcher to Adjunct Professor to Product Specialist in a Marketing Department. Less than three years into my first corporate job, I was awarded Employee of the Year, my product line achieved 150% growth (best in the company), I traveled and taught people around the world, and I served on countless interview panels. I want to help you do the same or better! My goals for this talk are to share my story reflecting on what I learned along the way, discuss my unique role at Shimadzu Scientific Instruments, highlight the importance of mentors and networking at every stage, and (maybe most importantly) provide some interview tips for finding a career you love as much as I do. If I can do it, you can too!

3:45 PM *BI02.01.05

Changing My Perspective - Navigating The Transition From Academic To Industrial Research Jeffrey Cain; General Motors Company, United States

Accepting inviation to serve as panelist in BI02: Early Career Development—Insights from Academia and Industry

Mentoring—Flavors from Industry R&D, National Laboratory and Academia Jagjit Nanda[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

In a career spanning more than two decades at National Laboratories, Industry R&D and Academia, my professional journey focused both on transformational and translational research on batteries, nanotechnology and energy conversion. Personally, the career choice and opportunity provided ample scope to mentor students, postdocs and early career researchers. In my talk I will highlight the similarities and differences in mentoring early career professionals embarking their journey in National Labs, Academia and Industry. A clear understanding of overall goals, objectives and emphasis of the three different institutions will prepare early careers for a successful career path. Specific examples and cases will be highlighted in the talk.

10:30 AM *BI02.02.02

A Career at a U.S. National Lab—Perspective from a Mid-Career Scientist Anubhav Jain; Lawrence Berkeley National Laboratory, United States

I have now worked at the same institution for 13 years - Lawrence Berkeley National Laboratory in Berkeley, CA, USA - where I now run a research group of ~8 students and postdocs. There are many things I didn't know when I started my journey as a national lab scientist. In this talk, I will cover in detail the ins and outs of my job - aspects like funding, the level of administrative and committee responsibilities, and differences versus my professor and industry research colleagues. Furthermore, I will do my best to clarify that just as not all industry jobs are the same, not all national lab jobs are the same either. I will bring in stories and experiences from other national lab scientists to clarify the breadth of experiences that one might encounter in such a career.

11:00 AM *BI02.02.03

Lessons Learned from the Bench to Leadership Chris Heckle; Argonne National Laboratory, United States

There are two kinds of people in this world – those that learn from others' mistakes; and the rest of us. Come learn some common failure modes for technical people. Topics include:

Networks – what are they good for?
Communication – saying what people can hear; hear what people are saying
Intersections – explore the possibilities

Chris will share experiences as well as best practices and tips to succeed and she'd love to hear your thoughts and ideas during the panel and individual follow-ups.

Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 304

1:30 PM *BI02.03.01
Scientific Editing, Writing and Publishing—A Fulfilling Career Trajectory Gopal R. Rao; Materials Research Society, United States

While materials researchers early in their careers typically contemplate traditional academic or industry career pathways, “nontraditional” career options in science and engineering that veer away from hands-on active research can also lead to fulfilling and productive scientific careers. I will try to make the case that an active and productive scientific career in publications and publishing, including scientific editing and writing, directly influences and can have a positive impact on scientific advancement. Professional editors are scientists first and foremost, and your peers in the scientific enterprise.

Writing good papers and publishing them after peer review in scholarly journals is a crucial part of the scientific endeavor, to convey research breakthroughs and advances to peers. Without scholarly scientific publications, research results cannot be conveyed to the community in an organized and trustful way. In this talk, I will highlight my career in materials science and engineering as an example of a path that eventually led to a fulfilling professional career in scientific editing, writing, and publishing. This path took me through graduate school, a postdoc, a research position at a National Lab, on to multiple content roles at a scientific professional society (MRS), and eventually to the editorship of *MRS Bulletin*, the flagship publication of MRS. I will describe how I became interested in editing and writing early in my career during my graduate school days and subsequently was open to the possibility of a career in this area when the right opportunity came up.

As an early career materials researcher, there are many options to enter the fields of editing, writing, and publishing both scholarly publications as well as articles intended for different audiences. This begins with publishing your own research of course, but also helping others write, offering to edit and review papers of colleagues, offering to review journal papers, reaching out to journals and editors, and being open to opportunities. I will discuss these various paths. For those early career materials scientists and researchers with an inherent deep interest in writing and editing, I hope to convince them that a career as an editor is a viable option for a satisfying professional scientific career.

2:00 PM BI02.03.02
Principles of Science Communication for Early Career Researchers Steven B. Torrisi; Toyota Research Institute, United States

Communication with the scientific community is the last step of any scientific project and is uniquely important. Even the best ideas, if not shared in a well-motivated and clear manner, will struggle to gain traction among peers and future sponsors of your work. Despite this, formal instruction in the principles of communication is rarely a component of core curricula. This talk will outline some principles of scientific communication that can be used to tune your message for either a general (non-technical) or specialist audience, which is a transferable skill in industrial, academic, and governmental settings alike. Example venues and target audiences will be covered, alongside a general framework for thinking about any research project which will empower you with strategies to maximize the impact of your work.

2:15 PM *BI02.03.03
Publishing in High Impact Journals Vincent Dusastre[1,2]; [1]Université Côte d'Azur, France; [2]MRS Energy & Sustainability, United States

As Head of International Scientific Visibility at Université Côte d'Azur, my mission is to interact closely with the research community to enhance its international scientific profile and visibility. Building on my 25 years editorial experience at Nature, my role is to help researchers improve the quality and impact of their research by advising on their publication strategy and aiming to publish in highly selective international journals. Other activities involve participation in scientific and editorial workshops, seminars and masterclasses on scientific writing, editing, and communication practices to graduate and postgraduate students and researchers. As launch Editor for Nature Materials, the first Nature publication in the physical sciences, my editorial career allowed me to broaden my scientific knowledge, stay in close contact with the research community and influence the scientific, editorial, and publishing strategy of Nature. As the Chief Editor of Nature Materials, I was responsible for the multidisciplinary vision and performance of the journal while managing an international editorial team covering all aspects of materials research. On top of my outreaching activities towards a broad scientific community, I was also in charge of submissions and contributions in the areas of electrochemistry and materials for renewable energy. The journal takes an interdisciplinary, integrated and balanced approach to all areas of materials research while fostering the exchange of ideas between scientists involved in very different disciplines. The journal offers an engaging, informative and accessible product including papers of exceptional significance and quality in a discipline which will greatly influence the development of society in years to come. This presentation will aim to provide some tips and support to early career researchers about scientific publishing across a range of essential topics, such as publishing in high impact journals, editorial careers, scientific writing, communicating science to the public, and many more.

2:45 PM PANEL DISCUSSION

3:00 PM BREAK

SESSION BI02.04: Strategies for Securing Research Grants

Tuesday Afternoon, December 3, 2024
Hynes, Level 3, Room 304

3:30 PM *BI02.04.01
Research Support Opportunities at the NSF's Division of Materials Research Germano S. Iannacchione; National Science Foundation—Division of Materials Research, United States

The National Science Foundation is well-known for supporting innovative and transformative research across the disciplines throughout the careers of researchers. The Division of Materials Research (DMR) is an exemplar of this philosophy and supports fundamental materials research through a wide range of mechanisms such as the eight Topical Materials Research Programs (TMRPs): Biomaterials, Ceramics, Condensed Matter and Materials Theory, Condensed Matter Physics, Electronic and Photonic Materials, Metals and Metallic Nanostructures, Polymers, and Solid State and Materials Chemistry for single or collaborative researchers. For teams and centers level activities, DMR supports research and materials education directly as well as providing capabilities to the various communities at large. In addition, DMR's major facilities and instrumentation portfolio provides significant experimental capabilities to facilitiate cutting edge research This presentation addresses opportunities to engage with DMR either as a principal investigator on a proposal or as a reviewer.

4:00 PM *BI02.04.02
Research Opportunities at ARL's Army Research Office (ARO)—ARO Overview, Sciences of Extreme Materials Branch and The Materials Design Program Evan L. Runnerstrom; U.S. Army Research Office, United States

Dr. Evan Runnerstrom currently serves as the Program Manager for Materials Design at the United States DEVCOM ARL Army Research Office. He will present an overview of ARL and ARO and describe funding opportunities available from ARO. He will also present the research interests of ARO's Sciences of Extreme Materials Branch and describe specific research thrusts underway in the Materials Design Program. The Materials Design Program pursues new smart materials concepts through high-impact fundamental science in self-assembly, reconfigurable materials, and computer-aided materials design. The long-term goal of the program is to effect scientific advances needed in self-assembly and soft materials to enable the creation of three-dimensional materials with arbitrary geometry and composition, functionality, and dynamic reconfiguration. If successful, this program will break free of the limitations of conventional top-down processing techniques (e.g., photolithography) and enable the realization of Army-relevant 3D metamaterials; multifunctional materials; reconfigurable optics and electronics; and biomimetic shape-, color-, and texture-changing materials.

4:30 PM PANEL DISCUSSION

BI02.05.01
A Study on the Perception of Research Activities and Career Development of Korean Doctoral Students and

Postdoctoral Researchers in Material Science and Engineering Jihong Kim; Korea Institute of Science & Technology Evaluation and Planning, Korea (the Republic of)

As improving the importance of the professionals in the field of material science and engineering in industry and academia, it has been important how to manage and design the career as material scientists and engineers with serving the information to the next generations. Especially, in order to attract next generation more into material science, it is needed to investigate and consider for diversity of career the professionals with Ph.D.
In this study, in order to figure out the issues for career steps of next generation of material scientists and researchers in Korea, the perception of their research activities and career development were surveyed from doctoral students and postdoctoral researchers in the field of material science and engineering. As a result of the survey, it would be observed research activity status, such as spending time for their research activity, research type, and research collaboration, and satisfaction of their research, and career plans. Through figuring out current research activity status and desired career paths of the early career researchers, it could be expected to discuss about what they want for their career, how to think about future plan, and how to support them efficiently. Additionally, it could be also discussed about diverse career options as professionals in material science and engineering, and ways of career development.

SESSION BI02.06: Academic Pathways I
Session Chairs: Sepideh Akhbarifar and Babak Anasori
Wednesday Morning, December 4, 2024
Hynes, Level 3, Room 304

8:15 AM *BI02.06.01
Inclusive Strategy and Accomplishments of Underrepresented Minority Students in Energy Materials Research and Degree Attainment Dhananjay Kumar[1], David Schall[1] and Frank Wise[2]; [1]North Carolina Agricultural & Technical State University, United States; [2]Cornell University, United States

The North Carolina A&T State University and Cornell University PREM partnership was established in the fall semester of 2021 via the PREM SEED award for three years with the goal of creating a pathway to broaden participation of African American (AA) students at all levels in research and development of new and novel materials for energy related applications. Research was focused on integrating autonomous experiments and theory, merging physics-based models with AI models expedite the design of materials with new compositions and crystal structures which have superior (photo)electrocatalytic properties. Specifically, we developed methods of rapidly screening large crystallographic structure data sets based on experimental inputs such as x-ray diffraction data, optical and electrical properties. The tight coupling between simulation and experiment led to enhanced collaboration between the theoretical and experimental graduate and undergraduate cohorts. We believe this enhanced interaction led to a deeper understanding between both parties which led to a more cohesive team of students who felt more a part of the bigger picture.
The PREM underrepresented minority (URM) student recruitment, retention, and degree attainment record has been outstanding. The central component of the URM recruitment, retention, and degree attainment strategy was to work strictly along our chosen PREM framework. The framework started with a synergistic research plan built using the material research strengths of both NCAT and the Cornell MRSEC (CCMR). It was then followed by executing an integrated education and research program of activities guided by literature best practices and constant evaluation and assessment of the program. The key research and educational practices involved

outreach, recruitment, retention, and degree attainment activities for K-16, undergraduate, and doctoral students. These activities and efforts were designed to continuously feed the PREM pathway by means of vibrant exposure to and engagement in material research. The retention strategies involved keeping students engaged in research, encouraging them to attend professional development workshops and seminars, supporting and encouraging them to attend and present papers at conferences, motivating them to publish papers in peer-reviewed journals, and assigning a graduate student as a direct mentor to high school and undergraduate students. PREM students at all levels have been 100%, meaning that *no PREM students have left the PREM program without completing their respective degrees*.
The NCAT-Cornell PREM Seed has impacted the research and education of 14 graduate students (8 PhD, 6 MS), 13 Undergraduate students, and 4 High School students at NCAT during the award period. The PREM has also impacted over 500 students (URM: 80%, Female: 32%) via jointly teaching materials-related undergraduate and graduate new courses/course modules, organizing seminars, and conducting joint materials workshops. A large percentage of PREM students, after graduation, have already started the next step in their career path. The success story that revolves around the importance of quality and culturally responsive mentoring of students at each cross-section within the PREM pathway clearly illustrates the impact the NCAT-Cornell PREM Seed has made.

This research was supported by NCAT-Cornell PREM Seed, Collaborative Research and Education in Energy Materials (CREEM) via NSF-Partnership for Research and Education in Materials Research (PREM) grant # DMR-2122067.

8:45 AM *BI02.06.02
My Tortuous Path from an Industrial Research Lab to Academia Yue Qi; Brown University, United States

After working in industry (General Motors Research) and academia (first Michigan State University and currently Brown University), I'd like to share some of my personal experiences, observations, and thoughts to survive and thrive in both systems. The common skill sets include creating an impactful and unique research identity, building a research network, balancing life and work with priority setting; and managing mentor/mentee relationships... While there are so many choices along the journey, each has its pros and cons. Should I reach the goal via random walk or intentional preparation? Should I do the projects that I like or my boss likes? How to balance research and teaching duties? Is it possible to "have it all" or simply to catch the falling ball? I hope the discussions on the pros and cons can help to lower the stress and anxiety junior researchers face.

I have been involved in volunteering and administrative roles to promote diversity and inclusion in engineering. I'd like to discuss how can we jointly create a culture in academia, that embraces different career pathways and work-life choices, to attract women and minorities.

9:15 AM *BI02.06.03
Black Sheep—The Choice is Yours (Revisited) Suveen N. Mathaudhu; Colorado School of Mines, United States

Some may recognize that this title matches a classic 1991 track from the Black Sheep with the lyrics, “You can get with this, or you can get with that.” This rap group name represents the struggles of the members of a group who are often perceived as outliers, and the term often implies waywardness. This specific song presents listeners with concepts of key choices in life. The pathways to success for “black sheep” (may it be race, gender, ethnicity, sexual orientation, educational background, religion, physical ability, nationality and many others) are decidedly different from those who align with majority “preferable” groups across disciplines, and the Materials Science and Engineering community is not immune to these biases. Through the lens of this song and anecdotal stories, this talk will present career choices that can be made to overcome the “black sheep effect” in materials science and engineering industry and academia. Further, strategies on exploiting the factors that make one unique for positive outcomes in your research, teaching, mentoring and service activities will be discussed.

9:45 AM BREAK

10:15 AM BI02.06.04
Taking Self-Empowerment to New Levels to Accelerate Early Career Professional Development Donatella Puglisi; Linköping University, Sweden

There is an increased need of talented professionals able to lead teams and exceed goals regardless of their specific career goals and experience level. From identifying key problems and building team dynamics to innovating complex solutions and setting objectives, Agile leaders and project managers are key players in any corporate structure that thrives on efficiency, productivity, problem solving, and decision making. In academia, the importance of offering leadership training to the next generation of professionals early in their career development is overlooked. Typically, leadership courses are offered to senior scientists with staff responsibility who are already recognized by their organization as team leaders. It is like letting someone drive a car without checking that they know how to drive and then offering them a course to make sure they get their license. Said in these terms, it goes without saying that associating leadership only with certain job positions and titles is wrong. Anyone, in any career and at any career stage, can be a leader. Being a leader is a choice that involves values, vision, voice, and action. It is not something that simply happens due to a specific position, title, role or promotion obtained, but a learning process that requires skills and evolves dynamically over time. Like any other learning process, this too is faster and more effective if it starts as early as possible. Therefore, the widespread thought of considering only professionals who have reached specific positions on the proverbial corporate ladder as “leaders” as well as the common practice of offering leadership courses only to certain categories of employees need to be reconsidered to build a stronger community of future leaders.
At Linköping University, Sweden, we designed an engineering course on leadership principles and Agile management for PhD students and early career researchers in STEMM disciplines who want to gain leadership and project management skills by exploring innovative pedagogical approaches that combine challenge-, project-, problem-, and Agile-based learning. The course is offered online, in live streaming, to facilitate logistics, eliminate commuting times, and allow participation from different geographical areas. This results every year in a multidisciplinary and international team of course participants from different subject areas, departments, universities, nationalities and even continents. In this context, the valorization of diversity at an individual and collective level plays a pivotal role in fostering inclusion and best achieving the intended learning outcomes. The combination of masterclasses, lectures, preparation tips, and conventional learning materials with hands-on exercises, discussion forums, quizzes, and interactive games help create an active learning environment and increase motivation and student interaction, supported by sustained, freewheeling conversation. Class hours are alternated with remote activities to give students more control over their schedule and priorities, more freedom to reflect and respond with deeper thinking, and more sophisticated arguments than is possible in a classroom setting.
Here, we show how the proposed teaching methods and mentoring strategies lead to the development of a virtuous and engaging co-creation process that strengthens, in practice, mutual trust, open communication, active participation and cooperation between all stakeholders, transforming the classroom setting in true teamwork. As confirmed by the results achieved and feedback received from students in the period 2021-2024, the successful pedagogical approaches used help students not only to unleash productivity, motivation, and commitment or improve and accelerate strategic thinking, problem solving, and decision making, but also to better understand their work environment and work culture, which is essential for deciding their next step in

academia or transition to industry.

10:30 AM BI02.06.05

Strengthening the Academic Pipeline for Underrepresented Students via Early Exposure to Graduate Education Sebastian Fernandez, Claire Anderson, Alex M. Boehm and Daniel Congreve; Stanford University, United States

Of the 75,722 total master's and doctoral engineering degrees awarded in 2021 in the US, only 6.90% (5,222) were awarded to underrepresented minorities (URMs) according to the American Society of Engineering Education (ASEE).[1] Additionally, only 28.9% and 25.5% of the total master's and doctoral engineering degrees, respectively, were awarded to women in 2021.[1] In order to successfully teach and mentor these student populations for future graduate engineering programs, various mentorship initiatives have been developed across numerous institutions.[2,3] However, mentorship programs that target undergraduate upperclassmen (i.e., junior and senior undergraduates) might provide guidance too late to yield successful admission into graduate engineering programs.

Teaching underrepresented students the unspoken expectations of graduate school early on in their undergraduate career, coupled with a mentorship program that supports these students throughout the majority of their undergraduate years, is a viable pathway that could increase students' readiness for graduate school.

Here, we discuss the implementation of the Stanford Engineering Research Introductions Organization (SERIO), whose mission is to increase inclusion, diversity, equity, and access in engineering departments across the US by teaching, mentoring, and supporting underrepresented students as early as their first year in college.[4] By introducing early-stage undergraduate students to details regarding graduate engineering education and providing a dedicated mentorship program to support them throughout the remainder of their undergraduate career, we can measurably increase both their likelihood to pursue a graduate engineering degree and their preparedness to do so, as demonstrated by participant surveys. Additionally, we highlight both the successes and challenges regarding the activities conducted by SERIO. Lastly, we suggest future directions for peer institutions considering implementing an organization similar to SERIO in order to enhance inclusion, diversity, equity, and access in US engineering departments. Our efforts demonstrate that early-stage instruction and mentorship are effective tools towards developing talented underrepresented students for a future graduate engineering degree and will hopefully encourage more peer institutions to consider launching initiatives and organizations similar to SERIO.

The Many Hats You Need to Wear in Academia Mona Zebarjadi; University of Virginia, United States

I applied for a professorship position with a focus on research. I enjoy coding and conducting experiments in the lab, skills I acquired during my Ph.D. and postdoctoral research. However, excelling as a professor requires more than scientific expertise. You can be an exceptional scientist yet struggle as a professor. A professor must also be a good teacher, mentor, manager, and importantly, an entrepreneur and leader, not solely a good researcher. Balancing these diverse roles was challenging for me upon entering the field. Managing time effectively, optimizing every aspect of the job, and knowing when to decline tasks are crucial skills that accompany these responsibilities. In this talk, I will discuss some of these struggles and the lessons I have learned over the past 10 years of my career.

11:15 AM *BI02.06.07
So, You Want to be a Professor? Briana L. Simms; University of Cincinnati, United States

As a 3rd-year graduate student, I officially made the decision to stick with academia for my career. It made perfect sense. I love teaching. I love learning. I love research. I even love writing proposals and sharing my findings at conferences.
Even with all of these things in my mind, there was a lot that I did to prepare for becoming a faculty member. And yet, with a year of professorship under my belt, there was still a lot that I didn't know and even more that I am continuing to learn.
This talk will take you through my academic journey. I will highlight the following topics/areas: 1) How my previous research experiences led me to what I am researching now, 2) How I decided to teach at an R1 institution and found my lab home, and 3) the importance of a strategic plan and the things I do to stick to it. I'll highlight the highs and lows of the professoriate (as I know it) and the things I wish I knew before starting this role.

The Faculty Career Journey Begins with a Single Step David F. Bahr; Purdue University, United States

Finding a faculty position reads a little like a choose-your-adventure story; there are many ways to get to success and more ways to get to pitfalls. This presentation aims to de-mystify the application to interview stages of a career search and cover the steps involved in that process. Given that there are more people "doing materials" than faculty in "materials departments", the differences between an MSE-only and a more shared model will be examined. Common points in application materials for faculty positions for a range of departments, schools, and universities will be noted; in particular the presentation will highlight the need to demonstrate independent thought and ownership of research activities, maturity and dedication to education at the appropriate level of the institution and articulating a vision of career success at both short- and long-term time scales. The presentation will cover the "letter" to "on-site interview" stages of the journey and will emphasize the need to identify the audiences at various stages.

2:00 PM *BI02.07.02
Navigating Academia Across Continents—Balancing a Global Academic Career with Family Life Christine Luscombe; Okinawa Institute of Science and Technology, Japan

In an increasingly globalized world, the pursuit of an academic career often entails crossing geographical and cultural boundaries. This talk will explore the multifaceted experiences of navigating starting in Japan, then a formal education in the United Kingdom, starting my independent career in the United States, and then finally returning to Japan. In addition to running a lab, I had had the opportunity to lead outreach activities and take on leadership roles within universities. Drawing from personal experiences, this presentation aims to provide insights into the unique challenges and rewards of an international academic journey and offer some advice of integrating professional and personal life. The talk will share anecdotes and reflections on managing the dual roles of being a dedicated academic and a present parent. Strategies for time management, setting boundaries, and maintaining mental and physical well-being will be discussed, although I will fully admit that I often fail. The aim is to provide a realistic portrayal of the trials and triumphs of balancing a demanding career with the joys and challenges of raising a family.

10:30 AM *CH01.01.01

Process Monitoring and Near-Surface Control Using *In-Situ* Characterizations in Microelectronics Applications Remy Gassilloud[1], Christophe Vallee[2], Nicolas Posséme[1], Thierry Chevolleau[1], Marceline Bonvalot[3], Stephane Cadot[1] and Bernard Pelissier[3]; [1]CEA-Leti, France; [2]University at Albany, State University of New York, United States; [3]Université Grenoble Alpes, France

In advanced electronic devices in particular field effect transistors (FETs), thin films materials are commonly processed at atomic scale. The thickness control and uniformity over large surface are reaching atomic limits where the surface properties become dominant on bulk or volume counterpart. As example, we use to process 2nm-thick materials, such as HfO_2-dielectric as gate-material in transistor production, with a control below $\sigma<1\%$ in thickness deviation on 300mm silicon wafer. Moreover, the control in thickness is now close to the atomic roughness, not only at the surface but also between layers at interfaces. Another good example is the sputtered depositions of advanced Al or La angstrom-scale encapsulated layers in metal nitrides to adjusted transistors threshold voltages using dipoles formation. In such technology, very thin 5-10A layers are sandwiched in the metal gate, and one must insures that the thin doping layer is continuous at angstrom scale. The geometric inspection of such layered materials has becoming a challenge, in particular when a “reactive” surface is exposed to air-break between processes. This in turn may affect device performance and yield. For example, trace of organic contaminants and water potentially absorbing on the surface of wafers have become an increasingly critical issue, such in equivalent oxide regrowth in MOS gates. *In-situ* or *quasi-insitu* characterizations solutions have been developed to limit these adverse effects, and to help the process engineers to monitor their processes.

In this presentation, we will illustrate the status regarding *in-situ* deposition processes monitoring, by showing three practical examples. The first one will address *in-situ* process monitoring using optical emission spectroscopy (OES) used to monitor plasma properties in plasma enhanced atomic layer deposition (PEALD) of tantalum nitride gate materials for FETs. In this first example, the beneficial effect of adding a weak low frequency (LF) power to the RF power was correlated to a modification of the precursor fragmentation as observed by OES monitoring of the plasma during deposition. Then, we will introduce the concept of quasi *in-situ* transfer, using a specific substrate carrier keeping high quality static vacuum between process and/or analyses tools. We will illustrate this concept by a study we performed on metal nitride and 2D-sulphides growth by ALD, and where we followed the surface modifications half-cycle by half-cycle during atomic growth by X-ray photospectrometry. In the third example, we will show some examples of *in-situ* residual gas analysis (RGA) to monitor reactive gas flow rate in vacuum chambers and to evaluate the amount of water in a liquid thiol-based chemical precursor. We will explain the limits of such RGA in reactor’s technical implementation, and give some insight for future improvements.

Finally, we will conclude and give some perspectives and future trends, where we adapted current *in-situ* solutions to monitor doping of Al and La in nitride layer for advanced sub-10nm node FETs

***In Situ* Monitoring of Self-Assembly and Self-Healing of Molecular Layers Using the Photothermal Deflection Spectroscopy** Maximilian Hupfer, Sarah Jasmin Finkelmeyer and Martin Presselt; Leibniz Institute of Photonic Technology, Germany

Monolayer self-assembly provides a robust approach to achieve thermodynamically stable surface functionalization in molecule-surface-solvent systems. Despite its advantages, routine methods for real-time monitoring of self-assembly (SA) are limited. In this work, we present the application of photothermal deflection spectroscopy (PDS) as an innovative technique to study the in situ self-assembly of monolayers.[1]

PDS allows us to determine SA kinetics over a measurement area of a few square micrometers, with photothermal deflection spectra being directly proportional to absorption spectra. This capability allows the detection of short-range molecular order and the identification of J- or H-aggregates of dye molecules by their distinct spectral signatures. Unlike other methods, PDS is not affected by light scattering or reflection, has high surface sensitivity, and is not limited by the spectral sensitivity of the detector.

Leveraging these advantages, we have used PDS to develop a novel approach for self-healing of molecular layers degraded by light exposure. This advance makes PDS as a versatile tool for in situ characterization of self-assembled monolayers. Our results demonstrate the efficacy of PDS in providing critical insights into the dynamics and stability of self-assembled monolayers, paving the way for improved surface functionalization techniques in various applications.[1,2]

Real-Time Coherent X-Ray Scattering Studies of Plasma-Enhanced Atomic Layer Deposition Thin Film Growth Karl F. Ludwig[1], Peco Myint[1,2], Jeffrey Woodward[3], Chenyu Wang[1], Xiaozhi Zhang[4], Lutz Wiegart[5], Andrei Fluerasu[5], Randall L. Headrick[4] and Charles R. Eddy, Jr.[3]; [1]Boston University, United States; [2]Argonne National Laboratory, United States; [3]U.S. Naval Research Laboratory, United States; [4]The University of Vermont, United States; [5]Brookhaven National Laboratory, United States

Real-time x-ray studies of surface growth processes using “low-coherence” x-ray sources have proven to be a powerful tool for studying average surface evolution during thin film growth processes. Enabled by the continued increase in accelerator-based x-ray source brightness, however, coherent x-ray scattering experiments are sensitive to fluctuations around the average, revealing dynamics information not accessible through “low-coherence” x-ray scattering or, typically, through any other means. We discuss recent studies utilizing the coherent scattering technique of X-ray Photon Correlation Spectroscopy (XPCS) to examine the epitaxial plasma-assisted atomic layer deposition (PEALD) of InN [1]. XPCS uses the evolution of the x-ray scattering speckle pattern in reciprocal space to obtain detailed information about the microscopic evolution of the sample. It shows that the plasma exposure component of the growth cycles does not simply freeze in a structure that is then built upon in subsequent cycles. Instead, there is significant surface evolution throughout all parts of the PEALD growth cycle, including gas purge periods.

Integrated Methods for Plasma and Surface Monitoring in Complex Etch Applications Sergey Voronin, Qi Wang, Nicholas Smieszek, Carl Smith, Hamed Hajibabaei, Akiteru Ko and Christophe Vallee; TEL Technology Center, America, LLC, United States

The continuous shrinkage of critical dimensions, introduction of new materials, and increase of integration complexity in semiconductor technology imposes stringent requirements on plasma processing techniques. A fundamental understanding of the plasma-surface interaction mechanisms in these applications is paramount to enabling better etch performance and developing novel solutions to complex processes. These challenges necessitate modern surface and gas phase diagnostic techniques to meet these complex requirements and drive advancements in technology. Examples include comprehensive surface analysis without vacuum break, precise in-situ etch and deposition rate measurements and control, plasma parameter diagnostics, and charged and electrically neutral species transport analysis. In this presentation, we describe these diagnostic methods and techniques, their practical utilization for different etch applications (including vertical and lateral etch for “3D”), and their resulting correlation and analysis.

***In-Situ* Observation of Reaction Layer in Surface for Damage-Free Atomic Layer Etching** Tsutsumi Takayoshi[1], Hiroki Kondo[2], Makoto Sekine[1], Kenji Ishikawa[1] and Masaru Hori[1]; [1]Nagoya University, Japan; [2]Kyushu University, Japan

The atomic layer etching (ALE) process, which is advantageous because of its atomic-scale precision and damage-free, uniform processing, is expected to be one of the processes used to achieve the aforementioned requirements. Here, “damage-free” etching means that the defect density in surface is maintained before and after the etching process. Although ALD is an effective method for forming thin films layer by layer, it is not capable of depositing films with high crystallinity. Therefore, CDE and ALE will be important processes for etching while maintaining the defect density. It is required to investigate the surface reaction mechanism by atomic-scale surface observation. Changes in crystal structure after ion bombardment have been reported by simulations, and it has been reported that ion-induced damage can extend over several layers. [1,2] However, experimental investigation has not yet been reported. This is because surface analysis equipment with atomic-spatial resolution is required to observe the damage formation mechanism. Furthermore, surface contamination due to air exposure of the surface interfere with the elucidation of the reaction model. We have reported that reaction layer in surfaces irradiated by ions and radicals in ALE have been analyzed by various *in-situ* analysis system, and highlights the importance of *in-situ* analysis. [3-5] It is necessary to perform all surface analysis by *in-situ* system. Horiike group had performed atomic layer etching (ALE) for Si by alternating CF_4/O_2 and Ar plasma in 1990. [6] Fluorinated Si layer is desorbed by Ar ion bombardment as volatile species like SiF_4. However, the ion bombardment induces several damages in a reaction layer within a few nanometers. Processed samples should be transported from a reactor to a surface analysis chamber without exposure to air in order to investigate the reaction layer. We report changes in the crystal structure of Si (111) surfaces during dry etching and Atomic Layer Etching (ALE) processes, which have rarely been reported. [7] The observation requires the elimination of a small amount of surface contamination, which we achieved by developing a sample transfer system to move the sample with keeping high vacuum level between the STM/AFM atomic resolved surface analyzer and the plasma reactor. The etching Si by F radicals occurred while forming a few atomic layers of fluorination layer. The layer was completely removed by heating and restored to its original crystal structure without any damage. This is a very effective process for manufacturing advanced semiconductor devices. Furthermore, it was found that irradiation with Ar ions, which have energies lower than energy threshold of sputtering, did not destroy the crystal structure. However, the combination of F radicals and Ar ions simulating ALE did not recover the crystal structure, and holes with a depth of sub-nanometer were formed on the surface. We experimentally elucidated that atomic-scale damage occurs in the reaction layer and that this damage inhibits the reconstruction of the crystal structure, such as the formation of reaction layers consisting of several atomic compositions and the destruction of the crystal structure. A damage-free ALE requires a process that does not generate such damage.

Width-Dependent Self-Heating Properties in Self-Aligned Top-Gate InGaZnO Thin-Film Transistors Kyuhyun Kim, Hyeonseo Lee and SeungHyun Oh; Kangwon National University, Korea (the Republic of)

As the display industry trends towards higher pixel densities, managing heating and temperature variations within panels becomes increasingly crucial. In this context, our study explores the width-dependent self-heating effects in self-aligned top-gate indium-gallium-zinc oxide (InGaZnO) thin-film transistors (TFTs). By varying the channel width from 21 μm to 105 μm, we systematically analyze the self-heating properties of these transistors under different operational conditions.

Utilizing infrared thermal microscopy and electrical characterization, we detect significant variations in self-heating across different channel widths. Our findings indicate that wider channels experience higher temperature increases at the same input power density (also known as thermal resistance, R_{th} [m^2K/W]), which correlates with increased electrical stress and potential reliability concerns. This result can be better understood by observing the width-normalized I_{ds} plot. Theoretically, width-normalized I_{ds} should show no width dependence, but there is a width dependence in the real device. We observed that as the channel width decreases, the influence of edge effects increases, whereas as the channel width increases, the impact of self-heating becomes more pronounced. Additionally, we examine the impact of self-heating from a single device to the array platform, incorporating thermal resistance values and numerical heat transfer simulations. The results underscore the pivotal role of device geometry in thermal management and performance in TFTs, providing key insights for designing more reliable and efficient electronic devices based on InGaZnO.

This research offers a foundational understanding of self-heating phenomena in TFTs, which is critical for optimizing device architecture and enhancing the performance of next-generation flexible electronics

***In-Situ* Studies of the Electrodeposition of Polymer Networks as Conformal Ultrathin Coatings** Joerg G. Werner, Wenlu Wang, Zhaoyi Zheng and Ruiyang Chen; Boston University, United States

Most natural systems, synthetic materials, and devices feature thin films and interphases that control the flow of mass and energy or stabilize incompatible materials. Thin-film coatings on planar and macroscale structures are enabling and performance-determining in technologies such as electronics, structural composites, touch screens, and even simple commodities such as sunglasses. Polymer networks are of particular interest for their tunable chemical and physical properties combined with their structural integrity. With technologies transitioning to non-planar and three-dimensional architectures, novel deposition methods for realizing conformal thin films are required. To this end, we introduce the Electrodeposition of Polymer Networks (EPoN) as a general approach to uniformly coat polymeric thin films on planar and non-planar conductive materials alike. Conceptually, EPoN utilizes electrochemical crosslinkers as a minority component as low as 1% of the polymer to confine the network formation exclusively to the surface upon charge transfer, yielding a passivating and self-limiting growth of conformal and uniform thin films with tunable 10-500 nm in thickness. Generally, the modular polymer design allows for the decoupling of the thin film functionality from its deposition chemistry, though we find that the thin film properties are also dependent on the deposition protocol and conditions. To understand these composition-processing-property relationships of our novel EPoN concept and the derived thin films, we investigate their growth in situ, including deposition in Electrochemical Quartz-Crystal Microbalance with Dissipation (E-QCM-D). In these studies, we find a substantial influence of the deposition potential on the thin film growth stages, including the solvent-film interactions during growth, for example, which alter the resulting thin film properties such as thickness and permeability. The knowledge gained from our in-situ growth studies enables further tunability of the thin film properties, and also broadens the applicability of EPoN to various polymer architectures and electrochemical crosslinkers by providing general design criteria.

Chemical Triggers Behind Pt Nanoparticle Growth During Post-Deposition O_2 Annealing by *In Situ* Near-Ambient Pressure X-Ray Photoelectron Spectroscopy Matthias Filez[1], Matthias M. Minjauw[1], Eduardo Solano[2], Giulio D'Acunto[3,4], Payam Shayesteh[3,4], Joachim Schnadt[3,5], Christophe Detavernier[1] and Jolien Dendooven[1]; [1]Ghent University, Belgium; [2]ALBA Synchrotron, Spain; [3]Lund University, Sweden; [4]Stanford University, United States; [5]MAX IV, Sweden

Nanoparticles (NPs) are crucial in a manifold of applications, owing to their plasmonic, magnetic and catalytic properties. In the past decades, increasingly advanced fabrication methods have been developed – such as ALD[1] – to atomically tailor the structure of NPs, thereby fine-tuning their functional properties. However, during application, as-deposited NPs can undergo significant restructuring, such as NP growth or shape changes[2], thereby perturbing the initial performance. In such cases, the as-deposited NPs evolve from their metastable initial state to the global minimum of the Gibbs free energy landscape. As a result, rationalizing and controlling the nanoparticle changes during operation is equally important as advancing the tailoring precision of nanofabrication techniques.

Herein, we explore *in situ* synchrotron-based near-ambient pressure X-ray photo-electron spectroscopy (NAP-XPS) to understand the chemical triggers behind Pt NP growth during post-synthesis O_2 annealing (50–500 °C, 1 mbar O_2). Such study finds relevance in the field of catalysis, where high temperature/pressure gas treatments induce atomic mobility and NP growth during the operation of catalysts, such as archetypal SiO_2-supported Pt NPs. From NAP-XPS, the chemical state of the NPs is probed from spectral signatures at relevant edges (Pt 4f, O 1s, C 1s, N 1s), while the relative coverage of the Pt NPs on the surface oxidized Si substrate is extracted from the

Si 2p intensity. Before annealing, Pt NPs with controlled size and spacing are deposited on a SiO_2/Si wafer by applying the $MeCpPtMe_3$-O_2 and $MeCpPtMe_3$-N_2 plasma (N_2*) ALD processes[3] at 300 °C.

When annealing the Pt NPs deposited with the O_2-based Pt ALD process, the initial C-layer on the Pt NP surface is burned around 200 °C. This yields metallic Pt NPs terminated with chemisorbed O-adatoms (~0.25 ML coverage). From 400–500 °C, the Pt oxidation state increases gradually but significantly from Pt^0 to Pt^{+x}, resulting from thermally-activated Pt oxidation deeper inside the Pt NP sub-surface, yielding a Pt-PtO_x core-shell structure. However, surprisingly, Pt oxidation beyond 400 °C does not lead to atomic mobility and concomitant NP growth, which was expected from mobile (partially) oxidized PtO_x species. Quite the opposite, mild Pt NP growth takes place gradually at the start of annealing at 50 °C, even upon the presence of the C-surface layer.

The annealing process of the Pt NPs deposited by the N_2*-based ALD process behaves markedly different. First, the as-deposited state of the Pt NPs consists of oxidized Pt^{+x} species with CN-type ligands – still resulting from the N_2*-based ALD process. This metastable state decomposes upon thermal activation at 300 °C in O_2, yielding more stable metallic Pt NPs with chemisorbed O-adatoms (~0.25 ML coverage). Subsequently, as for the NPs of the O_2-based ALD process, these metallic Pt NPs transform into Pt-PtO_x core-shell particles by sub-surface Pt oxidation beyond 400 °C. During this annealing process, sudden atomic mobility of Pt and NP growth is observed upon fast decomposition of the oxidized Pt-CN phase into metallic Pt NPs. Again, no significant NP growth is observed upon Pt-PtO_x core-shell formation, identical to the mechanism observed for Pt NPs deposited by the O_2-based Pt ALD process.

This study shows that the chemical nature of the as-deposited phase by ALD can strongly depend on the ALD processes applied for its fabrication, in casu yielding metal Pt NPs with C-layer versus oxidized Pt-CN-type NPs. The initial, metastable state of these NPs will determine its pathway through free energy space, and hence result in different chemical mechanisms to evolve to a global minimum of the Gibbs free energy landscape.

In Situ Monitoring of Thin Film Growth by PECVD Using Time Resolved Ellipsometry and Plasma Diagnostics

Agnes Granier[1], Antoine Goullet[2], Simon Chouteau[2], William Ravisy[3], Maria Mitronika[4], Luc Stafford[5] and Mireille Richard-Plouet[1]; [1]Centre National de la Recherche Scientifique, France; [2]Université de Nantes, France; [3]HEF, France; [4]Infineon Technologies AG, Austria; [5]Université de Montréal, Canada

Although thin film deposition by plasma processes has been investigated for many years and is currently used in many industrial areas, the plasma surface interaction mechanisms are still not fully understood due to the fact that each case of deposition is unique. More recently, nanocomposite thin films consisting of nanoparticles embedded in a solid thin film matrix, have attracted growing interest as multifunctional coatings. Their high tunability have made them great candidates for various applications where innovative simultaneous properties are needed.
In this talk I will focus on experiments carried out in the case of thin oxide films deposition in a low pressure plasma enhanced chemical vapor deposition (PECVD) process based on an inductively coupled RF plasma source

(ICP) [1]. This reactor is equipped with a UV-visible spectroscopic ellipsometer in order to monitor *in situ* the film growth whereas the plasma is investigated by optical emission spectroscopy (OES). I will mainly consider two studies of thin film growth: photocatalytic TiO_2 thin films deposited at low temperature and nanocomposite thin films made of TiO_2 nanoparticles embedded in a silica matrix.

In the case of TiO_2 deposition at low temperature (< 120°C), real time *in situ* spectroscopic ellipsometry (RTSE) was used to study the growth kinetics and to monitor the film structure as a function of the deposition time, e.g. the film thickness. In the deposition conditions considered (O_2/TTIP plasma, 3 mTorr, 400W) *ex situ* analyses by Scanning Electron Microscopy (SEM) and transmission electron spectroscopy (TEM) have shown that anatase was obtained. Nevertheless SEM and TEM analyses performed for different film thicknesses have shown that the coalescence of large polycrystalline columns emerging from an assembly of thin columns happened at a critical thickness, designed as coalescence thickness. It was shown that this latter can be determined from RTSE analysis: it corresponds to a slope change in the variation of the film roughness as a function of the film thickness (as measured by RTSE). The coalescence thickness was shown to depend on the deposition conditions and was measured to be about 150 nm in an oxygen rich O2/TTiP 98:2 ICP plasma at a rf power of 400 W. In addition, the formation of large columnar structure was shown to be associated with an important increase in the photocatalytic activity. [1].

The approach retained for nanocomposite deposition was a hybrid deposition process, combining low-temperature plasma deposition and pulsed injection of colloidal solutions. More precisely, a monodisperse TiO_2 nano-colloidal solution was injected in the form of droplets in the low-pressure ICP plasma operated in O_2/HMDSO gas mixtures for the growth of a SiO_2 thin film matrix. The colloidal droplets were used to deliver the nanoparticles to the substrate while protecting them from the reactive plasma. Ideally, the liquid solvent evaporates during transport, leaving nothing but the nanoparticles on the surface of the sample, which will be quickly covered by the continuous deposition of the matrix.

Plasma pressure, time-resolved optical emission spectroscopy and *in situ* RTSE were used to examine the kinetics driving nanocomposite thin film deposition. It was found that the sharp pressure increase following pulsed liquid injection lowers the electron temperature and density, which mitigates the matrix deposition rate as the nanoparticles are supplied to the film. This effect creates alternating matrix-rich and nanoparticles-rich deposition periods, which can be used as an additional knob for judicious control of the nanoparticle fraction in the film and hence its macroscopic properties [2].

Analyzing Synthesis–Structure Relationships in Epitaxially–Grown Semiconductors with Quantum and Classical Supervised Machine Learning Andrew S. Messecar[1], Steven M. Durbin[2] and Robert A. Makin[1]; [1]Western Michigan University, United States; [2]University of Hawaii at Mānoa, United States

Thin film crystal growth experiments occur within highly multidimensional processing spaces often defined by sets of multiple experiment design parameters. Identifying the optimal values for each synthesis parameter is conventionally performed through an Edisonian, trial–and–error approach to experiment design that is often costly in terms of both time and resources. Considerable interest exists in the development of machine learning–based methodologies for the rapid and accurate identification of optimal materials designs and synthesis conditions that result in material samples exhibiting target properties of interest.

In this work, data detailing several hundred distinct plasma–assisted molecular beam epitaxy (PAMBE) thin film crystal growth trials of ZnO as well as various nitride semiconductors have been organized into separate, material composition–specific data sets. For each growth record, the complete set of experiment parameters (substrate temperature, metal source effusion cell temperatures, plasma source forward power, growth duration, etc.) are associated with binary measures of crystallinity (1 for monocrystalline, 0 for polycrystalline) and surface morphology (1 for atomically flat, 0 for uneven) as determined by *in–situ* reflection high–energy electron diffraction (RHEED) patterns. A Bragg–Williams derived measure of lattice ordering ($0 \leq S^2 \leq 1$) is included as an additional, continuous figure of merit for investigation. Calculations of p–values, Pearson's correlation coefficient, and decision tree splitting rules are utilized to assess the PAMBE operating parameters which are most statistically influential upon each of the three structural metrics. From these analyses, substrate temperature and nitrogen chamber pressure are determined to be most statistically influential upon the crystallinity of epitaxially–grown GaN thin film crystals as assessed via RHEED patterns. In the case of epitaxially–grown ZnO thin film surface morphology, the settings of oxygen gas flow rate and zinc effusion cell temperature are found to be the most statistically important operating parameters. Radio frequency plasma settings and substrate temperature values are shown to be influential upon S^2 in epitaxially–grown thin film crystals of ZnO as well as GaN.

Quantum as well as conventional supervised machine learning algorithms – including logistic regression, tree–based models, and quantum support vector machines – are trained on the data in order to investigate the relationships between the PAMBE process parameters and resulting sample crystallinity, surface morphology, and measured S^2. When predicting the occurrence of monocrystalline GaN via PAMBE, supervised learning algorithms designed to incorporate quantum computers display significant advantage over their classical machine learning counterparts. Predictions of InN crystallinity are most accurately made by an optimized and trained k–nearest neighbors algorithm. The class conditional probabilities of obtaining monocrystalline and atomically flat thin film crystals are predicted across processing spaces of the two PAMBE synthesis parameters determined to be most statistically significant, and S^2 is also forecasted across the same growth spaces. These predictions are compared to conventional experimental wisdom as well as the results described within published literature regarding the PAMBE synthesis of these materials. The predictions indicate that different growth conditions are of interest depending on whether a single crystalline sample, a flat surface, or a well–ordered lattice is the most desired outcome. The superior generalization performance displayed by the quantum machine learning algorithms when predicting GaN crystallinity implies the potential for quantum machine learning algorithms to be beneficial for studies of synthesis–structure relationships in other material systems.

Photo-Assisted Atomic Layer Deposition of Pt—An *In Situ* X-Ray Scattering and Fluorescence Study of the Nucleation and Growth Juan Santo Domingo Peñaranda[1], Jolien Dendooven[1], Ville Miikkulainen[2], Sylwia Klejna[3], Eduardo Solano[4], Martin Rosenthal[5], Zeger Hens[1] and Christophe Detavernier[1]; [1]Ghent University, Belgium; [2]Aalto University, Finland; [3]AGH University of Krakow, Poland; [4]ALBA Synchrotron, Spain; [5]European Synchrotron Radiation Facility, France

Atomic layer deposition (ALD) has emerged as a powerful method to grow nanostructured noble metals such as Pt. Its capabilities to tailor the morphology from nanoparticles to thin films and to coat 3D substrates conformally are highly desired in electrical, catalytic and electrochemical applications. For ALD of Pt with the (methylcyclopentadienyl)trimethylplatinum ($MeCpPtMe_3$) precursor, previous work has shown that the choice of reactant has considerable impact on the nucleation [1]. The commonly used O_2 gas leads to the formation of mobile PtO_x species, responsible for the coarsening of nuclei into larger particles during the initial growth regime. In contrast, surface diffusion is suppressed with N_2 plasma as reactant and a high density of small islands is obtained, leading to films with a smooth surface when the islands coalesce into a continuous layer [2].

Photo-assisted ALD is a variant of conventional thermal ALD in which additional energy is provided to the reactions by exposing the sample to UV light [3]. Absorption of photons by precursor molecules in the gas phase or adsorbed on the surface can lead to excitation and even dissociation of the molecules, yielding active species that enable or speed up thin film growth. Photo-activation may also allow for lower deposition temperatures, increased growth rates and modified film properties. However, despite the fact that promising advantages of photo-assisted ALD have indeed been demonstrated, the number of reports using photo-assisted ALD is limited.

In this work, photo-assisted ALD of Pt is investigated for the first time by implementing UV-illumination during $MeCpPtMe_3$-O_2 ALD. The nucleation and growth are investigated *in situ* via X-ray fluorescence (XRF) and grazing incidence small angle X-ray scattering (GISAXS) at the BM26 beamline of the ESRF synchrotron, yielding the Pt surface density (#Pt atoms/cm^2) and size and coverage (#nuclei/cm^2) of the nuclei, respectively.

For all temperatures tested, the *in situ* growth curves reveal a significant increase in Pt deposition when the UV-illumination is turned on continuously during the ALD process. To understand the effect of photo-assistance during each ALD step, the timing of the illumination in the ALD cycle is varied, and it is found that illumination during the $MeCpPtMe_3$ exposure triggers the growth enhancement. This suggests that the precursor is activated in the gas phase prior to adsorption, potentially via dissociation of the Pt-Me bonds [4], enabling a larger Pt uptake on the surface.

Remarkably, depositions in which a number of photo-assisted ALD cycles is followed by thermal ALD also show a drastic increase in Pt uptake, even if only few photo-assisted ALD cycles are carried out. This confirms a crucial role for the UV-light in the nucleation process. The *in situ* GISAXS patterns revealed that a larger amount of smaller islands is formed with photo-assisted ALD compared to conventional thermal ALD, indicative of an increased nucleation density. This shows that UV-light is a promising external trigger to control nucleation during noble metal ALD.

Damage Analysis in Proton-Irradiated Barium Titanate Single Crystal Using Rutherford Backscattering Spectrometry/Ion Beam Channeling Darshpreet Kaur Saini, Todd Byers, Mohin Sharma, Mritunjaya Parashar, Gary A. Glass and Bibhudutta Rout; University of North Texas, United States

Ferroelectric materials such as barium titanate ($BaTiO_3$/BTO) have garnered enormous interest for various applications, such as in semiconductor devices, and nonlinear optics due to their remarkable properties that include large pockel coefficients, high dielectric constant, and good thermal stability. These properties enable its use in high optical switching devices, fabrication of transducers, and fast modulation in photonic devices like interferometers and biosensors. In order to optimize the optical modulator performance metrics such as RF loss and optical loss, a thin membrane of BTO with ~500 nm thickness is bonded to a waveguide patterned silicon-on-insulator (SOI) wafer. Over the last couple of decades, ion beam exfoliation or smart cut techniques have been employed in Si, InP, SiC, $LiNbO_3$, $SrTiO_3$, and BTO crystals to lift-up thin layers from single-crystal wafers [1-2]. In general, this technique employs an energetic light ion beam (typically H or He ions) to induce damage at a certain depth inside the crystal which is later exfoliated as a thin film. Since it uses an energetic ion beam, the damage and artifacts are introduced inside the region of interest as a by-product of ion irradiation affecting the crystalline nature of the film which needs to be studied carefully before any further application. For the damage or crystallinity analysis, Rutherford Backscattering Spectrometry in channeling orientation (RBS/C) is an excellent technique to characterize elemental compositional depth profile and their crystalline quality. RBS/C involves aligning substrates along their crystallographic axis with the incident ion beam (typically 1-3 MeV He^+) direction which reduces the backscattering yield drastically. The ratio between the backscattering yield in a channeling direction and a random direction provides a quantitative analysis of the crystallinity and the degree of damages caused by ion implantation/irradiation. In the present work, proton implantation at 300 keV with varying fluences has been studied in the BTO sample to create targeted damage layers (in the range of 500-1500 nm) for thin film exfoliation. Additionally, the nature of damages, defects and recovery in crystallinity of the sample with thermal annealing is further analyzed with subsequent in-situ ion channeling technique. The results from this study will help in optimizing the fabrication procedure for the thin film BTO.

***In-Situ* Characterization of High Aspect Ratio Plasma Processing Through Manipulation of C_4F_8 Plasma Gas Phase Interactions** Austin D. Krauss and Christophe Vallee; University at Albany, State University of New York, United States

Low-pressure fluorocarbon plasmas have proven to be essential in various modern semiconductor fabrication processes, including thin film deposition or dielectric etching depending on the gas mixture, power, and sample distance from the plasma source. However, the continuous pursuit of shrinking the integrated circuit node has presented challenges emphasizing precise control of the plasma species involved in high aspect ratio (HAR) plasma processes. With increasing aspect ratios (AR), the control of electrically neutral plasma species (i.e. radicals) plays a crucial role in the channel critical dimension (CD) of a HAR etched feature. This is attributed with changes in radical composition as a function of channel depth, influenced by gas-phase and gas-surface interactions of radicals throughout the etched channel. As such, in-situ diagnostic techniques must be performed to determine the radical species distribution and composition of the fluorocarbon plasma prior to entering a given HAR etched feature.

For better understanding of such mechanisms and better control over neutral species delivery and distribution inside etch channels, we characterized the transport of radical species in the process chamber as a function of the distance from the plasma source. The experiments were performed in an inductively coupled $C_4F_8/O_2/Ar$ discharge at 20 mTorr to minimize collisions between molecules. The composition of the radicals diffusing toward the sample holder was controlled by varying the sample distance from the plasma source and was monitored in-situ by spatially-resolved optical emission spectroscopy (SROES) and spatially-resolved mass spectrometry (SRMS). The plasma phase chemistry composition and the nature of the radicals transported to the sample holder were controlled by adjusting the O_2 flow rate. Using the sample plasma, experimental films were grown on SiO_2 stacked structures mounted with capillary plates with varied AR. The SiO_2 stacked structure was made to mimic the equivalent of the greatest capillary AR at a millimeter scale to compare surface interaction discrepancies as a function of channel depth. The composition and deposition rates of the films were determined as a function of AR via X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM), respectively.

In-situ gas analysis indicated that the C_4F_8 plasma dissociation and recombination rates increased with O_2 flow rate and distance from the plasma source. An O_2 addition threshold that yielded the greatest CF_3 concentration and minimal CF and CF_2 production was identified. Surface analysis indicated similarities in film composition between the millimeter and micrometer scale HAR structures. The observed reduction in carbon content film deposition (CF_3 rich surfaces) with the increase of the channel length could be addressed to higher recombination and consumption rates of CF and CF_2 species on the via wall. Additional characterization of the radical flux, its spatial distribution, and its impact on the film properties will be discussed.

Application of Infrared Reflection–Absorption Spectroscopy for Characterizing Vapor-Phase Infiltration (VPI) Processes Chang-Yong Nam; Brookhaven National Laboratory, United States

Infrared reflection–absorption spectroscopy (IRRAS) is an optical technique used to study ultrathin and even sub-monolayer of molecules absorbed on IR-reflective substrates such as metals. Experimentally, it involves measuring the change in the reflectance-absorption spectra of the substrate with respect to incident angle and/or polarization of an IR probe. The method has been widely adopted for the in-situ monitoring of surface chemical reaction in the catalysis research field. In this talk, I will present the application of IRRAS on understanding the process and material characteristics of vapor-phase infiltration (VPI), an organic-inorganic hybridization method derived from atomic layer deposition (ALD). The examples to be discussed include inorganic infiltration into photoresists such as ZnO into SU-8, an epoxy-based negative-tone photoresist, and Hf organometallic precursor into poly(methyl methacrylate) (PMMA), a well-known positive-tone electron-beam resist. Though the given examples represent ex-situ studies, IRRAS has potential for in-situ interrogation of vapor-phase thin-film processes.

Advanced *In Situ* Scattering Studies During Thin Film Deposition via Printing, Spin Coating, Spray Coating and Sputter Deposition Peter Muller-Buschbaum; Technische Universität München, Germany

Thin film devices are complicated functional stacks that combine layers of different material classes, such as oxides, polymers, and metals. In many cases, different thin film deposition methods are required to build-up the entire functional stack. Any mistake in one of these multiple layers will lower the device efficiency or even cause a device failure. Therefore, a detailed understanding of the different thin film deposition processes is mandatory. With advanced in situ scattering studies at synchrotron radiation facilities, the complicated underlying film formation processes can be deciphered. Thin film processing is followed with a very high temporal and spatial resolution due to the available small-sized beams and high beam brilliance. In particular, with in situ grazing incidence small- and wide-angle X-ray scattering (GISAXS and GIWAXS) studies, we gain information on the kinetics of inner structures forming during thin film processing. The crystalline structure is probed with GIWAXS and the mesoscale structure is determined with GISAXS. From these data, models about the morphology evolution are extracted and these models guide the fundamental understanding to increase reproducibility in the device fabrication. Here, we focus on the solar cell fabrication of organic and perovskite solar cells, which are both exciting next-generation solar cell types. In particular, we compare examples from thin film deposition via printing [1], spin coating [2], spray coating [3], and sputter deposition [4].

Real-Time *In Situ* X-Ray Study of the Near-Threshold Mechanisms of Ion Beam Nanopatterning—Ion Incidence Angle Dependence Benli Jiang[1], Anubhav Wadehra[1], Kenneth Evans-Lutterodt[2], Andrei Fluerasu[2] and Karl F. Ludwig[1,1]; [1]Boston University, United States; [2]Brookhaven National Laboratory, United States

Ion bombardment can lead to a spontaneous formation of a range of nanopatterns on an initially flat surface, including nanodots, nanoscale ripples, and nanoscale pits or holes under different ion irradiation conditions. However, important fundamental questions remain about the driving force to pattern formation and how they can be controlled and optimized. Here, we are utilizing the high brilliance of a 3rd generation synchrotron to perform real-time *in situ* Grazing-Incidence Small-Angle X-ray Scattering (GISAXS) and X-ray Photon Correlation Spectroscopy (XPCS) based on coherent GISAXS to study the kinetics of Ar^+ beam nanopatterning process of Silicon near the pattern formation threshold.

A recent theory predicts the development of well-ordered ripples when the ion incidence polar angle θ is close to the critical angle [1]. The critical angle is one of the thresholds governing the pattern formation. When θ is increased through a critical value, a pattern forms on the solid surface. The experimental challenge for studying this near-threshold prediction is that the ripple amplitude is small (<5 nm) close to the threshold, while the exquisite sensitivity for probing surface morphology of GISAXS makes it a perfect tool for this study. Combining the advantage of GISAXS with the high brilliance of National Synchrotron Light Source II (NSLS-II) enables the investigation of the kinetics of ion beam nanopatterning near the threshold to empower further theoretical study. First, a series of real-time "low-coherence" GISAXS measurements were used to study the average kinetics during 500 eV Ar^+ beam nanopatterning of Si at room temperature with different θ near the critical angle at NSLS-II beamline 4-ID. Next, to truly utilize the high brilliance of NSLS-II, a series of similar experiments were carried out at beamline 11-ID to perform a real-time "coherent" GISAXS for XPCS, which can give us the temporal fluctuation dynamics about the average kinetics. Since the near-threshold prediction is based on a more universally applied model for ion beam nanopatterning, by feeding the quantitative kinetic record extracted from the near-threshold GISAXS and XPCS to the theoretical model, new insights could be introduced to the global understanding of the ion beam nanopatterning process.

This work was supported by NSF grant DMR-2117509.

ALD-Fabricated MgO-Overcoats to Control Sintering of Model Pt Nanoparticle Catalysts—The Power of Synchrotron X-Ray Scattering Tools Kinanti H. Aliyah[1], Matthias Filez[1], Zhiwei Zhang[1], Eduardo Solano[2], Christophe Detavernier[1] and Jolien Dendooven[1]; [1]Ghent University, Belgium; [2]ALBA Synchrotron, Spain

Nanoparticle sintering is a prime mechanism of catalyst deactivation.[1] During sintering, nanoparticle growth decreases the amount of active surface area for catalytic reaction, leading to performance losses. Amongst the explored design strategies to prevent nanoparticle sintering, partial overcoating of the catalyst surface presents a viable route. Recently, we demonstrated the application of atomic layer deposition (ALD) to deposit sub-monolayer MgO overcoats on model SiO_2-supported Pt nanoparticle catalysts to physically prevent sintering, while keeping controlled fractions of the Pt surface available for reaction.[2] The deposited MgO layer can range from sub-monolayers to nm-range and has been proven to exhibit an increase in the onset temperature of sintering.

Herein, we explore synchrotron-based X-ray scattering and diffraction tools to monitor the structural evolution of ALD-fabricated, MgO-overcoated Pt nanoparticles *in situ* during gas treatments which stimulate sintering. In particular, the MgO-overcoated Pt nanoparticles are subjected to propane dehydrogenation reaction and O_2 regeneration cycles at 600^0C and compared to their overcoat-free Pt analogues. The real-time Pt nanocrystal size and orientation are respectively probed by complementary *in situ* grazing-incidence small-angle X-ray scattering (GISAXS)[2, 3] and wide-angle X-ray scattering (GIWAXS)[4] (ALBA synchrotron). *In situ* GISAXS evidences that the MgO-overcoat leads to a decreased rate of nanoparticle sintering. Surprisingly, complementary GIWAXS data shows that the crystallographic evolution of nanoparticles, and in particular their orientation on the SiO_2 support, is strongly influenced by the MgO-overcoat. We therefore anticipate that ALD-tailored partial overcoats not only form a technology to control the sintering rate of nanoparticles, but can also be instrumentalized to direct crystal orientation under harsh post-synthesis processing conditions.

Synchrotron X-Ray Scattering for *In Situ* Characterization of Thin Film Morphology and Structure—An Overview from ALBA Synchrotron

Eduardo Solano; ALBA Synchrotron, Spain

The use of synchrotron X-ray scattering has emerged as an essential tool to probe and understand the morphology and structure of thin films. The high brilliance and tunability of synchrotron light enable new *in situ* and *in operando* characterization possibilities during thin film nucleation, growth, post-processing, and active functioning. Specifically, Grazing Incidence Small Angle X-ray Scattering (GISAXS) provides crucial insights into the size, shape, and arrangement of nanoscale structures, whereas Grazing Incidence Wide Angle X-ray Scattering

(GIWAXS) offers detailed information on the crystallographic structure, orientation, and phase transitions within the material. Additionally, a parallel multi-technique approach during synchrotron characterization enhances the results by parallelizing techniques and methodologies to record information, resulting in a more comprehensive and detailed understanding of the material's properties by capturing a wide range of data simultaneously and efficiently.

Following a brief introduction to X-ray scattering, this presentation will describe examples of *in situ* characterization during thin film nucleation, growth, and post-processing from various fields. The methodology, specialized instrumentation, and results will be discussed, drawing from research conducted at the NCD-SWEET beamline, the X-ray scattering facility at ALBA synchrotron in Spain. For instance, topics will include the *in situ* thin film growth using an adapted spin coating system, the *in situ* thermal sintering of supported nanocatalysts, and the *in situ* multi-technique ultra-fast growth (1000 nm/s) of superconducting thin films. Brief descriptions of complementary examples will highlight the diverse applications and capabilities of synchrotron X-ray scattering in thin film research.

10:30 AM CH01.03.05

***In Situ* Characterization of Oxide Thin Film Synthesis and Transformation by Surface and Coherent X-Ray Scattering—APS-U Perspectives** Hua Zhou, Xi Yan, Yan Li, Hawoong Hong and Dillon Fong; Argonne National Laboratory, United States

The *in situ* characterization of thin film synthesis and processing is crucial for advancing the development of multifunctional material heterostructures and devices. The greatly increased brightness and coherence of fourth generation X-ray lightsource like the upgraded APS (APS-U) will implement and deliver the world-class experimental platforms for in situ/operando surface X-ray and coherent X-ray scattering characterization, which will enable transformative investigations into thin film material synthesis and transformation under realistic conditions, which are critical for energy, quantum engineering and information technologies. In this talk, we would like to demonstrate two exemplary studies to highlight synchrotron surface X-ray capabilities to investigate the synthesis and phase transformation of oxide thin films.

Firstly, we explore remote epitaxy, a novel synthesis technique that allows for the fabrication of thin, freestanding single crystals and nanomembranes. This process involves a sacrificial layer, such as graphene, between a thin film and a single-crystalline substrate. This technique can create single crystal heterostructures with optimized properties by minimizing material incompatibilities. However, details of nucleation and growth via remote epitaxy remain largely unknown, necessitating in situ studies with atomic-level resolution. In this context, we will demonstrate our in situ synchrotron X-ray investigation of perovskite oxide thin film growth by molecular beam epitaxy onto graphene-coated SrTiO3 (001) substrates. Using X-ray phase retrieval methods, we reconstructed electron density profiles from X-ray crystal truncation rods measured under various growth conditions. Our in situ observations, combined with post-growth spectroscopy, provide critical insights into the behavior of graphene in the synthesis environment and its effects on complex oxide/graphene heterostructures.

The second example focuses on the topotactic reduction process to achieve superconducting infinite-layer nickelate thin films. In spite of significant progress has been made in the synthesis of parent phase nickelate thin film (e.g., RE0.8Sr0.2NiO3, RE = La, Nd, Pr...), the chemical reduction process to achieve the infinite-layer nickelate structure remains challenging and not fully understood. We will present our *in situ* synchrotron surface X-ray scattering studies combined with element-specific spectroscopies to probe the key steps of the topotactic reduction of epitaxial Nd0.8Sr0.2NiO3 thin films into Nd0.8Sr0.2NiO2 through a low-temperature reaction with CaH2. Our *in situ* X-ray observations provide essential structural and chemical insights into the formation of the square-planar structure critical for superconductivity in nickelate heterostructures. We discovered that the infinite-layer phase initiates at the heterointerface and propagates toward the film surface, with a dynamic surface boundary layer introducing hydrogen and removing apical oxygen ions. This study offers precise experimental guidance to improve effective reduction for intrinsic superconductivity behaviors.

In the end, we will give brief perspectives on emerging opportunities in X-ray *in situ* studies of multifunctional thin film and heterostructures enabled by the exciting advancements at the APS-U beamlines, in particular with enhanced high-energy, coherence and spatiotemporal capabilities (e.g. HESXRD, XPCS), which offer guidance for advancing the field of probing complex processes in thin film synthesis and processing.

10:45 AM CH01.03.06

Thickness Scaling Effects on Structural Transformations in Flash Annealed HZO-Based Capacitors via Time-Resolved Synchrotron Grazing Incidence X-Ray Diffraction Cristian Ruano Arens[1], Balreen Saini[1], Vivek Thampy[2], Douglas Van Campen[2], John Baniecki[2] and Paul McIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

In order to extend computational power beyond the era of conventional area scaling of semiconductor circuits, back-end-of-line (BEOL) integration is a promising pathway towards 3D integration of non-volatile memory with logic, to increase integration density and reduce latency and energy consumption associated with data transfer. With improved properties over perovskite-structure ferroelectrics, HfO_2-ZrO_2 (HZO) alloys are promising candidates for future nonvolatile memories because of their CMOS compatibility, sub-nanosecond switching speed, and scalability of ferroelectric properties to the nanoscale. However, synthesis of ferroelectric HZO typically requires rapid high temperature heating to stabilize the metastable ferroelectric phase, typically employing a rapid thermal annealing (RTA) procedure to quickly thermalize the entire device stack for processing times of seconds to minutes. In contrast, flash lamp annealing (FLA) quickly thermalizes materials with sub-ms pulses of light that can be potentially localized to the top layers of the device stack and to protect underlying interconnect and front-end-of-line (FEOL) structures while crystallizing higher level materials. Because thermalization depends on the optical and thermal properties of the materials in the device stack, tuning of the film properties (thickness, surface roughness, etc.) can impact the temperature gradient experienced during annealing.

Previous work has demonstrated FLA processing of 10-nm HZO metal-ferroelectric-metal (MFM) capacitors exhibiting similar remnant polarization and coercive field as RTA processed MFM capacitors, but with an imposed thermal budget three orders of magnitude lower than for RTA processing. However, for industrial-scale adoption, the HZO film thickness must decrease to improve ferroelectric memory device performance and energy efficiency. Thus, it is important to determine how thickness scaling of the metallic and ferroelectric layers affect the stabilization of the ferroelectric phase during FLA processing to yield ferroelectric devices with good performance while minimizing the thermal budget imposed for compatibility with BEOL processing.

Our work uses time-resolved synchrotron glancing incidence X-ray diffraction (GIXRD) for in-situ visualization of lattice dynamics to understand phase evolution during FLA processing of metal-ferroelectric-metal (MFM) capacitors with varying HZO and metallic layer film thicknesses. Static GIXRD was subsequently performed to carefully monitor the changes in lattice parameter at discrete elevated temperatures. Electrical measurements were also performed on the MFM capacitors to correlate device performance with phase evolution and optimize processing conditions for integration into memory devices, with the imposed thermal budget of processing calculated using a calibrated computational model. We have found that the optical properties of the metallic electrodes vary significantly with thickness, impacting the thermal budget imposed on the MFM stack during FLA and ultimately affecting the stabilization of the metastable ferroelectric phase. This study has advanced understanding of phase evolution of HZO thin films during FLA processing in efforts for adoption in BEOL device processing.

11:00 AM CH01.03.07

In Situ Synchrotron GISAXS Studies of InN Plasma-Enhanced Atomic Layer Deposition Nucleation and Growth Kinetics

Jeffrey Woodward[1], David R. Boris[1], Michael J. Johnson[1], Mackenzie E. Meyer[1,2], Daniel Pennachio[1], Samantha G. Rosenberg[3], Zachary R. Robinson[4], Scooter D. Johnson[5], Neeraj Nepal[1], Jennifer K. Hite[6], Michael A. Mastro[1], Karl F. Ludwig[7], Charles R. Eddy[8] and Scott G. Walton[1]; [1]U.S. Naval Research Laboratory, United States; [2]NRC Postdoctoral Research Associate, United States; [3]Lockheed Martin, United States; [4]State University of New York at Brockport, United States; [5]Honeywell, United States; [6]University of Florida, United States; [7]Boston University, United States; [8]Office of Naval Research Global, United Kingdom

The *in situ* characterization of atomic layer deposition (ALD) processes is challenged by the highly contaminating metal precursors, relatively high pressures, and harsh process environments which preclude the use of the powerful electron-based techniques commonly employed for ultrahigh vacuum thin film growth methods. An alternative approach is to utilize hard x-ray techniques which are compatible with arbitrary pressures and allow for the placement of both source and detector outside the reactor through the incorporation of x-ray transparent windows. Among such techniques, grazing incidence small-angle x-ray scattering (GISAXS) using synchrotron radiation is particularly well-suited to the study of ALD processes due to its exceptional surface sensitivity and ability to probe nanoscale structure as it evolves in real time. The application of GISAXS for the investigation of plasma-enhanced ALD (PEALD) processes is especially compelling, as even relatively simple plasmas may contain a broad range of species which influence the growth kinetics and resulting film properties.

In this work, the nucleation and early stage growth kinetics of InN PEALD processes are investigated using *in situ* GISAXS in a custom reactor. The InN films are grown on c-plane GaN using trimethylindium and N_2/Ar plasma as the metal precursor and reactant, respectively. Different regimes of plasma species generation, which are accessed by adjusting the relative flows of N_2 and Ar into the inductively coupled plasma (ICP) source, are explored, and the plasma properties are characterized by optical emission spectroscopy (OES) and Langmuir probe measurements. These plasma diagnostics are supported by modeling with the 2D Hybrid Plasma Equipment Model (HPEM), which is used to predict the fluxes of various reactive species produced in the plasma to the sample, including atomic N and metastable N_2. The growth mode is observed to be correlated to the concentration of atomic N in the plasma, with high concentrations promoting Volmer-Weber (i.e., island) growth and low concentrations promoting Stranski-Krastanov (i.e., layer-plus-island) growth. Under conditions of high atomic N production, both the mean island radius and critical thickness for island formation are found to increase with ion flux. The InN island center-to-center distance and areal density are found to change only during plasma exposure, and to continue changing with exposure even after the methylindium adlayer is believed to have fully reacted with the plasma. [1]

Building on these results, a similar series of InN films are grown on c-plane GaN using a commercial reactor and characterized by atomic force microscopy (AFM), high resolution x-ray diffraction (HRXRD), in-plane grazing incidence diffraction (IP-GID), synchrotron grazing incidence wide-angle x-ray scattering (GIWAXS), and transmission electron microscopy (TEM). Plasma diagnostics are used in order to confirm reasonable consistency in plasma properties between the commercial and custom reactors. The films are found to exhibit wurtzite phase and sixfold rotational symmetry with a clear epitaxial relationship to the GaN. Low concentrations of atomic N are found to promote larger domains, increased crystalline order, and smoother morphology compared to films grown with high atomic N concentrations, and a change in the dominant kinetic roughening mechanism from direct deposition on existing islands to diffusion to existing islands. For high atomic N concentrations, increasing the ion flux is found to promote a very rough morphology containing large cluster-like features and decreased in-plane crystalline order.

11:15 AM CH01.03.08

In-*Operando* Study of Epitaxial Thin Film with Dark Field X-Ray Microscopy Zhan Zhang[1], Seohyoung Chang[2], Hua Zhou[1] and John W. Freeland[1]; [1]Argonne National Laboratory, United States; [2]Chung-Ang University, Korea (the Republic of)

Domain exists in all sorts of crystalline materials on nano- to micro-meter length scale, whose formation, interaction, and evolution under external stimuli might dictate success or failure of the material. Studying domain evolution would require tools with good spatial-resolution, large enough sampling area/volume, as well as great structure sensitivity. A diffraction based, dark field X-ray microscopy method, the X-ray reflection interface microscopy (XRIM), can be such a tool in studying domains dynamics on the meso-scale at the surfaces, buried interfaces, and throughout a thin film.

By satisfying proper scattering conditions, XRIM can selectively track different structural domains, making it an excellent candidate to study thin films in-operando in real time. Combined with the reciprocal space mapping (RSM), the spatially resolved structure evolution can be identified as external stimuli are applied. A couple of examples will be discussed to demonstrate the capability of XRIM method and its potential applications in a broader field.

High Throughput Specimen Architecture for *In-Situ* Transmission Electron Microscopy Paul Miller, Tyler Hill, Michael Bradshaw, Mark Polking and Frances M. Ross; Massachusetts Institute of Technology, United States

In-situ Transmission Electron Microscopy (TEM) provides powerful insights into material synthesis, processing and failure. Of particular importance are in-situ heating experiments due to the importance of temperature in a wide variety of kinetic and thermodynamic processes. The current state of the art microheaters on silicon nitride membranes provide rapid and precise heating and are compatible with a wide variety of material systems. However, a limitation of in-situ TEM is the rate at which experiments may be conducted, primarily due to the time needed for sample preparation, preventing the acquisition of statistically robust datasets or adequate probing of parameters.

To address this concern, we propose and fabricate a new specimen architecture in which multiple individual microheaters are patterned on a single device. An array of microheaters on a silicon nitride window is fabricated using traditional Micro Electrical and Mechanical Systems (MEMS) techniques. To make the architecture scalable and compatible with a wide range of existing systems, Complementary Metal Oxide Semiconductor (CMOS) logic is introduced directly onto the device, allowing for control of a large number of devices with only four electrical contacts to the sample holder. On a prototype device this is achieved via bump bonding of a commercial, off the shelf digital to analog converter capable of driving eight microheaters directly onto the microheater array. Fabrication, testing and temperature calibration of the microheater array will be discussed.

To test the utility of this concept, the kinetics of the amorphous to crystalline transition in the magnetron sputtered phase change material Ge4Sb4Se2Te1 will be explored utilizing this chip in a conventional TEM, generating movies based on intensive use of real space imaging and diffraction to determine the crystallinity as a function of temperature and time. The impact of these experiments for nucleation statistics and rapid exploration of the Time Temperature Transformation (TTT) diagram will be discussed.

To scale up this concept to larger numbers of microheaters, an application specific integrated circuit (ASIC) is designed and fabricated at the 150nm CMOS node to integrate logic directly into the same silicon housing the microheaters and membrane, anticipated to allow for independent and simultaneous driving of up to 100 devices. Design and integration with existing MEMS fabrication will be discussed, as will the broader applications and implications for high throughput materials research.

11:45 AM CH01.04.02

Oxidation of Hafnium Thin Films on Amorphous and Crystalline Substrates Studied *In Situ* Using Transmission Electron Microscopy Rishabh Kothari, Zhenjing Liu, Dionysios Sema, Ngoc-Cuong Nguyen, Spencer Wyant, Nicolas Hadjiconstantinou, Youssef M. Marzouk, Rafael Jaramillo and Frances M. Ross; Massachusetts Institute of Technology, United States

In situ environmental transmission electron microscopy (ETEM) enables the observation of controlled metal oxidation, a process of broad relevance to applications ranging from aeronautics to microelectronics. We focus on the oxidation of hafnium due to its role in high-performance alloys that operate in extreme conditions and the use of hafnia as a high-k dielectric for microelectronics. We present *in situ* results from ETEM, results from supporting experiments including atom probe tomography (APT), and data from large-scale and long-time molecular dynamics (MD) simulations. Our overall goal is to achieve process control for materials in microelectronics and predictive simulations of material failure in extreme conditions.

We deposit Hf films via magnetron sputtering on amorphous substrates built into ETEM heating chips. These films show columnar grains with Hf(0001) film normal texture. TEM imaging during sample heating and oxygen exposure reveals sequences of phase transformations during oxidation, and concurrent secondary electron collection (*i.e.*, SEM) aids in separating processes that take place within the film and at the surface. Similarly deposited Hf films are also investigated by complementary *ex situ* studies, carrying out oxidation in a tube furnace with controlled atmosphere. Combining atomic force microscopy (AFM) and high-resolution cross-section TEM reveals morphology, oxide thickness, and oxide-metal orientation relationship as a function of oxidation time and temperature. X-ray photoelectron spectroscopy (XPS) depth profiling demonstrates the presence of a suboxide phase at the oxide-metal interface. APT is used to measure the dissolved oxygen concentration profile in the unoxidized metal found below the oxide growth front. Diffusivity of oxygen in Hf metal and morphology changes in ETEM are compared with MD simulation for evaluation refinement of machine-learned interatomic potentials.

The Hf-O system contains many oxide phases that may be metastable. *In situ* ETEM experiments allow transient phases to be detected, but analysis can be challenging given the polycrystalline nature of the underlying Hf film. To improve the visibility of oxide phases, we deposit single crystal Hf thin films epitaxially on crystalline 2D material substrates, such as graphene, using ultra-high vacuum (UHV) electron-beam evaporation. These crystals are characterized in an TEM connected by UHV to the evaporator, and are then transferred through air and oxided *in situ* in the ETEM. We find an oxidation sequence for these crystals that includes an amorphous phase and a crystalline, hexagonal phase that we label h-HfO_x. Automated phase quantification allows us to interpret the time evolution of our films, enabling selection of phase and orientation during oxidation.

By studying oxidation of both epitaxial and non-epitaxial Hf films, we identify oxidation mechanisms that are relevant to the performance of alloys in extreme conditions. Using simulation results to refine state-of-the-art atomistic simulations improves the ability of computation to model and predict failure mechanisms. Insights from modelling and ETEM together can also reveal processing routes to select the properties of hafnium thin films. In particular, we include MoS_2 among our 2D substrates studied to evaluate the use of ultra-thin hafnium metal films as seed layers to improve fabrication of semiconductor-dielectric layers for 2D microelectronics.

Cross-Sectional Observing Bias-Induced Phase Transformation of Multilayer TiSe2 Devices via *In Situ* Transmission Electron Microscopy

Hsin-Ya Sung[1], Ping-Hung Yeh[2] and Wen-Wei Wu[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Tam Kang University, Taiwan

Over the past few decades, two dimensional transition metal dichalcogenides (TMDs) have attracted much attention due to their promising applications in electronics, optoelectronics, and catalysis. Titanium diselenide ($TiSe_2$), a notable member of the Group IV TMDs family, has attracted significant attention in both bulk form and its emerging two-dimensional form due to its interesting physical properties, such as charge density waves (CDW) and unconventional superconductivity. In this research, the device behaviors of $TiSe_2$ cross-sectional samples are revealed *via* in-situ biasing experiments and recorded by transmission electron microscope (TEM). Furthermore, we measured the *ex-situ* current-voltage curve as temperature changed and demonstrated the presence of titanium-rich regions on the surface of multilayer 2H-$TiSe_2$ in both *ex-situ* measurements and *in-situ* induced biasing using atomically resolved scanning transmission electron microscopy (STEM). During bias-induced phase changes, we also observed extreme current changes during applied voltage bias. In addition, we discussed how different thicknesses of 2H-$TiSe_2$ affect the maximum current value, noting that as the thickness increases, the voltage required for the phase change also increases. Herein, the electronic structure of the titanium-rich surface produced after biasing was probed by electron energy loss spectroscopy (EELS). It can be clearly seen that the valence states of both Ti and Se elements have changed significantly. This study clarifies the detailed mechanism behind the phase transformation process and explores the structural and electrical properties of Group IV TMDs. Furthermore, it highlights their additional application value and establishes a groundwork for future developments in this field.

1:45 PM CH01.05.02
Atomic-Scale Control and Detection of Ferromagnetic Phase Transformation by Using Atomic-Scale Probe

Kun Xu[1], Xiaoxi Huang[2], Hongrui Zhang[2], Ramamoorthy Ramesh[2] and Arun Majumdar[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States

Controlling and detecting ferromagnetic phase transformations at high spatial resolutions are crucial for

advancing our understanding of spintronics and high-density information storage applications. Traditional methods for achieving these transformations typically involve thermal treatment or chemical agents, which can significantly alter the thermodynamic phase diagram of bulk compounds. However, these methods have a fundamental limitation for local modification, as the entire sample is subjected to the same environment. Alternative approaches, such as using light excitation, biasing, or scanning tip-based methods, have been proposed and demonstrated to manipulate thermodynamic stability at the microscale. Nevertheless, achieving control at the nanoscale remains challenging due to the intrinsic length scale constraints of these methods. In this work, we propose a unique method using a high-resolution electron beam to control and detect the transition from non-ferromagnetic to ferromagnetic phases at the atomic level. We demonstrate that an atomic probe can initiate the phase transition between the rock salt and spinel structures in $NiFe_2O_4$. The electron beam allows for precise control of this transition, enhancing the material's properties at high spatial resolutions. The transition between ferromagnetic and non-ferromagnetic phases can be both controlled and imaged at the atomic scale. Furthermore, the ferromagnetic signal can be detected at the nanoscale using electron magnetic circular dichroism (EMCD), enabling the manipulation and detection of ferromagnetic phases with high spatial precision. Our study also provides insights into the mechanisms behind the ferromagnetic transition. Imaging of light elements revealed that the oxygen network in the rock salt films undergoes structural distortions, and transitional metal cations migrate through various lattice sites. These movements are facilitated by the presence of cation vacancies and lead to the formation of the ferromagnetic spinel phase when the rock salt films are exposed to an electron beam. This atomic-scale engineering enables potential applications in magneto-optic-based information storage and related devices.

Real-Time Monitoring of Chemical Treatment on TMDs Juhwan Lim, Jiho Han, Christoph Schnedermann, Manish Chhowalla and Akshay Rao; University of Cambridge, United Kingdom

Chemical treatment is one of the major route for tuning the properties of two-dimensional transition metal dichalcogenides (TMDs), a class of ultrathin semiconductors. Firstly, solution-based chemical approaches using TFSI-based ionic salts (e.g. using Li-TFSI) enhance semiconducting properties by passivating surface defects and unwanted doping, notably enhancing photoluminescence (PL) yield. Secondly, chemical lithiation using organolithiation agents (e.g. n-butyllithium) changes the crystallographic phase of TMDs from the natural trigonal prismatic (2H) to octahedral (1T). Here, employing various home-built microscopy techniques, we monitored the time- and spatially-resolved PL enhancement and phase transition of mono-, and few-layered MoS_2 during solution processes. For Li-TFSI treatment, we focused on the evolution and homogeneity during the chemical treatments. We defined the treatment time, and figured out the inhomogeneity remains during the treatment, which presented non-varying intrinsic defect density over time. In organolithiation-based phase engineering of MoS_2, we discovered that this process is a charge-limited, surface-driven intercalation that can be tuned by illumination energy.

2:15 PM CH01.05.04

Ångström-Scale Topography in Neutral Helium Microscopy—Evaluating Thin-Film Coatings over Large Areas

Paul Dastoor; The University of Newcastle, Australia

Nanoscale thin film coatings and surface treatments are ubiquitous across industry, science, and engineering; imbuing specific functional or mechanical properties (such as corrosion resistance, lubricity, catalytic activity and electronic behaviour). Non-destructive nanoscale imaging of thin film coatings across large (ca. centimetre) lateral length scales, crucial to a wide range of modern industry, remains a significant technical challenge. By harnessing the unique nature of the helium atom–surface interaction, neutral helium microscopy images these surfaces without altering the sample under investigation. Since the helium atom scatters exclusively from the outermost electronic corrugation of the sample, the technique is completely surface sensitive. Furthermore, with a cross-section that is orders of magnitude larger than that of electrons, neutrons and photons, the probe particle routinely interacts with features down to the scale of surface defects and small adsorbates (including hydrogen). Here, we highlight the capacity of neutral helium microscopy for sub-resolution contrast using an advanced facet scattering model based on nanoscale features. By replicating the observed scattered helium intensities, we demonstrate that sub-resolution contrast arises from the unique surface scattering of the incident probe. Consequently, it is now possible to extract quantitative information from the helium atom image, including localised ångström-scale variations in topography. Its unique ability to observe the effects of sub-nanoscale features upon scattered helium intensity makes the SHeM a powerful tool for the evaluation of nano-coatings and thin films across large areas. Looking ahead, once a material system is well characterised with SHeM, such analysis will readily become a routine part of quality control; a unique tool for improving production yields and throughput.

Atomic Scale Understanding of Cu and Cu Alloy Oxidation Using *In Situ* Environmental TEM Judith C. Yang[1,2], Meng Li[1], Matt Curnan[3] and Wissam Saidi[4,2]; [1]Brookhaven National Laboratory, United States; [2]University of Pittsburgh, United States; [3]Korea Institute of Energy Technology, Korea (the Republic of); [4]U.S. Department of Energy National Energy Technology Laboratory, United States

How metals and alloys oxidize is of critical importance to numerous energy, environmental, and microelectronics industries. A fundamental understanding of the surface oxidation of metals and alloys are essential for improving existing processes and designing new functional materials that use oxidation for nanomaterials formation. Experimental tools capable of observing in situ the early-stage oxidation at the atomic scale are key to predictive oxidation. Here, we use in situ environmental transmission electron microscopy (ETEM) experiments, with advanced data analysis and correlated theoretical simulations, to investigate the initial stages of Cu and CuNi oxidation. Single-crystalline ~60 nm Cu and CuNi thin films were prepared by ebeam evaporation and then transferred to a dedicated ETEM with a home-built gas delivery system. The onset of surface reconstruction, nucleation and initial growth of the epitaxial oxides are followed in situ. In-depth analysis of these atomic scale processes is completed via automated ETEM data-processing and statistical techniques. For gaining fundamental understandings, a multiscale theoretical framework is being developed for simulating longer time scales to correlate directly with experimental observations. Mechanistic understanding of the role of surfaces, defects and composition is obtained. The authors acknowledge funding from National Science Foundation (NSF) grants DMR-1410055, DMR-1508417, DMR-1410335, and CMMI-1905647, as well as support from Hitachi-High-Tech and technical assistance from the Nanoscale Fabrication and Characterization Facility (NFCF) in the Petersen Institute of Nano Science and Engineering (PINSE) at the University of Pittsburgh. In Situ Environmental TEM Observation of Early-Stage Nucleation Behavior of GaN Growth on SiN Substrate

Abby Liu[1], Dmitri Zakharov[2], Zhucong Xi[1], Meng Li[2], Fernando Camino[2], Judith C. Yang[2,3], Liang Qi[1] and Rachel S. Goldman[1]; [1]University of Michigan, United States; [2]Brookhaven National Laboratory, United States; [3]University of Pittsburgh, United States

Semiconductor polytype heterostructures, which consist of chemically homogeneous structures formed via an abrupt change in crystal structure, offer opportunities for performance exceeding those of composition-based semiconductor heterostructures. Of particular interest are heterostructures formed via an abrupt change in atomic plane stacking sequence, such as the transition from the wurtzite (WZ) polytype to the zincblende (ZB) polytype. It has been suggested that the formation of ZB segments within WZ nanowires (NWs) can act as quantum dots (QDs) in NWs, which are promising candidates for single-photon emitters.

We recently discovered a Ga-mediated molecular-beam epitaxy (MBE) process to nucleate ZB and WZ GaN NWs on Si(001) [1]. Key to this process is a Ga pre-deposition step, in which Ga droplet arrays are formed prior to NW growth. We have also examined the origins of polytype selection during metal-mediated epitaxy of GaN NWs. Quantitative EDS reveals a notably higher average Si atomic fraction in ZB NWs than in WZ NWs. Correspondingly, DFT calculations predict that incorporation of Si atomic fractions > 0.08 onto the Ga sublattice stabilizes ZB GaN. We hypothesize that the high Ga BEP during the Ga pre-deposition enables dissolution of excess Si into the liquid Ga, thereby stabilizing ZB GaN. To further study the initial stages of the GaN growth process under real time, environmental transmission electron microscopy (E-TEM) was utilized to observe nucleation and growth of GaN from Ga droplets under ammonia exposure.

In this work, in preparation for E-TEM studies, Ga droplet samples were prepared using MBE on micro-electromechanical systems (MEMS)-based chips with SiN_x thin film windows as substrates. A specialized holder was designed for MBE growth to securely mount the chips, using a mask to expose only the SiN_x thin film windows and prevent deposition on the electrodes, avoiding electrical shorts. Two different growth conditions were utilized: (1) Ga droplets and (2) pre-nucleated GaN within Ga droplets using N plasma in MBE. In the absence of pre-nitridation in MBE, circular Ga droplets with the diameter of 24.3 ± 0.2 nm were formed on SiN_x film of MEMS-based chips. On the other hand, exposure of Ga droplets to N plasma leads to faceted GaN formation at the edges of the Ga droplets, resulting in partially-nucleated GaN within Ga droplets. Since both samples were exposed to the atmosphere after MBE growth, thin oxide layers (1-2 nm) were observed on their surfaces.

With Ga droplet samples under ammonia exposure in E-TEM, GaN formation was not observed after heating up to 800°C. Instead, Ga desorption and oxidation occurred. Interestingly, with pre-nucleated GaN within Ga droplets, after heating up to 800°C during ammonia exposure, Ga desorption occurred first at lower temperature (~ 500°C), followed by facet formation at higher temperatures (> 600°C). High-resolution TEM (HRTEM) after ammonia exposure shows uniform crystal orientation within particles, indicating epitaxial growth of GaN in E-TEM along pre-nucleated GaN. The competition between Ga desorption rate, ammonia decomposition rate, and GaN growth rate on Ga/SiNx and Ga/GaN interface will be discussed.

Visualization of Localized Degradation in Ni/BaTiO$_3$-Based Multilayer Ceramic Capacitors Under Electric Fields by *In-Situ* STEM Keeyong Lee[1], Dongjun Jung[2], Jeehun Jeong[1], Young Ghyu Ahn[2] and Sang Ho Oh[1]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]Samsung Electro-Mechanics, Korea (the Republic of)

Ni/BaTiO$_3$-based multilayer ceramic capacitors (MLCCs) have been widely used in mobile communication, aerospace, and electric vehicle applications. For commercially available MLCCs, 'reliability', defined as the ability to maintain performance from the measurement of voltage until dielectric breakdown, is one of the important properties. Previous research has employed the highly accelerated lifetime test (HALT), which involves applying a DC voltage to MLCCs at high temperatures and monitoring the resistance changes over time to figure out the mechanism of degradation. These studies have indicated that oxygen vacancies play a crucial role in the overall degradation behavior of MLCCs. However, variations in resistance among individual MLCCs during HALT suggest that degradation primarily occurs in localized regions. According to the weakest link theory, degradation in localized areas accelerates, leading to rapid dielectric breakdown.

In this study, infrared optical beam induced resistance change (IR-OBIRCH) was applied to identify potential degradation regions with low resistance on the surface of pre-breakdown MLCCs with applied voltage at high temperatures. These identified regions were subsequently cross-sectioned using focused ion beam (FIB) techniques to apply IR-OBIRCH again on the cross-section sample to pinpoint further locally degradation regions in three dimensions. Following the process, locally degraded area has been securely contained within a (S)TEM specimens using FIB to conduct in-situ biasing STEM. Four-dimensional scanning transmission electron microscopy (4D-STEM) experiments were performed to measure the deflection of a transmission beam with a small convergence angle of 60 μrad, depending on the applied voltage, to determine the electric field strength within the specimen. Subsequently, the chemical composition distribution of dopants and the distribution of oxygen vacancies were analyzed using STEM electron energy loss spectroscopy (STEM EELS) and energy-dispersive X-ray spectroscopy (EDS). The analysis revealed that the regions identified as degraded by IR-OBIRCH did not exhibit differences in grain size or the number of grain boundaries when compared to normal regions. However, these degraded regions demonstrated a significantly smaller electric field than the non-degraded regions. This phenomenon is hypothesized to result from changes in conductivity attributed to the distribution of oxygen vacancies, which arise from dopant segregation. This study aims to figure out the mechanisms underlying the formation of locally degraded areas by observing the distribution of oxygen vacancies, dopants, grain size, grain boundaries, and electric field distribution under in-situ conditions.

3:45 PM CH01.05.08

Controlling Gold Atom Mobility in Nanocomposite Films Through Zirconia Co-Deposition—An *In Situ* TEM Investigation Andrea Falqui[1], Alberto Casu[1], Claudio Melis[2], Giorgio Divitini[3], Filippo Profumo[1], Riccardo Dettori[2], Yurii P. Ivanov[3], Francesca Borghi[1], Luciano Colombo[2] and Paolo Milani[1]; [1]Università degli Studi di Milano, Italy; [2]Università degli Studi di Cagliari, Italy; [3]Istituto Italiano di Tecnologia, Italy

The thermal behavior and dewetting dynamics of nanocomposite thin films composed of gold and zirconia (ZrO_2) have been investigated by *in situ* heating transmission electron microscopy (upon low electron dose) and molecular dynamics simulations. Gold nanostructured films with branched microstructure, both with and without zirconia, were subjected to thermal stimuli to observe their response. In pure gold films, thermally induced solid-state dewetting initiated at temperatures just above 100°C, causing a gradual retraction of gold clusters. This process progressed slowly until around 800°C, then accelerated significantly, reducing the gold-covered substrate area from 47% to 10% by 1000°C.

The inclusion of zirconia significantly enhanced the thermal stability of the gold films. Indeed, ZrO_2 clusters limited the mobility and diffusivity of gold atoms, raising the temperature threshold for dewetting and reducing its rate, thereby improving the overall thermal resilience of the films. Specifically, gold-zirconia nanocomposite films

demonstrated much slower dewetting and greater retention of substrate coverage compared to pure gold films. The MD simulations corroborated these findings, showing that the introduction of zirconia decreased gold atom diffusivity by approximately a factor of three, due primarily to zirconia's high melting point and associated thermal threshold.
These results highlight zirconia as a critical stabilizing agent in nanostructured materials, effectively mitigating gold dewetting at elevated temperatures while preserving the structural integrity of the films. This improved thermal stability opens new opportunities for tailoring the thermal properties of nanocomposite thin films, with potential applications in advanced technologies requiring robust thermal performance.

Implementation of *In Situ* and *Quasi-In Situ* Characterization Techniques for the Development of Deposition Processes Enabling Atomic Scale Precision for Device Fabrication Marceline Bonvalot[1,2,3], Martial Santorelli[2,4] and Christophe Vallee[5]; [1]Université Grenoble Alpes, France; [2]CEA-Leti, France; [3]J-FAST, Japan; [4]STMicroelectronics, France; [5]University at Albany, State University of New York, United States

Over the past 20 years, the microelectronics industry has undergone numerous technological developments in fabrication strategies in order to sustain the constant miniaturization pace of integrated devices dictated by Moore’s law. The era of ultra-miniaturized device fabrication with dimensions scaling below 10 nm is currently on its way, enabled simultaneously by the introduction of exotic materials (eg graphene and 2D materials), highly complex 3D architectures and advanced atomic-scale fabrication processes.
In this presentation, conventional in situ diagnostic tools enabling atomic-scale deposition process monitoring will be reviewed in details, based on examples taken from the literature, with special attention devoted to their strength and limitation in reaching the nanoscale size. The atomic-scale plasma processing strategy recently developed at LTM laboratory in Grenoble based on a bottom-up selective thin film formation will be described. Plasma – surface interaction mechanisms at play during growth will be identified, thanks to the assistance of dedicated in situ and quasi in situ techniques, such as ellipsometry, X-Ray photoelectron spectroscopy and Quartz Crystal Microbalance, illustrating how a careful definition of various experimental parameters can lead to atomic-scale precision in terms of both thickness and placement.

4:30 PM CH01.06.02

Formation of Porous Conjugated Polymer Films via Spontaneous Phase Separation and Their Gas Sensor Applications—Theoretical Examination of Pore Structures and Sensing Kinetics Yejin Ahn, Yeongkwon Kang, Hyojin Kye, Min Seon Kim, WiHyoung Lee and Bong-gi Kim; Konkuk University, Korea (the Republic of)

Controlling the miscibility between mixture components induces spontaneous phase separation into distinct domain sizes. This process results in porous conjugated polymer (CP) films with varying pore sizes after the selective removal of auxiliary components. In this study, we propose a phase separation method for fabricating meso/macroporous CP films by mixing CP with auxiliary components that induce phase separation during film formation. By adjusting the content of PCBM, a well-known material for creating heterojunction structures, a porous structure was successfully fabricated. Additionally, we designed several model compounds to mix with CP and calculated the solubility distance using the Hansen solubility parameter, providing insights into the solubility of organic materials. As the difference in solubility parameters between the matrix CP and the auxiliary components increases, the pore size also increases. The pore size was effectively observed through atomic force microscopy, revealing increased root mean square and surface area, which allows precise control over the degree of phase separation.

Moreover, we explored the application of porous CP films as field-effect transistors (FETs) type gas sensor platforms. The porous structure enhances detection sensitivity and improves detection speed when used in FET-based gas sensors for NO_2 detection. The electrical properties of the CP are largely maintained even after pore formation. However, excessive pore formation can cause pores to extend near the dielectric layer of CP-based FETs, resulting in partial degradation of the carrier-transporting active channel in the FET. The performance of the sensor can be enhanced by employing a FET-based gas sensor with porous structure to facilitate the adsorption and desorption of NO_2. The porous structure-based gas sensor exhibited remarkable sensitivity of 3,800 %/ppm and selectivity for $NO_{2,}$ with an exceptional limit of detection of 10 ppb. The initial adsorption of the analyte occurs rapidly through the pores, generating a charge influenced by the electrical properties of the employed CP. Therefore, the quantitative analysis of the response-recovery trend of the FET sensor using the Langmuir isotherm suggests that the response speed can be improved by more than 2.5 times with a 50-fold increase in NO_2 sensitivity compared with pristine CP, which has no pores.

These findings highlight the potential of utilizing blend films and porous structures for various applications, showcasing their effectiveness in controlling solubility parameters, promoting phase separation, and enhancing the performance of electronic devices and gas sensors.

4:45 PM CH01.06.03

***In-Situ* Multi-Scale RGB Imaging Studies of Spin Coating Using 3 Wavelength Laser or Broadband White Stroboscopic Illumination** Jack Atkinson and Jonathan Howse; The University of Sheffield, United Kingdom

Spin coating remains a valuable technique for thin film fabrication due to the wide range of materials that can be processed, and its inherent speed and reproducibility. The microscopic morphology of these films is of critical importance to the associated performance in their applications, which vary from sensors to photovoltaics and electronics. Wafer-scale metrology is also significant for the characterization and detection of defects and nonuniformity, especially in semiconductor manufacturing. Inherently, spin coating provides a challenging platform to directly observe dynamic topological and morphological information on, especially with direct methods such as imaging, due to high angular velocities and processing times of a few seconds. In addition, ex-situ measurements are often needed to unambiguously interpret in-situ optical data due to fringe order ambiguities.

In previous work [1] we have demonstrated how broadband illumination can provide full-wafer thickness reconstruction of spun coat solvent topology through the development of an in-situ colour-to-thickness relationship. Here, we present a multi wavelength laser illuminated microscopy technique on spun coat films to produce colour videos of the process. This configuration also takes advantage of a standard colour camera's Bayer filter to provide facile and inexpensive multi wavelength metrology. This allows us to produce colour images using simultaneous 406, 520 and 642nm wavelength illumination. The crosstalk in the camera has been removed and thus the resultant images can be considered 3 wavelength snapshots of the process, that can be interpreted to reveal spatially resolved thicknesses at each time point. Our investigation of the proposed technique involves the observation of a variety of model systems, at different objective lens magnifications, from simple pure solvent and single polymer systems to polymer blends and more complex systems. Theoretical analysis shows that extraction of instantaneous phase differences between colour bands can unambiguously provide thickness values across the whole FOV, without the need for additional ex-situ techniques.

This work represents a landmark because the technique can provide unambiguous and spatially resolved thickness measurements without the need for time consuming and expensive ex-situ techniques. It has far-reaching implications across numerous thin film materials, especially where the final structure is critical, by providing a tool to investigate morphological developments in situ. Increased understanding of the development of these structures is key to unlocking the full potential of materials processed by spin coating.

In Situ Characterisation of Plasma Electrolytic Oxidation for Fabrication of Enhanced Catalytic Membranes

Wing Kiu V. Yeung; National Taipei University of Technology, Taiwan

Membrane technologies exhibit significant competitiveness, particularly when combined with customisable properties. Catalytic membranes offer diverse benefits, including reusability and enhanced efficiency. Furthermore, the straightforward and environmentally friendly fabrication process remains critical in addressing fundamental principles. This work focuses on the in situ characterization of the Plasma Electrolytic Oxidation (PEO) process using Optical Emission Spectroscopy (OES) and dynamic Electrochemical Impedance Spectroscopy (EIS). A tungsten-based electrolyte with sodium hydroxide was employed to demonstrate the facile fabrication of a photocatalytic and photodegradation membrane. Data from these processes facilitated the formation of a multilayered porous membrane without pretreatment or posttreatment, using an environmentally friendly electrolyte. The resulting membrane was confirmed through cross-sectional energy-dispersive X-ray spectroscopy (EDX) and scanning electron microscopy (SEM). The presence of a tungsten-rich top porous layer followed by a phosphorus-rich layer exhibited unique properties that enhanced overall catalytic efficiency in comparison to those of nonlayered PEO membranes. These findings have significant implications for the development and understanding of porous catalytic membranes. Such membranes improve mass transport and cavity catalysis and enhance chemical integration, offering substantial benefits in various applications.

CH01.07.02

Improving Optoelectronic Film Properties by Controlling Supramolecular Structures in Y6 Langmuir Films

Yisak Tsegazab Gerase[1,2] and Martin Presselt[2,1]; [1]Friedrich-Schiller-Universität Jena, Germany; [2]Leibniz Institute of Photonic Technology, Germany

Supramolecular structures are critical to the optoelectronic properties of films. The Langmuir-Blodgett (LB) technique provides precise molecular assembly, enabling control and homogenization of the morphology of Y6 Langmuir films, which is essential for scalable fabrication and commercial production. Y6, a non-fullerene acceptor, has significantly improved the power conversion efficiency of organic solar cells. By assembling Y6 at

the air-water interface, we achieved well-defined quasi-2D Langmuir films with superior morphologies compared to spin-cast films.

We monitored the in-situ formation of Y6 Langmuir films using Brewster angle microscopy (BAM), surface pressure isotherms, and fluorescence spectroscopy. Isotherms revealed high packing densities, while compression-expansion cycles showed increased stiffness due to intermolecular rearrangements. BAM images confirmed smooth, well-defined quasi-2D films, and in-situ fluorescence spectroscopy identified the existence of Y6 fluorophore at the air-water interface and with lateral compression growth in supramolecular structure were observed. In agreement with in-situ observations, these well-ordered morphologies were further characterized after deposition on solid supports. Y6 films used in organic thin-film transistors (OTFTs) showed a mobility of about $7*10^{-3}$ cm^2/Vs as cast film, comparable to other deposition techniques.

Our study demonstrates the potential of the LB technique to manipulate Y6 film structures at the air-water interface, providing a scalable approach for fabricating organic thin films with enhanced optoelectronic properties critical for various applications.

CH01.07.03

Study of Argon Flow Effects on Transmittance in Multilayer Thin Films for Aviation Lighting Soyoung Kim, Ju Hyeon Choi, Jung-Hwan In, Seon Hoon Kim, Karam Han and Jehwan Hwang; Korea Photonics Technology Institute, Korea (the Republic of)

Lighting devices installed on airfields and runways are regulated in terms of the color, intensity, and angle of the light they emit according to their function. This study aims to improve the performance of thin films used in taxiway lights, which require high transmission efficiency in the wavelength range of 510-550 nm.
First, the multilayer thin films were designed using the Essential Macleod program, combining SiO_2 and Nb_2O_5 materials. The composition and thickness of each layer were optimized to achieve over 95% of transmittance in the 510-550 nm wavelength range. The designed multilayer thin films were deposited using an RF sputtering method under different argon flow rate (50 sccm, 75 sccm, 100 sccm). X-ray Diffraction (XRD) analysis confirmed that all thin films under the three conditions exhibited amorphous characteristics. Elemental compositions were verified through Energy Dispersive X-ray Fluorescence (EDXRF) analysis. The L and K characteristic lines of the Nb and Si multilayer thin films were characterized at high and low photon energy range. The relative concentration of the Nb were compared using count per second (CPS) under different argon conditions. The surface and uniformity of the deposited layers were evaluated using Scanning Electron Microscopy (SEM). The total thickness of the multilayer thin films is about 5.5μm based on cross section images. X-ray Photoelectron Spectroscopy (XPS) analysis presented that the Nb_2O_5 phase was predominant under the 50 sccm of argon flow rate. However, the presence of the NbO_2 phase was revealed under the 100 sccm of argon flow, indicating reduction of Nb oxides from Nb_2O_5 to NbO_2. The transmittance measurements of the fabricated multilayer thin films showed the highest transmittance of 95.3% under the 50 sccm of argon flow. Overall results indicated that the NbO_2 phase in multilayer thin films may contribute to the reduction in transmittance. Current results in this study suggest the potential for significantly improving the efficiency of taxiway lights.

CH01.07.04

Enhancing Solution-Derived Piezoelectric Modified $BaTiO_3$ Films Through *In-Situ* Microstructural Characterization Hannes Rijckaert, Jeroen Beeckman and Klaartje De Buysser; Ghent University, Belgium

Today, piezoelectric materials play an important role in numerous applications such as sensors, actuators, transducers, and energy harvesters. Piezoelectric energy harvesters cannot reach the efficiency and scale of solar cells or wind turbines, but they are excellent power sources where electrical cables are undesired and miniaturization is a key factor. Lead-based piezoelectric materials such as $Pb(Zr,Ti)O_3$ (PZT) are currently the most widely used material in such systems. This is due to their strong piezoelectric coefficient and electromechanical coupling coefficient. However, the use of PZT is not an option due to the presence of lead, and the development of alternative "greener" and "superior" materials with comparable or better piezoelectric properties is required. Barium titanate ($BaTiO_3$) is one of the suitable lead-free piezoelectric candidates due to its promising piezoelectric properties. To improve its piezoelectric properties, several $BaTiO_3$-based solid solutions with different substituents have been studied. In 2009, some researchers have reported a significant breakthrough in $BaTiO_3$ perovskite doped with Ca and Zr atoms, leading to the $(Ba,Ca)(Ti,Zr)O_3$ (BXT) solid solution with an outstanding piezoelectric coefficient.

Since BXT material offers promising piezoelectric properties, making thin films of this material is of particular interest for use in various applications. Also, the integration of piezoelectric films on silicon (Si) or silicon nitride (SiN) based platforms is crucial for the miniaturization of electronic and photonic components. In this work, chemical solution deposition (CSD) technique is introduced as a rapid integration to develop a cost-effective, reproducible and high-quality industrial pathway to piezoelectric BXT film on desired substrate. Therefore, the formulation of the environmentally friendly BXT precursor solution is highly important and must be stable prior to the CSD process with good wetting behavior and good homogeneity on desired substrate. Here we are able to develop the environmentally benign BXT inks based on the short carboxylic acid route as metal organic decomposition (MOD) method. It results in BXT material with promising piezoelectric properties, but has a Curie temperature of 85 °C and thus shows a poor piezoelectric thermal stability upon heating, which deeply limits its practical application.

Therefore, in this work, several compositional and microstructural modifications via the combination of CSD and pulsed laser deposition (PLD) techniques are introduced (and with the support of computational screening) to enhance temperature stability and the piezoelectric response of BXT films. These films are investigated via electrical and microstructural measurements (both in-situ and ex-situ) to understand the modification of BXT film. Here, in-situ high temperature conventional x-ray diffraction (XRD) measurements will be carried out to understand the temperature-dependent microstructural evolution (nucleation and growth mechanism during the thermal processing) in these modified BXT films. This approach present some new specific challenges to improve the properties of BXT films for the successful implementation of piezoelectric lead-free material in several applications.

Impedance-Assisted Neural Network-Based Model for Real-Time Prediction of H_2S Using Pd Anchored $CuCrO_2$ Sensor

Amit Kumar; Indian Institute of Technology Jodhpur, India

The presence of highly toxic hydrogen sulfide (H_2S) in the atmosphere can have adverse effects on human health. Therefore, it is crucial to monitor this gas for gas leak alarms and security purposes. Considerable efforts have been focused on creating and improving gas sensors to enhance their performance in detecting H_2S. Creating a simple method to manufacture H_2S sensors with both exceptional performance and prolonged stability presents a notable challenge. To address this challenge, the integration of the Internet of Things (IoT) and Machine Learning (ML) in sensor technology is crucial for advancing gas sensing capabilities. In this context, we introduced an ML-based H_2S gas sensor utilizing Pd-anchored $CuCrO_2$, designed for ultra-low concentrations and operating at 150 °C for accurate concentration prediction. Most MOS-based sensors typically operate in chemiresistive mode, offering a univariate output of DC resistance at a specific moment. However, due to inherent issues with MOS-based sensors, a univariate output is inadequate for accurately estimating concentration. Various strategies have been employed to enhance sensor performance and achieve precision. These strategies include creating sensor arrays, applying temperature modulation to boost sensor responses, and utilizing broad-range impedance spectroscopy. Notably, these techniques yield multivariate outputs from single or multiple sensors, allowing real-time comparison of multiple variables for accurate environmental assessment. Sensor array platforms and temperature modulation approaches are progressing towards imminent field implementation. Ongoing research in the field is dedicated to overcoming these challenges and further improving sensor capabilities. Our study focuses on developing a composite of $CuCrO_2$-based material to prevent sulfur poisoning during continuous sensor operation. Additionally, the material is adorned with Pd to enhance selectivity towards H_2S. Furthermore, the $CuCrO_2$-based MOS sensors are integrated with an impedance-based multivariate analysis technique. This involves considering multiple impedance-related variables, facilitating more sophisticated data processing. The use of a neural network-based multi-layer perceptron (MLP) allows the system to analyze a combination of impedance-based variables at multiple frequencies. This approach enables the system to better discern genuine changes in H_2S concentration from external factors or drift, contributing to improved accuracy and reliability. These intelligent systems, capable of real-time monitoring and adaptive responses, aim to offer more dependable and efficient gas detection solutions across various industries.

Keywords: chemiresistive gas sensors, multi-layer perceptron (MLP), concentration prediction, Impedance measurement.

Enhancement of H_2S Gas Sensing by Spillover Effect in Pd-Decorated Electrospun SnO_2/CuO Composite Nanofibers

Shaik Ruksana; Indian Institute of Technology Hyderabad, India

Hydrogen sulphide (H_2S) sensing is crucial in various industrial and environmental contexts, including chemical processing, safety applications, and environmental monitoring. In this research, we introduce a hydrogen sulphide sensing structure composed of Pd-doped SnO_2/CuO nanofibers. The core innovation in our approach lies in the synergistic combination of electrospinning and DC sputtering techniques. Electrospinning offers nanofibers with a high surface area, tunable morphology, and enhanced gas diffusion, which significantly boosts the sensitivity of gas sensors. The XRD peaks depicts the high crystalline nanofibers shows rutile and monoclinic structures of SnO_2 and CuO present in the nanofibers . The surface roughness explained in FESEM analysis is the key feature for the gas sensing as the diameter of the fibre reduced from 552 nm to 385 nm. The bare SnO_2/CuO nanofibers exhibited response (Ra/Rg) of 6.95 when exposed to 50 ppm of H_2S gas at 200 °C. Pd sputtering acts as a catalyst that plays a dual role in enhancing sensitivity. Firstly, it catalytically splits hydrogen sulphide (H_2S) into SH and H radicals on its surface. This process liberates electrons, resulting in an abundance of charge carriers and significantly improving the sensor's response to H_2S. Secondly, Pd has the remarkable ability to split oxygen (O) molecules on its surface without the need for external energy. This process creates additional active sites on the sensor's surface, further enhancing its capacity to interact with gas molecules and leading to improved gas sensing performance. The presence of Pd (sputtered for 9 s) catalyses the metallization of SnO_2/CuO heterojunctions, leading to an increase in 8.5 response to 50 ppm of H_2S gas at 200 °C. This dual approach, combining the benefits of electrospinning and Pd sputtering, results in the exceptional sensitivity observed in our nanofibers. The unique properties of Pd-doped SnO_2/CuO nanofibers, such as their extraordinary sensitivity even for 0.5 ppm (response of 2.6) and selectivity for H_2S gas, make them valuable tools for various applications where the precise detection of hydrogen sulphide is paramount.

Real-Time Stress Development of Thin Si During Low-Energy Ion Bombardment by an *In-Situ* Optical Measurement Method

Haojin Li[1,1], Faith Hines[2], Weijing Chen[1], Benli Jiang[1], Anubhav Wadehra[1], Walter

Mendoza[3], Aviva Harmon[1], Christina Wan[1,4], Derek Qin[1,5], Peco Myint[1,6], Jiaqi Tang[1], Joy Perkinson[7], Michael J. Aziz[8] and Karl F. Ludwig[1,1]; [1]Boston University, United States; [2]Emory University, United States; [3]University of California, Davis, United States; [4]Princeton University, United States; [5]California Institute of Technology, United States; [6]X-ray Science Division; Argonne National Laborator, United States; [7]The Charles Stark Draper Laboratory, Inc., United States; [8]Harvard University, United States

Observations of self-organized periodic patterns forming on solid material surfaces induced by ion beam irradiation have been long known. With continuing disagreement on the role of stress during ion beam nanopatterning, more consistent experimental measurements of stress are necessary. Multi-Optical Stress Sensor (MOSS) has been shown to be a reliable real time, in-situ technique to measure stress development in thin films from the resulting wafer curvature. Here, it is used to measure the stress development of the thin amorphized layer on the top of a Si wafer during room temperature Ar+ ion bombardment. In addition, the effect of removing the native oxide on the wafer is investigated. Resulting patterns on the Si surface are characterized by atomic force microscopy (AFM).

CH01.07.08

Symmetry Driven Anomalous Growth of Epitaxial Anatase TiO2 on LAO (100) Substrates Benjamin Summers[1], Akash Gadekar[2], Sumit Goswami[1], Pralay Paul[1], Sreehari Puthan Purayil[1], Dhiman Biswas[1], Casey P. Kerr[1], Horst Hahn[3,1], Xiaoqing Pan[4,4] and T. Venky Venkatesan[1,5]; [1]The University of Oklahoma, United States; [2]National University of Singapore, Singapore; [3]Karlsruhe Institute of Technology, Germany; [4]University of California, Irvine, United States; [5]National Institute of Standards and Technology, United States

Conventionally, thin film growth is known to follow any of the three well-studied growth mechanisms: layer-by-layer growth (Frank-van-der-Merwe), island growth (Volmer-Weber), and layer-by-layer followed by island growth (Stranski–Krastanov) [1]. Surprisingly, the growth of anatase TiO2 doesn’t follow any of the usual growth mechanism, even when it’s grown on closely lattice-matched substrate like lanthanum aluminate (LAO), for which, in general, layer-by-layer growth should be favored. In this work, we have monitored the initial growth dynamics of pulsed laser deposited (PLD) anatase TiO2 films of thicknesses ranging from as low as 1/4 of a monolayer to 40 nm on LAO (100) substrate using in-situ reflection high-energy electron diffraction (RHEED) diagnostic tool. We show that at very early stage, i.e., up to 10-unit cells, the film grows 3D island-type, forming so called “dead layer”. Above this thickness, we started seeing RHEED oscillations confirming layer-by-layer growth. We also found that the dead layer reorders itself as the film grew further, shrinking the dead layer and making the film closer to a single crystal near the interface. This kind of growth mechanism is quite contrary to the usual thin film growth schemes and could be explained based on which of the three segments of the anatase TiO2 unit cell starts growing on the substrate. We have characterized the films ex-situ using Scanning Transmission Electron Microscopy (STEM), which validates the presence of the interface “dead-layer” and its subsequent crystalline regrowth. In addition to this, we have shown that other materials like YBa2Cu3O7 (YBCO) and Sr3Al2O6 (SAO) also follow a similar growth process, making it a “general” thin film growth mechanism.

Review of Refractive Index Refinement Approaches in Atomic and Molecular Physisorption Phenomena in the Case of Thin Mono Layers on a Substrate Materials within Recent Spectroscopic Ellipsometry Improvements Frederic Ferrieu[1] and Christophe Vallee[2]; [1]Opticnano Consulting, Switzerland; [2]University at Albany, State University of New York, United States

Spectroscopic Ellipsometry (SE) has advanced with integrated photonic no-moving-part designs, enhancing accuracy. Recent developments include IoT integration and cloud protocols (HTTP, MQTT), enabling automatic, remote control and analysis. SE serves as a versatile "Swiss knife" tool, optimized further with AI for full automation and deep learning.It is crucial for studying deposited or molecular beam epitaxy-grown monolayers, facing challenges in thickness and refractive index determination. It finds applications in biology and protein adsorption. SE competes with Surface Plasmon Resonance (SPR) in refractive index precision (~10^-3 to 10^-4). In situ SE acts as real-time process control, though very thin layer measurements often lack simultaneous thickness and refractive index correlation. This paper revisits P. Drude equations, approximating ellipsometry for ultra-thin layers with a first-order Taylor expansion.During growth or deposition involving atomic layers, SE excels. Unlike SPR, SE using discrete wavelengths offers broader applications with analytical indices law , enhanced by stable vacuum chamber configurations for precise refractive index and thickness measurements. Depolarization factor considerations give additional value, and SE's "no moving part" photonics provide superior capability over SPR, ideal for ALD, MBE, CVD, and PVD techniques.The instruments, while broad in spectroscopic range and angle techniques, face challenges detecting monolayers and ultra-thin layers. Ongoing advancements promise to address these limitations, reinforcing SE as a powerful tool for research and practical applications.This letter explores the future expanding capabilities and applications of SE, highlighting its pivotal role in advancing multi-technology tools.

Real-Time Control of Sputtering Parameters to Achieve Stable Vanadium Oxide Thin Films with Consistent Electrical and Optical Properties Won Young Choi, Jin-Seok Hwang, Seojun Lee, Hyeon-kyo Song and Soodeok Han; VanaM Inc., Korea (the Republic of)

Vanadium oxide (VOx) possesses various oxidation states, each exhibiting unique electrical and optical properties that have made it a subject of research for decades, with potential applications in smart windows, batteries, catalysts, and various sensors. Particularly, VO2 exhibits metal-insulator transition (MIT) characteristics at 60-70 degrees Celsius, promising diverse applications. However, within the range of x = 1.5 to 2.5, there are more than 15 oxidation states, which can easily lose their properties due to minor process variations. Thus, maintaining a consistent oxidation state and crystal structure presents a significant challenge. Even if the entire thin film maintains a consistent oxidation state and crystal structure, limiting the second phase that occurs during MIT is another major challenge. Due to these characteristics, it is essential to monitor the plasma state in real time and adjust the process variables to create a stable growth environment during the growth process of vanadium oxide thin films.

The primary equipment used to observe the sputtering process is Optical Emission Spectroscopy (OES). OES operates during plasma process to measure the intensity of light in the 200-1000 nm wavelength range. Process variables include working pressure, sputtering power, and the distance between the sample and target, while the preparation process before and after sputtering is consistently maintained. Various combinations of sputtering process variables are used to analyze changes in the OES results, defining the relationship between each variable and the overall spectrum. Based on this, a controller is developed to ensure the spectrum remains consistent. The VO_2 thin film is subjected to resistance measurements in response to temperature changes to determine the total resistance change, maximum resistance change rate, and transition temperature according to MIT. A multilayer neural network is constructed to examine the relationships between the complete spectrum data and these results. The goal is to adjust the process variables based on the real-time observed OES spectrum to achieve a thin film with consistent performance.

CH01.07.11

Development of an *In-Situ* Raman Spectroscopy Setup for Monitoring 2D-TMDs Growth in a CVD Chamber

Wei-Chun Chen, Hung-Pin Chen, Wei-Lin Wang, Yu-Wei Lin, Hua-Lin Chen and Fong-Zhi Chen; National Applied Research Laboratories, Taiwan Instrument Research Institute, Taiwan

In-situ characterization methods are powerful for revealing structure–performance correlations of 2D-TMDs under reaction conditions. When reactions occur in TMD materials, understanding the structural properties is crucial for the in-situ characterization of dynamic processes. *In-situ* Raman spectroscopy can provide molecular-level information during the synthesis of 2D-TMD materials under the CVD process, making it highly valuable for the study of TMDs. Additionally, *in-situ* measurements can help avoid the effects of low impurity adsorption on the surface of TMDs. In this paper, we present the results obtained from a self-designed in-situ Raman spectroscopy setup during the CVD process for 2D-TMD growth. The results show a Raman scattering signal at 366 cm^{-1} corresponding to the WS_2 E_{2g} peak. Additionally, the PL spectrum was measured at 620 nm in vacuum. These findings demonstrate the effectiveness of our *in-situ* Raman spectroscopy setup in capturing crucial structural and optical properties during the CVD process, providing valuable insights into the synthesis and performance of 2D-TMD materials.

SESSION CH01.08: Optical and Electrical Studies II

Ellipsometry Applied to Real Time Process Characterization Christophe Defranoux[1], Laszlo Makai[1], Peter Basa[1], Balint Fodor[1] and John Byrns[2]; [1]Semilab Semiconductor Physics Laboratory Co. Ltd., Hungary; [2]Semilab USA LLC., United States

In situ characterization during thin-film processing is crucial for optimizing film properties and ensuring quality control and process reliability in various applications, like semiconductors or photovoltaics. Initially dedicated to the control of R&D processes, it is now more and more used in Production control. Spectroscopic ellipsometry (SE) emerges as one of the powerful non-destructive optical techniques that provides real-time monitoring and detailed analysis of thin-film growth and properties.

We will explore the advancements and applications of *in situ* SE in thin-film processing, highlighting its ability to measure film thickness, optical constants, and layer composition with high precision.

The integration of SE in different deposition techniques, such as chemical vapor deposition (CVD), physical vapor deposition (PVD), and atomic layer deposition (ALD), will be examined, showcasing its role in achieving desired film characteristics.

Case studies demonstrating the successful application of *in situ* SE in monitoring and controlling film uniformity, interface quality, and material transitions will be presented. The discussion will extend to recent technological advancements in SE instrumentation and data analysis methods, which enhance its sensitivity and accuracy. Practical aspects of implementing *in situ* and *in line* SE in industrial and research settings, understanding its impact on improving process efficiency and material performance. This presentation aims to underscore the significance of spectroscopic ellipsometry as an indispensable tool in the evolving landscape of thin-film processing technology.

Understanding the evolution of thin film properties during post-deposition treatments is also vital for optimizing

their performance in various applications, including electronics, optics, and coatings. In situ characterization of thin films during these critical post-deposition processes using advanced optical metrology techniques will be presented with their application in optimization of the process, and how monitor and control changes in thin film properties during annealing, curing, and other thermal or chemical treatments can be done.

Chiral Preservation Across Phase Transitions in Twisted Crystals Justin Bendesky; New York University, United States

Crystal twisting in organic molecules is most often observed during crystallization from the melt as banded spherulites comprising of bundles of helicoidal fibers rotating in concert about the growth direction. When viewed between cross-polarizers, concentric rings of interference colors appear due to continuously rotating refractive indices. In addition to modulating material properties, crystal twisting, either clockwise or counterclockwise about the growth direction, also introduces chirality to films. Here we examine chiral preservation in banded spherulites of 4-heptyloxy-4’-cyanobiphenyl (7OCB) through the crystal-to-liquid crystal transition. When crystallized from the melt at temperatures between 0 C and 25 C, 7OCB forms banded spherulites with pitch (i.e. spacing between colored bands) ranging from 2-300μm. In situ petrographic imaging during thermal cycling through the crystal-to-nematic phase (54 C) and nematic-to-isotropic phase (75 C) transitions revealed the preservation of interference bands. Mueller-Matrix Imaging (MMI), a full polarimetry method to spatially map the linear birefringence (LB), linear dichroism (LD), circular birefringence (CB), and circular dichroism (CD) in films, further demonstrated that circular birefringence was preserved when banded spherulites were heated to the liquid crystal phase. The magnitude of the CB signal varied with temperatures and was reversible. These results suggest the initial formation of chiral mesostructures in the crystalline phase as a promising strategy to introduce tunable optical activity in crystalline films.

8:45 AM CH01.08.03

***In Situ* Transport Characterization of Hydride-Induced Thin-Film Reduction** Jiayue Wang[1], Yijun Yu[1,2], Jiarui Li[2], Eun Kyo Ko[1,2], Vivek Thampy[2], Yi Cui[1,2] and Harold Y. Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Metal hydrides, such as CaH_2, have recently emerged as highly promising reducing agents for facilitating the low-temperature reduction of metal oxides. A unique advantage of hydride reduction is its capability to synthesize metastable materials that are otherwise inaccessible through conventional high-temperature reactions. Notably, hydride reduction techniques have been utilized to create unusual NiO_4 square-planar coordination in nickelates, a structure known to host superconductivity [1]. Beyond novel materials discovery, metal hydrides hold substantial potential in applied engineering, as previous studies have demonstrated that CaH_2 can lower the temperature required for H_2 reduction of iron oxide, offering benefits for clean hydrogen-based ironmaking [2]. Despite these wide-ranging applications, a pivotal scientific question remains: *What is the true active reducing species in hydride reduction?* Answering this question is crucial for unlocking the full potential of metal hydrides in both fundamental research and practical applications.

In this study, we investigate the CaH_2-induced reduction kinetics of metal oxides using epitaxial α-Fe_2O_3 thin films as a model system. To elucidate the intrinsic reducing capability of CaH_2, we seal the iron oxide thin-film samples along with CaH_2 powders in an evacuated quartz tube and analyze the reduction behavior within this closed system. We developed an experimental platform that enables real-time monitoring of the CaH_2 reduction process through transport measurements. Using this setup, we quantified the phase transformation kinetics from iron oxide to metallic iron by continuously tracking the evolution of electrical resistivity in the thin-film sample.

Consequently, we determined the apparent activation energy of hydride reduction under conditions where samples were either in contact with or separated from CaH_2 powders. In both cases, the apparent activation energies were identical and comparable to those obtained from gas-phase H_2 reduction. These findings indicate that CaH_2 reduction predominantly occurs via solid-gas interactions, with gas-phase H_2 being the primary reducing agent. This study highlights the power of combining thin-film systems and *in situ* transport measurements to understand critical material processing reactions, which can help accelerate materials design and optimization.

***In Situ* Phase Transformations of 3D Nanoislands on 2D Materials in the Ti-Graphene System** Pip J. Knight, Kate Reidy, Aubrey Penn, Alexandre Foucher and Frances M. Ross; Massachusetts Institute of Technology, United States

The epitaxial growth of functional three-dimensional (3D) nanoislands on two-dimensional (2D) materials is important for controlling interfacial properties when optimising the integration of 2D materials into devices. One way to expand the family of materials that can form epitaxial interfaces with 2D materials is to react epitaxial metallic nanoislands grown on 2D materials with a relevant gaseous precursor. For such reactions, it is important to consider how strain in the nanoislands will influence the reaction. Bonding between the metal and 2D material is typically quasi-van der Waals and can be strong enough to cause coherency strain in the metal, as occurs in the Ti-graphene system. Such coherency strains can cause the metal to form in islands that contain a thicker region in the centre with reduced strain, that is often dislocated. Strain and thickness in the Ti are likely to influence the way phase transformations occur locally within these nanoislands. Furthermore, the effect of surfaces and interfaces at the nanoscale may cause differences from the bulk phase diagram. To explore such effects, we study how Ti nanoislands on graphene react at high temperature with oxygen or with disilane under ultra-high vacuum (UHV) conditions. This system is device-relevant because certain silicides of Ti and the anatase form of TiO_2 are good photocatalysts and cocatalysts, with higher photocatalytic activity when combined with 2D materials.
We first characterise the strains present in single crystal titanium nanoislands of varying thicknesses, deposited using slow evaporation rates in UHV conditions on clean suspended graphene. Then, we carry out reactions of UHV-deposited Ti islands with each of the reactive gases *in situ* in a Hitachi H-9000 UHVTEM connected to the UHV deposition chambers, recording movies to provide an understanding of the mechanism and kinetics of the reactions. Post-growth analysis includes additional imaging via atomic resolution scanning transmission electron microscopy; electron energy loss spectroscopy; and atomic force microscopy. These are used to explore the role of strain in how nanoislands of different thicknesses transform, and to characterise the structure of the interfaces between transformed areas and the original Ti matrix. Finally, we explore the opportunities presented by the unique morphology and strain states in the Ti islands, contrasting this with the results of similar depositions on conventional 3D substrates. This provides the opportunity to control structure and composition within specific

regions of the 2D/3D heterostructure.

9:15 AM CH01.09.02

Investigation of Perovskite Defects Reduction and Non-Radiative Recombination Kinetics Using *In-Situ* PL Measurements Under Aerosol Treatment Madsar Hameed[1], Joe Briscoe[1], Xuan Li[2,1], Zeyin Min[1] and Stoichko Dimitrov[1]; [1]Queen Mary University of London, United Kingdom; [2]Helmholtz-Zentrum Berlin, Germany

Lead-halide perovskites have firmly established themselves in the fields of photovoltaics and optoelectronics, demonstrating increasingly competitive power conversion efficiencies comparable to traditional solar cells [1]. However, achieving further enhancements in performance necessitates mitigating defect-assisted, nonradiative recombination of charge carriers within the perovskite layers. A comprehensive understanding of perovskite formation and associated process control is essential for effectively reducing defects. In this investigation, we examine the crystallization kinetics of the different lead-halide perovskite $MAPbI_3$, $FAPbI_3$, $CsFAPbI_3$ etc. during thermal annealing under aerosol treatment employing in-situ photoluminescence (PL) spectroscopy. Previously, we have demonstrated a method for performance and stability improvements in $FAPbI_3$ and other perovskite compositions by crystallization in the presence of a solvent aerosol treatment [2,3].The in situ PL measurements results demonstrate that aerosol treatment induces favorable morphological changes, leading to improved charge transport properties and reduced defect density within the perovskite film. This characterization approach enables the real-time assessment of optoelectronic properties during perovskite formation and development of improved crystals producing a uniform film with improved morphology under the effect of facile and scalable aerosol treatment. These findings not only shed light on the underlying mechanisms governing the aerosol-assisted modification of perovskite materials but will pave the way for the development of more efficient and stable perovskite-based optoelectronic devices.

9:30 AM CH01.09.03

Piezoelectric Resonance Method for *In Situ* Monitoring of Formation of Pd-Based Bimetallic Nanoparticles Synthesized by Sputtering Nobutomo Nakamura, Koji Matsuura, Akio Ishii and Hirotsugu Ogi; Osaka University, Japan

When metallic material is sputtered on a solid surface, isolated nanoparticles are formed by nucleation, and a continuous film is formed after the nanoparticles grow and contact with each other. Just before the continuous film is formed, gaps of the order of a few nanometers appear between nanoparticles. This state is called nanogap nanoparticles. The nanogap nanoparticles show electrical properties different from those of isolated nanoparticles and continuous films, and it has been applied to hydrogen gas sensors.

The nanogap nanoparticles can be synthesized by interrupting the sputtering just before the nanoparticles contact. However, the nanoparticles are formed when the height of the nanoparticles becomes around a few nanometers, and it is difficult to identify the moment to interrupt the sputtering. To solve this problem, we developed the piezoelectric resonance method. This method identifies the formation of nanogap nanoparticles by utilizing the resonant vibration of a piezoelectric material without contacting the substrate or the nanoparticles. Using this method, the gap size can be controlled, and it has been demonstrated to improve the performance of hydrogen gas sensors.

After the above studies, we found that the piezoelectric resonance method is also applicable for in situ monitoring of the formation processes of bimetallic nanoparticles synthesized by sputtering. Bimetallic nanoparticles have attracted attention due to their properties, which are different from those observed in bulk materials or nanoparticles composed of a single metallic element. Since the properties change depending on the internal structure (core-shell structures, mixed structures, and intermetallic alloy structures), it is important to understand the internal structure and the associated formation process. However, observing the formation process during the synthesis is difficult, and it has not been clarified completely. In this presentation, we show that the formation process of core-shell nanoparticles can be monitored using the piezoelectric resonance method. Pd-based bimetallic core-shell nanoparticles are synthesized by sequential sputtering of two metals, and their growth is monitored. In the experimental results, sputtering of metal A followed by metal B tended to form B-shell/A-core nanoparticles. However, in the Pd-Au system, restructuring occurs during the synthesis, and core and shell turnover occurs. To validate the experimental results, we performed molecular dynamics simulations, and the availability of the developed method is demonstrated.

Seeing It Happen—Insights Into the Surface Chemistry of HfO_2 and TiO_2 ALD from *Operando* Ambient Pressure X-Ray Photoelectron Spectroscopy Joachim Schnadt[1,2]; [1]Lund University, Sweden; [2]MAX IV Laboratory, Sweden

The development of ALD processes is based on a number of different considerations and factors. One consideration is the envisaged ALD surface chemistry, which has to match not only the desired process outcome and processing conditions, but also the reaction properties of both the precursor and the surface. For many precursors, their surface chemistry is assumed to follow general reaction schemes. For example, the thermal ALD of transition metal oxides from amido complex and water precursors is typically assumed to follow a ligand exchange mechanism. The wide spread of such general reaction schemes results from that they often provide a sufficiently successful prediction of the ALD process outcome, but also because experimental tools are lacking that allow direct insight into reaction mechanisms. Indeed, it has been noted that surface chemistries can be both more complex and varied than general reaction schemes make believe [1,2].

Methods that allow the time-resolved monitoring of ALD processes, such as quartz crystal microbalance measurements, quadrupole mass spectrometry, pyroelectric calorimetry and ellipsometry can provide deepened insight into ALD surface reaction mechanisms. Recently, these methods have been joined by two chemically sensitive techniques for the time-resolved characterisation of ALD processes, namely infrared spectroscopy [3] and ambient pressure x-ray photoelectron spectroscopy (APXPS) (cf., e.g., [4,5]). These two methods are capable of following the ALD surface chemistry in real time and at processing pressures equal or similar to those in an ALD reactor.

Using the metal amido complex- and water-based ALD of HfO_2 and TiO_2 on different surfaces as examples, I would like to demonstrate the usefulness of time-resolved APXPS for the elucidation of surface species and their evolution as well as for the observation of substrate processes such as oxygen transport. Such information allows to formulate ALD reaction mechanisms. Thus, we observe reaction pathways that deviate from the standard models of ALD surface chemistry, including, in particular, bimolecular reaction pathways that are feasible also on non-reactive surfaces. But also on partially hydroxylated surfaces non-standard reactions occur, which draws attention to the fact that full surface hydroxylation cannot always be achieved. Further, for reducible surfaces we find that oxygen ion transport may play a major role in the initial ALD.

I will also demonstrate how the time resolution in *operando* APXPS experiments during steady-state ALD can be improved so that surface chemistry monitoring under conditions that resemble those in standard ALD reactors becomes feasible. Altogether, APXPS provides us with entirely new information on ALD reaction mechanisms during both the initial phases of ALD as well as steady-state ALD, which is important input for the future optimisation of ALD processes.

Dynamic Nanocrystal Superlattices with Thermally Triggerable Lubricating Ligands Yifan Ning[1], Shengsong Yang[1], Dai-Bei Yang[1], Yi-Yu Cai[1], Jun Xu[1], Ruipeng Li[2], Yugang Zhang[2], Cherie R. Kagan[1,1,1], Jeffery G. Saven[1] and Christopher B. Murray[1,1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States

The size-dependent and collective physical properties of nanocrystals (NCs) and their self-assembled superlattices (SLs) enable the study of mesoscale phenomena and the design of metamaterials for a broad range of applications. However, the limited mobility of NC building blocks in dried NCSLs often hampers the potential for employing postdeposition methods to produce high-quality NCSLs. In this study, we present tailored promesogenic ligands that exhibit a lubricating property akin to thermotropic liquid crystals. The lubricating ability of ligands is thermally triggerable, allowing the dry solid NC aggregates deposited on the substrates with poor ordering to be transformed into NCSLs with high crystallinity and preferred orientations. The interplay between the dynamic behavior of NCSLs and the molecular structure of the ligands is elucidated through a comprehensive analysis of their lubricating efficacy using both experimental and simulation approaches. Coarse-grained molecular dynamic modeling suggests that a shielding layer from mesogens prevents the interdigitation of ligand tails, facilitating the sliding between outer shells and consequently enhancing the mobility of NC building blocks. The dynamic organization of NCSLs can also be triggered with high spatial resolution by laser illumination. The principles, kinetics, and utility of lubricating ligands could be generalized to unlock stimuli-responsive metamaterials from NCSLs and contribute to the fabrication of NCSLs.

Epitaxial Growth and Characterization of Potassium Titanyl Phosphate Derivated Thin Films by Pulsed Laser Deposition Mathieu Salaun[1,2], Adrien Clavel[1] and Benoit Boulanger[1,2]; [1]Institut Néel, France; [2]Université Grenoble Alpes, France

The mm2 orthorhombic potassium titanyl phosphate crystal, *i.e.* $KTiOPO_4$ (KTP), is a famous biaxial nonlinear optical crystal widely used commercially for second harmonic generation (SHG) or optical parametric oscillation (OPO) pumped by a 1.064 µm Nd:YAG laser for example. Most of its applications are based on bulk single KTP crystals. However, there is a strong interest to elaborate submicrometric waveguides in the framework of integrated photonic devices. Among several waveguide-fabrication techniques such as proton exchange, ion implantation or dicing [1], a serious alternative is Pulsed Laser Deposition (PLD). Indeed, it was reported that type-II second-harmonic generation and sum-frequency mixing could be realized in uniform epitaxial $RbTiOPO_4$ (RTP) films over KTP channel waveguides prepared by PLD [2]. Such waveguides could be a serious alternative to efficient low energy nonlinear optical devices in particular for Telecom or spectroscopic applications.

PLD is a technique particularly well suited for growing single oxides films with complex chemical composition. This technique consists in a high energy laser ablation of a material with the same chemical composition than that of the desired layer. The plasma of the ablated material is then condensed on the substrate and heated to a temperature such as the aggregates can self-organize on the atomic lattice of the substrate leading to the epitaxial layer.

In this study, we performed epitaxial growth of the RTP phase on KTP single crystals by PLD. The target that has been used was a single RTP crystal. However, by chemical analysis and Xray diffraction we demonstrated that due to alkali interdiffusion between film and substrate, it was not possible to achieve a pure epitaxial layer of RTP but

most likely an mixed stoichiometry $K_xRb_{(1-x)}TiOPO_4$ [3].
More recently, we proposed to grow another material similar to KTP to avoid any diffusion. The material which has been chosen is KTiOAsO4. Indeed, this isomorphic structure to KTP has a common alkaline and a different building block. This may avoid any diffusion. Moreover, the refractive index difference is more favorable for waveguiding and even phase matching.

Substrate Dependance on YIG Thin Film Crystallization for Suspended Magnon Devices Maria Roman, Tito Busani, Caleb Annan and Nicolas Barragan; The University of New Mexico, United States

Thin film Yttrium Iron Garnet (YIG) is a promising material for nanoscale magnonic/spintronic device applications because it has the potential for magnon mode engineering while also being compatible for nanofabrication. Crystalline YIG films less than 100nm thick allow the manipulation of magnetic shape anisotropy to realize magnon modes with out-of-plane magnetization which would require very low bias fields. While crystalline YIG has only been realized on gadolinium gallium garnet (GGG), because of the lattice matching between YIG and GGG, GGG is not an ideal substrate as it is both difficult to process and can introduce additional magnetic damping do the deleterious paramagnetic response. Given that YIG, when deposited as a thin film, is in its amorphous phase, in this work we present the formation of crystalline YIG on Si and SiO_2 substrates through annealing at temperatures between 400°C to 800°C. We also investigate crystallization as a function of substrate stress and seed patterns in SiO_2.
YIG was deposited using RF sputtering on Si substrate with and without SiO2 buffer layer and onto Si/SiO_2 patterned samples. The patterned substrate consists of micro hole pairs in the SiO_2 of 1µm or 2µm diameters, separated by 5µm or 10µm, and repeated every 50µm. SiO_2 was etched using a dry plasma fluorine gas and stopped at the Si substrate. Then the YIG was deposited. Scanning Electron Microscopy (SEM) was used to verify pattern quality and uniformity. Thin films were analyzed using Ellipsometry, Profilometry, and SEM to confirm thickness. The stoichiometry of the deposited films was done using Ellipsometry, Electron Disperse Spectroscopy (EDS), and X-Ray Diffraction (XRD). The YIG samples were then annealed inside a furnace using O_2 and N_2 atmosphere at temperatures between 400°C to 800°C. To confirm crystallization, we used in-situ XRD annealing measurements and Raman at room temperature.
YIG crystallization was found to be dependent on both annealing time and temperature. The typical crystallization temperature was found to be 750°C for YIG deposited on both Si and Si/SiO_2 substrate. Typically, the Raman peak at 270 cm^{-1} increases with the annealing temperature and the annealing time and it saturates at 750°C after 3 hours. The XRD confirms the Raman results and clearly shows that the annealed YIG is polycrystalline. The patterned samples re-crystallize at the same conditions; however, they have a more uniform structure with less boundary grains. Both Raman and XRD indicate that the pattern samples also have a stronger re-crystallization showing the non-patterned samples are less polycrystalline.
Ellipsometry measurements on thin films were fitted using the b-spline model within 1eV to 6.0 eV and correlated with the EDS data and profilometry data (i.e thickness and composition of the YIG). The Ellipsometry method we are reporting is well adapted to model the thin film structure, to measure the thickness of the film, and the

complex index of refraction. We found that the samples remain stochiometric through the annealing indicating that there is not reaction between the YIG and the substrate. The thickness changes between the amorphous films and the polycrystalline or crystalline indicates the formation of a denser phase. The index of refraction was ranging from 2.1 to 2.3 for a wavelength of 1550 nm. From the obtained n and k, we evaluated the complex e, using e =$(n+ik)^2$. Real part of e as a function of the photon energy shows a peak in the region of 4.5eV to 5.2eV, depending upon the annealing condition. Patterned samples show a peak shifted towards 5.2 eV. This peak was assigned to charge transfer (CT) type transitions in YIG.
We will finally present a fabrication method for crystalline YIG suspended on Si using the patterned samples and explain how the crystallization is initiated at the patterned holes and propagates effetely after removing the SiO_2.

11:30 AM CH01.09.08

***In Situ* Monitoring the Drying Process of the Bulk Heterojunctions (BHJs) in Organic Solar Cells with a Multi-Spectroscopy** Fengling Zhang[1], Yanfeng Liu[1,2], Nannan Yao[1,3] and Ergang Wang[4]; [1]Linköping University, Sweden; [2]Jiaxing University, China; [3]Zhejiang University, China; [4]Chalmers University of Technology, Sweden

The performance of solution processed organic solar cells (OSCs) is primarily governed by the morphologies of bulk heterojunctions (BHJs) consisting of electron donors and acceptors formed during the drying process. The morphologies of the BHJs depends on many factors, such as solubility of donors and acceptors, solvent, solution concentration, coating methods etc. Stability of OSCs, a key parameter for commercialization, also strongly depends on the morphologies. Therefore, it is essential to understand morphology evolution from solutions to solid films to manipulate the morphology of BHJs for further development of OSCs.
Combining multiple optical techniques in an in situ mode, including laser scattering, absorption, and steady-state photoluminescence (PL), we comprehensively study the morphology evolution and donor/acceptor interactions in different BHJs.
First, to understand how the drying process impacts the blend morphology in OSCs, we studied the film formation processes of three representative BHJs composed of donor PBDB-T with acceptors PC71BM, IT-M, and N2200 by monitoring the drying process from liquids to films with the in situ ultraviolet-visible (UV-vis) absorption spectra and photoluminescent (PL) spectroscopy. The drying and PL quenching dynamics are analyzed during the film formation of both pristine and BHJ films, which indicate that the component with higher molecular weight dominates the blend film formation and the final morphology. This work contributes to a deeper understanding of microstructure formation determined by interplay between donor, acceptor, and solvent during the film drying. (Liu et al., *Small Methods*, 2021, 2100585, https://doi.org/10.1002/smtd.202100585)
Furthermore, we investigated solvent impacts on the morphology of blend films and performance of the OSCs by monitoring the drying process of PBDBT:PF5–Y5 blends in chlorobenzene (CB), and ortho-xylene (o-XY) with the in situ multifunctional spectroscopy. Finer-mixed donor/acceptor nanostructures obtained in CB-cast layer corresponding to more charge generation in corresponding solar cells was observed. (Yao et al., Sol. RRL 2023, 2201134, https://doi.org/10.1002/solr.202201134)
In addition, we also revealed the function of a commonly used solvent additive 1-Chloronaphthalene (CN) in enhancing the performance of all-PSCs based on PBDB-T:PF5-Y5 by studying the drying process, which suggests that improved performance of PBDB-T:PF5-Y5 solar cells originated from enhanced crystallinity and hole mobility since CN promotes self-aggregation of PBDB-T during the drying process. (Liu et al., J. Phys. Chem. Lett. 2022, 13, 11696, https://doi.org/10.1021/acs.jpclett.2c03397)
Overall, the versatile in situ spectroscopies can be an important tool for optimizing performance of OSCs via manipulating drying process. Furthermore, the results can be extended to future develop other blend inks for solution-cast organic or hybrid electronics.

11:45 AM CH01.09.09

Dynamic Model Development for the Temperature-Dependent Characterization of $CsPbI_2Br$ Perovskite Thin Films via Spectroscopic Ellipsometry Athina Papadopoulou[1,2], Rafikul Ali Saha[1], Maria Isabel Pintor Monroy[2], Wenya Song[2], Itai Lieberman[2], Eduardo Solano[3], Maarten Roeffaers[1], Robert Gehlhaar[2] and Jan Genoe[1,2]; [1]KU Leuven, Belgium; [2]imec, Belgium; [3]ALBA Synchrotron, Spain

Spectroscopic ellipsometry (SE) is a widely used characterization technique for estimating the thickness and optical constants of thin films. Less commonly, it is performed as a function of temperature, providing valuable insights into the temperature dependence of a film's optical and morphological properties. This information can prove useful in various contexts, from enhancing the fundamental understanding around a material's structure to optimizing a device's optoelectronic performance. Most studies on temperature-dependent SE adopt a methodology where the sample is allowed to stabilize at consecutive temperature intervals, for each of which a static model is developed. However, this approach is likely to conceal information around real-time mechanisms and effects.

In this work, we propose a new approach for the fitting of temperature-dependent SE results. This approach relies on the use of a continuous heating ramp and the development of a singular dynamic model that can describe in real-time the evolution of a thin film under increasing temperature. Unlike most previous studies, special emphasis is placed on the inclusion of thickness and roughness variations, due to lattice expansion/contraction and grain coalescence. In particular, the increase of the surface roughness, despite being commonly overlooked, can lead to erroneous fitting results due to increased light scattering.

We use this modelling approach to characterize the real time annealing effect on thermally evaporated $CsPbI_2Br$ thin films and quantify various temperature-dependent parameters. This way, we gain insight into the crystallization mechanism of vacuum evaporated inorganic perovskites, which is still under-investigated when compared to the crystallization of solution-processed films. The as-deposited films, which are initially in the orthorhombic perovskite phase, exhibit extremely low roughness, associated with small grain size. As the temperature increases, the transition to the tetragonal phase is marked by a significant shift in bandgap energy. Followingly, the transition to the cubic phase is indicated by a pronounced increase in the film's roughness, signaling the onset of grain coalescence. Once this process is complete, prolonging the annealing duration does not significantly impact the grain size and morphology. Finally, we extract and interpret various temperature-dependent parameters, like the Urbach energy, the thermo-optic coefficient, and the interband transition energies.

The validity of the presented results is further corroborated through additional ex and in situ characterization measurements, including grazing incident wide angle X-Ray scattering, atomic force microscopy, profilometry, and reflectance/transmittance measurements. This demonstrates that the proposed dynamic modeling of temperature-dependent SE results constitutes a high-throughput, reliable, and versatile characterization approach that can partially replace multiple, even costlier and less accessible, techniques.

SESSION CH01.10: High-Throughput and Machine Learning

***In-Situ* Characterization of Metal-Oxide Films Deposited by Atmospheric-Pressure Spatial ALD—Deposition, Properties and Post-Deposition Performance Studies** Kevin Musselman, Olivia Marchione, Kissan Mistry and Guvanch Gurbandurdyyev; University of Waterloo, Canada

Atmospheric-pressure spatial ALD (AP-SALD) is a rapid, scalable, open-air method for the deposition of thin films with nanoscale thickness control. We employ in-situ characterization to monitor the properties of ZnO and AlOx films during their deposition by by AP-SALD. Custom-made printed circuit boards and reflectance spectroscopy provide information about electrical and optical properties during the film growth. Both also provide insight into film nucleation. For fibrous substrates like textiles, a Virtual Interface model is used for in-situ estimation of the thickness of conformal shells formed on the substrate fibers. In-situ reflectance spectroscopy is also leveraged to provide feedback to the deposition system, enabling accurate control of the deposition rate. The conformal, pinhole-free nature of the AP-SALD films makes them promising for encapsulation applications. We develop machine-learning-enabled imaging methods to characterize the encapsulation performance of AP-SALD AlOx films when they are exposed to high humidities during calcium transmission-rate tests and perovskite solar cell degradation tests.

4:00 PM CH01.10.02

Accelerating Discovery of Nanoarchitectures in Thin Films Through Laser Thermal Gradient Treatment Induced Solid-State Metal Dealloying Cheng-Chu Chung[1], Ruipeng Li[2], Gabriel Veith[3], Honghu Zhang[2], Bruce Ravel[4], Fernando Camino[2], Ming Lu[2], Nikhil Tiwale[2], Kevin Yager[2] and Yu-chen K. Chen-Wiegart[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]National Institute of Standards and Technology, United States

The Thin-film solid-state metal dealloying (SSMD) process is emerging as an innovative method for fabricating nanoarchitectured materials. Due to the solid-state processing, and unique properties of nanoscale features, which alter equilibrium thermodynamics and phase stability, SSMD enables the formation of finer feature sizes in bi-continuous nanostructures with lower temperature treatments and shorter processing times compared to liquid metal dealloying. SSMD thus opens new opportunities in applications related to thin film processes. However, the exploration of the materials library to design new dealloyed nanostructures is inefficient and often relies on experimental serendipity which limits the ability to choose appropriate engineering parameters that are connected to fundamental physical and chemical characters of the systems.

In this work, we present a comprehensive method to fabricate machine-learning (ML)-predicted potential systems, specifically Nb-Al/Sc and Nb-Al/Cu (an A-B parent alloy dealloyed by a C solvent metal), within a thermal gradient treatment condition ranging from 100 to 800 °C via laser heating. The high-dimensional thin-film sample was rapidly characterized through a suite of multimodal synchrotron X-ray techniques, including Grazing Incidence Wide-/Small-Angle X-ray Scattering (GIWAXS/GISAXS), and X-ray Absorption Spectroscopy (XAS). This characterization was combined with an autonomous approach utilizing ML for decision-making in the experimental search process. Subsequent Transmission Electron Microscopy (TEM) and Scanning Transmission Electron Microscopy (STEM) were carried out for detailed analysis and validation.

The results demonstrated critical transitions in phase and morphology across a broad thermal space, revealing a potential dealloying process responsible for the formation of the nanostructure. These findings provide valuable insights into the design of new dealloyed nanostructures, elucidating key processing conditions and enhancing our understanding of the dealloying mechanism. This includes insights into phase transitions, chemical bonding statuses, and morphological changes, thereby paving the way for more efficient and targeted development of

advanced nanoarchitectured materials for future applications.

4:15 PM CH01.10.03

Autonomous Control of a Roll-to-Roll Printing Device Andrew I. Campbell[1], Jonathan Howse[1], George Panoutsos[1], Anthony Rossiter[1], Stephen Ebbens[1], Rachael Rothman[1], Dennis Cumming[1], Ian Reaney[1], Liam Blunt[2], Hussam Muhamedsalih[2], Rachel Smith[1], Alex Routh[3], Mothana Hassan[2], Nathan Dodd[1], Jack Atkinson[1], Christopher Passmore[1], Derek Sinclair[1], Zezhi Tang[1], Patrick Welche[3] and Kai Wu[1]; [1]The University of Sheffield, United Kingdom; [2]University of Huddersfield, United Kingdom; [3]University of Cambridge, United Kingdom

Roll-to-roll (R2R) slot-die coating is widely used in industry in the manufacture of a diverse range of products; e.g. lithium-ion batteries, solar cells and optical films. The printing of such films is dependent on the precise control of the printing parameters to control coating properties such as film thickness and width. During the coating process, an ink is pumped into the slot-die and exits through a narrow opening onto a moving substrate (web). The optimisation of roll-to-roll printing parameters is commonly achieved through a process of trial and error, relying on the skill and experience of the operator. When ink formulations are changed due to material supply issues or advancements in the materials used, a change in the printing parameters is required. Furthermore, disturbances to the optimised process conditions can arise during a coating run from changes in pump pressure, changes in web velocity and changes in the gap between the slot-die and the substrate.

Here, we will present details of a lab scale R2R printing rig that we have constructed. This rig features various additional sensors not found on industrial R2R rigs, including cameras mounted side-on and face-on to the slot-die print head. We have written a set of LabView VIs both to operate the rig and to process and analyse the data from the sensors. Autonomous control of the printing parameters is provided by a machine learning (ML) function.

Our use of cameras focussed on the slot-die head provides real-time in-situ data. This enables the ML function to respond in real-time during a coating run to disturbances in the parameters of the printed film. Changes to the slot-die gap, web speed and ink flow rate can be made by the ML function to modify and maintain the film width and thickness. We also demonstrate that a third camera positioned a short distance from the slot-die and above the web, can be used to monitor and provide feedback to the ML function on the cross-profile of a clear film using a structured light setup.

In conclusion, we will show that our use of sensors provides real-time monitoring of the printed film and that this stream of data can be applied to a ML function for automatic optimisation and responsive control of the printing parameters. Our rig is able to automatically respond to disturbances in the printing parameters that can arise from, for example, changes in the gap due to asymmetry of the pull-on roller or changes in pump pressure. This represents a significant advance over current industrial methods where the printing parameters are fixed at the start of a printing run.

4:30 PM CH01.10.04

Autonomous Thin Film Coating Enabled by AI/ML in Combination with Multi-Modal in Line/*In Situ* Diagnostics

Nathan Woodward[1], Boyu Guo[1], Ruipeng Li[2] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]Brookhaven National Laboratory, United States

Autonomous coating platforms equipped with inline sensing have the potential to become companion tools to thin film researchers that accelerate time-to-solution by 10X to 100X with the appropriate implementation of multimodal sensors, machine learning and artificial intelligence (ML/AI). Moreover, their implementation at the synchrotron will allow human-machine-AI teaming to address complex thin film problems in real time during the synchrotron beam time with the help of active learning, exploration and exploitation under uncertainty. In this presentation, we will present the RoboCoat AI, an autonomous spin-coater equipped with multi liquid dispensing, substrate cleaning and annealing, as well as multi-modal in-line optical sensors, real-time analytics and AI/ML. RoboCoat AI is shown to be compatible with synchrotron operation and has been successfully integrated at NSLS II's CMS beamline to utilize inline/*in situ* grazing incidence wide angle x-ray scattering (GIWAXS) measurements to incorporate into multi-objective optimization of thin film coatings. We will present an example of hybrid perovskite antisolvent processing to demonstrate how we have successfully addressed several key challenges, including (1) AI-guided mapping of perovskite film fabrication across a multi-dimensional parameter space navigated by AI, (2) autonomous development of optimal perovskite coating recipe using AI decision algorithms, (3) integration of multimodal inline diagnostics with synchrotron-based characterization to combine optimizations of coating quality and property with its microstructure, and (4) leveraging in situ metadata to develop interpretable coating knowledge.

4:45 PM CH01.10.05

Assessing the Impact of Polydispersity on the Thickness of Polystyrene Thin Films to Adapt a Monodisperse Polystyrene Machine Learning Model Eli Krasnoff[1], Dhruva Bhat[2], Dvita Bhattacharya[3], Isabelle Chan[4], Aditi Kiran[5], Brenna Ren[6], John Jerome[7] and Miriam Rafailovich[7]; [1]The Loomis Chaffee School, United States; [2]Foothill High School, United States; [3]Kent Place School, United States; [4]Michael E. DeBakey High School for Health Professions, United States; [5]BASIS Independent Fremont, United States; [6]The Harker School, United States; [7]Stony Brook University, The State University of New York, United States

Spin-coated polystyrene (PS) thin films have many industrial applications including biomedical devices, photonics, organic electronics manufacturing, and nanomaterial synthesis. The thickness of these thin films determines their mechanical, electrical, and thermal properties. A previous study by Wang et al. utilized a curve-fit machine learning model to produce a 3D manifold relating molecular weight (MW), solution concentration, and film thickness of spin-coated monodisperse PS samples [1]. However, the curve-fit model's applicability to polydisperse PS, which has greater industrial applications due to its ease of production and affordability, has yet to be fully assessed. This study aims to evaluate the accuracy of the model when applied to spin-coated polydisperse PS thin films. In this case, we simulated polydispersity by forming solutions of monodisperse PS polymers of different MW compositions. We examined the relationship between the weighted average MW and total polymer concentration of the solutions to the film thickness. The results were then used to determine the extent to which the curve-fit model is able to predict this relationship as a function of polydispersity and average MW.

First, binary PS solutions of MWs 30k/50k, 30k/200k, 30k/311k, 30k/650k, and 30k/2000k were dissolved in toluene and combined at concentrations of 10, 15, 20, 25, and 30 mg/mL. The solutions were made at ratios of 1:9, 1:3, 1:1, 3:1, and 9:1. Polished silicon wafers [1,0,0] were cleaved and particulates were removed under nitrogen gas flow. The native oxide layer was removed using diluted hydrofluoric acid. Three wafers were then spin-coated for each PS solution for 30.0 seconds at a fixed rate of 2500 rpm and acceleration of 1000 rpm/s. Ellipsometry was conducted to determine the thickness of the PS films, which were averaged and used for further data analysis.

Initially, the average film thickness and the weighted average of the MWs in each solution were used as inputs to the model used by Wang et al. [1]. The model consistently predicted lower concentrations for each thickness than the actual experimental values. The graphs of thickness vs. concentration for each MW combination showed that thicknesses for a given ratio were consistently shifted towards the predicted thickness of the 30k MW. By assessing the ratio of the thickness difference between the sample and the lower bound MW over the thickness difference in higher and lower monodisperse bounds, a linear relationship was determined at each concentration for each ratio. For instance, the 30k/2000k combinations had an R2 value of 0.9991 for a linear curve-fit. As such, error can be quantified and the monodisperse model can be adjusted for any binary polydisperse PS samples, given sufficient experimental data. van Ruymbeke et al. proposed the theory of constraint release on long chains being driven by quicker relaxation times of short chains, leading to tube dilation [2]. Their physical model provides a reasonable explanation for our observed data, since their model predicts lower viscosity for binary solutions with large MW differences in solution; moreover, we observed a decrease in error of the model used by Wang as the MW difference in solution decreases. Future research will involve gathering more data to empirically model the larger impact of the lower MW in a polydisperse sample on film thickness. Furthermore, testing polymers below entanglement weight would prove valuable in determining the reasoning behind the disproportionate impact based on weight. Testing the thickness of polydisperse solutions with more than two different MWs would be necessary to draw broader conclusions on the effects of polydispersity on the characteristics of thin films.

1:30 PM *CH02.01.01
Guidelines for Imaging and Analysis of Reactive Lithium Metal Negative Electrode Ying Shirley Meng[1,2]; [1]The

University of Chicago, United States; [2]Argonne National Laboratory, United States

It has been a few years since the first report of cryo electron microscopy imaging and analysis on lithium metal negative electrode and its solid electrolyte interphases. Over the past few years the large amount of data in the literature has expanded our understanding of the reactive nature of these materials, however there is some inconsistency and variability which causes valid concerns about the data reliability and reproduciblity. In this talk I will discuss a few critical matters regarding the best practices for preparing, transporting, imaging and analyzing this type of beam-sensitive and reactive energy materials.

2:00 PM *CH02.01.02

Electron Microscopy and Spectroscopy Probing of Structural and Chemical Evolution of Interfacial Process in Rechargeable Batteries Chongmin N. Wang; Pacific Northwest National Laboratory, United States

Ex-situ and in-situ high resolution electron imaging enable direct observation of structural and chemical evolution, phase transformation and their correlation with mass and charge transport, providing insights as how active materials fade during the cyclic charging and discharging of a battery. In this presentation, I will highlight recent progress on ex-situ, in-situ and operando S/TEM for probing into the structural and chemical evolution of interfacial process in energy storage materials. In perspective, challenges and possible direction for further development of the in-situ S/TEM imaging and spectroscopic methods for energy storage materials and other field will also be discussed. Most importantly, integration of different analytical tools appears to be the key for capturing complementary information, which can be used to guide the design of electrode materials.

2:30 PM CH02.01.03

***Operando* Optical Microscopic Imaging of Interfacial Properties and Li-Ion Transportation in All Solid-State Batteries** Bicy Kottathodi[1], Gegari Thomas[2], Vallabha Rao Rikka[1], Migo S. Ng[1], Wan S. Tang[1], Xiaonan Shan[2] and Judith Jeevarajan[1]; [1]UL Research Institutes, United States; [2]University of Houston, United States

Lithium-ion batteries, which utilize separators wetted with liquid electrolytes, are well-established as prominent energy storage devices due to their long life, energy density, and power density. The development of all solid-state batteries (SSBs), which use solid-state electrolytes (SSE), offers further improvements in key areas such as safety and energy density. However, the performance of SSBs is affected by several factors, including interfacial resistance, dendrite growth, thermal and electrochemical stability, among others. *Operando* investigations provide important physical and chemical information that plays a major role in resolving the challenges of SSBs. The present study focuses on the interfacial properties and lithium-ion transport through solid interfaces during electrochemical cycling, using an in-house, specifically designed and built sample holder coupled with an optical microscope. Optical changes were observed in the cathode particles during de-lithiation and lithiation, together with void and crack formations. The high-temperature performance of the anode-SSE interface was also evaluated during the charging and discharging process. Hence, *in-situ* investigations of interfacial properties during electrotechnical cycling enable a deeper understanding of battery failure modes in solid-state batteries.

2:45 PM CH02.01.04

Atomic Dynamics of Electrified Solid–Liquid Interfaces in Liquid-Cell TEM Qiubo Zhang[1], Zhigang Song[2], Xianhu Sun[1], Yang Liu[3] and Haimei Zheng[1,4]; [1]Lawrence Berkeley National Laboratory, United States; [2]Harvard University, United States; [3]University of California, Los Angeles, United States; [4]University of California, Berkeley, United States

Electrified solid–liquid interfaces (ESLIs) play a key role in various electrochemical processes relevant to energy,

biology and geochemistry. The electron and mass transport at the electrified interfaces may result in structural modifications that markedly influence the reaction pathways. For example, electrocatalyst surface restructuring during reactions can substantially affect the catalysis mechanisms and reaction products. Despite its importance, direct probing the atomic dynamics of solid–liquid interfaces under electric biasing is challenging owing to the nature of being buried in liquid electrolytes and the limited spatial resolution of current techniques for in situ imaging through liquids. Here, with our development of advanced polymer electrochemical liquid cells for transmission electron microscopy (TEM), we are able to directly monitor the atomic dynamics of ESLIs during copper (Cu)-catalysed CO2 electroreduction reactions (CO2ERs). Our observation reveals a fluctuating liquid-like amorphous interphase. It undergoes reversible crystalline–amorphous structural transformations and flows along the electrified Cu surface, thus mediating the crystalline Cu surface restructuring and mass loss through the interphase layer. The combination of real-time observation and theoretical calculations unveils an amorphization-mediated restructuring mechanism resulting
from charge-activated surface reactions with the electrolyte. Our results open many opportunities to explore the atomic dynamics and its impact in broad systems involving ESLIs by taking advantage of the in situ imaging capability.

3:30 PM ^CH02.01.05
Revealing Local Microenvironments at Active Electrochemical Interfaces with *Operando* Freezing Cryogenic Electron Microscopy Nikita S. Dutta, Peter J. Weddle, Oscar Hathaway, Mowafak Al-Jassim and Katherine L. Jungjohann; National Renewable Energy Laboratory, United States

Local structural and chemical heterogeneities at active electrochemical interfaces are critical to determining safety, lifetime, and energy density in batteries and other devices, but they have long been challenging to characterize at the nanoscale. Here we present *operando* freezing cryogenic electron microscopy (cryo-EM) as a new technique to preserve device interfaces in an active electrochemical state for high-resolution structural and chemical characterization. We reveal that ion-depleted microenvironments form locally in the electrolyte adjacent to the lithium deposition interface in lithium metal batteries and are correlated with heterogenous growth morphologies. Moreover, we find that these depleted environments can arise locally even under conditions for which ion depletion is not predicted at steady state; this provides a mechanistic explanation for why dangerous lithium morphologies can still propagate in such systems and lead to thermal runaway. *Operando* freezing cryo-EM thus provides a method to directly visualize nanoscale heterogeneities that arise locally at electrochemical interfaces and play a key role in device failure.

***Operando* Probing of Nanocracking in CuO-Derived Cu During CO_2 Electroreduction** Jiawei Wan[1,2], Ershuai Liu[1], Woong Choi[1], Denis Leshchev[3], Mark Asta[2,1], Alexis Bell[2,1], Walter Drisdell[1] and Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Brookhaven National Laboratory, United States

Cu is the only metallic catalyst for the CO_2 electroreduction reaction (CO_2RR) that produces significant multicarbon (C_{2+}) products. Among various Cu-based materials, the oxide-derived Cu (OD-Cu) exhibits enhanced electrocatalytic activity. Although diverse types of grain boundaries and residuary Cu^+ from precatalyst reconstruction have been reported as the active species, the formation mechanisms and design principles for OD-Cu catalysts remain lacking. A major hurdle is the inability to directly monitor the structural evolution of OD-Cu catalysts under operating conditions due to the fast, complex dynamic transformation behavior of precatalyst activation during CO_2RR. Here we reported operando studies of OD-Cu catalysts origin and evolution from CuO nanowires during CO_2RR using a multimodal platform coupling the newly developed high-resolution electrochemical liquid cell transmission electron microscopy (EC-TEM) with time-resolved and high energy resolution fluorescence detected X-ray absorption spectroscopy (XAS). We discovered the formation pathways of catalytic active sites through nanocracking of CuO nanowire precatalyst during rapid reduction to metallic Cu. The nanocrack networks further reconstructed to a high surface-to-volume ratio structure, resulting in a high density of active sites. Electrocatalytic performance testing in reactors of different scales (TEM micro-electrolyzer, H-type cell, and MEA), coupled with complementary ex situ structural characterizations, suggested this behavior was general across all catalytically relevant conditions and was critical for enhanced C_{2+} activity. These findings suggested a means to optimize OD-Cu structures for high activity and our advanced operando approach opened new opportunities for mechanistic insights to enable improved control of catalyst structure and performance from precatalyst.

Stabilized Cuδ+-OH Species on *In Situ* Reconstructed Cu Nanoparticles for CO2-to-C2H4 Conversion in Neutral Media Lei Wang and Yimin Wu; University of Waterloo, Canada

Achieving large-scale electrochemical CO2 reduction to multicarbon products with high selectivity using membrane electrode assembly (MEA) electrolyzers in neutral electrolyte is promising for carbon neutrality. However, the unsatisfactory multicarbon products selectivity and unclear reaction mechanisms in an MEA have hindered its further development. Here, we report a strategy that manipulates the interfacial microenvironment of Cu nanoparticles in an MEA to suppress hydrogen evolution reaction and enhance C2H4 conversion. In situ multimodal characterizations consistently reveal well-stabilized Cuδ+-OH species as active sites during MEA testing. The OH radicals generated in situ from water create a locally oxidative microenvironment on the copper surface, stabilizing the Cuδ+ species and leading to an irreversible and asynchronous change in morphology and valence, yielding high-curvature nanowhiskers.

Precision Electrosynthesis of Heterostructured Bimetallic Nanoparticles by Scanning Electrochemical Cell Microscopy Heekwon Lee and Hang Ren; The University of Texas at Austin, United States

ABSTRACT
Heterostructured bimetallic nanoparticles, such as core-shell and multishell configurations, exhibit unique properties that surpass those of their monometallic counterparts. However, the complexity of their synthesis in controlling size, structure, and composition underscores the need for high-throughput techniques to accelerate materials discovery. This presentation introduces a method for the serial electrosynthesis of bimetallic nanoparticles with precise compositional and structural control within individual particles. This approach utilizes a dual-channel nanopipette within a scanning electrochemical cell microscopy (SECCM) framework, where a voltage bias between the channels regulates the local electrolyte environment. [1, 2] This localized nanofluidic control enables the sequential deposition of metal precursors (Pt-Cu and Pt-Ni in this work), facilitating the precise construction of core-shell and multishell nanoparticle structures. By controlling the electrodeposition rate through designated reduction potentials and deposition times, precise control over shell thickness and layer order

is achieved. Synthesized nanoparticles are characterized using SECCM for electrocatalytic activity (e.g., hydrogen evolution reaction) and dark-field microscopy for optical properties, demonstrating the systematic fabrication of core-shell bimetallic nanoparticles. This methodology paves the way for automated synthesis and screening systems that can accelerate material discovery in electrocatalysis.

SHINERS, ECMS and ECSTM Study of Cu Surface Chemistry Thomas Moffat, David Raciti and Angela R. Hight Walker; National Institute of Standards and Technology, United States

Copper electrodeposition is a central process in the metallization of microelectronics and more recently has found application as the most effective electrocatalyst for the conversion of CO_2 to hydrocarbons. Gaining mechanistic insight into the reactivity of Cu surfaces requires *in situ* and better still *operando* measurements. Herein the utility of the combination of vibrational spectroscopy (SEIRAS, SHINERS), electrochemical mass spectrometry (EC-MS) and scanning tunneling microscopy (ECSTM) to examine the competitive and co-adsorption interactions between potential dependent halide adsorption, molecular adsorption, underpotential metal deposition and hydride formation on low index Cu single crystals surface will be detailed. Further still, the opportunity to study the impact of such interactions on metal deposition reactions will be discussed.

SESSION CH02.02: *In Situ/Operando* Characterization of Interfaces Using X-Ray Based Techniques

8:30 AM *CH02.02.01
Structure and Dynamics of Electric Double Layer Michael F. Toney; University of Colorado Boulder, United States

The electric double layer (EDL) is a fundamental component of electrode/electrolyte interfaces that governs many key electrochemical processes, including charge transport across interfaces, passivation of solid-electrolyte interphases, and chemical stability of the electrolyte. More than a century of study has yielded general models for the ion distribution through the EDL, yet little experimental evidence for the speciation, uniformity, and dynamics of the potential-dependent EDL structure is available due, in part, to the challenges with experimentally probing buried interfaces in situ. I present an investigation of the potential-dependent structure and chemistry of the EDL formed between single crystal conductive electrodes and aqueous electrolytes spanning a diverse range of compositions, ions, and concentration, including BaCl2 and CsCl. Synchrotron X-ray reflectivity and resonant anomalous X-ray reflectivity reveal distinct ion distributions that evolve as a function of potential. Time-dependent X-ray reflectivity during cyclic voltammetry reveals an unexpected hysteresis in the EDL structure during polarization switching, suggesting an energy penalty for EDL reconfiguration. These experimental results will be connected to analytical models and molecular dynamics simulations. This work brings new molecular-level insight to the potential dependence in the static and dynamic EDL structure.

9:00 AM *CH02.02.02
Synchrotron-Based X-Ray Characterization of Electrochemical Interfaces Johanna N. Weker; SLAC National Accelerator Laboratory, United States

Synchrotron-based X-rays are a powerful characterization tool that can probe across many relevant length scales (from atomistic to millimeter) with different techniques that are sensitive to distinct features such as microstructure, chemistry, and morphology. Because of the high flux available and penetrating power of X-rays, interfaces within batteries and water electrolyzers can be probed under realistic, operating conditions. This enables the study of mechanisms that are electrochemically and chemically driven such as deposition, corrosion, phase changes, and oxidation state change. This insight provides deeper understanding of the key mechanisms driving failure.

We will highlight the advanced characterization available at Stanford Synchrotron Radiation Lightsource (SSRL) at SLAC National Accelerator Laboratory for studying electrochemical interfaces under *in situ* and *operando* conditions. We will then provide specific examples such as the use of *operando* transmission X-ray microscopy to study Zn plating and corrosion in Zn-metal batteries and the use of radiography to image gas bubble formation in water electrolyzers.

9:30 AM CH02.02.03
***Operando* TEY-STXM—Spectromicroscopy of the Solid-Liquid Interface** Evan Z. Carlson[1,2], Xiao Zhao[1,2], Angel Burgos[1], Tyler Mefford[1], Hendrik Ohldag[2] and William C. Chueh[1]; [1]Stanford University, United States; [2]Lawrence Berkeley National Laboratory, United States

Rational design of electrochemically active materials requires a better understanding of the structure and chemistry of solid-liquid interfaces. However, the buried nature of these interfaces makes them especially challenging to probe *in-operando* with high surface-sensitivity. The use of faceted nanoparticles in practical devices further necessitates the development of *operando* techniques that combine high spatial resolution with surface sensitivity and chemical specificity.

In this talk, I will discuss our development of *operando* total electron yield scanning transmission x-ray microscopy (TEY-STXM). This new technique combines the 25 nm spatial resolution of *operando* STXM[1] with the 3 nm surface-sensitivity of *operando* TEY-XAS,[2] enabling simultaneous spectromicroscopy of the surface and bulk of electrochemically active materials under reaction conditions. Beyond the solid, *operando* TEY-STXM enables spatially resolved investigation of the electric double layer, including how its structure depends on electrolyte speciation, electrode material and applied voltage. This talk will discuss instrumentation and image contrast mechanism, as well as highlight novel insights into the interfacial reaction microenvironment on aqueous battery electrodes and oxygen electrocatalysts.

An Atomistic Interpretation of the Oxygen K-Edge X-Ray Absorption Spectra of Layered Li-Ion Battery

Up-to-date as of November 14, 2024

Cathode Materials Namrata Ramesh and Rebecca J. Nicholls; University of Oxford, United Kingdom

The Li-ion battery has been instrumental in the development of many important consumer electronics, and is supporting the trend towards increased use of renewable energy sources. The energy density and cost of modern Li-ion batteries is currently limited by the available cathode materials, which are typically based on layered metal-oxides that can readily intercalate Li (e.g. $LiCoO_2$). Current efforts to increase accessible cathode specific capacity and reduce cost have focused on replacing scarce and hazardous elements (e.g. Co) with less expensive elements (e.g. Mn and Ni), giving rise to resulted lithium nickel-manganese-cobalt oxides (NMC)[1]. The charge compensation mechanism, in which both the transition metals (TMs) and the oxygen atoms can participate, needs to better understood to optimise the structure and composition of NMC materials. Understanding the role of oxygen in the charge compensation mechanism is thought to be particularly crucial due to its possible role in increasing the achievable voltage and therefore accessible capacity, whilst also providing a pathway to mitigate potentially being involved in certain degradation mechanisms[2]. X-ray absorption spectroscopy (XAS) of the O K-edge is an experimental probe of the oxygen environment, and can also be atomistically interpreted through first-principles simulation methods based on density functional theory (DFT).

Here, we will introduce our recent work on systematically interpreting the O K-edge of layered lithium transition-metal (TM) oxides from first principles using DFT[3]. Our benchmark spectra show that the semi-local meta-GGA functional rSCAN provides a better match to experiment of the excitation energies of spectral features compared to the GGA functional PBE, or PBE with a Hubbard U correction, especially at energies close to the main edge. Using rSCAN, DFT modelling of the O K-edge XAS of $LiNiO_2$ and a simulation cell that includes a Jahn-Teller distortions, a closer match to the experimental spectra is achieved. This reveals that the pre-edge contains information about not only the chemical species, but also geometric distortion. Atomistic interpretation of the O K-edge XAS of layered Li TM oxides is also shown to be sensitive to other changes in the octahedral environment, including changes in the chemical identity and the magnetic configuration of coordinating species.

The direct comparison of theoretical spectra arising from simple structural models with experimental data has highlighted the heterogeneity present even in nominally pristine materials. Understanding such heterogeneous structural and electronic environments in pristine materials and beyond, lies in the ability to create fingerprint spectra from more complex models of materials[4]. Thus, preliminary results of clustering projected density of states that arise from molecular dynamics (MD) trajectory of $LiNiO_2$ will also be discussed. The use of smooth overlap of atomic positions (SOAP) descriptors to connect changes in the partial density-of-states (pDOS) to the local environment is
shown, along with the use of a regression model to learn the electronic structure of the trajectory. This methodology could be readily extended to observe the impact on the spectral shape arising from the material in different states of charge, or the effect of a change in the composition, to help optimize NMC materials and design novel ones.

Thus, the work shown in this presentation, and the future directions that it opens up, highlight the power of the atomistic tool of DFT to interpret the oxygen environments of layered Li-ion battery cathode materials, and helps bridge the gap between theory and experiment.

Experimental Approaches Toward Understanding Productive Electrochemically Induced Conversion Processes Within Battery Electrodes Kenneth J. Takeuchi; Stony Brook University, The State University of New York, United States

In intercalation materials, the kinetics and uniformity of mass transport across the nanocrystalline domains dictate the structural reversibility and transport capability at the macroscopic level. Conversion materials which undergo more significant changes of state and/or phase upon electrochemical redox bring added challenges for phase identification at the interface and prediction of resultant electrochemical behavior at the systems level. Recent advances in advanced characterization toward understanding productive electrochemically induced conversion processes within battery electrodes will be described in this presentation, including the benefit of complementary *in-situ* and *operando* techniques.

11:00 AM CH02.02.06

Unconventional Current-Morphology Dependence in Electrodeposition of Zn Anode Revealed by *In Situ* XRD Yifan Ma[1], Jakbu Pepas[1], Guangxing Zhang[1], Minju Kang[2], John Carsley[2] and Hailong Chen[1]; [1]Georgia Institute of Technology, United States; [2]Novelis Inc., United States

Aqueous Zn-ion batteries (ZIBs) show great promise for large-scale energy storage due to their use of safe, low-cost aqueous electrolytes and earth-abundant elements such as Zn and Mn. Similar to Li-ion and Na-ion batteries, ZIBs face challenges with harmful zinc dendrites forming on the anode, significantly reducing cycling life. Previous studies have demonstrated that the morphology and texture of deposited Zn are crucial for the cycling life of ZIBs. A (002)-textured Zn surface, where the (002) planes are uniformly oriented parallel to the substrate/current collector, is reported to be beneficial as it is dense, flat, and free of dendrites.

The deposition current significantly influences the formation of the (002) texture, but the current-texture dependence and its underlying mechanism remain unclear, primarily due to the lack of in situ characterization capabilities. Here, we report new findings on the current-texture dependence in Zn deposition and its underlying mechanism, revealed by our recently developed synchrotron-based high-throughput in situ X-ray diffraction tool (HT in situ XRD). Using this tool, we systematically investigated zinc deposition under various conditions, including different current densities, electrolyte concentrations, and types of substrates, in an expedited high-throughput manner. We also developed a unique quantitative texture characterization protocol.

Our results reveal an unprecedented growth mechanism of deposited Zn, summarized as an "evolutionary orientation selection" mechanism. These new findings advance our understanding of metal deposition and provide valuable guidelines for developing new cycling protocols for ZIBs, significantly extending their durability.

Potential Dependence in the Static and Dynamic Structure of Electric Double Layers in Aqueous Batteries Samuel Marks[1], Rafael Ferreira de Menezes[1], Erin Dunphy[1], Lacey Roberts[1], Hans Steinrueck[2], Kayla Sprenger[1] and Michael F. Toney[1]; [1]University of Colorado, United States; [2]Forschungszentrum Jülich GmbH, Germany

The electric double layer (EDL) is a fundamental component of electrode/electrolyte interfaces in aqueous batteries that governs many key electrochemical processes, including charge transport across interfaces, passivation of solid-electrolyte interphases, and chemical stability of the electrolyte. More than a century of study has yielded general models for the ion distribution through the EDL, yet little experimental evidence for the speciation, uniformity, and dynamics of the potential-dependent EDL structure is available due, in part, to the challenges with experimentally probing buried interfaces in operando conditions. We present a study that connects applied potential to the ion distribution and double layer capacitance in the EDL formed between conductive boron-doped diamond electrodes and aqueous electrolytes spanning a diverse range of compositions, valence, and concentration. Operando synchrotron X-ray reflectivity and resonant anomalous X-ray reflectivity reveal distinct ion distributions that evolve as a function of potential. Time-dependent X-ray reflectivity during cyclic voltammetry reveals a hysteresis in the EDL structure during polarization switching that suggests an energy penalty for reconfiguring the interface. This work brings new molecular-level insight to the potential dependence in the structural, chemical, and functional properties of the EDL in aqueous batteries.

11:30 AM CH02.02.08

Influence of pH on Indium Deposition Rates—A Comprehensive Electrochemical Analysis Abdullah Faisal Pasha, Zachary L. Larson, Peter Borgesen and Nikolay G. Dimitrov; Binghamton University, The State University of New York, United States

New-generation semiconductor components need low-temperature soldering to enable compact yet efficient 3D stacking configuration for the integrated circuit (IC) boards. Due to lead (Pb) toxicity, binary tin-indium (In-Sn) and ternary tin-indium-bismuth (In-Sn-Bi) alloys are great substitutes for the low-melting Sn-Pb alloys because of their mechanical and chemical reliability. Unfortunately, co-plating of those alloys is rather complex because of the substantial differences in their constituent's reduction potentials. Successive electroplating of the constituent metals followed by a high-temperature reflow is a more convenient process for synthesizing the alloys for low-melting soldering. In spite of that, even the latter approach can be challenging for In-based alloys due to the lack of systematic knowledge on the kinetics of In deposition.
This activity focuses on studying the electrodeposition rate of pure In with an emphasis on the impact of different pH conditions. The current report presents a detailed analysis of the deposited In thickness and its cross-sectional morphology at pH 2.2, 2.5, 2.9, and 3.3. Additionally, it explores the electrochemical behavior of two different $In_2(SO_4)_3$ baths across the mentioned pH range with the aim of identifying the optimal deposition conditions. Lastly, X-ray diffraction (XRD) and differential scanning calorimetry (DSC) were used to assess the structural integrity of the electroplated In samples. The research established that In deposited in a solution of 0.115 M $In_2(SO_4)_3$ and 0.7 M Na_2SO_4 at pH 2.9 yields the thickest and most evenly distributed and structurally homogeneous layer.

11:45 AM CH02.02.09

Investigation of Electrical Double Layers of Ionic Liquids in Graphene-Capped Liquid Cells by Multimodal Synchrotron Infrared Nanospectroscopy for Advanced Energy Storage Devices Zixuan Li[1], Ka Chon Ng[1], Maximilian Jaugstetter[1], Xiao Zhao[1,2], Miquel Salmeron[1,3], Hans Bechtel[1] and Stephanie Gilbert Corder[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Stanford University, United States; [3]University of California, Berkeley, United States

Electrical double layer capacitors (EDLCs), often categorized as a subset of supercapacitors, are prominent energy devices owing to their advantages such as rapid charge/discharge processes, extremely long cycle life, and environmental and safety benefits. However, the generally low energy density of EDLCs hinders their broad application. A major strategy to improve the energy density of EDLCs involves employing electrolytes capable of high operation voltages. Ionic liquids (ILs) are a novel class of electrolytes typically composed of asymmetric organic cations and weakly coordinated anions. They appear to be ideal candidates to replace the diluted aqueous and organic electrolytes in current EDLCs for their wide electrochemical windows, which enable operation voltages much higher than conventional EDLCs and thus significantly improve the energy density. Moreover, the unique properties of ILs, including high thermal stability, non-flammability, high charge density, as well as their distinct EDL structure with oscillating ion concentration, not only make them safe and environmentally friendly options for EDLCs, but also present great possibilities for superior performance to traditional electrolytes. The implementation of ILs as electrolytes in EDLCs for enhanced performance and functionalities is contingent upon understanding the structure of IL EDLs, a knowledge gap that exists thus far. Here, we incorporate ILs in custom-made graphene-capped liquid cells, which allow for synchrotron infrared nanospectroscopy (SINS) investigation of IL EDLs, in combination with density functional theory (DFT) analysis and other atomic force microscopy (AFM) characterizations, including high-resolution structural imaging and Kelvin probe force microscopy (KPFM). This approach effectively correlates the chemical and vibrational bond information of IL EDLs with their nanoscale ion ordering and displacement behaviors, leading to a comprehensive understanding of IL EDLs that was previously inaccessible. The insights into IL EDL behaviors is expected to reveal the molecular-level dynamics corresponding to charge storage, thus providing valuable guidance for the design and creation of next-generation EDLCs based on novel IL-containing electrolytes.

SESSION CH02.03: Multimodal Characterization of Solid-Liquid Interfaces
Session Chairs: Regina García-Méndez and Jinghua Guo
Tuesday Afternoon, December 3, 2024
Sheraton, Third Floor, Gardner

1:30 PM *CH02.03.01
Nano-FTIR Spectroscopy and Imaging of Electrochemical Interfaces in Li-Ion Batteries Robert Kostecki and Andrew Dopilka; Lawrence Berkeley National Laboratory, United States

Electrochemical interfaces are central to the function and performance of electrochemical energy storage devices. Thus, the development of new methods to characterize these interfaces, in conjunction with electrochemical performance, is essential for bridging the existing knowledge gaps and accelerating the development of energy storage technologies. These analytical hurdles related to sensitivity, specificity, selectivity and environmental control related to deployment of X-ray, electron, neutron, optical, NMR, and scanning probe methods stimulate the development of new experimental approaches to characterize electrochemical interfaces to overcome some subset of these challenges for a variety of specific materials and interface architectures. Of particular need is the ability to characterize surfaces or interfaces in a non-destructive way with adequate resolution to discern individual structural and chemical building blocks.
Optical spectroscopy techniques such as Raman and Fourier transform infrared spectroscopy (FTIR) have been regarded as a gold standard for nondestructive chemical and structural fingerprinting of electrode materials and electrochemical interfaces. This is due to the relatively low energy of visible and IR light, and the techniquess sensitivity to changing electric dipole moments and/or polarizability, such as those in molecular and crystal lattice vibrations. Moreover, the vast majority of electrode and electrolyte materials are vibrationally active and possess a unique spectrum signature, thus optical spectroscopies are ubiquitous in both academia and industry. However, because of the relatively long wavelengths of VUS/IR light and related diffraction limit, the spatial resolution for optical techniques has been limited to *ca.* 1 - 1,000 micrometers. Thus, their utilization during the so-called "nano-revolution" during the last *ca.* 35 years has played an insignificant role in the characterization of nanostructures and associated nanoscale phenomena due to its inadequate spatial resolution.
However, over the last decade, with the coalescence of scattering-type, scanning near-field optical microscopy (s-SNOM), high power broadband IR sources, IR interferometry, and lock-in amplification techniques, an emerging

class of infrared near-field nanoimaging and nanospectroscopy (nano-FTIR methodologies has been realized to study electrochemical energy storage materials and interfaces, non-destructively, with nanoscale resolution, and in some cases, while within their native environment. To this end, sub-diffraction-limit low-energy optical probes that exploit near-field interactions, such as pseudoheterodyne imaging, photothermal AFM-IR, and nanoscale Fourier transform infrared spectroscopy, are powerful emerging techniques for electrochemical science and technology.
Moving toward the characterization of electrochemically controlled surfaces and interfaces in echargeable battery materials and systems is critical for catalyzing advanced energy storage technologies. Most ecent efforts progressing to this end based on infrared near-field probes will be outlined. The working mechanisms and implementations of the scattering- and photothermal- types, and highlighted works in which these tools were employed to characterize energy storage materials, surface chemistry and structure, and interfaces and interphases will be discussed together with the key detection and processing steps involved in producing scattering-type near-field nanoscale Fourier transform infrared spectra. *In situ* and *operando* approaches by the integration of bulk electrochemistry and custom nanofabrication, with near-field IR nanoimaging and/or spectroscopy of the Si/electrode interface will also be described.

2:00 PM CH02.03.02

Innovative Fluorescence Microscopy and Cloud-Based Algorithm for Real-Time Analysis of Electroconvection Dynamics Duhan Zhang; Massachusetts Institute of Technology, United States

In high-current electrochemical cells, electroconvection significantly influences the morphology of electrodeposited metals, leading to dendrite formation and potential battery failures. Despite extensive theoretical and experimental efforts, the intricate structure and dynamics of electroconvection remain elusive due to the lack of high-resolution observation tools and robust data processing algorithms.

To address this gap, we developed an advanced optical electrochemical cell compatible with in situ imaging using a super-resolution fluorescence microscope. This setup allows us to capture real-time motions of electrolytes, providing unprecedented high temporal and spatial resolution views of electroconvection flows. Complementing our visualization studies, we designed a cloud-based analysis algorithm that integrates a high-resolution Particle Image Velocimetry (PIV) algorithm with a machine learning model. This combination enables the generation of detailed velocity distribution data over the entire optical field of view at nanoscale or microscale resolutions.

The resulting velocity maps from our optical electrochemical cell allow for a comprehensive quantitative analysis of the initiation and evolution of hierarchical microstructures within electroconvection under a unidirectional electric field. Using these advanced tools, we investigated the impact of polymer viscoelasticity on electroconvection and electrodeposition. Introducing ultrahigh molar mass polyethylene oxide into the electrolytes altered the fluid state to viscoelastic, modifying the electroconvection's time and voltage dependence and resulting in smoother electrodeposition on the metal anode due to the unique rheological properties of the polymer. Notably, the behavior of long polymer chains in the electrolyte presents a promising method to inhibit dendrite growth. These experimental findings were further analyzed using direct numerical simulations for both Newtonian and viscoelastic fluid models, revealing a strong correlation between the quantitative analysis of experimental data and simulation predictions. This integrated approach offers a powerful framework for understanding and controlling electroconvection dynamics, enhancing battery performance and safety.

2:15 PM CH02.03.03

Facet Type Determination with Combined Atomic Force Microscopy and Electron Backscatter Diffraction

Ralf Bruening[1], Sawyer C. Stanely[1], Mehrad Hajati[1], Abhijit Singh[1], Tobias Bernhard[2], Sascha Dieter[2] and Gregoire

Dietrich[2]; [1]Mount Allison University, Canada; [2]Atotech Deutschland GmbH, Germany

The distribution of crystal facets at the surface of polycrystal films represents a critical factor influencing surface functionality. However, there is currently no established method for determining this distribution. We present a technique that allows for the identification of hundreds of crystal facets in a scanning electron microscope (SEM) micrograph with minimal user input. To achieve this, SEM-based electron backscatter diffraction (EBSD) and atomic force microscopy (AFM) data are acquired on the same patch of the sample surface. The EBSD provides maps of crystal orientations and the band contrast. The latter shows the degree of definition of these orientations by the measurement. The AFM topography defines the angles of the exposed crystal facets, which in conjunction with the EBSD data enables the determination of the Miller indices {*hkl*} of the exposed facets. The challenge is to transfer the EBSD data into the coordinate system of the AFM measurement. A new methodology for achieving this has recently been developed, where the anticipated EBSD band contrast is simulated based on the AFM topography, and then aligned with the measured band contrast through a least-squares fitting process with non-linear parameters. This results in an excellent mapping between the data types. The methodology is illustrated through the analysis of an etched copper clad laminate (CCL) and various types of electroless Cu films deposited on the CCL. This example pertains to the selection of facets in electroless and galvanic plating processes in printed circuit board manufacturing. An uncontrolled transition from epitaxial to non-epitaxial growth can result in surfaces with unacceptable roughness, which may be problematic in the context of printed circuit board manufacturing.

2:30 PM *CH02.03.04

Unveiling Catalyst Restructuring and Composition Evolution During Nitrate Electrocatalytic Reduction Through Correlated *Operando* Microscopy and Spectroscopy Beatriz Roldán Cuenya; Max Planck Society, Germany

The electrocatalytic reduction of nitrate (NO_3–) and nitrite (NO_2–) enables sustainable, carbon-neutral and decentralized routes to produce ammonia (NH_3). Copper-based materials are promising electrocatalysts for NOx– conversion to NH_3. However, the underlying reaction mechanisms and the role of different Cu species during the catalytic process are still poorly understood.
Here I will present our findings on structure/composition/reactivity correlations obtained for size-controlled Cu_2O nanocube pre-catalysts by combining quasi in situ X-ray photoelectron spectroscopy (XPS), operando X-ray absorption spectroscopy (XAS), transmission X-ray microscopy (TXM), Raman spectroscopy and electrochemical liquid cell transmission electron microscopy (EC-TEM). In particular, we unveiled that Cu is mostly in metallic form during the highly selective reduction of NO_3–/NO_2– to NH_3. On the contrary, Cu(I) species are predominant in a potential region where the two-electron reduction of NO_3– to NO_2– is the major reaction. Moreover, we revealed how redox kinetics determine the working catalyst morphology and found drastic differences in catalyst restructuring during operation and a strong dependency of its composition on the applied potential and the chemical environment, including the choice of electrolyte.
Electrokinetic analysis was also used to propose possible steps and intermediates leading to NO_2– and NH_3, respectively. This work establishes a correlation between the catalytic performance and the dynamic changes of the structure and chemical state of Cu, and provides crucial mechanistic insights into the pathways for NO_3–/NO_2– electrocatalytic reduction.

Revealing the Effects of Polymer Additives on Zn Dendrite Suppression in Aqueous Zn Batteries via *In-Situ*

EC-AFM Ying Xia[1,2], Jinhui Tao[2], Mingyi Zhang[2], Zheming Wang[2], Chenyang Shi[2], Jingshan S. Du[2], Sun Hae Ra Shin[2], Praveen K. Thallapally[2], Christine A. Orme[3], Maria Sushko[2], James J. De Yoreo[2,1] and Jun Liu[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States

Polyethylene glycol (PEO) is a commonly used polymer for achieving flat and uniform electrodes to enhance the performance of batteries, such as those based on lithium or zinc (Zn). However, the impact of PEO on the electrochemical deposition of Zn metal on electrodes and the mechanism by which it maintains electrode flatness remains uncertain. In this study, we addressed these knowledge gaps by using *in situ* electrochemical atomic force microscopy (EC-AFM) to observe the nucleation and growth of Zn metal plates on copper (Cu) substrates in the presence of different concentrations of $ZnSO_4$ and PEO. Here the $ZnSO_4$ solution provided the electrolyte and the Cu substrates served as the electrodes, both of which are widely utilized in Zn batteries.

Our results indicate that PEO biases the crystallographic orientation of the initially deposited Zn metal nuclei, but does not have an obvious influence on subsequent growth of the resulting Zn platelets. The consistent aspect ratio of the Zn plates combined with the lack of an effect on growth rates suggests that PEO does not interact significantly with the surface of the newly formed Zn plates. High-speed and high-resolution *in-situ* AFM, along with *in-situ* Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) reveal that Zn metal undergoes rapid surface reorganization in a mildly acidic aqueous solution due to oxidation, which is not affected by PEO adsorption. Adhesion force maps, obtained through contact fast force mapping under flowing AFM, demonstrate real-time PEO adsorption and distribution on Cu and Zn surfaces, confirming a strong Cu-PEO interaction and a weak PEO-Zn interaction after oxidation. Based on these findings, we hypothesize that PEO primarily interacts with the Cu substrate to adjust the interfacial structure and energy of the Cu-electrolyte interfaces. To test this hypothesis, we conducted molecular dynamics (MD) simulations to simulate the electric double-layer structure in the presence and absence of PEO. We also calculated the Cu-Zn and Zn-solvent interfacial energies under both conditions.

Our findings provide a clear picture of how PEO flattens the electrode: PEO first adsorbs onto the Cu substrate, then Zn metal nucleates as Zn (002) beneath the PEO, followed by PEO detachment as the Zn nuclei grow. Subsequently, the Zn platelets grow layer-by-layer using the first layer of Zn (002) as a template. The results suggest key design and engineering principles for flat electrode synthesis in energy-related applications, emphasizing the use of polymer additives that exhibit appropriately strong binding to the substrate metal and weak binding to the deposited metal.

Work by C.O. was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Comprehensive *In-Situ* Characterization of Electrodeposition and Corrosion in Aqueous and Nonaqueous Metal-Based Batteries Daniel Sharon; The Hebrew University in Jerusalem, Israel

Understanding electrodeposition and corrosion processes in metal-based batteries is crucial for enhancing their performance and longevity. Our research investigates these processes across various electrolytes, including aqueous, nonaqueous, and solid-state systems, and metals such as lithium, zinc, and iron, using advanced in-situ characterization techniques.

A primary tool we frequently employ is the Electrochemical Quartz Crystal Microbalance with Dissipation (EQCM-D). EQCM-D provides real-time insights into the liquid-solid interface by measuring both mass changes and dissipation factors. These measurements allow us to monitor the kinetics of electrodeposition and corrosion with high precision. The mass changes reflect deposition and dissolution rates, indicating the occurrence of side reactions, while the dissipation data reveal the viscoelastic properties of the interfacial layer, facilitating the

inference of passivation layer formation and its stability. This deeper understanding aids in evaluating the kinetic stability and structural changes occurring during electrochemical reactions.
Additionally, dynamic spectroscopic measurements complement the EQCM-D data, offering detailed insights into the chemical composition and structural evolution of the interfaces during electrodeposition and self-discharge reactions. These techniques enable the identification of corrosion products and the elucidation of degradation mechanisms of metal electrodes, which are pivotal for enhancing the durability of metal-based batteries.

***Operando* Electrochemical Liquid-Cell STEM at Dynamic Catalyst Interfaces During CO2 Reduction** Yao Yang[1] and Yimo Han[2]; [1]Cornell University, United States; [2]Rice University, United States

Electrocatalysis lies at the interface between materials science and electrochemistry and represents one of the most promising approaches for enabling renewable energy technologies to mitigate carbon emissions through the use of hydrogen fuel cells and the electrochemical reduction of CO_2. One of the key challenges is understanding how to achieve and sustain electrocatalytic activity under operating conditions for extended time periods, and such fundamental understanding calls for the use of time-resolve nanoscale *operando* analytical methods.[1]

In this presentation, I will introduce our recent progress on developing *operando* electrochemical liquid-cell scanning transmission electron microscopy (EC-STEM), which simultaneously enables quantitative electrochemistry on microelectrodes and quantitative STEM based imaging, diffraction and spectroscopy.[2] *Operando* electrochemical 4D-STEM in liquid,[3] driven by machine learning,[4] has shown great potentials to interrogate complex structures of active sites of energy materials at solid-liquid interfaces.[5] In particular, we will present our latest work on multimodal *operando* studies of combining EC-STEM and correlative synchrotron based X-ray methods[6,7] to elucidate the longstanding enigmatic nature of Cu active sites as Cu nanograins for selective CO_2 electroreduction.

Using In-*Operando* Raman to Understand Interface Evolution in Anode Free Solid and Gel Electrolyte Systems Rhyz Pereira[1], Taber Yim[1], Zhenghuan Tang[2], Subhadra Jamkar[3], Ayush Morchhale[2], Jung-Hyun Kim[2] and Vibha Kalra[3]; [1]Drexel University, United States; [2]The Ohio State University, United States; [3]Cornell University, United States

Advanced ceramic and polymer electrolyte systems offer many advantages over their liquid counterparts, promising higher energy densities, and safer performance. Gel polymer electrolytes consisting of a polymer matrix mixed with lithium salts possess excellent processability, flexibility, safety, and good interfacial contact with electrodes by forming robust electrode electrolyte interfaces. However, they present inferior thermal and electrochemical stability, and unsatisfactory ability to suppress lithium dendrite growth. Inorganic ceramic electrolytes require no supporting solvent, possess a broad electrochemical window, and high mechanical strength, but have poor interfacial contact with electrodes driven by imperfect surface contact, and the formation of adverse degradation products on the lithium metal surface.

Herin we directly observe and compare the evolution of the interfacial chemistry of a gel polymer electrolyte and a sulfide ceramic electrolyte in an "anodeless" configuration using *in-operando* Raman spectroscopy. For the gel polymer electrolyte we used 1:1 dimethoxyethane (DME) and dioxolane (DOL) with lithium bistrifluoromethanosulfonyl imide (LiTFSI) and lithium nitrate entrapped in Poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP). This gel-polymer system exhibited excellent stability in symmetric cell cycling demonstrating stable performance for over 500 hours. The ceramic counterpart we compared it to is sulfide based argyrodite, $Li_6PS_5Cl_{0.5}Br_{0.5}$. To understand the fundamental interfacial phenomenon governing lithium deposition and growth in these systems an anode less Cu|Li cell was constructed to perform *in-operando* Raman. Copper was sputtered onto the polymer and sulfide electrolyte before assembly with a thickness of 20nm, providing an optically transparent electrode through which the Raman laser can pass through to detect interfacial species. In doing so we not only observe initial interface species forming on the copper surface but the growth and evolution of the lithium metal and associated interphase during the plating and stripping cycle.

4:30 PM CH02.03.09

Investigation of the Interfacial pH at Catalyst-Ionomer Interface Using *In-Situ* Surface-Enhanced Raman Spectroscopy Pulkit Jain, Nhan H. Tran and Zhu Chen; University of Massachusetts Amherst, United States

Renewable energy-powered electrochemical CO_2 reduction reaction (CO_2RR) offers a potentially viable method to close the carbon cycle and produce high-value multicarbon(C_{2+}) products. Ionomers such as Nafion, commonly used as a binder in nanostructured CO_2RR catalytic systems, can also affect the selectivity of CO_2RR by modulating the local pH and alkali cation transport to the catalyst surface. However, literature reports have shown either a decrease, increase, or no effect of Nafion on C_{2+} selectivity, demanding a better understanding of the catalyst-ionomer interface. In this study, we utilized in-situ Raman spectroscopy to monitor changes in local pH on a plasmonic rough gold surface, both with and without ionomer coating, using a pH-sensitive probe. We used the Hydrogen evolution reaction (HER) as a model reaction because, similar to CO_2RR, it can also increase the local pH by consuming protons or producing hydroxide ions. Our results on bare gold surface show no change in the local pH with applied potential when tests are conducted in strongly acidic medium. However, in mildly acidic or near-neutral bulk conditions, the local pH quickly changes to alkaline post-HER onset. Upon conducting these tests with Nafion-coated gold electrodes, we observed both lower local pH and current at the same applied potential compared to bare electrode. However, when similar current densities are applied, the difference in local pH compared to bare electrode is not significant, indicating that improvement in C_{2+} selectivity, as proposed by earlier reports, might not be due to the local pH increase from the OH- trapping effect of Nafion.

Probing Oxo-and Superoxo-Intermediates in the Water Oxidation Cycle of a Molecular Ir Catalyst at the Electrode/Electrolyte Interface Boqiang Chen[1], Hongna Zhang[1], Tianying Liu[1], Gary Brudvig[2], Dunwei Wang[1] and Matthias Waegele[1]; [1]Boston College, United States; [2]Yale University, United States

Water oxidation plays a crucial role as the anodic half-reaction in various renewable fuel-formation processes, including carbon dioxide reduction, hydrogen evolution, and nitrogen activation. However, the slow kinetics of water oxidation limits the overall efficiency of renewable fuel synthesis. Molecular Ir catalysts are particularly interesting due to their high water-oxidation activity. They also serve as important model systems for elucidating structure-function relationships that inform the design of heterogeneous Ir-based electrodes. To advance this design, a deeper mechanistic understanding of Ir-mediated water oxidation catalysis is essential. However, the intermediates of Ir molecular catalysts at the electrode/electrolyte interface have not been investigated with structure-sensitive methods. In this work, we identified two reaction intermediates in the electrocatalytic water oxidation cycle of a molecular Ir catalyst known as the “Ir blue dimer” at the Au electrode/aqueous electrolyte interface. This advance was enabled by combining phase sensitive detection (PSD) with surface-enhanced infrared absorption spectroscopy (SEIRAS). By coupling these two techniques, we were able to detect infrared bands with amplitudes as low as a few of μOD. We determined that with increasing potential, the predominant intermediate changes from Ir-oxo to Ir-superoxo. We rationalize this change in intermediate population in terms of the accumulated oxidative charge on the catalyst. This study demonstrates that PSD-SEIRAS is a versatile and sensitive method for probing reaction intermediates at electrode/electrolyte interfaces.

Advanced Electrochemical Investigations of Hybrid sp^2/sp^3-Bonded Carbon Interfaces Consisting of Boron-Doped Carbon Nanowalls and Diamond Films Sanju Gupta[1,2]; [1]The Pennsylvania State University, United States; [2]Gdansk University of Technology, Poland

The integration of allotropic sp^2-/sp^3-bonded carbon (sp^{2}C/sp^{3}C) has evoked increasing attention since they offer a versatile and rich playground for carbon electronics, electrochemical sensing platforms, and optoelectronic neuromorphic computing attaining enhanced performance [1]. In this work, we synthesized lightly boron-doped carbon nanowalls/diamond (BCNW/D) interfacial architectures using microwave plasma-enhanced chemical vapor deposition on nanodiamond seeded p-Si(100) and SiO_2/p-Si(100) substrates. The hierarchical features constituted by complex morphology defined with microcrystallite diamond grains intertwined with vertically-aligned BCNW as a thin layer revealed using electron microscopy complemented with structural, electrical, and electrochemical properties such as activation energy (E_a), electron transfer rate (k_{eff}) and redox potential shifts (ΔE_p). The hydrogen plasma during deposition plays an effective role in the transformation of sp^{2}C ↔ sp^{3}C, eventually leading to various complex morphologies. While the flat band potential and hole-acceptor carrier concentration were estimated using the Mott-Schottky relationship, the fabricated hybrid carbon interfaces exhibited electroactivity toward the ferro/ferricyanide redox couple. The redox peak separation value ranged between 82-94 meV for all the samples studied and the electron transfer rate was determined using different analytical procedures. The experimental findings are ascribed to the graphitic sp^{2}C pathway paired with the surface conductive channel of H-terminated diamond films surface for electron transportation and their robust nature. This work promotes the development of high-performance electroanalytical and photoelectrochemical platforms based on hybrid carbon interfaces and the method proposed here also provides an effective strategy to construct diamond and graphene-related nanostructures for diverse applications. The author (S.G.) acknowledges funding (Nobelium IDUB Award). [1] S. Gupta *et. al.,* submitted (2024).

CH02.04.02

‘Multipronged’ Approach to Investigate Interfacial Processes on Graphene-Based Hybrid Electrodes at Solid/Liquid Interfaces for Electrochemical Energy Storage Sanju Gupta[1,2]; [1]The Pennsylvania State University, United States; [2]Gdansk University of Technology, Poland

Intense research in alternative sources of renewable and clean energy is stimulated by increasing global demand for electric energy. Electrochemical energy conversion/storage systems (super-/pseudocapacitors and batteries) represent the most efficient and environmentally benign technologies for sustainable advancements. Therefore, there is an urgent need for engineered electrochemical electrodes to enable high-performance next-generation energy storage devices to approach industrially relevant specific energy and power densities and deliver electrical power rapidly and efficiently. Among various nanocarbons, graphene showing its quantum nature continues to promote extensive developments since its inception due to exceptionally rich surface chemistry and tunable physicalchemical properties. In this talk, I will present (a) potent strategies geared towards the rational design of multifunctional graphene-based hybrids with tailorable structural and electrochemical properties. We aimed to create an enhanced function from both atomic-scale interfaces and nanoscale morphology, with a strong emphasis on exploring micro(nano) structure-property-activity relationships using complementary analytical tools. Specifically, we invoked chemical hybridization for mixed dimensional carbons (2D graphene and 1D carbon nanotubes) and molecular bridging nanostructured transition metal oxides via electrostatic assembly and electrodeposition, respectively. (b) Secondly, fundamental insights into the dynamic processes occurring at the electrode-electrolyte interfaces and activity over large electrode areas are gained by utilizing scanning electrochemical microscopy. Finally, (c) identifying the origin of pseudocapacitive behavior and charge storage mechanisms (surface redox, intercalation) was carried out using operando Raman spectroscopy. The experimental findings complemented density functional theory that signified the available density of states in the vicinity of the Fermi level contributing to higher activity. These investigations pave the way for potential application at the grand challenges of clean energy-water-sensing nexus.

CH02.04.03

Molecular Insights into Electrostatically Modulated Transport of Ions Along The Graphene-Water Interface

Lingzhi Cao, Wen-jie Jiang, Zhe Liu and Dan Li; The University of Melbourne, Australia

Ion transport at charged interfaces is crucial for a wide range of applications across the energy, water, and biological sectors. Conventionally, ion permeation driven by a concentration gradient is thought to be reduced due to co-ion depletion and Donnan exclusion, a cornerstone principle in nanofluidics [1,2]. This phenomenon is also evident in widely used ion exchange membranes. Our experimental observations reveal that the ion permeation rate through water-mediated graphene membranes can be modulated unexpectedly higher than that in the bulk solution, upon applying a variable gate potential. This finding markedly contrasts with predictions, which anticipate suppression of ion permeation Nevertheless, a lack of molecular-level insights impedes a comprehensive understanding of this counterintuitive behaviour, as probing the ion structure and dynamic transport processes at electrified interfaces presents significant experimental challenges.

Here, we conducted all-atom molecular dynamics simulations to explore the non-equilibrium ion transport behaviour in the water-filled graphene nanochannel, where the concentration gradient between the entrance and exit is meticulously maintained using a constant chemical potential algorithm [3]. Our results reveal that ion permeation fluxes in negatively charged graphene nanochannels significantly can surpass those in neutral nanochannels, with flux increasing in proportion to the surface charge density on the graphene, which is contradictory to classical mean-field theories yet consistent with our experimental observations. Furthermore, an increase in co-ion concentration within the negatively charged nanochannel, which exceeds that of the bulk solution and effectively amplifies the concentration gradient to the drain reservoir, plays a pivotal role in enhancing ion flux. Our dynamic analyses further reveal that the evolution of counter-ion hydration behaviour at the charged interface contributes to charge overscreening, thereby enhancing in-channel co-ion density. This structural arrangement also facilitates counter-ion mobility along the diffusion direction, comparable to that observed in the bulk solution. In contrast, this enhancement is absent in positively charged graphene nanochannels due to a differing evolution of the surface water dipole arrangement, an observation that is consistent with our experimental findings.

Our molecular-level simulations highlight the critical role of the non-classic, short-range structure of interfacial water and ion solvation behaviour, factors often overlooked in classical theories, in governing the electrical response and dynamic transport behaviour of ions at the electrified solid-water interfaces. These insights reveal that complex, subtle interactions at the electrified surface enable the prompt modulation of ion transport in nanochannels by applying gate potential, paving the way for developing advanced applications in electrochemical systems, including energy harvesting and storage, energy-efficient ion separation, neuromorphic computing, and other emerging technologies.

Tuning the Electrocatalytic Activity of Pd Nanocatalyst Toward Hydrogen Evolution and Carbon Dioxide Reduction Reactions by Nickel Incorporation Soumita Chakraborty[1,2]; [1]TCG Centres for Research and Education in Science and Technology, India; [2]JNCASR, India

Electrochemical H2 generation and CO2 reduction address the energy and environmental crisis plaguing the world. An efficient electrocatalyst would require the lowest overpotential for these reactions. Given its position on the volcano plot near platinum, palladium presents itself as a viable alternative for the hydrogen evolution reaction (HER). However, the activity is limited by a high overpotential. It is also a good electrocatalyst for the CO2 reduction reaction (CO2RR) due to the favorable position of the d-band center. Nevertheless, the CO poisoning of the active site results in low electrocatalytic stability. Herein, we report a Niincorporated palladium catalyst, NiPd, which reduces water to H2 at a very low overpotential of 25 mV (η10). Furthermore, it reduces CO2 to formate with a very high faradaic efficiency of 97% at a potential of −0.25 V (vs RHE). DFT studies show that Ni inclusion leads to the facile activation of CO2 due to a bent adsorption configuration at the catalyst surface. The NiPd catalyst exhibits a strong and stable performance for HER (400 h) as well as for CO2RR (9 h) with high structural integrity as proven by postreaction characterization studies.

CH02.04.05

Enhancing Urea Oxidation in Alkaline Media for Renewable Energy Applications—The Impact of Reduced Graphene Oxide on Nickel Phosphide's Electro-Catalytic Activities Dejen K. Demssie; National Taiwan University of Science and Technology, Taiwan

To date, various active materials have been developed for converting urea's chemical energy into electricity. However, there is a pressing need for cost-effective and efficient materials in the urea oxidation system to produce electricity. This study focuses on enhancing the electro-catalytic activities of nickel phosphide (NiP) toward alkaline urea oxidation by synthesizing reduced graphene oxide (rGO) as an effective supporting material via a straightforward chemical reduction method. Characterization of the developed materials involved FESEM, XRD, FTIR, and UV-VIS analyses. The physical characterization revealed multifaceted phases of NiP dispersed on the rGO surface, confirming molecular interaction and plasmonic resonance of Ni2+ from FTIR and UV�VIS spectra. Cyclic voltammetry (CV) was used to test the electro-catalytic activities, displaying the superior performance of rGO-supported NiP. This hybrid material exhibited a lower onset potential of 0.32 V vs. SCE and a peak potential of

0.41 V vs. SCE, generating a current density of 36.8 mAcm-2. The as-synthesized materials demonstrated a higher electrochemically active surface area, improved kinetics, and enhanced stability compared to bare NiP. This remarkable electrochemical performance suggests a synergistic effect between NiP and rGO. Consequently, the newly developed NiP@rGO catalyst surpassed the performance of NiP, presenting a promising electrode material for direct urea fuel cells.

CH02.04.06

Development of United Atom Model for Ionic Liquids and Studying Their Structure and Dynamics on Gold Surfaces Under Various Bias Voltages Md Fahim M. Newaz, Haohui Zhang, Takashi Sumikama and Takeshi Fukuma; Kanazawa University, Japan

Over the past two decades, ionic liquids (ILs) have become very popular solvents in various devices, particularly in electrochemistry. At charged surfaces such as electrodes, IL ions create denser electric double-layer (EDL) structures compared to traditional field-effect transistor (FET) surfaces, leading to differences in the performance of electric double layer transistors (EDLT). However, the relationship between their structure and device function remains unclear. Advanced scanning force microscopy, such as three-dimensional force microscopy (3D-SFM), allows for the visualization of 3D force distribution and is a cutting-edge technology [1] to reveal the sub-nanoscale 3D distribution of ionic liquids on the charged surface to elucidate the relationship. Our laboratory successfully imaged bias-dependent changes in the interfacial structures of DEME-TFSI sandwiched between Au (111) surfaces at sub-nanoscale resolution by 3D-SFM, and their dynamics at different bias voltages were reproduced using molecular dynamics simulations. Recent research has shown that electrolytes composed of oligomeric molecules, such as IL4-TFSI and IL2-TFSI, outperform monomeric BMI-TFSI and DEME-TFSI in terms of generating high EDL capacitance [2]. Specifically, it has been reported that the bias dependence of charge accumulation in EDLTs varies with the cation species of the ionic liquid, necessitating a comparison of these differences at the molecular scale.

In this research, we developed united-atom models of BMI, IL2, and IL4 cations and simulated the dynamics of BMI-TFSI, IL2-TFSI, and IL4-TFSI sandwiched between Au (111) surfaces at various biasing voltages. The charges on BMI, IL2, and IL4 were calculated by *ab initio* calculation using Gaussian09 at the MP2 level with a 6-311+G* basis set followed by ESP assignment. The charges on hydrogens were summed into heavy atoms. Partial charges were scaled along with Lennard-Jones parameters of σ to simulate the ionic liquids, particularly to reproduce the viscosity at 300K. A bulk equilibrium system consisting of 1,000 BMI and 1,000 TFSI molecules was prepared by running a 500 ns simulation under successively changing conditions: 10 ns in NPT, 390 ns in NVT, and 100 ns in NVE. This equilibrated system was placed between 5,376 gold atoms arranged in six layers, with three layers at the bottom and three at the top. Charges were uniformly assigned to the gold atoms in the layer closest to the bulk when biased between -1V and +1V, and the system was further equilibrated at different biasing voltages.

To validate our equilibrium state, we calculated viscosity from mean square displacements and used the Poisson-Boltzmann equation to calculate the biased voltages. 3D-SFM imaging by our laboratory of the interfaces between BMI-TFSI and Au (111) electrodes showed multiple layer-like contrasts and their dependence on biased voltages. Additionally, ongoing studies are being conducted on IL2-TFSI and IL4-TFSI. Hence, we are trying to reproduce such voltage-dependent multilayer formation using MD simulations.

CH02.04.07

A Novel Ion Microscope with a Compact Magnetic Sector SIMS for Nano-Analytics Torsten Richter, Peter Gnauck and Alexander Ost; Raith Group, Germany

Advanced material characterization techniques with high lateral resolution and sensitivity are essential for studying nanoscopic materials and their transformations in three dimensions at relevant spatial scales. Focused Ion Beam (FIB) technologies, coupled with Secondary Ion Mass Spectrometry (SIMS), offer powerful capabilities in visualizing nanoscale 3D structures and analytical surface measurements.

SIMS, utilizing energetic primary ions to sputter the surface and generate secondary ions for chemical analysis, boasts high sensitivity and dynamic range. Various analysis modes like mass spectrum recording, depth profiling, and 2D/3D imaging provide comprehensive information for diverse fields including materials science, semiconductors geology, and biology.

A newly developed nano-analytics system integrates a Liquid Metal Alloy Ion Source (LMAIS) with a special designed compact magnetic sector SIMS unit, enabling correlative high-resolution 2D/3D imaging and nano-analysis.

The SIMS unit is equipped with an insertable/retractable extraction optics to transfer the generated secondary ions through a mass analyzer onto a focal plane detector. The latter allows parallel acquisition of full mass spectra for each scanned pixel within the chosen field of view which gives the user a multitude of possibilities to post-process and correlate the SIMS image data. Further key strengths of this novel FIB-SIMS platform are the possibility to use application specific primary ion beams from Liquid Metal Alloy Ion Sources (LMAIS). The LMAIS emits multiple ion species simultaneously, offering flexibility in choosing primary ions depending on the application. This setup offers various primary ion species from a single source and automated workflows by taking advantage of switching quickly between reactive primary ion species to maximize either positive (e.g., Au+ or Bi+ single primary ions and clusters) or negative ionization (e.g., Li+ primary ions) of the sputtered particles. The small beam diameter of the lightest primary ions (Li+ and Si2+) allows to perform high spatial resolution imaging in SIMS (< 20 nm). The low penetration depth of heavy Bi+ and Au+ (and clusters) primary ions into the material enables excellent depth resolution.

In this contribution we outline the working principles and features of the focal plane magnetic SIMS detector combined with a LMAIS, demonstrating its capabilities through applications such as CIGS solar cells, semiconductor samples and geological samples. By combining LMAIS technology with a stable laser interferometric sample stage and sensitive SIMS unit, this system offers a pathway for advanced nano-analytics, surpassing conventional methodologies for sample analysis.

CH02.04.08

Semiconducting Metal Oxide Gas Sensors—Exploring the Nature of Siloxane Poisoning Mechanisms

Shannon G. Gerard[1,2], Sierra Astle[1], Kazi Rifat Bin Rafiq[1] and Anna Staerz[1]; [1]Colorado School of Mines, United States; [2]University of Florida, United States

Semiconducting metal oxide (SMOX) based gas sensors are cheap, easy to manufacture, battery powered, respond rapidly and when used in an array can detect specific gases. These qualities make them attractive for different applications ranging from indoor air quality monitoring to industrial safety. SMOX sensors are more robust than other options, e.g. electrochemical sensors, and can therefore be used in applications that require elevated temperature and with large variation in humidity. Nonetheless commercially available SMOX sensors, largely based on SnO2, are known to significantly degrade in the presence of siloxane vapors (Si-O-Si bond). Over the past 10 years, the number of products containing siloxanes, e.g. hair and body products, oil-based lubricants, sealants and even anti-foaming agensts, have continuously increased. As a result of this omnipresence, simply avoiding siloxanes is no longer feasible. The intentional design of more robust sensors requires an understanding of why even low siloxane concentrations degrade SnO2 based sensors. Through systematic comparison with two other n-type materials, In2O3 and WO3, already used for sensors, it will be explored how the acidity of the oxide influences its susceptibility to degradation by siloxanes. Insights into the mechanism will be gained from simultaneous in-operando DRIFT spectroscopy and EIS. Understanding the relation between material acidity and its propensity for degradation is essential for identifying intrinsically robust oxides.

CH02.04.09

Evidence for a Quantum Transition State During Redox Xiaoyang Chen and Al-Amin Dhirani; University of Toronto, Canada

Field effect transistors (FETs) and electrochemical devices have enabled tremendous advances, ranging from various electronics, applications on industrial scales and studies of fundamental phenomena. Here, we have developed charge exchange transistors (CETs) that combine FET with electrochemistry and use CETs to probe metallocene–electrode redox during cyclic voltammetry. This talk will present multiple evidence, including various data, kinetic modelling and density functional theory modelling, that are consistent with a multi-step redox pathway that includes the formation/destruction of a quantum transition state. These results provide important new insight into quantum mechanisms involved in charge exchange; conversely, they point to an important application of CET as a means for probing and potentially exploiting such quantum phenomena.

CH02.04.11

Mechanistic Role of External Stack Pressure on the Thermal Stability of Solid-State Batteries Md Toukir Hasan, Avijit Karmakar, Bairav S. Vishnugopi and Partha P. Mukherjee; Purdue University, United States

Solid-state batteries (SSBs) present a promising advancement in next-generation energy storage devices due to their high energy density, power density and non-flammability. However, advancing SSBs necessitates a deep understanding of the electro-chemo-mechanical interactions at different solid/solid interfaces. While the impact of interfacial mechanisms such as interphase formation and void growth on cell performance has been studied, their core influence on the thermal stability of SSBs remains a complex area requiring further investigation. This work examines the effect of external stack pressure on the electrochemical performance and thermal stability of $Li_{10}SnP_2S_{12}$ (LSPS) solid electrolyte with Li metal anode. A detailed mechanistic link has been established between applied pressure, interphase propagation, and the severity of thermal runaway at the LSPS/Li interface. Additionally, the thermal runaway mechanism of $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$(NMC622) and LSPS cathode composite has been thoroughly evaluated. Based on these comprehensive thermo-electrochemical interactions across anode/solid-electrolyte/cathode interfaces, cell-level thermal safety maps have been developed.

Discovering the Fundamental Processes of Anodic Mg Corrosion Through *Ab Initio* Calculations Mira Todorova[1], Sudarsan Surendralal[1], Florian Deissenbeck[1], Stefan Wippermann[1,2] and Joerg Neugebauer[1]; [1]Max Planck Institute for Sustainable Materials, Germany; [2]Philipps University Marburg, Germany

The longevity of materials is an essential component of a sustainable economy. It is closely linked to our ability to control corrosion through materials design, which requires a fundamental understanding of the mechanism that leads to corrosion, starting with the most basic process of metal dissolution. Investigations based on electronic density functional theory seem predestined to provide insights at the most fundamental level of electrons, atoms and molecules.

Over the last few years, we have developed an efficient computational electrode [Phys. Rev. Lett. **120**, 246801 (2018)] and a thermopotentiostat [Phys. Rev. Lett. **126**, 136803 (2021)] approach that enable realistic calculations of electrified solid/liquid interfaces under potential control. The unprecedented insight into atomic-scale processes provided by these developments will be demonstrated using the example of the anodic corrosion of Mg. The processes underlying the observed enhanced hydrogen evolution and Mg dissolution have remained elusive for more than 150 years, despite intensive investigation. Our study reveals two previously unknown mechanisms that provide a completely new perspective on experimental results that have eluded interpretation [Deißenbeck at al (submitted)].

CH02.04.13

Impact of Formation Rate on the Performance of Anode-Free Lithium Metal Batteries

Juliane Fiates[1,2], Soochan Kim[3,4], Pravin N. Didwal[5,2], Robert S. Weatherup[5,2], Michael De Volder[4,2] and James A. Dawson[1,2]; [1]Newcastle University, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Sungkyunkwan University, Korea (the Republic of); [4]University of Cambridge, United Kingdom; [5]University of Oxford, United Kingdom

Anode-free lithium metal batteries (AFBs) hold significant promise for high-energy-density storage applications. However, their practical deployment is hindered by a limited cycle life, primarily due to heterogeneous lithium deposition and dendrite formation. These issues lead to rapid capacity fade as lithium inventory is consumed in side reactions, compounded by the lack of a lithium reservoir that conventional Li-metal anodes possess. To enhance AFB stability, various strategies have been proposed, including innovative current collector designs, optimized electrolytes, tailored cycling protocols, and increased stack pressure, all of which have shown notable improvements in lithium plating/stripping behavior.[1-4]

Our proposed talk will focus on elucidating the interaction between lithium and copper surfaces under varying charge conditions, utilizing classical molecular dynamics simulations of 1M $LiPF_6$ in EC/DEC at the copper interface, complemented by XPS and SEM analyses. Our findings indicate that PF_6^- ions begin to integrate into the lithium solvation shell near the interface as voltage increases, corroborated by XPS data showing elevated LiF formation at higher current densities. The resultant LiF-rich solid electrolyte interphase (SEI) is crucial for enhancing stability in subsequent cycles. We demonstrate that the initial formation protocol significantly influences the long-term cycling stability of AFBs. Therefore, optimizing the current density during the formation cycle is a critical factor in improving the performance and durability of anode-free lithium metal batteries.

CH02.04.14
Reaction and Ion Transport at Solid-State Battery Electrode-Electrolyte Interface from Machine Learning Molecular Dynamics Jingxuan Ding[1], Menghang (David) Wang[1], Laura Zichi[1], Albert Musaelian[1], Yu Xie[1], Matteo Carli[1], Anders Johansson[1], Simon Batzner[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC Research and Technology Center, United States

Atomistic-level understanding of the chemical reactions forming the solid-electrolyte interphase (SEI) in solid-state lithium batteries has remained challenging, primarily due to the difficulty of experimental characterization techniques for buried interfaces and the insufficient speed and accuracy in previously available large-scale simulations. In this work, we combine on-the-fly active learning based on Gaussian Process regression (FLARE) with local equivariant neural network interatomic potentials (Allegro) to construct a first-principles machine-learning force field (MLFF) to perform large-scale long-time explicit reactive simulation of a complete symmetric battery cell. We observe prominent fast reactions and interdiffusion at the interface and characterize the dominant reaction products along with their evolution time scales, using unsupervised learning techniques based on atomic geometry descriptors. Our simulation reveals the kinetics and the passivation involved in the chemical reaction responsible for the SEI formation. Remarkably, we observe formation of phases different from those predicted by thermodynamics, illustrating the importance of explicit modeling of kinetics. The methods in this study are promising for accelerated analysis of atomistic mechanisms in complex heterogeneous scenarios, such as solid state synthesis and stability of heterostructure, such as electrochemical systems.

CH02.04.15
First Principle Study of Mechanical Degradation in Sulfide Solid Electrolytes—The Role of Li-Ion Concentration Zakariya Mohayman[1], Dalia Coffman[2] and Akihiro Kushima[1,1,1]; [1]University of Central Florida, United States; [2]North Carolina State University, United States

All-solid-state batteries (ASSBs) utilizing sulfide solid electrolytes are considered a promising alternative to traditional lithium-ion batteries due to their high lithium-ion conductivity, modulus, and chemical compatibility with lithium metal anodes. These characteristics are anticipated to inhibit lithium penetration within the electrolyte and prevent cell short-circuiting. Nonetheless, instances of lithium penetration occurring within sulfide-based electrolytes during battery operation have been reported. One of the major reasons why this happens can be due to the mechanical degradation of solid electrolytes during battery operations. In this study, using first-principles atomistic simulations, we investigate the impact of lithium-ion concentration on the mechanical properties of sulfide-based solid electrolytes Li_6PS_5Cl (LPS). By systematically varying the concentrations of Li ions, we aim to explore how different levels of ion removal/addition influence the mechanical stability and performance of the solid electrolyte. Our analysis focuses on key mechanical properties such as elastic modulus, tensile strength, and fracture toughness. By simulating and analyzing the deformation of computational cells across various lithium concentrations, this study identifies a critical relationship between lithium concentration and the deterioration of mechanical properties. This deterioration is implicated as a potential cause of mechanical failure in ASSBs. We also perform a comparative study with the effects of electrochemical reactions of LPS by altering Li atomic concentration to provide a comprehensive understanding of the structural and mechanical implications at the solid electrolyte grain boundaries and electrode interface. The results showed that there is a significantly more reduction in the mechanical strength when there is a decrease in the Li^+ concentration. This indicates that LPS may have internal weak spots that can lead to fracture and promote lithium metal penetration. The findings from this research contribute to understanding the root cause of ASSB failure and the optimization and design of sulfide-based solid electrolytes for advanced battery technologies, potentially leading to improved performance and longevity of next-generation energy storage systems.

Early-Stage Battery Safety Evaluation by Quantitative Analysis of Reaction Thermochemistry Using Calorimetry Measurements Bhuvsmita Bhargava, Zixuan Wang, Taiwo Ogundipe and Paul S. Albertus; University of Maryland, United States

Early-stage battery chemistry work typically focuses on demonstrating performance at the materials, coin, and pouch cell level, with evaluation and design for safety left for later stages.[1] In this work, we will describe the opportunities for assessing the safety of a battery chemistry at the earliest stages of its development using Differential Scanning Calorimetry (DSC) experiments, as soon as the active materials and electrolyte have been identified.

We use DSC samples comprising of Anode-Cathode-Electrolyte (ACE), requiring only tens of milligrams of materials. Measuring and analyzing heat flow from ACE samples is challenging and has not been performed extensively in the past despite its clear advantages. This is because it involves overlapping exotherms over a wide temperature range from gas driven crosstalk reactions and interfacial reactions between the cathode, electrolyte and anode components making careful measurement and analysis difficult. We have demonstrated the value of this approach for a Li_xCoO_2+C+PVDF cathode sheet /LLZO/Li metal material set, where we identified the previously under-appreciated role of the cathode sheet conductive additive and binder in the reaction pathways upon heating to 500°C in a DSC pan.[2] In this work, we will discuss the insights from DSC heat flow measurements on ACE samples from various chemistries including high-Ni cathodes that are commercially relevant for electric vehicle applications, sulfide electrolytes, liquid electrolytes with graphite and lithium metal anodes. We will also present the DSC methodology required to obtain accurate measurements on milligram-scale samples, emphasizing the sample preparation and DSC methods needed to obtain accurate, repeatable results. Approaches associated with DSC baselining and integration methods will also be presented.

Spatiotemporal Quantification of Multiphase Systems Chris Zhou, Yi Lu, Xin Lu, Xin Shu, Xuetong Shi, Chenglong Zhang, Ran Bi, Frank Ko, John D. Madden and Orlando J. Rojas; The University of British Columbia, Canada

The strategic integration of multiple phases is often engineered to counteract the intrinsic limitations of single-phase systems, significantly enhancing electronic, ionic, and photonic mobility, mechanic or fluidic characteristics, and mass transport. Despite these advancements, related complex fluids, such as emulsions and foams have not been comprehensively investigated *in situ*, which restricts time-dependent mechanistic studies. High-resolution microscopy and ultra-fast detection provide insights into the spatial and temporal domains, respectively. However, they sacrifice features in the other domain and, therefore cannot explore the inherent connection to spatiotemporal and dynamics features of co-existing multi-phases. High-throughput technologies for spatiotemporal visualization and quantification are promising but remain largely underdeveloped. To address this gap, we have recently developed a visualization platform employing high-throughput light polarization matrix detection combined with photonic partial coherence. This platform is specifically designed to visualize and quantify the dynamic chemical and physical processes occurring at interfaces between gases, liquids, and solids with an unprecedented spatiotemporal resolution (1 μm and 1 μs). It enables precise mapping and quantification of complex fluids relevant to mechanical/electrical, biomedical/bio-engineering components, and living matter such as plant extracts and bacterial growth. By integrating the spatiotemporal equivalence of photon cluster dynamics with partial coherence detection, we further extend the scattering signals from the interfaces as spatiotemporal voxel-resolved matrix decompositions, which improve the generality of the platform and related quantifications for different multiphase systems. Overall, this study is the first attempt to use light-polarization for high-throughput spatiotemporal description of multiphase systems.

CH02.04.18

Digital-Twin Approach for Characterizing and Modeling Photocatalyst/Liquid Interfaces Haoqing Su and Shu Hu; Yale University, United States

Particulate photocatalysts, usually in a powder suspension or immobilized on a panel, host multiple concurring redox processes such as coevolving H_2 and O_2. The challenges of materials and interface characterizations lies in nanoscale proximity of reductive and oxidative sites, supported on photocatalyst surfaces. While co-evolving H_2 and O_2 is unsafe, instead, one can develop schemes of redox-mediated water splitting: H_2-evolving photocatalysts will produce hydrogen while selectively oxidizing, e.g., I^- to IO_3^- in solutions; a dichroic mirror splits the solar spectrum to allow O_2-evolving photocatalysts to absorb the solar light unused by the H_2-evolving photocatalysts; and the O_2-evolving catalysts produce oxygen while selectively reducing, e.g., IO_3^- back to I^- in a second solution. In all cases, the conversion efficiency remain low. Instead of trial-and-error, we develop tools to probe the photocatalyst/liquid interfaces. In particular, we synthesized thin-film model photocatalysts by topographical transformation of nanoparticulate semiconductors into planar thin films, and we probe the front and back potentials of thin-film model photocatalysts using nanoscale scanning electrochemical potentiometry. Especially the challenge is to probe the deep hole charge potentials of O_2-evolvign photocatalysts having O 2p or N 2p levels at the valence band maximum. Using a novel hole-selective contact and open-circuit potential (OCP) measurements in O_2/redox mixtures as a characterization framework, we show that nanoscale photocatalyst-cocatalyst interfaces are critical if not more than the catalytic performance of . We employ x-ray photoemission spectroscopy for liquid interfaces to probe the local energetics. Thse kinetics and energetics characterizations establish a new digital/physical-twin approach to quantify and visualize the spatially distributed parameters that vary for 1 eV potential energy across nanoscale during photocatalyst operation. A systematic validation approach for the digital model will be discussed and analyzed.

CH02.04.19

Computational Investigation of Pt-Based Alloys as Electrocatalysts for Formic Acid Oxidation Michael Woodcox, Kathleen Schwarz and Thomas Moffat; National Institute of Standards and Technology, United States

Exploration of a closed carbon loop based on electrochemical oxidation of formic acid to CO_2 along with the inverse process provides an interesting pathway to integrate renewable energy into portable energy conversion devices for power generation and CO_2 mitigation. Significant work has revealed competing oxidative reaction pathway from dehydration to dehydrogenation, and while the kinetics of direct formate oxidation can be quite rapid, other pathways both minor or major can lead to CO production that results in poisoning of the performance and lifetime of these devices. While bulk Pt is very susceptible to this poisoning, experimental and computational studies have found that Pt-based alloys can drastically improve the resistance to the formation of surface CO bonds. We use density functional theory (DFT) to explore a series of alloys to determine surface stability relative to the susceptibility of poisoning these materials.

CH02.04.20

Nanophase Evolution, Local Water Content Distributions and Protonation Levels in Nafion—A Vibrational Spectroscopic and Molecular Dynamics Approach Dan J. Donnelly III[1], Moon Young Yang[2], Seung Soon Jang[3], Nicholas Dimakis[4], William A. Goddard III[2] and Eugene S. Smotkin[1,1]; [1]Northeastern University, United States; [2]California Institute of Technology, United States; [3]Georgia Institute of Technology, United States; [4]The University of Texas at Rio Grande Valley, United States

Nafion has been a dominant ionomer membrane for low-temperature (~80 °C) fuel cells and electrolyzers for nearly 50 years, because of its superior chemical-mechanical stability and high protonic conductivity. Nafion morphology comprises hydrophobic (semicrystalline), interphasial (interphasial), and water-rich domains. The hydration-level-dependent size, shape, and interconnectivity of domains remains elusive, and has limited ionomer development for high-temperature operations.

For any hydrated Nafion membrane, characterized by a bulk $H_2O/SO_3(H)$ ratio (λ), our classical molecular dynamics (CMD) simulations show a wide distribution of local λ values (λ_{loc}). We used density functional theory (DFT) based vibrational normal mode analysis to generate unique λ_{loc} = 0-15 spectra, each of which contributes to overall membrane FTIR transmission spectra. For $\lambda_{loc} < 3$, the SO_3H proton remains covalently bound (i.e., C_1 local symmetry), and yields normal modes that correspond to IR bands ~1414 and ~910 cm^{-1} (C_1 bands). For $\lambda_{loc} \geq 3$, the proton dissociates to form SO_3^- (C_{3V} local symmetry), which yields normal modes corresponding to C_{3V} bands ~1060 and ~970 cm^{-1}. We now correlate the coexistence of C_1 and C_{3V} bands during membrane hydration/dehydration to SO_3^-/SO_3H ratios (i.e., protonation levels) generated by reactive force field (ReaxFF) MD simulations.

CMD simulations, governed by classical equations of motion, fail to model the dynamic exchange of protons between $SO_3(H)$ groups (i.e., exchange sites) and water/hydronium. We used ReaxFF in Nafion MD simulations to model this exchange, and to derive λ-dependent protonation levels. This is the first such use of ReaxFF, to the best of our knowledge. Our MD systems comprised 320 exchange sites, and were hydrated as follows: λ = 0, 1, 2, 3, 5, 7, 10, 15, 20. We relate the ReaxFF generated protonation levels to C_1 and C_{3V} transmission-IR band intensity changes, resulting from sub-λ aliquots of water vapor injected into an initially dehydrated Nafion membrane. Illustrations of ReaxFF MD structures reveal nano-phase segregation and heterogeneity in water environments. Inner-sphere waters contribute to λ_{loc} values and outer-sphere waters do not. Inner sphere waters either bridge multiple exchange sites (bridged) or hydrate single $SO_3(H)$ groups (non-bridged). Outer-sphere waters are either isolated or bulk-like. The applicability of our coordinated experimental/theoretical approach to hydrocarbon-based ionomers will be described.

CH02.04.21

Operando X-Ray Diffraction and Dilatometry Analysis of Coated Ni-Rich Layered Oxide Material at High-Voltage Operation Princess Stephanie Llanos[1], Zahra Ahaliabadeh[1], Ville Miikkulainen[1], Xiangze Kong[1], Filipp Obrezkov[1], Jouko Lahtinen[1], Lide Yao[1], Hua Jiang[1], Ulla Lassi[2] and Tanja M. Kallio[1]; [1]Aalto University, Finland; [2]University of Oulu, Finland

By extending the cutoff potential of a Ni-rich layered metal oxide cathode material, specifically $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NMC811), lithium-ion batteries (LIB) can effectively deliver higher energy density output. However, this approach negatively impacts the structural and interfacial stability of NMC811 during cycling, which leads to poor electrochemical performance and shorter cycling duration. The application of a protective coating on the surface of Ni-rich NMC has been recognized as an effective procedure in improving the cycling stability of NMC-based LIBs. However, there is limited analysis available on the structural and interfacial evolution experienced by a coated Ni-rich NMC cathode during cycling at a high voltage operation.

In this work, a $Li_xW_yO_z$ (LWO) coating is developed on the NMC811 active material to address the instability issues. The coated NMC811 sample reports a higher capacity retention at 85% compared with an uncoated NMC811 at 80% after 100 charge-discharge cycles at 1C with a high cutoff potential of 4.6 V vs Li/Li^+. Operando X-ray diffraction (XRD) and operando electrochemical dilatometry are combined with ex-situ characterization techniques to provide an inter-mapping and compare the degradation mechanisms that occur in the uncoated and coated Ni-rich NMC. The multiscale analysis show that the coated Ni-rich NMC experiences a suppressed lattice contraction along the c-axis at high state-of-charge (SOC), consequently producing lesser particle cracking and electrode thickness change compared with the uncoated sample. Moreover, the coating shields the bulk material from the electrolyte which mitigates the parasitic side reactions and facilitates the ease of Li^+ movement across the electrode-electrolyte interface. The results can help elucidate the role of surface coatings in enhancing the cycling stability of Ni-rich NMC at an extended voltage operation and assist in developing more advanced coating strategies to optimize electrode design for high energy density LIBs.

CH02.04.22

Polyanion Dynamics Leads to High Ionic Conductivities in Site-Exchanged Antiperovskites Chaohong Guan; Shanghai Jiao Tong University, China

Sodium anti-perovskite conductors (APs) are a promising class of solid-state electrolytes attributing to their high structural tolerance and good formability. However, limited APs have been synthesized experimentally, pursuing the exploration of the other potential chemical spaces. Herein, through combined particle swarm optimization algorithm, high-throughput first-principles calculations, ab initio molecular dynamics and long timescale machine-learning molecular dynamics, the strategies based on site-exchanging and anion clusters are shown to simultaneously enhance the thermal stability and the sodium diffusivity in the designed APs. Among these APs, the highest ionic conductivity of 39.05 mS/cm is achieved in Na_3BrSO_4 at room temperature, due to the strong coupling of cluster rotation and sodium migration. We highlight not only the rotation dynamics but also its coupling with Na diffusion, as confirmed by the proposed rotational tolerance factor and local difference frequency center to evaluate rotation possibility and coupling degree, respectively. Particularly, according to this simple descriptor, rotational tolerance factor, the anion rotation possibility in APs can be predicted from the lattice structure, which can be applied for screening of superionic conductors with cluster rotation dynamics.

CH02.04.23

Aluminum Doped Polycrystalline Silicon as an Anode in Li-Ion Batteries—First Principles Study Sree Harsha Bhimineni[1], Shu-Ting Ko[2], Casey Cornwell[1], Yantao Xia[1], Sarah H. Tolbert[1,1], Jian Luo[2,2] and Philippe Sautet[1,1]; [1]University of California, Los Angeles, United States; [2]University of California, San Diego, United States

Addressing sustainable energy storage remains crucial for transitioning to renewable sources. While Li-ion batteries have made significant contributions, enhancing their capacity through alternative materials remains a key challenge. Micro-sized silicon is a promising anode material due to its tenfold higher theoretical capacity compared to conventional graphite. However, its substantial volumetric expansion during cycling impedes practical application due to mechanical failure and rapid capacity fading. We propose a novel approach to mitigate this issue by incorporating trace amounts of aluminum into the micro-sized silicon electrode using ball milling. We employ density functional theory (DFT) to establish a theoretical framework elucidating how grain boundary sliding, a key mechanism involved in preventing mechanical failure, is facilitated by the presence of trace aluminum at grain boundaries. This, in turn, reduces stress accumulation within the material, reducing the likelihood of failure. To validate our theoretical predictions, we conducted capacity retention experiments on undoped and Al-doped micro-sized silicon samples. The results demonstrate significantly reduced capacity fading in the doped sample, corroborating the theoretical framework and showcasing the potential of aluminum doping for improved Li-ion battery performance.

CH02.04.24

Electro-Chemo-Mechanical Behaviors of Composite Si Anode in Solid-State Batteries Zijie Lu; Ford Motor Company, United States

Solid-state batteries (SSBs) are a promising next-generation propulsion technology for electric vehicles due to their improved safety, high gravimetric and volumetric energy densities, and increased reliability. Silicon is one of the limited choices for the anode material in SSBs due to its high applicable capacity, low operating potential, and natural abundance. However, significant challenges remain for the commercialization of Si anode based SSBs.

The primary challenge for silicon anodes is the substantial volume expansion upon charging, resulting from phase transitions and lattice volume changes. For example, the formation of the $Li_{15}Si_4$ phase can cause a volume expansion as high as 300%. This drastic volume expansion frequently leads to the breakdown of silicon particles, also referred to as pulverization. Numerous performance degradation mechanisms of silicon anodes can be attributed to volume expansion-induced particle pulverization, including the loss of conducting paths (both electronic and ionic), electrode delamination, the formation of cracks/voids, and dynamic solid electrolyte interface (SEI) formation. To maintain electrical contact in Si anode based SSBs, high stack pressures, ranging from several MPa to several tens of MPa, are typically applied.

This work aims to achieve a better understanding of the electro-chemo-mechanical failure mechanisms of composite Si/Li_6PS_5Cl anodes in solid-state batteries via a combination of electrochemical impedance spectroscopy (EIS) and real-time stack pressure measurement. The growth of the solid electrolyte interphase (SEI) and the microstructure evolution of the composite anode are revealed by EIS. The stress-strain characteristics of the composite Si anode and their correlations with the LixSi phase changes are displayed by the stack pressure spikes and stack pressure degradation.

Understanding these electro-chemo-mechanical mechanisms helps provide guidelines for the design of improved electrode materials and architectures, as well as optimized pressure management.

CH02.04.25

Water as an Additive in Lithium-Sulfur Batteries Electrolytes—Mechanism Elucidation via *Operando* FTIR and XPS Analysis Érick A. Santos[1,2], Hudson G. Zanin[1] and Johanna N. Weker[3]; [1]Universidade Estadual de Campinas, Brazil; [2]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; [3]Stanford Synchrotron Radiation Lightsource, United States

Additives in the electrolytes of Li-S batteries aim to increase overall capacity, improve ion conductivity, enhance cyclability, and mitigate the shuttle effect, which is one of the major issues of this system. Here, the use of water as an additive in the commonly used electrolyte, 1.0 M LiTFSI/1.0% (w/w) $LiNO_3$ and a 1:1 mixture of 1,3-dioxolane (DOL) and 1,2-dimethoxyethane (DME) was investigated. Electrochemical tests determined 1600 ppm as the optimal water concentration, significantly reducing the shuttle effect. Post-mortem X-ray photoelectron spectroscopy (XPS) analysis focused on the lithium metal anode revealed the formation of Li_2O layers in dry electrolyte and LiOH in wet electrolyte. Better capacity was observed in wet electrolyte, which can be attributed to the superior ionic conductivity of LiOH at the electrode/electrolyte interface, surpassing that of Li_2O by 12 times. Finally, operando Fourier-transform infrared spectroscopy (FTIR) experiments provided real-time insights into electrolyte degradation and solid electrolyte formation (SEI) formation, elucidating the activity mechanisms of H_20 and Li_2CO_3 with cycling. These results could aid future advancements in Li-S battery technology, offering possibilities to mitigate its challenges with inexpensive and scalable additives.

CH02.04.26

Understanding Reconstruction Dynamics on Porous Electrodes Tailored for CO_2 Reduction by *In-Situ* Electrochemical Atomic Force Microscopy

Marinos Dimitropoulos, Barbara B. Polesso, Viktoria Golovanova and F. Pelayo Garcia de Arquer; ICFO–The Institute of Photonic Sciences, Spain

Classical electrochemical techniques, such as cyclic voltammetry, can provide vital information on the catalyst electrochemical interface, yet they remain suggestive in determining reconstruction dynamics at the nanoscale. In situ/operando characterization with nanoscale spatial resolution is paramount for understanding, regulating, and tuning the local electrochemical functionalities. Electrochemical Atomic Force Microscopy (EC-AFM) has been proven as a revealing method for characterizing catalysts under realistic CO_2 reduction (CO_2RR) conditions, in-situ [1]. Furthermore, controlling the reaction microenvironment at the catalyst-electrolyte interface with inorganic and organic additions is an established approach to promote reactivity, selectivity, and stability [2],[3],[4]. The rational design of these electrocatalysts requires detailed knowledge of spatial property variations across their interface. By linking reactivity and reconstruction, stable and efficient electrodes can be engineered on-demand.
Herein, advanced AFM tools have provided novel insights into locally probed electrochemical mechanisms with nanometer resolution. The structure-property relationships of porous electrodes (Polytetrafluoroethylene/Cu) and their heterojunctions with organic coatings (Nafion) are disentangled, and the impact of reconstruction dynamics on their catalytic activity is highlighted. Complementary to these findings, nanoscale spectroscopic characterization with Tip-Enhanced Raman Scattering (TERS) allows us to evaluate the catalyst chemical structure before CO_2RR. The engineered catalysts are ultimately assessed in real catalytic conditions for CO_2RR for the generation of C2+ products. In situ/operando tools are shown to provide a viable pathway to fine-tune electrochemical processes by pinpointing the active sites and translating this information to efficient and sustainable catalyst design.

Determining Physicochemical Properties of Metal-Organic Framework (MOF)–Electrolyte Interfaces

Shasanka Lamichhane, Anton Perera and Chad Risko; University of Kentucky, United States

Metal-organic frameworks (MOF) are a diverse, highly tunable and porous materials class that are of interest across fields as diverse as energy conversion and storage, gas adsorption, and drug delivery. For electrochemical-based energy conversion and storage and catalytic applications, there is need to understand the nature of the MOF interface with electrolyte solutions. Here, we develop and implement a series of equilibrium and non-equilibrium molecular dynamics (MD) simulations to elucidate the interfacial interactions that take place at the MOF-solution interface. As a paradigmatic MOF, we examine the interface of the zeolitic imidazolate framework 8 (ZIF-8) MOF with acetonitrile-based electrolyte solutions. The electrolyte salts include $LiPF_6$, and TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy)-PF_6, and mixtures thereof; the latter two models use TEMPO to represent an electroactive molecule undergoing charge/discharge. To expedite the model throughput, we also report on the development of QSolFlow (QSF), a Python platform to automate MD simulations by creating a high throughput, highly parallelized, MD workflow. QSF allows for rapid generation of MD-derived data that can be used to facilitate the generation of chemical descriptors for machine learning models.

CH02.04.28

Understanding the Electrokinetic Role of Ions on Electricity Generation in Hydrovoltaic Systems Min Sung Kang and Sung Beom Cho; Ajou University, Korea (the Republic of)

Hydrovoltaic is emerging as a promising energy harvesting technology with the remarkable capability of generating energy through the direct interaction of water and material. The hydrovoltaic generates voltage-level potentials without any external force, and its electrical performance can be enhanced by using an aqueous solution. However, it is not clear how ions affect or interact with the material. Herein, the theoretical model was used to provide an in-depth analysis of working principles. The model, validated with experimental results, incorporates four physics: water flow in unsaturated porous media, transportation of ions, chemical reactions, and electrostatics. It was found that the distribution of ions is key to improving the voltage output. The higher gradient of ions' concentration leads to strong potential differences, and its asymmetry of concentration is mainly governed by the water flow and concentration distribution. Additionally, we analyzed the parametric effects of substrate porosity, and relative humidity under the various solutions. The results showed that the presence of salt ions makes the electrical performance highly sensitive to porosity, but less sensitive to relative humidity. These findings improve the understanding of hydrovoltaic mechanisms and pave the way for the practical use of hydrovoltaic systems.

CH02.04.29

Overcoming EIS Modelling Obstacles Michael A. Maguire; Private Consultant, Canada

Choosing an appropriate Electrical Circuit Model (ECM) is the major obstacle in fitting and interpreting Electrochemical Impedance Spectroscopy (EIS) data. The traditional approach is to choose an ECM based on a physical perception of the system. However, this approach is daunting: it assumes the ECM can fit the data. Often there are: A) too many parameters (i.e. large parameter error) requiring 'optimized' fit routines, B) too few parameters to adequality fit spectra or, C) there is information in the data not described by the ECM. The answer to this dilemma is to use a 'universal' ECM that can adapt to the data and then, achieving convergence, explore physical modes. What is this universal model? To answer the question requires revisiting EIS basics.

EIS is an electrical response technique. Using the potentiostatic method, the surface is held at a constant DC potential while an AC voltage perturbation is applied as function of frequency. The instrument measures the resulting current to the stimulus at each frequency and the software calculates the impedance. Traditionally, the ECM is in Randles form, made up of parallel RC elements, e.g. 2-Response cascading Randles circuit R(C(R(C(R))), where each parallel RC element has a characteristic relaxation RC time constant. Admittedly, the Randels form is not an arbitrary choice because it resembles common physical system characteristics. However, recognizing circuit equivalence, the ECM can be written in Debye form using parallel series RC elements, e.g. 2-Response Debye circuit (RC)(RC)(R), where each series 'RC' element has a characteristic by-pass filter Cut-Off frequency (Fc).

The Debye form has significant advantages that may not immediately obvious:
1) Each individual response represents an parallel current path between the Working and Counter electrode.
2) Each current path is an electrical by-pass filter with associated Fc.
3) At frequencies above Fc, current is limited by R and at frequencies below Fc current is blocked by C.
4) Each current path relates to a physical characteristic of the system.
5) Each observed response 'dominates' the spectra about its characteristic Fc.
6) A Constant Phase Element (CPE) having both C and the power law parameter n can describe many types of responses; near ideal response n approaches 1, non-ideal dielectric response 1 > n > 0.5, disperse diffusion (Warburg) n approaches 0.5.
7) All ECM parameters are determined by approximating Fc directly from the Bode Plot.
8) Convergence is obtained using stepwise process of hold/releasing parameters and observing the fit. The user stays involved in the process.

The simple concept of using a Debye form rather than Randles form is a game changer. The Debye ECM effectively models the electrical response data as independent current paths as a function of frequency. The number of responses present in the EIS spectra can be accomodated by adding or subtracting 'RC' current paths. It separates the fitting operation from the physical interpretation. It is universal because the ECM form stays the same, while the number of responses (i.e. parameters) are changed during the fit.

Poly-crystalline oxide films on the two-phase Zr 2.5Nb alloy used in CANDU nuclear power reactors amply demonstrate the technique. EIS results of anodized, thermal (out-reactor), and themal/irradiated (removed pressure tubes after service) oxide films are presented and discussed. Although this application includes only capacitive dielectric behavior of poly-crystalline oxide films, it is easily adapted to other systems as well (e.g. reactive inductance). The concept of using a universal ECM to fit the EIS data followed by the physical interpretation has broad applicability to EIS and overcomes the obstacles of adopting a perceived physical ECM.

Explicit Interface Modeling of LiNb(Ta)O_3 Coating on $LiCoO_2$ Cathodes: A DFT Study on Li-Ion Transport.

Zizhen Zhou and Tateyama Yoshitaka; Tokyo Institute of Technology, Japan

In solid-state batteries, the interface between cathodes and solid electrolytes is crucial and coating layers play a vital role. $LiNbO_3$ has been known as a promising coating material, whereas recent studies showed its degradation via releasing oxygen and lithium during cycling. This computational study addresses the elucidation of essential characteristics of the coating materials by examining $LiNbO_3$ and its counterpart $LiTaO_3$ interfaces to a representative layered cathode, $LiCoO_2$. Employing the interface CALYPSO method, we constructed explicit models of both coatings on $LiCoO_2$. Our findings indicate that $LiTaO_3$ offers easier Li^+ migration at the interface due to the smaller difference in Li adiabatic potential at the interface, whereas $LiNbO_3$ more effectively suppresses oxygen activity at high delithiation states via lowering the O 2p states. This comparative analysis provides essential insights into optimizing coating materials for improved battery performance.

SESSION CH02.05: Understanding Chemomechanics at Solid-Solid Interfaces

Advanced Operando Analysis of Diverse Interfaces for All Solid State Batteries Se Young Kim, Yiseul Yoo, Jiwon Jeong and Kyung Yoon Chung; Korea Institute of Science and Technology, Korea (the Republic of)

All-solid-state batteries (ASSBs) have gained significant attention for their potential to enable highly safe and durable batteries, which are key technologies for the success of energy storage systems and electronic devices. With the improved ionic conductivity and atmospheric stability of solid electrolytes (SEs), the bottleneck for the commercialization of ASSBs extends beyond SE materials alone. Research has primarily focused on individual materials, revealing various issues in the interactions between materials within ASSBs. These issues can be broadly categorized into reduced contact due to volume changes and the formation of unwanted new layers from side reactions.

During the intercalation/deintercalation process of lithium between the anode and cathode active materials, volume changes occur. Solid-state materials in ASSBs may fail to fill the empty spaces created by these volume changes, reducing contact between materials. This reduction in interfacial contact increases the battery's internal resistance, thereby diminishing its capacity and efficiency.

While materials developed through different research efforts may individually exhibit excellent performance, there has been limited research on their interactions when combined. If lithium does not move smoothly between materials or if the materials are highly reactive, a new layer can form at the interface. This newly formed layer lacks electronic and ionic conductivity, acting as a high resistance. Ultimately, these issues accumulate, significantly contributing to the degradation of cell performance. Therefore, understanding and addressing these mechanisms are crucial for improving cycle life and efficiency.

To investigate the various phenomena occurring at the interface, we developed in-situ/operando analytical techniques capable of structural, imaging, evolved gas, chemical bonding, and pressure variation analysis. These techniques have enabled a comprehensive understanding of ASSBs. Our investigation into the interphase evolution at the electrode interface in all-solid-state batteries using sulfide or halide solid electrolytes will be discussed at the meeting.

In-*Operando* Interfacial Electrochemical-Mechanical Coupling Measurements in Thin-Film Batteries Using a Nanoindentation Platform Bhuvsmita Bhargava, Yueming Song, David Stewart, Alec Talin, Gary Rubloff and Paul S. Albertus; University of Maryland, United States

Solid-state batteries require stress for well-formed interfaces during fabrication and to maintain intimate contact during operation. The interaction between applied and generated stress and electrochemistry significantly impacts performance and degradation. However, accurately measuring the stress-electrochemistry coupling is challenging due to mechanically coupled and irregular interfaces, leading to non-uniform stress distributions. In this work, we use a nanoindenter to apply controlled uniaxial compressive forces to thin-film electrochemical devices and batteries that offer uniform and planar interfaces. This allows us to study the effect of stress on interfacial electrochemistry more directly, with greater quantitative accuracy and control. Using a planar cell with sputter-deposited V_2O_5 electrodes as the working electrode, a NASICON-type LATP solid electrolyte as the substrate, and a Li metal counter electrode with a PEO-LiTFSI interlayer, we can mechanically decouple the electrode interfaces. This setup enables us to measure only the in-operando stress-potential response from the V_2O_5-LATP interface. We further discuss the origins of the observed coupling and its dependence on the lithiation state of the V_2O_5 electrode.

Chemo-Mechanics of Silicon Anodes via *Operando* Acoustic Transmission in Solid-State Batteries Kerry Sun, Gunnar Thorsteinsson and Daniel Steingart; Columbia University, United States

Silicon (Si) anodes paired with solid electrolytes have recently risen as a promising energy storage solution for energy-dense Li batteries. However, Si lithiation and delithiation can exacerbate electrochemical degradation due to its high mechanical dynamics, especially against a solid electrolyte. In this work, we utilize operando acoustic transmission to probe the chemo-mechanical dynamics of Si. Acoustic transmission utilizes ultrasound propagation to nondestructively monitor the electrode's chemo-mechanics. The speed of sound through a material is proportional to its Young's modulus and inversely proportional to density. We show that in an all-solid-state system with a sulfide solid electrolyte, the mechanical dynamics of Si electrodes and its distinct phasing are monitorable through acoustic time of flight. We combine operando acoustics with ex-situ techniques such as SEM and XPS to gain physical insight into the fundamental electrode mechanics. We demonstrate that acoustics time-of-flight transmission is a useful tool in probing electrode dynamics that give further insight into the degradation modes of next-generation anode materials.

9:30 AM CH02.05.04

Evolution of Electrochemical Interface and Weakening Mechanisms of Li_6PS_5Cl Solid State Electrolyte—Space Charge Region and Acceleration of Lithium Penetration Akihiro Kushima; University of Central Florida, United States

All-solid-state lithium battery has been developed as a next generation energy storage device because of its potential to exceed current Li-ion battery technology by enabling high voltage cathode and lithium metal anode. However, there are several challenges that need to be overcome for before the practical implementation of the technology to real-world applications. These include lithium penetration, electrolyte/electrode cracking, stability of solid electrolyte, and low ionic conductivity across grain boundaries, to name a few. In particular, the lithium penetration can cause serious safety hazard and unexpected failure of the battery. Lithium deposition at the electrode electrolyte interface induces stress on the solid electrolyte. And at the same time, electrochemical reaction induces change in the mechanical property of the solid electrolyte in addition to the reduction in the ionic conductivity. This complex interaction of electrochemistry and mechanics is responsible for the lithium penetration. Moreover, a slow ionic conductance across the grain boundaries creates a lithium concentration gradient near the boundary forming space-charge regions within the solid electrolyte. The lithium excess or deficiency may decrease the mechanical strength of the electrolyte further promoting the lithium penetration. Understanding the evolution and behavior of electrochemical interfaces during the charge/discharge process is a key to identify root cause of the failure and performance degradation of the all-solid-state lithium batteries.

In this work, in situ transmission electron microscopy (TEM) and ab initio simulation are performed to study the electrochemomechanics of the lithium penetration in Li_6PS_5Cl (LPSCl) solid electrolyte typically used in all-solid-state lithium battery. Here, conductive atomic force microscopy (AFM) cantilever was integrated in the in situ TEM experiment to evaluate the mechanical force associated with the lithium penetration during the real-time observation of the process. It was shown that lithium can penetrate the solid electrolyte even with a minute interfacial force with lithium metal in contact. Ab initio modeling showed that this may be caused by the reduction in the mechanical property when the solid electrolyte is electrochemically reduced or oxidized at the interface with lithium. Additionally, a sign of a lithium concentration gradient and a space charge region was observed at the grain boundary of the solid electrolyte by in situ TEM analysis, and ab initio simulation showed a significant reduction in the mechanical strength of the solid electrolyte compared with electrochemically reacted LPSCl. This may contribute to formation of internal cracks in the solid electrolyte accelerating the lithium penetration.

Alloying Reactions as a Means of Controlling Morphological Evolution of Lithium Metal in All Solid-State Batteries Anton Van der Ven, Sesha Behara and Jeremiah Thomas; University of California, Santa Barbara, United States

All solid-state batteries promise significant increases in energy density because they will enable the use of lithium metal instead of graphite as anodes. However, there are significant challenges in controlling the morphology of metallic lithium during the plating and stripping of lithium between a solid electrolyte and the current collector. Metal additives that alloy with Li can facilitate the uniform deposition and stripping of metallic Li in anode-free all solid-state batteries by affecting nucleation, diffusion and growth kinetics. Very little is known about the fundamental thermodynamic and kinetic properties of lithium-metal alloys. Some alloying elements such as Mg form solid solutions with Li, while many other alloying elements, including Ag, Al, Ga, In, Zn, Sn, Sb and Bi, form a variety of intermetallic compounds. A crucial property is the mobility of Li within the intermetallic compounds that form during alloying reactions. First-principles statistical mechanics methods that rely on kinetic Monte Carlo simulations are able to elucidate diffusion mechanisms in substitutional alloys and predict the concentration dependence of diffusion coefficients. Li diffusion in solid solutions and intermetallic phases is mediated by vacancies, which in most alloys are predicted to be present at very dilute concentrations. The migration barriers for Li diffusion in most intermetallic phases is predicted to be very low, rivaling those of super-ion conductors. The complex crystal structure of most intermetallic phases leads to unusual diffusion mechanisms, including two-atom hops and multi-hop cycles to preserve long-range order. Several intermetallic compounds, such as the LiAl zintl phase, however, favor structural vacancies and have crystal structures with fully interconnected Li sublattices. This results in exceptionally high Li diffusion coefficients. Li alloys also exhibit intriguing mechanical properties due to the unusual energy surface of lithium metal along crystallographic pathways that connect the BCC crystal structure to close-packed crystal structures. First-principles calculations predict that high concentrations of alloying elements are necessary to modify the mechanical properties of lithium metal. The combination of the unique thermodynamic, kinetic and mechanical properties of Li alloys offers a rich pallet with which to control the morphological evolution of lithium metal in all solid-state batteries.

10:45 AM CH02.05.06
Mechanistic Interrogation of Alloy Interlayers in Solid-State Batteries Debanjali Chatterjee, Kaustubh G. Naik, Bairav S. Vishnugopi and Partha P. Mukherjee; Purdue University, India

Solid-state batteries employing lithium (Li) metal anodes have emerged as key enablers of a sustainable energy economy due to their high energy density and enhanced safety over their liquid electrolyte counterparts. However, achieving their full potential is limited by fundamental challenges arising from non-uniform reaction distribution and mechanical stresses at the Li metal-solid electrolyte interface, resulting in localized Li deposition, filament growth and subsequent short-circuit. Among the several strategies being developed to mitigate these interfacial instabilities, the use of a lithiophilic metal interlayer (e.g., Ag, Au) between the Li metal anode and the solid electrolyte has shown remarkable promise, exhibiting enhanced regulation of Li deposition-dissolution behavior and improved performance. However, the underlying mechanisms driving this improvement remain unexplored. In this work, we reveal the mechanistic interactions within alloy interlayers that enhance the stability of the Li metal anode. Through a mesoscale modeling framework that captures the coupled electro-chemo-mechanical interactions within the interlayer, we present the impact of thermodynamics, reaction kinetics, Li^+ ion transport, Li diffusion, and mechanical stresses on Li deposition behavior and contact loss. Further, we analyze the role of volume expansion accompanying alloying and heterogeneities in reaction and mechanical stresses on the spatiotemporal evolution of the interlayer architecture. Overall, this work offers fundamental insights into interface stability with alloy interlayers for the design and development of robust solid-state batteries.

11:00 AM CH02.05.07

Mechanistic Analysis of Solid Electrolyte Interphase Interactions in Sodium Metal Electrodes Aditya Singla, Kaustubh G. Naik, Bairav S. Vishnugopi and Partha P. Mukherjee; Purdue University, United States

Sodium (Na) metal batteries have emerged as promising candidates for next-generation low-cost energy storage systems. However, the formation of a heterogeneous solid electrolyte interphase (SEI) at the anode results in high interfacial resistances and morphological instabilities, posing a major challenge for the practical implementation of Na metal batteries. Heterogeneities in the SEI can lead to ionic transport limitations and influence the reaction distribution at the Na/SEI interface. The resulting current heterogeneity induces non-uniform morphological growth and stress hotspots in the SEI. In this work, we develop a spatiotemporal mesoscale model to study the mechanics-coupled electrochemical interactions governing the electrodeposition stability of Na metal electrodes. We reveal that the evolution of mechanical stresses in the SEI and Na metal strongly influences the reaction kinetics by altering the mechanical overpotential. We analyze the effect of electrochemical and mechanical properties of the SEI on interface growth and onset of cell failure. Three distinct SEI failure modes primarily driven by the mechanical, transport, and reaction kinetic interactions at the Na/SEI interface have been delineated.

11:15 AM CH02.05.08

Electrochemical-Mechanical Coupled Modeling of Thin-Film Solid-State Energy Storage Devices Yueming Song, David Stewart, Taeho Jung, Bhuvsmita Bhargava, Gary Rubloff and Paul S. Albertus; University of Maryland, United States

The application of solid electrolytes not only provides opportunities to solve the safety issues of lithium-ion batteries with flammable organic electrolytes but also enables the application of thin-film techniques in battery fabrication processes that can develop high surface-to-volume ratio structures which may further improve the performance of solid-state batteries [1]. Thin-film structures are potentially good candidates for fundamental electrochemistry studies considering their high purity and structural control. However, the cyclic volume change of an all-solid-state cell may introduce significant stresses, altering thermodynamics, kinetics and even induce mechanical degradation and failure [2]. Due to the difficulties in conducting mechanics-related experiments with thin-film batteries, developing multi-physics-based models that couple electrochemistry and solid mechanics will not only help in understanding how mechanics affects battery performance mechanisms but can also provide useful information for fabrication and experiment design strategies.

The present work incorporates intercalation-induced stress and stress-driven diffusion to the standard battery FEA model in COMSOL [3]. We choose to simulate an AAO 3D thin-film battery (TiO_2/LiPON/V_2O_5) as a representative and experimentally achievable device that highlights the impact of electrochemical-mechanical coupling (ECM) on battery performance and potential device failure modes. Both electrode regions are modeled as a continuum intercalation-type material with constant expansion rates as a function of lithium content. The single-ion conductor assumption is utilized to annihilate composition variations in the solid electrolyte region. Simulation results show a significant amount of stress can be introduced by joint influences from lithium transport-induced volume expansion tendency and mechanical boundary conditions. The stress gradient provides an additional transport mechanism to redistribute the lithium content to a more uniform pattern which improves the capacity behavior. However, the induced stress on the interface could lead to mechanical-related degradation mechanisms including interfacial decohesion and yielding or cracking of the solid electrolytes. The induced stress will also change the thermodynamic state of the lithium atom along the interface which has been incorporated into the Butler-Volmer equation to capture mechanics-modified interfacial kinetics. This study shows multiple electrochemical-mechanical coupling mechanisms have collective influences on the battery performance and structural integrity. The consistency and inheritance of concepts and assumptions from classic electrochemistry formulation greatly reduces the gaps between experimental and simulation works.

Implications for Corrosion Inhibition of Electrochemical Interfaces Through Atomistic Insights into Phosphate Thin Film Growth on Lead-Containing Materials Peng Yan and Joseph Bennett; University of Maryland, Baltimore County, United States

Integrating modeling of surface coatings with electrochemical interface dynamics can offer valuable insights into the fundamental mechanisms that govern the stability and effectiveness of phosphate coatings. This approach not only advances our knowledge of phosphate-based coatings but also contributes to the broader field of surface coating modeling. The implications extend to various technologies involving surface coatings, such as energy storage systems, fuel cells, and electrolysis, where optimized coatings can significantly enhance performance and durability. In this study, we investigate the interfacial processes involved in the growth of phosphate thin films on lead-containing materials, with the goal of designing more effective corrosion inhibitors and improving the performance of electrochemical interfaces. Using density functional theory (DFT) and thermodynamic simulations, we model the adsorption and growth of phosphate films on PbO and $PbCO_3$ surfaces, examining the effects of pH, temperature, concentration, and applied potential on these processes. Our research provides a detailed atomistic understanding of how phosphate films interact with lead-containing materials, revealing the critical factors that influence their efficacy as corrosion inhibitors. We discuss how our findings can be leveraged to develop improved surface coatings and electrochemical interfaces, addressing key challenges and advancing the design of more efficient and durable systems.

SESSION CH02.06: Multiscale Modeling of Interfacial Structure and Chemistry

Universal Interatomic Potential and Simulation of Kinetics Ju Li; Massachusetts Institute of Technology, United States

Electrochemical interfaces are chemically and structurally so complex [Advanced Materials 34 (2022) 2108252; Energy & Environmental Science 14 (2021) 4882; Advanced Materials 33 (2021) 2100404] that they typically evade simple models. I will describe the recent development of a universal neural interatomic potential (UNIP) that covers 96 elements on the periodic table, from Hydrogen to Curium. More than two thousand GPU years were used to generate the ab initio training data guided by active learning. Diverse test simulations have shown this universal potential has outstanding performance, with energy error significantly less than the chemical accuracy (43 meV/atom) for even chemically very complex systems. Going from a few hundred atoms in DFT to up to 50,000 atoms with UNIP, one can study realistic microstructures such as curved interfaces, realistic phase transformations, plastic deformation and damage evolution, electrochemical interfaces, etc. A reinforcement learning (RL) technique to guide long-timescale simulation is also introduced. [J Materiomics 9 (2023) 447; Advanced Science 11 (2024) 2304122]

2:00 PM *CH02.06.02
Modeling of Complex Electrolytes and the Impact of Electric Double Layer (EDL) on SEI Formation Yue Qi; Brown University, United States

Next-generation electrolytes designed for high-energy batteries with Li-metal electrodes or operating under extreme conditions (e.g. fast charging and low temperature) can no longer be viewed and simulated as a dilute system with fully solvated ions.
In this talk, we first categorize homogenous electrolytes, based on the solvent-ion interactions, salt concentration, solubility limit, and the availability of free solvents, into low-concentration electrolytes (LCE); high-concentration electrolytes (HCE) or medium concentration electrolytes (MCE). Heterogeneous structures can form in liquid electrolytes when combined with non-ion-solvating diluents. We named these heterogeneous structures as "micelle-like structures" in localized HCE and localized MCE, as LHCE and LMCE, respectively.
This talk will discuss the computational design of these chemically and compositionally complex electrolytes as well as the solid electrolyte (SEI) interface they form in batteries. The structures of the complex electrolytes were obtained first by Molecular Dynamics (MD) simulations. Starting from different initial configurations with salt-solvent clusters with varying sizes embedded in diluent, instead of randomly mixed structures, accelerated the process to identify the lowest energy configurations
Ion transport in these electrolytes is strongly coordinated in these complex electrolytes. Ion correlations must be considered, e.g. via the Green-Kubo relationship to accurately predict the experimentally measured ion conductivities as a function of concentration. We will show how ionic conductivity varies in the formation, percolation, and branching of salt-solvent clusters.
The formation of the solid electrolyte interphase (SEI) is influenced by the Electric Double Layer (EDL) structure, which is dramatically different from their bulk structures. Therefore, the MD simulated EDL structures were feedback to ab initio calculations to determine the species will be reduced and form SEI.

Understanding Chemical Evolution at Interfaces in Solid-State Batteries Using Machine Learning Force Fields <u>Kwangnam Kim</u>[1], Suyue Yuan[1], Nicole Adelstein[2], Brandon Wood[1] and Liwen Wan[1]; [1]Lawrence Livermore National Laboratory, United States; [2]San Francisco State University, United States

Solid-state batteries (SSBs) are next-generation energy storage technologies with improved safety and potentially higher energy densities compared to conventional Li-ion batteries, which is enabled by using fast ion-conducting solid electrolytes (SEs). However, practical applications of SSBs are hindered by the electro-chemo-mechanical instabilities at grain boundaries (GBs; i.e., internal interfaces) as well as external interfaces between SEs and electrodes, which deteriorates Li transport and the chemical and mechanical integrity of the cell. To resolve these issues, fundamental understanding of the intrinsic physico-chemical properties at interfaces is required. To this end, we explore the evolution of interfaces in SSBs directly in atomic scale by machine-learning-driven large-scale molecular dynamics simulations and investigate the structure-property relationship at the interfaces that governs Li-ion transport and stability of SSBs.

In this talk, we will discuss the characteristics of garnet $Li_7La_3Zr_2O_{12}$ (LLZO) SE/$LiCoO_2$ (LCO) cathode interfaces as well as the internal interfaces within LLZO. It is observed from our simulations that the propensities for interfacial degradation strongly depend on the surface chemistry of LLZO and LCO. Dopants in LLZO are found to have a segregation effect at the LLZO GBs. Here we will discuss its implication towards secondary phase formation and Li transport kinetics. At last, we will address the micro-crack propagation behavior and mechanical responses in LLZO. In summary, our results reveal how atomic details of the dynamically evolving interfaces dictate the performance of SSBs, and provide guidance for processing and interface design to achieve desired performance.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract number DEAC52-07NA27344. Authors acknowledge funding support from the Vehicle Technologies Office, Office of Energy Efficiency and Renewable Energy, U.S. Department of Energy and computational resource support from the Innovative and Novel Computational Impact on Theory and Experiment (INCITE) program. This research used resources of the Argonne Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC02-06CH11357. Additional computational resources were sponsored by the Department of Energy's Office of Energy Efficiency and Renewable Energy located at the National Renewable Energy Laboratory and the Computing Grand Challenge program from Lawrence Livermore National Laboratory.

3:45 PM CH02.06.04

Unveiling Solid Electrolyte Interphase Formation in All-Solid-State Batteries—Computational Insights into Li-Metal/Electrolyte Interfaces at the Molecular Level <u>Javier Carrasco</u>[1,2], Andrey Golov[1], Grace Chaney[3], Ambroise van Roekeghem[3], Natalio Mingo[3], Pierre Lannelongue[1], Simon Lindberg[1], Elena Gonzalo[1], Francisco Bonilla[1], Juan Miguel Lopez del Amo[1], Thomas Marchandier[4], Artur Tron[5] and Pedro Lopez[1]; [1]CIC energiGUNE, Spain; [2]IKERBASQUE, Basque Foundation for Science, Spain; [3]Université Grenoble Alpes, CEA-Liten, France; [4]Saint-Gobain Research Paris, France; [5]AIT Austrian Institute of Technology, Austria

Solid-state ionic conductors are crucial for advancing energy storage technologies, particularly all-solid-state batteries (ASSBs). These materials offer high ionic conductivity and stability, but realizing their full potential in high-performance electrochemical devices requires a deep understanding of ionic mobility and reactivity at interfaces. Our research delves into the intricate interfacial phenomena of halide- and sulfide-based solid electrolytes with lithium metal, using advanced atomistic modeling integrated with cutting-edge characterizations to provide new insights and guide next-generation battery design. Specifically, we highlight critical enhancements in modeling capabilities through diverse case studies that combine ab initio molecular dynamics (AIMD) with machine-learned potentials to address real-world complexities beyond idealized systems [1-4].

We first explore $Li_3YCl_4Br_2$, known for its high ionic conductivity, ductility, and electrochemical stability. Yet, reactivity with lithium metal can form secondary compounds, hindering practical utility. Through a combination of physico-chemical and electrochemical characterizations with AIMD simulations, we have studied the Li/electrolyte interface's dynamics and evolution during cycling. We find that reaction products form a structured SEI with mixed ionic and electronic conductivity, crucial for a cells' outstanding cycling stability. In particular, this SEI structure enables symmetric cells with $Li_3YCl_4Br_2$ and bare Li-metal electrodes to withstand 1000 hours of Li electrodeposition-dissolution with low overpotential.

Furthermore, expanding AIMD simulations, we use machine-learned interatomic potentials to simulate SEI growth for Li_6PS_5Cl on unprecedented time and length scales. These simulations reveal a two-step growth mechanism: an initial chemical reaction forming an amorphous phase, followed by a slower crystallization into a $5Li_2S$-Li_3P-LiCl solid solution [4]. This detailed understanding supports recent experimental hypotheses and sheds light on complex SEI evolution processes.

Overall, by elucidating atomic-level processes and their impact on macroscopic properties, we demonstrate how advanced modeling techniques can optimize solid-state battery performance, guiding the development of more effective energy storage solutions.

Towards Principles of Electronic Structure Modeling of Battery Interfaces Kevin Leung; Sandia National Laboratories, United States

Battery Interfaces affect charge/discharge rates, cycle life, safety, and many other aspects of battery operations. Electronic structure modeling should significantly accelerate the understanding and design of such interfaces. Due to their complexity and the lack of established, guiding principles governing such modeling efforts, most research groups working in this area apply different models and sets of approximations, making it difficult for the experimental or casual theoretical reader to understand how different modeling approaches fit together (or not). For example, the calculation and control of voltages in DFT settings remain active research topics. In this presentation, we propose key scientific principles involved in battery interface modeling, how they relate to principles in other electrochemical disciplines, and the differences between cathodes and anodes. We emphasize the need to deal with the “dirty” nature of realistic battery electrode surfaces (covered by multi-layer surface SEI or CEI films), the need to go beyond the “initial’ stages of surface film growth, the focus on kinetics rather than thermodynamics, the almost inevitable presence of overpotentials on metallic electrode models, and the choice of DFT functionals when dealing with electrolyte oxidation on cathode surfaces.

4:30 PM *CH02.06.06
Towards AI^2 Electrochemistry Jun Cheng; Xiamen University, China

It is known that electrode materials undergo dynamic structural changes at *in-situ/in-operando* conditions. Yet, the majority of computational studies only consider the static structures of electrode materials. When the materials are submerged in liquid solution, dynamic solvation effects are often completely ignored, or treated with dielectric continuum models, often lacking validation. The situations are about to change. Thanks to the latest development of *in-situ* experimental techniques and state-of-the-art computational methods, dynamics of electrode materials has recently drawn more and more attentions in many research areas. In this talk, I will present our recent progress on modeling dynamic catalysis and electrochemistry using *ab initio* molecular dynamics (AIMD). The high computational cost of AIMD however limits its application to small model systems consisting of hundreds of atoms at timescale of tens of ps. While, the latest development of AI accelerated AIMD (AI^{2}MD) significantly increases the size and timescale, showing great promise for in situ modeling of realistic electrochemical systems.

Combining Experiments and Modeling to Identify the Limitations at Electrochemical Interfaces Anja Bieberle-Hütter; DIFFER, Netherlands

The limiting processes taking place at the electrodes in photo-electrochemical water splitting are not well understood yet, though this is necessary not only from fundamental point of view, but also to improve the electrodes for possible commercialization. In this presentation, I will explain our combined experimental and computational approach towards identifying limiting processes at electrodes for water splitting [1,2]. From the experimental side, I will focus on recent studies on Fe_2O_3 [3], WO_3 [4-7], and $BiFeO_3$ [8] as oxygen and hydrogen evolution electrodes and will discuss specific limitations in these electrode materials. I will touch upon operando Attenuated Total Reflectance-Fourier Transform Infrared spectroscopy measurements and its challenges [9] and will present a new, promising pathway for highly sensitive and reproducible measurements.
After this experimental insight, I will explain our multiscale modeling approach to simulate the same data that we are measuring in experiments [10,11]. The heart of the approach is a microkinetic modeling code that is based on a state-space representation with the electrified interface included [10,11]. I will present the approach including its latest extensions which allow for simulating the dynamics of the hole and electron densities over space and

time from the electrolyte into the bulk of the electrode [12]. Finally, I will explain how the modeling in combination with sensitivity analysis [13] enables us to understand experimental data better.
I will finish up the presentation with giving you a glance on the new Pulsed Laser Deposition infrastructure for energy research (PLD4Energy) that we are currently building at DIFFER. I will explain how this infrastructure will help to further investigate the limitations at electrochemical interfaces.

Insight into Surface Changes on Battery Electrodes via (DFT- Parameterised) Kinetic Monte Carlo Simulation

Ulrike Krewer[1], Janika Wagner-Henke[1], Michail Gerasimov[1], Kie Hankins[1] and Walter Cistjakov[2]; [1]Karlsruhe Institute of Technology, Germany; [2]Technische Universität Braunschweig, Germany

A good battery performance requires a large and active electrode surface with intimate ionic contact to the electrolyte. Yet, in Li-ion and next-generation batteries, the electrode surface is often buried under a layer of degradation or solid reaction products, which passivate the surface and lead to performance and capacity losses. For Li- and Na-based batteries, this is the solid-electrolyte interphase at negative electrode; Li-sulfur cells feature precipitation of an insulating product, Li_2S, during discharge. Operando analysis of the growth of these mostly only nm-thin layers is still posing huge challenges. This holds even more, if the formation takes place within seconds, as e.g. happens on Li metal. Models may give essential insights into what happens at the surfaces, why and how fast. Whereas continuum models cannot explain or reproduce the observed heterogeneity of the layers, molecular modeling is limited to very short time-spans (usually ps), and, thus, can only observe a small and only initial fraction of the growth period.
This talk shows that Kinetic Monte Carlo (kMC) models can deliver the wanted insight. They are excellent for surface heterogeneous growth studies and can cover wide time ranges. They may be parameterised by DFT to ensure realistic reaction and degradation kinetics [1,2], or they may be partly experimentally parameterized. Further, they may be coupled to continuum models of full battery cells to reveal causes for local changes in growth, composition, and performance. [3] Potential evolution and the impact of potential on kinetics is accounted for as well.
This talk introduces how to formulate and use kMC simulations for understanding and tuning surface layer growth,

morphology and passivation; applications comprise the solid-electrolyte interphase growth on Li metal and Na-ion anodes, and the Li_2S precipitation on Li-S cathodes. Besides temporal evolution of the surface structure, morphology, composition and the reaction front, the talk will show the impact of modifying electrolyte composition or surface properties for tuning the interphase properties. Binding energies are shown to have a strong impact on precipitate morphology and dissolution and on surface passivation. Thus, activity and stability are addressed by the method. kMC simulations are thus a highly potent method to advance in knowledge-driven interphase design.

9:15 AM CH02.07.03
[BMPY] or [BMIM]—Which is Better for H_2 Sensing? Yining He[1], Tobias Glossmann[2], Xiangqun Zeng[3] and Wei Lai[1]; [1]Michigan State University, United States; [2]Mercedes-Benz Research and Development North America, United States; [3]University of Missouri–Columbia, United States

Ionic liquids (ILs) are good electrolyte materials for the fabrication of highly sensitive H_2 sensors, and two IL molecules, $[bmpy]^+[ntf_2]^-$ and $[bmim]^+[ntf_2]^-$, are commonly used. On the one hand, previous experiments show that $[bmim]^+[ntf_2]^-$ demonstrates higher ionic diffusivity and conductivity than $[bmpy]^+[ntf_2]^-$. However, recent tests revealed that $[bmpy][ntf_2]$ is more sensitive than [bmim][ntf2] as an H_2 sensor. This seemingly contradictory phenomenon hitherto lacks a reasonable explanation due to the limitations on current experimental techniques' spatial and temporal scales. In this study, we performed molecular dynamics (MD) simulations to investigate the Electric Double Layer (EDL) structure and H_2 dynamics, to determine the difference between the [bmpy] and [bmim] cases. First, the number distribution of the IL molecules was analyzed, revealing that the EDL structure in ILs consists of more than one layer, extending over 1 nm into the bulk. The entire structure can be categorized into 3 distinct regions based on their distance from the metal electrode: the 1st EDL (a.k.a. “boundary layer”), the 2nd EDL (a.k.a. “transition zone”), and the bulk phase, in agreement with previous studies. The number distribution of the 1st EDL features sharp peaks, extending approximately 6 Å from the electrode. In contrast, the number distributions in the 2nd EDL are more like waves instead of peaks, extending over 15 Å towards the bulk phase, whose number distributions remain quite flat with little fluctuation. In addition, the molecule orientation distribution, angular movement, and molecular displacement in the direction perpendicular to the electrode surface were investigated. In the 1st EDL, most molecular groups tend to remain parallel to the Pt surface, with constrained angular movement. Meanwhile, molecular displacement in the perpendicular direction is highly restricted. As for the 2nd EDL, the molecule orientations are mostly in a random distribution, but with a slight preference for staying parallel to the Pt surface. In addition, the angular movement in the 2nd EDL becomes unconstrained. Although the molecular displacement in the perpendicular direction becomes multiple times larger than that in the 1st EDL, it is still limited when compared to the bulk phase, where the molecular displacement becomes completely unconstrained and even multiple times larger than that in the 2nd layer. In the bulk phase, the molecular orientations are totally random, with unconstrained and large angular movements. The EDL structures of the [bmpy] and [bmim] cases are mostly similar, except for the 1st EDL near the Pt PE, where the H_2 redox reaction occurs. Compared to [bmim], [bmpy] groups have a more scattered orientation distribution in the 1st EDL. This allows more H_2 transport pathways to the Pt surface, leading to a higher possibility of H_2 redox reaction in the [bmpy] case. This is also validated by our calculation of the cumulative number distributions of H_2 near the electrodes, which shows that there is indeed a higher probability for H_2 to stay inside the 1st EDL near the Pt PE in the [bmpy] case. Thus, we conclude that this is because there is a higher probability for H_2 to move across the 1st EDL layer to reach the Pt PE, that $[bmpy]^+[ntf_2]^-$ is a more sensitive electrolyte material for H_2 sensors than $[bmim]^+[ntf_2]^-$.

Oxygen Interstitial Atoms as Diagnostics and Potential Participants in the Electrochemical Oxygen Evolution Reaction Heonjae Jeong, Ian Suni, Raylin Chen, Xiao Su and Edmund Seebauer; University of Illinois, United States

Much remains unknown about the electrochemical oxygen evolution reaction (OER) catalyzed by metal oxides. Some proposed mechanisms posit participation of lattice oxygen from the oxide, mediated in part by diffusive exchange of oxygen atoms with the bulk oxide. Little consideration has been given to the lower thermodynamic formation energies for O interstitials than O vacancies at the surface of some metal oxides. Furthermore, lowered chemical coordination at clean metal oxide surfaces facilitates the creation of interstitial O atoms (O_i) from adsorbed O atoms with energy barriers near or even below 1 eV. [1] The atomic configurations for interstitial injection resemble those for site hopping in the bulk, with barriers only slightly higher. The modest hopping barriers of O_i in oxides, coupled with those for injection, make clean surfaces effective pathways for populating the nearby bulk with O_i near room temperature. Surfaces of several different oxides generate the requisite adsorbed O when submerged in liquid water. Since adsorbed O is a vital intermediate species in the OER, the injection phenomenon may be used to probe the surface concentration of this species. Furthermore, it is possible that O_i participates in the reaction mechanism itself. Using oxygen in rutile TiO_2 single crystals as a model system, we describe isotopic self-diffusion measurements near room temperature to show that (1) use of a conventional 3-electrode electrochemical cell accelerates the injection rate of O_i, and (2) dissolved O_2, if present, contributes a significant fraction of the injected O_i. We greatly refine interpretation of the experimental results via multiscale modeling that couples atomic-scale simulations of O_i injection and diffusion by density functional theory with a mesoscale microkinetic representation of O_i diffusion, lattice exchange and trapping within the solid. In addition, we present experimental evidence that even good-quality single crystal surfaces present a variety of sites exhibiting a broad spread of activities for full water deprotonation and/or injection.

Charged Interfaces, Linear and Point Defects in Ionic Ceramics—Equilibrium and Kinetic Effects Edwin Garcia; Purdue University, United States

The properties of ionic solids enable the development of a wide variety of applications that range from sensors and actuators to structural materials, and from energy capture and conversion to storage technologies. For all these applications, a wide variety of processing routes exist to consolidate an initial granular powder that will be later used as a starting point for the fabrication of carefully thought out layers and multifunctional architectures. Sintering of ceramics, in particular, is a processing methodology that is a result of the underlying contributions from individual point (vacancies and interstitials) line defects (dislocations), and surfaces and interfaces, as they interact in a local microstructural, mechanical, chemical, and electrical field induced through local or external stimuli. In this presentation, by starting from fundamental thermodynamic concepts, a phase field theory is presented to describe the chemical and electric field-induced mechanisms that control their microstructural evolution and resultant transport and structural properties. The impact of these mechanisms at the particle and grain level are assessed and compared against experimental observations

10:45 AM CH02.07.06

Elucidation of Difference in Anisotropy of the Volume Expansion Between i- and n-Type Silicon Pillars in the Lithiation Process Hideyuki Kamisaka, Qin Si, Masakazu Takao, Wataru Sekine and Seiji Takemoto; Murata Manufacturing Co., Ltd., Japan

The theoretical capacity of silicon as anode material for lithium-ion batteries (3,580 mAh/g) is much larger than that of the conventional anode material, graphite (372 mAh/g). However, its industrial application has been limited because of its large volume expansion that occurs during the lithiation. The expansion triggers pulverization of electrode and eventually leads to failure of the battery system.

For this reason, many research activities have been conducted by several authors to clarify the fundamental mechanism of the lithiation process anticipating a clue for possible suppression or control of the expansion. Previous studies have identified that crystal silicon (c-Si) expands preferably normal to its (110) facet, which was related to the emergence of cracks[1]. Besides, effects of doping were surveyed to modify the features of lithiation. A small addition of n-type dopants has been shown to affect morphologies of the growing Li_xSi phase[2].

In this presentation, we experimentally demonstrate that an Sb-doping at a quite dilute concentration (0.01 at%) diminishes the anisotropy of volume expansion which presents in pristine c-Si sample. The change in anisotropy and the scarcity of dopant strongly suggest existence of unknown mechanism that involves the surface structures and electronic states at atomistic level.

We conducted DFT-based first-principles calculations for several structure models to get an insight. Three types of models were constructed: (1) Li in bulk c-Si, (2) Li atoms on clean Si surfaces, and (3) interfaces between amorphous Li_xSi (x~3.6) and c-Si. In both (2) and (3) models, two types of surfaces, Si(110) and Si(100) are considered. The calculations were performed for charge-neutral condition and negatively charged one with an additional electron. Structural optimizations and NEB (Nudged Elastic band) calculations were conducted at GGA level (PBE functional) for Li migration/penetration paths. The initial structure models of (3) the amorphous-crystal interfaces were constructed using a commercially available machine-learning based force field. For structures with a Li atom at its equilibrium positions and ones at the top of barrier, successive calculations were conducted using hybrid HSE functional to obtain electronic structures more accurately as the band gap of c-Si would be reproduced quantitatively.

Our calculation results clearly indicated participation of the excess electron to the Li migration/penetration processes. The barrier heights of (1) Li migration in bulk and (2) penetration to (100) surface were noticeably lowered via formation of an electron trapping state. In the (3) Li migration from Li_xSi amorphous to c-Si, addition of an excess electron reversed the order of barrier height between the boundaries with (100) and (110) surfaces. The underlying electronic mechanisms of (3) was found to be different from (1)-(2).

All our calculation results are consistent with the experiments and explain the microscopic mechanism of phenomenon. It also shed light on the role of excess electron in lithiation process that have been overlooked for many cases to the best of our knowledge. More details and in-depth discussion will be provided in the presentation.

Computational Insights into Electrolyte-Dependent Li-Ion Charge-Transfer Kinetics at the Li_xCoO_2 Interface

Joakim Halldin Stenlid[1] and John W. Lawson[2]; [1]KBR Inc., NASA Ames Research Center, United States; [2]NASA Ames Research Center, United States

Interface engineering remains a largely underexplored area and yet it holds the keys to high performance Li-ion (Li^+) batteries. The charge transfer across electrode-electrolyte interfaces is oftentimes a significant obstacle for achieving fast charging and high power performance without compromising battery lifespan. In this work we employ a Boltzmann-averaged first-principles workflow based on constant potential and constrained density functional theory for evaluation of atomic scale factors influencing coupled ion-electron charge transfer kinetics across battery electrode-electrolyte interfaces. The approach estimates diabatic Li^+ interface energy landscapes as function of the interface character and operational conditions and use this information to simulate charging/discharging currents. Experimental trends for the Li_xCoO_2 ($0.5 \le x \le 1.0$) electrode are reproduced for varied organic electrolytes with $LiPF_6$ and $LiClO_4$ salts, identifying Li^+ transfer energy and Li^+ adsorption energy as decisive factors influencing the enhanced kinetics in $LiClO_4$-based electrolytes over $LiPF_6$. The talk will conclude by comparing the performance of the aforementioned high-fidelity methods with more approximative approaches. The latter methods result in a significant computational speed-up that allows for rapid screening of liquid- as well as solid-state electrolytes with fast interface kinetics.

11:15 AM CH02.07.08

Understanding Coupled-Ion Electron Transfer Kinetics at Li-Ion Battery Interfaces

Yirui Zhang[1,2], Dimitrios Fraggedakis[1], Ryan Stephens[3], Martin Z. Bazant[1] and Yang Shao-Horn[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States; [3]Shell International Exploration & Production Inc., United States

Enhancing the charge transfer kinetics of intercalation at the electrode-electrolyte interface is critical to further increase the power and energy performance of Li-ion batteries. Despite significant advancements in understanding Li-ion diffusion and discoveries of new electrodes and electrolytes, the molecular process of ion intercalation across electrode-electrolyte interfaces remains poorly understood. Liintercalation kinetics has been traditionally treated by the empirical Butler-Volmer kinetics, but remains poorly measured and understood. Here, by developing electrochemical characterizations, combined with a coupled-ion electron transfer (CIET) model,[1] we gain insights into the ion intercalation kinetics across the interface in Li-ion batteries. We developed experimental electrochemical methods using current-voltage responses and reaction-limited capacities to probe Li^+ (de-)intercalation kinetics, for common intercalation electrode materials including $LiCoO_2$ and NMCs. A universal dependence of the intercalation rate on the lithium-ion filling fraction was revealed. Further, the temperature and electrolyte effects supported the microscopic Li^+ intercalation mechanism of CIET, which describes classical ion transfer from the electrolyte is coupled with quantum-mechanical electron transfer from the electrode.[2,3] We further quantified the three kinetic parameters that govern ion intercalation kinetics and their dependence on electrode and electrolyte materials. Finally, rate capability tests on thin, porous electrodes showed that the CIET reaction limitation governed the usable capacity at low-to-moderate (dis)charging rates. Our findings suggest that the proposed mechanism applies to a variety of intercalation materials used in energy storage, and governs the power and energy density at reaction-limited conditions. The understanding of CIET reaction limitation also helps to set usable capacity and extend lifetime by avoiding large overpotentials. The possibility of modifying the reaction-limited current with electrodes and electrolytes opens new directions for interfacial engineering.

11:30 AM CH02.07.09
Free Energy Computations by Machine Learning-Aided Molecular Dynamics Simulations—From Bulk to Interfaces Ryosuke Jinnouchi[1], Saori Minami[1], Ferenc Karsai[2] and Georg Kresse[3,2]; [1]Toyota Central R&D Laboratories, Inc., Japan; [2]VASP Software GmbH, Austria; [3]University of Vienna, Austria

First principles (FP)-based simulations have become an indispensable method for predicting the thermodynamics and kinetics of homogeneous and interfacial electrochemical reactions. Various methods have been proposed and applied to compute the free energies of molecules and adsorbates, predicting their potential windows and reaction rates. However, due to the significant difficulty in conducting statistical samplings over the entire phase space—which often requires computationally expensive multiple nanosecond-scale molecular dynamics (MD) simulations—most simulations still heavily rely on simple statistical models (e.g., harmonic oscillators), statically optimized quasi-minimum structures, or approximate implicit solvation models. These approximations often make it difficult to judge whether the results are true theoretical predictions or artificial results specific to quasi-minimum structures intentionally chosen to reproduce experimental observations, especially when examining the effects of electrolytes that fluctuate anharmonically due to thermal motion. Here, we show that machine learning surrogate models [1-4] can solve this problem. Machine-learned force fields (MLFFs) can accelerate the required nanosecond MD simulations by orders of magnitude. Additionally, subsequent thermodynamic integration from the MLFF to the FP potential energy surface can accurately correct errors of MLFFs, yielding true first principles results. Validation calculations on electrochemical reactions in aqueous electrolytes demonstrated that this method can accurately predict the redox potentials of atoms and molecules [4]. Applications to electrolyte-Pt interfacial systems revealed that hydrogen-bond defects play an essential role in the activation of the oxygen reduction reaction on Pt catalysts.

Realistic Atomistic Simulations of Heterogeneous Electrocatalysis Yuanyue Liu; The University of Texas at Austin, United States

Heterogeneous electrocatalysis plays a crucial role in enabling a sustainable future. Existing catalysts, however, generally suffer from issues such as low activity, selectivity, stability, and/or high cost. These challenges highlight the need for a deeper understanding of performance-limiting factors, facilitating the rational design of new catalysts. To reach this goal, it's essential to develop computational methods for understanding and evaluating the catalysts' performance from first principles.
Conventional atomistic simulation methods often oversimplify the complexities at the electrochemical interface, such as explicit solvent and surface charge, thereby limiting their accuracy. Also, most calculations focus on reaction thermodynamics, while the kinetic information is largely missing. I will present our efforts in developing

more realistic methods, and their application to better understand and design heterogeneous electrocatalysis systems using examples of single atom catalysts for CO2 and oxygen reduction.

SESSION CH02.08: Modeling of Microstructural Impact on Electrochemical Performance

Thermodynamics and Phase-Field Model of SEI Formation in Li-Metal Batteries Kena Zhang[1], Yanzhou Ji[1,2], Qisheng Wu[3], Yue Qi[3] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]The Ohio State University, United States; [3]Brown University, United States

Understanding solid electrolyte interphase (SEI) formation mechanisms has been a long-standing challenge. This presentation will discuss the fundamental thermodynamics and kinetics of multiple electrochemical reactions at the electrode/electrolyte interface and an atomically informed phase-field model for studying the evolution of SEI products from nanoseconds to seconds. We analyze the role of electron tunneling in the stable thickness of SEI and the role of reactive and diffusive processes in the growth rate of different SEI products. This theoretical framework can be employed to effectively extract the timescale features and distinguish various kinetic processes during SEI formation, offering useful insights into improving battery performances through SEI engineering. It is generally applicable to processes taking place in multiphase and multicomponent electrochemical systems.

Computational Analysis of Manufacturing-Electrochemical Interface Linkages in Battery Electrodes
Alejandro A. Franco; Université de Picardie Jules Verne, France

Rechargeable batteries are being transformative for our societies. Their performance and durability are highly dependent on the manufacturing process, which impacts the microstructure and the interfaces between the materials (e.g. active material, carbon additive, binder) in the electrodes. These aspects are strongly governed by the electrode manufacturing parameters, such as the slurry formulation, the slurry mixing (for solvent-based processing), the coating speed and drying rate, the calendering pressure, temperature and speed. Additionally, electrolyte filling conditions are important (in the case of lithium ion batteries for instance).
In this lecture, I present my group's latest computational research in assessing the manufacturing-electrochemical interface linkages in battery electrodes. I report the latest developments of our dynamic 3D-resolved digital models able to predict how manufacturing parameters impact the microstructure of electrodes used in lithium ion and solid state battery cells. Such models, describing the different steps along the manufacturing process and calibrated with experimental data from our battery manufacturing pilot line, are supported on a sequential coupling of computational granular approaches like Coarse Grained Molecular Dynamics and Discrete Element Method. The electrode microstructures predicted by these models are injected into simulators of the electrolyte filling and the electrochemical performance, by using the Lattice Boltzmann Method and the Finite Element Method respectively. The latter simulates dynamically and in 3D the electrochemical and transport processes in the electrodes and captures at the mesoscale, the influence of manufacturing parameters on the spatiotemporal heterogeneities of lithiation/delithiation. Deep learning is also applied to derive surrogate models mimicking the behavior of the physics-based simulators with smaller

computational cost, and Bayesian Optimization is used to predict which manufacturing parameters need to be adopt in order to improve the quality of the electrochemically active interfaces. In my lecture I provide, in comparison with experimental data, application examples of our approach to several formulations and chemistries representative for lithium ion and solid state battery cell applications, for both solvent-based and dry processing approaches. Finally, I discuss our latest developments of Virtual and Mixed Reality tools to assess the virtually produced electrode microstructures and interfaces, and to train students and factory operators about the electrode manufacturing-microstructure-performance links.

3:00 PM CH02.08.03
Ionic Charge Dynamics in Electrified Nanoslit Networks Through Multiscale Modeling Jinsha Liao, Peiyao Wang, Wen-jie Jiang, Xiaoyang Du, Zhe Liu and Dan Li; The University of Melbourne, Australia

Porous electrodes are vital for enhancing electrochemical interface performance in applications such as energy storage devices, frequency filters, and neuromorphic systems. These applications often work under electrical inputs with rapid changes, making the understanding of ion dynamics and effects at electrode/electrolyte interfaces crucial for interpreting and predicting key electrochemical properties like capacitance and impedance of devices, especially as pore sizes decrease to the nanoscale.
However, traditional macroscopic models often fail to capture the complex interactions between interfacial electrochemical potentials and the cross-scale structural configurations of conventional nanoporous materials. Additionally, scale discrepancies in microscopic simulations, due to demanding computational resources, hinder the application of nanoscale insights to macroscopic electrochemical characterizations. These challenges complicate the understanding and utilization of nano- and meso-structural impacts on ion transport dynamics.
We employed multilayered graphene membranes (MGMs) and their computational representations, i.e., nanoslit networks, as novel model systems to study ion transport dynamics. Using finite element method-based numerical simulations and guided by the Poisson-Nernst-Planck theory with steric modifications, we systematically assessed the influence of nanostructures on ion movement from individual nanoslits to the entire network. We focused on cross-scale properties under dynamic electric inputs, including nanoscale in-slit ion concentration, ionic transport resistance in the nanoslit network, and global capacitance and impedance of the nanoporous electrodes.
This presentation will cover several key findings and developments. We established a slit-size-dependent scaling relation as a strategy to quantitatively examine the electrode thickness effects on dynamic ion accessibility. This relation unifies the macroscopic rate capacitance behaviors and mesoscopic dynamic ion accessibility in nanoslit-based electrodes across varying electrode thicknesses, ion diffusivities, and applied voltage. The revealed notable slit size dependency of the scaling relation indicates that the conventional, macroscopic transmission line models, which overlook the interfacial electrosorbed ions, significantly underestimate the benefits of nanoconfinement effects on dynamic ion accessibility. Our findings not only enable the dynamic behaviors of a thin nanoslit network electrode to predict those of its thicker counterparts, allowing for the correlation between simulated and experimental data regarding rate capacitance in MGM-based supercapacitors, but also offer a semi-quantitative guideline for designing nanoporous electrodes under multiple structural constraint scenarios facing diverse performance metrics.
Additionally, we developed a physics-informed mesoscale electrically equivalent circuit model to uncover the previously unknown effects of nanostructures and electrosorbed ions on the impedance in MGMs. The interfacial electrosorbed ions demonstrate distinct influences on ion transport within and across nanoslits, each exhibiting distinct slit-size-dependent conductivity, offering new physical insights for certain widely reported experimental outcomes. These efforts establish a connection between the electrodes' microstructure and their overall

electrochemical properties, demonstrating the utility of 2D membranes and PNP-based models as effective tools for simulating and understanding the behaviors of ions at electrochemical interfaces of nanoporous materials under dynamic operational conditions. Our work also lays the groundwork for a theoretical framework aimed at digitally designing the next generation of electrochemical and ionotronic technologies.

3:15 PM CH02.08.04

Interface Properties of LLZO/PEO Hybrid Electrolytes Dima F. Abubaker[1,2], Robert Mücke[1], Xiaochen Liu[1], Martin Finsterbusch[1], Payam Kaghazchi[1,3] and Olivier Guillon[1,2,4]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Institute of Mineral Engineering, RWTH Aachen University, Germany; [3]MESA+ Institute for Nanotechnology, University of Twente, Netherlands; [4]Jülich Aachen Research Alliance, JARA Energy, Germany

Composite or hybrid organic-inorganic electrolytes have attracted significant interest as promising candidates for next-generation solid-state batteries. By combining the advantages of polymers and ceramics, these electrolytes provide enhanced mechanical properties and effectively address the contact issues typically encountered in fully ceramic solid-state batteries.

In hybrid electrolytes, it was initially assumed that the ion conductivities of the individual ceramic and polymer components were the primary factors influencing overall conductivity. However, it has been found that modifications in the polymer material near ceramic particles and the transition area between the polymer and ceramic components within the hybrid structure play the significant role.

We conducted a systematic investigation of ceramic-polymer electrolytes to thoroughly explore the properties of the interface layer and the overall conductivity of the hybrid electrolyte as influenced by the parameters of this interface layer, specifically ionic conductivity and layer thickness. This analysis included examining various particle size distributions enabling the comparison and agreement with experimental data.

Moreover, the interfacial resistance between the filler and polymer matrix is crucial in determining the overall conductivity of solid-state batteries. High resistance values at this interface, exceeding 100 $\Omega.cm^2$, can impede ion transport and potentially negate the contribution of filler content to ionic conductivity, so this value was considered in our calculations.

Our investigation has shown a strong correlation between the ionic conductivity values predicted by our model and those obtained from experimental results. This alignment is particularly evident at specific conductivities and thicknesses of the LLZO/PEO interface. Notably, the ionic conductivity values of the interface layer are approximately ten times greater than the one of the bulk polymers, and the thickness of this layer is 10% of the uncoiled chain length of PEO. Under these conditions, the maximum conductivity matches the same content percentage of the filler material as indicated by experimental ionic conductivity measurements.

Correlating CT Of Real-World Batteries with Computational Models—Methods to Overcome Manufacturing Imperfections Joshua W. Gallaway and Dominick Guida; Northeastern University, United States

High-resolution X-ray computed tomography (CT) is an indispensable tool for its ability to probe material phase distributions from within sealed batteries. By correlating battery CT with a computational battery model, kinetic parameters can be refined, and transport effects can be better understood. However, for batteries with cylindrical symmetry like bobbin-type batteries, the typical Cartesian coordinates used to describe the CT image stack are not ideal. The most prominent bobbin-type battery is the alkaline $Zn-MnO_2$ AA cell. In this work we demonstrate recent mechanistic findings on the alkaline Zn anode, as well as methods used to cast the CT image stack into pseudo-cylindrical coordinates.[1] The pseudo-cylindrical method corrects for asymmetries observed in bobbin-type batteries because the pin is often off-center, and the separator often has a noncircular shape. This reconciles the ideal geometry of a battery model with the reality of battery manufacturing.

For the pseudo-cylindrical method, the pseudo-radius is defined as the relative distance in the anode between the central current collecting pin and the separator. This allows the radial volume fractions of Zn and ZnO in the anode to be converted to dimensionless 1D profiles that vary only in radius. Such a method allows direct comparison to a battery module, which also outputs material fractions as 1D radial profiles. Ten anodes from Zn−MnO_2 AA batteries with a range of discharge histories are used to validate that this method results in averaged 1D material profiles that, when compared to other methods, show a better quantitative match to individual local slices of the anodes in the polar θ-direction. The other methods tested are methods that average to an absolute center point based on either the pin or the separator, both of which are shown to be inferior.

Using this method, we analyze Zn−MnO_2 batteries discharged with both continuous and pulsed profiles.[2] ZnO is found to have a wide range of densities within discharged cells, and pulsed operation provokes lower-density ZnO to form. This sparsely-dense ZnO has significant microporosity and takes up a larger volume within the cell. These effects are shown to have a significant impact on ion transport across the cell.

Nanoscale Viscoelasticity of Living and Soft Matter with AFM <u>Sonia Contera</u>; University of Oxford, United Kingdom

The dynamic shapes of biological cells and tissues emerge from a complex interplay of physics, chemistry and genetics, which determines--at each temporal and spatial scale--the mechanical properties that eventually form the adaptive structures of living organisms. The shape and mechanical stability of living organisms rely on precise control in time and space of growth. This is achieved by dynamically tuning the mechanical (viscous and elastic) properties of their hierarchically built structures from the nanometer up. It is now well-established that cellular behaviour crucially depends on the mechanical properties of the cells and their environments. Much attention has been directed towards the importance of *stiffness* (i.e. the capacity of a material to elastically store mechanical energy) which has been the focus of most experimental research, however, neither cells nor the extracellular matrices are elastic. Biological systems dissipate energy (i.e. they are viscous), hence they do not respond to mechanical deformations instantaneously (like an ideal Hookean spring) but present different time responses at the spatial scales that characterise their responses to external stimuli. Measuring viscoelasticity (especially at the nanoscale) has remained experimentally challenging [1,2,3]. I will present atomic force microscopy (AFM)- based techniques, developed in my lab, to measure and map the nano-viscoelasticity of living organisms, cells, membranes, collagen, ECMs, and tissue engineering matrices across the spatial and temporal scales, and chirp-based spectroscopic techniques to assess viscoelasticity from Hz to 100s kHz at the nano and micro scale[4]. I will also present tests to assess which viscoelastic models fit better the experimental AFM results. Our results have uncovered that cell walls of plants [5] and tumours present an almost perfect linear viscoelastic behaviour. Finally, I will present our work to show how different properties of cells are coupled, such as mechano-electrical coupling in neurons [6,7], and how we are extending these techniques to become useful for the Net-Zero construction industry [8].

9:00 AM CH03.01.02
Influence of Beam Mechanics and Forces on Atomic Force Microscopy Nanomechanics Measurements Ryan Wagner and Akshay Deolia; Purdue University, United States

The forces between an atomic force microscope (AFM) tip, cantilever, and sample determine the results of all AFM measurements. Sample viscoelasticity and mechanical failure can introduce additional material behaviors into the tip-sample interaction force. Off-axis lateral forcing can change the apparent stiffness of surface features. Distributed body forces acting throughout the cantilever lead to bending shapes that complicate optical beam-based calibration of cantilever motion. Correctly identifying and accounting for these effects are necessary to avoid systematic errors in AFM nanomechanics measurements. Our efforts to improve understanding of beam mechanics and tip-sample interaction forces in AFM on soft materials include: (a) implementation of first principles adhesive, viscoelastic AFM contact mechanics modeling, (b) characterizing failure and slipping in force curves, and (c) accounting for complicated cantilever bending in photothermally driven sub-resonance force measurements.

Hysteretic, viscoelastic responses are observed on many soft materials when indented by an AFM tip. Use of ad-hoc viscoelastic modifications to Hertz contact mechanics can lead to non-physical predictions. However, use of first principles viscoelastic models, such as Attard’s model, are inhibited by modeling complexity. For Attard’s model, we have enhanced its computational efficiency and developed machine learning based approaches for fitting experimental data. These results increase the reliability and robustness of extracting viscoelastic material properties from AFM force measurements.

Cellulose can form rod-shaped nanostructures that are used in flexible displays, biofuels, and structural composites. It is possible to measure the failure strength of nanocellulose by depositing them on a porous sample and indenting them with an AFM tip. We find that force curves on suspended cellulose have a linear elastic response followed by a failure event in which the cellulose permanently deforms and the AFM tip slips with respect to the surface. The value of failure stress is important for understanding how nanocellulose responds to different processing techniques.

In sub-resonance photothermally driven force measurements, distributed forcing on the cantilever occurs due to position dependent thermal strain. Depending on cantilever stiffness, modulation frequency, and photothermal laser spot position the cantilever vibration shape can either be highly sensitive or insensitive to changes in tip-sample contact stiffness. In regions of high shape sensitivity, non-monotonic relationships between cantilever amplitude and tip-sample stiffness can exist, making normal measurement approaches difficult. In regions of low cantilever shape sensitivity, measurements are more feasible but limited in accessible sample stiffness values.

Understanding these different operating regimes improves the quantitative and qualitative accuracy of sub-resonance nanomechanical measurements using photothermal excitation.

***In-Situ* Adaptive Intracellular Force Mapping Inside Living Cells by Atomic Force Microscope in Response to Environment Stimuli** Hongxin Wang, Han Zhang and Jun Nakanishi; National Institute for Materials Science, Japan

The response of cells to environmental stimuli, under either physiological or pathological conditions, plays a key role in determining cell fate toward either adaptive survival or controlled death. The efficiency of such a feedback mechanism is closely related to the most challenging human diseases, including cancer. Since cellular responses are implemented through physical forces exerted on intracellular components, more detailed knowledge of force distribution through modern imaging techniques is needed to ensure a mechanistic understanding of these forces. In this work, we mapped these intracellular forces at a whole cell scale and with nanoscale resolution to correlate intracellular force distribution to the cytoskeletal structures. Furthermore, we visualized dynamic mechanical responses of the cells adapting to environmental modulations in situ. Such task was achieved by using an informatics-assisted atomic force microscope (AFM) indentation technique where a key step was Markov-chain Monte Carlo optimization to search for both the models used to fit indentation force–displacement curves and probe geometry descriptors. We demonstrated force dynamics within cytoskeleton, as well as nucleoskeleton in living cells which were subjected to mechanical state modulation: myosin motor inhibition, micro-compression stimulation and geometrical confinement manipulation. Our results highlight the alteration in the intracellular forces to attenuate environmental stimuli, such as rescue from mechanical stimulus-initiated cell death and initiation of cell migration.

Intra-Cellular Measurements of Nanodynamics and Nanomechanics by Nanoendoscopy AFM Takeshi Fukuma; Kanazawa University, Japan

Recently, we have developed in-cell AFM technique referred to as Nanoendoscopy AFM (NE-AFM). In this method, we insert a needle-like probe vertically into a living cell and direct interaction between the tip and intra-cellular components are detected. So far, we have successfully visualized intra-cellular structures such as nucleus, actin stress fibers, actin cortical fibers, and focal adhesion without giving significant damage to the cells. As the next step, now we are exploring the possibility of intra-cellular nanomechanical measurements. For example, we can directly indent the nuclear surface and produce nanomechanical maps of the nuclear surface. The nuclear elasticity is closely related to various diseases known and laminopathy, aging and infection. Thus, there is strong needs for direct quantitative measurements of nuclear elasticity. Meanwhile, we also investigate correlation between dynamic structural changes and nanomechanical properties. So far, we measured elasticity changes during the growth and disassembling of focal adhesions. These measurements suggest stiffening and softening of the focal adhesions during their growth and disassembling, respectively. These results demonstrate the potential of NE-AFM for opening up various possibilities of intra-cellular nanomechanics studies.

10:30 AM CH03.01.05

Light-Induced Modulation of Visco-Elastic Properties in Azobenzene Polymers via Bimodal AFM Stefano Chiodini[1], Fabio Borbone[2], Stefano L. Oscurato[2], Pablo D. Garcia[3] and Antonio Ambrosio[1]; [1]Fondazione Istituto Italiano di Tecnologia, Italy; [2]University of Naples Federico II, Italy; [3]BYM-Ingema, Spain

Photo-induced isomerization of azobenzene molecules drives mass migrations in azopolymer samples. [1] The resulting macroscopic directional photo-deformation of the material morphology has found many applications in literature, although the fundamental mechanisms behind this mass transfer is still under debate. [2] Hence, it is of paramount importance to find quantitative observables that could drive the community towards a better understanding of this phenomenon. In this regard, azopolymer mechanical properties have been intensively studied, but the lack of a nanoscale technique capable of quantitative visco-elastic measurements has delayed the progress in the field. Here, we use bimodal atomic force microscopy (AFM) as a powerful technique for nanomechanical characterizations of azopolymers. With this multifrequency AFM approach, we are able to map the azopolymer local elasticity and viscosity. We find that, while in the illuminated region a general photo-softening is measured, locally the Young modulus and the viscosity depend upon the inner structuring of the illuminating light spot. We then propose a phenomenological model based on a light-induced expansion plus a local alignment of the polymer chains (directional hole-burning effect).[3]

Force Spectroscopy and High Speed Atomic Force Microscopy in Viral Research Peter Hinterdorfer, Rong Zhu and Yoo Jin Oh; Johannes Kepler Universität Linz, Austria

Recent waves of COVID-19 correlate with the emergence of the Delta and the Omicron variant. In this study, we combined high-speed atomic force microscopy with single molecule recognition force spectroscopy to investigate, at single molecule resolution, the interaction dynamics of trimeric Spike with its essential entry receptor ACE2. We report that Spike trimer undergoes rapid conformational changes on surfaces, resulting in arc-like movements of the three receptor binding domains (RBDs) that collectively screen a circular range of almost 360° degrees. Acting as a highly dynamic molecular caliper, it thereby forms up to three tight bonds through its RBDs with ACE2 expressed on the cell surface. The Spike of both Delta and Omicron (B.1.1.529) variant enhance and markedly prolong viral attachment to the host cell receptor ACE2, which likely not only increases the rate of viral uptake, but also enhances the resistance of the variants against host-cell detachment by shear forces such as airflow, mucus or blood flow. We uncovered distinct binding mechanisms and strategies employed by circulating SARS-CoV-2 variants to enhance infectivity and viral transmission.

The capacity of lectins to block SARS-CoV-2 viral entry holds promise for pan-variant therapeutic interventions. Out of a lectin library, two lectins, Clec4g and CD209c, were identified to strongly bind to the Spike protein of SARS-CoV-2. Multiple bond formations lead to stable complex formation, in which the number of formed bonds enhanced the overall interaction strength and dynamic stability of the lectin/Spike complexes. We also determined the binding capacity of a molecularly engineered lectin cloned from banana, BanLec H84T, which was shown to display broad-spectrum antiviral activity against several RNA viruses. Our studies revealed that H84T-BanLec strongly interacts with the Spike protein of the original viral strain, Wuhan-1 and several variants of concern (Delta, Omicron), which makes it a promising clinical candidate for defeating viral infectivity and tramsmission.

Internal Friction in Folding/Unfolding of Short Peptides and Small Proteins via Computer Simulations, Analytical Modeling and Single-Molecule Force Spectroscopy Adam Swiatek[1], Krzysztof Kuczera[2] and Robert Szoszkiewicz[1]; [1]University of Warsaw, Poland; [2]University of Kansas, United States

This talk will summarize our recent developments in elucidating both theoretical [1-2] and experimental [3] information about friction coefficients and internal friction of selected simple peptides and proteins. Molecular internal friction obtained at the single molecule level is an interesting topic in physical chemistry/material science since this parameter can be used as proxy for elucidating/discriminating various structures/conformations in the case of simple proteins at physiologically relevant conditions. Such information can later be useful for various drug delivery systems as well as novel cancer-fighting strategies.

Acknowledgments: We are grateful to the National Science Center, Poland, for financing this research through an award 2018/30/M/ST4/00005 (PI: RSz).

Unraveling Chemical-Structural Properties of Soft Materials Down to the Single-Molecule Level Francesco Simone Ruggeri; Wageningen University, Netherlands

The introduction of photothermal infrared nanospectroscopy (AFM-IR) has revolutionized the field of nano-chemical analysis in a wide-open range of fields, including biological, material and polymers in soft matter sciences. Here, we will present an overview of our latest development and application of AFM-IR in combination with advanced spectroscopic analysis and chemometrics, as a real breakthrough for the analysis of heterogeneous soft mater down to the single molecule level.
To illustrate our path towards single-molecule AFM-IR, we first show the achievement of single protein molecule detection of infrared absorption spectra and maps by introducing off-resonance, low power, and short pulse ORS-nanoIR. [1] This approach enables the accurate single-molecule determination of the secondary structure of protein their assemblies in the amide band I region. We will then showcase the application of this unprecedented single molecule sensitivity to: i) unravel molecular structure and interactions of protein and organic molecules [2]; ii) origin of chirality in click chemistry polymers [3]; iii) detect nano-plastics in drinking water [4]. Finally, we

illustrate the application of this sensitivity to probe the surface and structural properties of functional materials, such as functional protein self-assemblies artificial model membranes [5-6].
Overall, our aim is to expand the capabilities of analytical nanoscience to shed light on the structure-activity relationship of biomolecules and functional materials design.

Investigating Domain Distributions in Polymer Composites and Their Influence on Macroscopic Performance Using AFM-IR and AFM-nDMA Bede Pittenger, Chunzeng Li and Peter De Wolf; Bruker Corporation, United States

The macroscale performance of polymer composites is influenced by both the microstructure of the material and the mechanical properties of microscopic components. As confinement effects and interphase formation can alter the mechanical properties of the microphases, only high-resolution measurements performed directly on the composite can provide the local property distribution needed to understand the relationship between microstructure and bulk.
With its proven ability to map mechanical properties at the nanometer level, Atomic Force Microscopy (AFM) has the resolution and sensitivity needed to investigate these microscopic domains. With careful calibration, nanomechanical results from AFM on homogeneous materials agree with bulk measurements from established rheological techniques like Dynamic Mechanical Analysis (DMA) and Nanoindentation. When AFM based mechanical property mapping techniques are applied to heterogeneous samples like polymer composites, new possibilities emerge for understanding the macroscopic behavior of these materials.
By additionally applying AFM-IR to the sample, it becomes possible to identify the spatial distribution of the chemical components of the composite -- providing insight into how to adjust the sample composition to maximize performance.
This presentation will discuss recent efforts to correlate bulk mechanical properties to nanoscale domain distribution. We will additionally demonstrate how co-located chemical composition maps and nanomechanical maps can be used to better understand composite behavior.

4:00 PM CH03.03.02

A Novel Method for High-Resolution Material Identification via Atomic Force Microscopy Ringing Mode and Machine Learning Nishant Kumar[1], Igor Sokolov[1], Mikhail Petrov[1], Pierre Nickmilder[2] and Philippe E. Leclere[2]; [1]Tufts University, United States; [2]University of Mons, Belgium

We present a novel methodology for high-resolution identification of material composition on sample surfaces utilizing atomic force microscopy (AFM) operating in sub-resonance tapping Ringing mode. This advanced technique leverages the unique capability of Ringing mode to simultaneously acquire multiple physical and mechanical property maps with subnanometer lateral resolution. Material identification is achieved by comparing these high-resolution maps against a database of known material properties. The material recognition is done at each pixel of the AFM image with the help of machine learning algorithms. The efficacy of this approach is demonstrated through its application to blends of distinct polymers, specifically polystyrene (PS), polyvinyl pyrrolidone (PVP), and polyethylene oxide (PEO). By precisely localizing the spatial distribution of these constituent polymers within the sample, our methodology enables detailed characterization of complex polymer systems with unprecedented resolution. Furthermore, we provide a comparative analysis of the advantages and limitations of our Ringing mode AFM and machine learning-based technique with respect to other established spectroscopy methods, such as confocal Raman and AFM-IR microscopy. This in-depth evaluation offers valuable insights into the potential applications and future developments of this cutting-edge approach in the field of material characterization and beyond.

4:15 PM CH03.03.03

Identification of Nanoscale Polymer Structures by AFM Based Infrared Nanospectroscopy Tobias Gokus[1], Artem Danilov[2], Frank Weston[2] and Andreas Huber[1]; [1]Attocube Systems AG, Germany; [2]Attocube Inc., United States

Nanoscale resolved imaging & spectroscopy (nano-IR) using tip-enhanced infrared (IR) microscopy & spectroscopy [1] achieves spatial resolution of < 10-20 nm enabling chemical identification of polymer nanostructures at unprecedented length scales and sensitivity.

Infrared nanospectroscopy is based on scattering-type Scanning Near-field Optical Microscopy (s-SNOM) or tapping AFM-IR (local detection of photothermal expansion) and enables bypassing the diffraction limit of light and to achieve a wavelength-independent spatial resolution. In this work we demonstrate identification of PMMA, PC and PVAC polymer nanostructures based on the comparison of measured nano-IR absorption spectra with ATR-FTIR reference spectra. Tuning the infrared laser source to specific frequencies (e.g. 1735cm^{-1} for PMMA or 700cm^{-1} for PS) enables to selectively map the spatial distribution of materials with sensitivity down to few nm thin particles. Nano-IR measurements on easy-to-handle silicon membrane filters compatible with microplastic analysis routines are demonstrated.

Nano-IR identification of polymer nanostructures has already been demonstrated for analysis of small micro- and nano-plastics which are difficult to access by other methods [2,3]. Further, weathering of PET was compared to fresh samples verified the high quality of nano-IR based material identification.

Lastly, introducing a novel liquid/flow cell design based on a liquid reservoir capped by an ultrathin SiN-membrane, we will demonstrate s-SNOM nano-imaging and spectroscopy of polymer micro- and nano-particles and living cells [4] immersed in aqueous environment.

***In-Situ* AFM Nanomechanics to Visualize Local Stress Distribution Inside Polymeric Materials** Ken Nakajima; Tokyo Institute of Technology, Japan

Atomic force microscope (AFM)-based nanomechanics is a powerful tool to investigate a wide variety of topics in polymer physics, which gives maps of static and dynamic moduli, adhesion etc. at nano-scale resolution. The recent progress of AFM nanomechanics will be reviewed in this presentation.
In-situ AFM nanomechanics during tensile or compression strains can provide more fruitful visualization of local stress distribution. One of the examples is the visualization of the micromechanical behaviors of carbon black (CB) filled rubber during compressive strain. We obtained a stress distribution image of carbon black (CB)-filled rubber at the nanoscale and we traced the microscopic deformation behaviors of CB particles. Through this experiment, we directly revealed the microscopic reinforcement mechanisms of rubber composites. We found that CB filled rubbers exhibited heterogeneous local microscopic deformations, which were related to the dispersion of CB particles in rubber matrices. The local stress distributions of the rubber composites showed heterogeneity, and the stresses were concentrated in the regions near the CB particles during compression. The area of stress concentration gradually expanded with increasing strain and eventually formed a stress network structure. This stress network bore most of the macroscopic stress and was considered the key reinforcement mechanism of CB-filled rubber. The stress transfer process in the rubber matrix was visualized in real space. Based on the image data from the AFM experiments, we used finite-element method (FEM) simulations to reproduce the microscopic deformation process of CB-filled rubber. The stress distribution images simulated by FEM showed heterogeneity consistent with AFM. In this study, an in-situ visualization of material deformation confirmed the predictions of microscopic deformation behavior from previous theories and models; it also provided new insights into the microscopic reinforcement mechanisms of CB-filled rubber composites based on microscopic stress distribution images.
Interfacial polymer layers with nanoscale size play critical roles in dissipating the strain energy around cracks and defects in structural nanocomposites, thereby enhancing the material's fracture toughness. However, understanding how the intrinsic mechanical dynamics of the interfacial layer determine the toughening and reinforcement mechanisms in various polymer nanocomposites remains a major challenge. Here, by means of a recently developed nanorheological AFM, also known as nanoscale dynamic mechanical analysis (nDMA), we report direct mapping of dynamic mechanical responses at the interface of a model epoxy nanocomposite under the transition from a glassy to a rubbery state. We demonstrate a significant deviation in the dynamic moduli of the interface from matrix behavior. Interestingly, the sign of the deviation is observed to be reversed when the polymer changes from a glassy to a rubbery state, which provides an excellent explanation for the difference in the modulus reinforcement between glassy and rubbery epoxy nanocomposites. More importantly, nDMA loss tangent images unambiguously show an enhanced viscoelastic response at the interface compared to the bulk matrix in the glassy state. This observation can therefore provide important insights into the nanoscale toughening mechanism that occurs in epoxy nanocomposites due to viscoelastic energy dissipation at the interface.

Accurate Mapping of Three-Dimensional Nanomechanics in Polymers and Soft Materials Using Interferometric Atomic Force Microscopy Roger Proksch; Asylum Research-Oxford Instruments, United States

Atomic Force Microscopes (AFMs) have become a standard tool for high resolution surface mapping of a wide variety of nanoscale samples. The vast majority of existing AFMs make use of an optical beam detector (OBD) that measures the bending of the flexible cantilever beam. Despite its popularity, accurate and reproducible mechanical measurements using this detection approach remains extremely challenging. Specific barriers to widespread accurate AFM include (i) highly inconsistent sensitivity calibrations, (ii) measurement noise floors significantly higher than thermal motion of the cantilever probes and (iii) uncontrolled mixing of vertical and in-plane forces acting on the tip. Component mixing inevitably complicates attempts at accurate mechanical measurements and can lead to enormous, and often unacknowledged uncertainties. In this work, we build on earlier previous interferometric results to develop and demonstrate new workflows that allow the full three-dimensional nanoscale mechanical response of samples – limited by the fundamental thermal (Brownian) fluctuations of the cantilever with an accurate sensitivity calibrated by the wavelength of light. These workflows are based around a new quadrature phase differential interferometer (QPDI) that routinely achieves a detection noise down to on standard commercial cantilevers. The QPDI measurement remains linear and accurate for large deflections (>1 μm) down to sub-picometer thermal fluctuations. This improved low noise floor and accurate calibration reveals details and features that have been hidden from view using conventional OBD measurements. We will demonstrate new workflows for soft material imaging and characterization enabled by this performance. Examples include frequency-dependent rheological measurements, high resolution tapping measurements with improved force quantification and accurate mapping of in-plane and vertical forces that are typically mixed in an uncontrolled manner with OBD.

SPM Methods in Conducting Polymer Materials and Hyphenated AFM-Electrochemistry and Surface Plasmon Spectroscopy (AFM-EC-SPR) Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

Nanostructuring involves the application of materials and processing methods to achieve unique dimensional structures at the nanoscale in flat surfaces and colloidal particulars. We have used electro-nanopatterning methods to conduct AFM and colloidally templated arrays. Electro-nanopatterning using current/potential control and the AFM tip enables quantification of patterning and heterojunction behavior characterization at the nanoscale. Our group has reported several innovative methods using AFM to characterize soft matter. The colloidal array fabrication scheme combines the electropolymerization process with template-assisted electropolymerization or template-directed electrosynthesis, followed by removal with SPM and conducting AFM, which play a pivotal role in characterization. Until now, colloidal template 2D electropolymerization remains an unexplored method, and there are only a few accounts on colloidal template electropolymerization techniques for micropatterning polymer films. Lastly, we describe an in-operando method of combined AFM-electrochemistry- -surface plasmon spectroscopy or AFM-EC-SPR to probe the electropolymerization kinetics, morphology, and dielectric constants simultaneously in conducting polymers. There is a high potential for applying AI/ML-driven workflows.

Tip-Enhanced Two-Photon Light Absorption and Emission in/from Soft Materials Bharathi Rajeswaran[1,2] and Yaakov R. Tischler[1]; [1]Bar-Ilan University, Israel; [2]Indian Institute of Science, India

Two-Photon Absorption (TPA) is a non-linear optical process in which the simultaneous absorption of two photons takes place in order to promote a molecule from its ground state to excited state[1,2]. Because there is a simultaneous absorption of two photons, the probability of such a process is proportional to the square of the light intensity. Two-Photon Emission (TPE) is the follow-on process whereby a molecule or material that has been excited via TPA, then fluoresces light. There are numerous studies on combining TPE with AFM, whereby the TPE signal becomes tip-enhanced, leading to Tip-Enhanced TPE (TE-TPE) signals with a greatly improved spatial resolution—on the order of the tip-diameter. To the best of our knowledge, here we show for the first time that AFM can also be combined with the TPA spectroscopy technique, to achieve co-located topographic information and simultaneously tip-enhanced non-linear TPA signals. The Tip-Enhanced TPA (TE-TPA) technique is more general than TPE because it can work even on non-photoluminescent materials. In this work, TPA and TPE measurements were carried out using an amplified fsec laser with a central wavelength of 1028 nm. The TPA was generated in a transmission geometry using a tuning-fork based AFM from Nanonics that was situated between upright and inverted microscopes. We developed different approaches to observe the tip-enhancement. We then used tip-enhanced TPA and TPE spectroscopy to map the optical and topographic properties of soft semiconductor materials such as organic dyes, thin films of $CsPbBr_3$ perovskites, a few layered WSe_2, amongst other soft-semiconductors. We observe strong TE-TPE when the material being studied has a prominent excitonic absorption peak centered at near the TPA wavelength of 514 nm, being nearly in “2-photon resonance” with the fsec pulsed excitation. We use a balanced detection scheme with a boxcar integrator to measure differential absorption. We also use an ultra-fast detector to measure TPE. The variation of the TPE signal was measured at different powers for different laser repetition rates. With the TE-TPA technique, we were able to characterize thin films of soft materials, and identify changes in the optical properties at the nanoscale grain boundaries and interfaces.

AFM-IR Depth Sensitivity, the Way to Tomographic Reconstruction Alexandre Dazzi[1], Jeremie Mathurin[1], Philippe E. Leclere[2], Pierre Nickmilder[2], Peter De Wolf[3], Martin Wagner[3], Qichi Hu[3] and Ariane Deniset-Besseau[1]; [1]Université Paris-Saclay, France; [2]University of Mons, Belgium; [3]Bruker Nano GmbH, United States

The principle of AFM-IR technique is based on the coupling between a tunable infrared laser and an AFM (Atomic Force Microscope). The sample is irradiated with a pulsed nanosecond tunable laser. If the IR laser is tuned to a wavenumber corresponding to sample absorption band, the absorbed light is directly transformed into heat. This fast heating results in a rapid thermal expansion localized only in the absorption region detected by the AFM tip. Thus, the detection scheme is analogous to photo-acoustic spectroscopy, except that AFM tip and cantilever are used to detect and amplify the thermal expansion signal instead of a microphone in a gas cell. The thermal expansion induces cantilever oscillations that are rigorously proportional to the local absorption allowing to build up IR absorption spectra. These spectra use to correlate very well conventional IR absorption spectra collected by FT-IR spectroscopy. In addition, mapping oscillations amplitude versus tip position, for one specific wavenumber, gives a spatially resolved map of IR absorption that can be used to localize specific chemical functions[1].
After 20 years of development and improvement the AFM-IR technique becomes now a robust and efficient tool for infrared analysis at nanometer scale. The AFM-IR system can now work in contact mode, tapping mode and peakforce tapping mode [2,3,4] with sensitivity and resolution around 5 nm with spectra bandwidth about 0.5 cm^{-1} (linked to the pulsed laser properties). The domain of applications is really huge, covering many diverse research areas like materials and polymer science, life science, astrochemistry, and culture heritage[1,4].
The capability of AFM-IR subsurface sensitivity has been demonstrated by the surface sensitive mode[2]. Recently we have shown the possibility to change the probing depth of analysis and fully calibrated each operating mode

with different cantilever types on soft material like polymers. The contact resonance mode is the most promising as each resonance modes possess is own specific probing depth which is inversely proportional to its frequency. This new outlook of the contact mode allows to propose a way to reconstruct the 3D shape of a non-absorbing polymer into an absorbing polymer matrix and this without destroying the sample. This opens to the AFM-IR technique a new mode of analysis and gives a unprecedent tool to characterize the polymer sample not only over the surface but also in depth.

Combined Multimodal Nanomechanical and IR-Absorption AFM Modes for the Study of Soft and Bio-Sourced Materials

Neus Domingo Marimon[1], Steven A. Soini[2], Dawn M. Raja Somu[2], Morgan Li[3], Rubye Farahi[1], Ali Passian[1], Kyle P. Kelley[1], Marcus Foston[3] and Vivian Merk[2]; [1]Oak Ridge National Laboratory, United States; [2]Florida Atlantic University, United States; [3]University of Washington, United States

The study of mechanical properties of soft and bio-sourced materials at the nanoscale can be intrinsically challenging due to the wide range of Young Modulus to be sensed. Several modes from mechanical force curves to non-contact viscoelastic mapping or contact resonance frequency can be applied to cover for the different ranges as a function of the material stiffness. However, most of the biomechanical studies of interest require the combination of chemical sensitivity and nanomechanics to stablish a structural functional properties correlation at the nanoscale. In this regard, correlative nanomechanical and NanoIR absorption spectroscopy are a good approach, however, when performing IR-absorption spectroscopy in contact mode the chemical and mechanical response of the sample become intrinsically coupled.
In this talk, I present the capabilities offered at CNMS, which is a US Department of Energy, Office of Science User Facility at Oak Ridge National Laboratory, for mechanochemical and biomechanical studies. I will review several examples of biomechanical studies with combined nanomechanical and NanoIR measurements of biological tissues from shark vertebral cartilage to different types of cellulose based materials. Biological tissues display complex hierarchical structures, which require the nanoscale resolution of AFM to be morphologically and mechanically characterized. Taken together, this research enhances our understanding of structure-function relationships in hierarchical biological materials, particularly the nanomechanical response of fibrillar multi-component systems or mechanochemical changes in the mutant cell walls at a sub-cellular or nanoscale level.

Viscoelastic Mapping of Living Cells Felix Rico; Aix-Marseille Université, France

The mechanics of cells relates to their biological function and state (1). While several works report a single value to define cell viscoelastic properties, cells are heterogeneous systems with viscoelastic properties depending on the composition and organization of the cytoskeleton across the cell body (2). This mechanical heterogeneity makes quantification difficult. I this talk, I will present an approach to map the viscoelasticity of cells from single force-distance curves and to compare the resulting map with complementary maps of, for example, traction forces and actin (3). I will detail sample preparation for averaging of mechanical maps, correlation with optical microscopies and correction of possible artifacts. I will focus on two systems: normal and malignant cancer cells, and resting monocytes and differentiated into macrophages (4). Our results reveal mechanical signatures related to biological function.

Mechanical Ways to Study Molecular Structure of Pericellular Layer—AFM Indentation and Ringing Mode Igor Sokolov[1], Mikhail Petrov[1], Malgorzata Lekka[2] and Kajangi Gnanachandran[2]; [1]Tufts University, United States; [2]The Henryk Niewodniczanski Institute of Nuclear Physics, Poland

Atomic force microscopy (AFM) has emerged as a powerful tool for investigating the mechanical properties of cells, particularly in the context of malignancy. Numerous studies have reported a softening of various cancer cells compared to their nonmalignant counterparts across multiple cell types. However, the majority of these AFM studies have overlooked the pericellular layer, which can significantly influence the measured cell rigidity and potentially obscure valuable information about the physical properties of this layer. Furthermore, it has been demonstrated that the pericellular layer can substantially change during cell progression towards cancer. Up to now, it is not clear what molecular changes in the pericellular layer are associated with progression towards cancer.

Here, we use two AFM techniques that are sensitive to the presence of the pericellular layer: AFM indentation technique processed through the brush model and AFM Ringing mode that allows imaging of the distribution of mechanical properties over the cell surface. Two cell lines, human bladder epithelial nonmalignant (HCV29) and cancerous (TCCSUP) cells were studied here. To translate the physical information, which is obtained within these two modalities, into biochemical terms more familiar to the cell biology community, we use heparinase and neuraminidase enzymatic treatments. These treatments selectively remove specific molecular components of the pericellular layer. We discussed the observed correlation between the removal of these specific molecular components and the observed changes in both mechanical properties of the pericellular layer and their distributions across the cell surface. We also compared these two methods in terms of their capability to distinguish between treated and nontreated cells.

Applying BioAFM to Study Structure and Mechanics of Biomaterials, Cells and Tissues in Life Science Florian Kumpfe, Dimitar Stamov, Joan-Carles Escolano, Alexander Dulebo, André Körnig, Torsten Müller, Thomas Henze and Yi Wei; Bruker Nano GmbH, Germany

Atomic force microscopy (AFM) is a surface technique that can be successfully applied for comprehensive nanomechanical characterization of single molecules, cells and tissues, under near physiological conditions. Some of the current biomedical research trends feature development of novel nano- and biomaterials for regenerative medicine, tissue engineering, and sample diagnostics. Further advances in large biosample analysis are driven by the demand for mapping of biological samples that are often inhomogeneous, rough, and difficult to modify/adapt in their native state. Recent AFM developments have also led to unprecedented imaging rates in fluid, enabling temporal resolution on the sub-20-milisecond scale.

We will show several BioAFM applications demonstrating how high-speed AFM, with a temporal resolution on the second to millisecond scale, can be applied to resolve dynamic processes in biological systems. We will introduce the concept of automated large area multiparametric characterization of densely packed cell layers and highly corrugated tissue samples, where full automation, smart mechanical sample analysis, multiple scanner technology, and optical integration is critical for data throughput and reliable correlative microscopy. We will discuss how these developments, in combination with advanced optical microscopy techniques, can overcome the inherent drawbacks of traditional AFM systems for characterizing challenging biological samples.

Mechanical Properties at the Nanoscale of Cardiac Organoids Investigated by Scanning Probe Microscopy
Federica Rigoni[1], Tommaso Savoldi[1], Simona Bufi[2], Rosaria Santoro[2], Dario Zappa[1] and Elisabetta Comini[1]; [1]Università degli Studi di Brescia, Italy; [2]Centro Cardiologico Monzino, Italy

Nowadays, the design of advanced *in vitro* models, allowing effective recapitulation of the complexity of cardiac *in vitro* pathophysiology, is critical 1) for the definition of the underlying mechanisms, 2) to test the efficacy of novel therapeutic treatments and 3) to move forward in the development of personalized medicine approaches. In this direction, the combination of induced pluripotent stem cell (iPSC) technology with microfabrication approaches, allowed the development of organoids, small dimension 3D structures, recapitulating organ multicellularity, geometrical organization and functionality. Cardiac pathologies often include arrhythmic and fibrotic phenotypes, thus raising the need of *in vitro* electromechanical measurements, to allow the phenotypization of the *in vitro* tissue and a functional read-out of the capacity of a treatment to restore the physiological phenotype. At this aim, we evaluated the feasibility to implement scanning probe microscopy and force spectroscopy-based techniques to quantify the pro-fibrotic commitment in our cardiac organoid model (iPSC based, 500 μm diameter spheroids). In this work, the mechanical properties of cardiac organoids were investigated at the nanoscale by scanning probe microscopy (SPM), and in particular atomic force microscopy (AFM). Force spectroscopy was carried out, after an accurate calibration of the probe mechanical response on a rigid Sapphire sample and a standard two-component polymer sample made of polystyrene (PS) and low-density polyethylene (LDPE). Local single force-distance (FD) curve and the FD curves mapping were carried out onto a surface of an organoid obtained by iPSC line from control or patient affected by known variant causing fibrotic deposition (FIB). Regarding the mechanical properties, obtained from the FD curves mapping down to 1.6x1.6 μm^2, a clear difference in the elastic modulus distributions on the surface of the organoids was observed, ranging from 25 to 2250 MPa, suggesting a different composition of the myocardium in response to the genetic background. The main experimental analysis focused on the elastic modulus investigation of the surface of the control and FIB cardiac organoids, indicating that AFM measurements can be a useful tool for phenotypization of fibrosis in cardiac organoids.

In addition, Raman spectroscopy was performed to discern the chemical compositions of the organoid. Further morphological analysis was performed by environmental scanning electron microscopy (ESEM), operating at variable pressure (50-200 Pa) allowing to obtain information on the global morphology of the biological samples up to 20k magnifications.
In conclusion, we demonstrated the feasibility to apply SPM techniques to investigate the spatial distribution of the elastic modulus along the surface of the organoid, thus allowing organoids phenotypization, opening the path to exploitation of this method for in vitro modelling scenarios.

Visualizing Hydrogel Interfaces and Their Properties Rosa M. Espinosa-Marzal; University of Illinois at Urbana-Champaign, United States

Hydrogels, three-dimensional networks of hydrophilic polymers capable of retaining large amounts of water, have garnered significant attention across various scientific disciplines including tissue engineering, regenerative medicine, and wearable technologies, due to their unique properties and versatile applications. Moreover, the development of smart hydrogels capable of responding to external stimuli offers unprecedented opportunities in controlled drug release and soft robotics. Our research is focused on the design of novel stimuli-responsive hydrogel interfaces, which relies on fundamentally understanding the underlying mechanisms. However, obtaining insight into the interfacial structure and dynamics of hydrogels is challenging due to the large amounts of water present. Recently, my lab has developed a technique to image hydrogel surfaces in a liquid environment at the nanoscale using Atomic Force Microscopy while spatially resolving interfacial properties like adhesion, friction, and surface compliance. The method is based on minimizing the viscoelastic deformation of the hydrogel surface by means of fast force spectroscopy. In my talk, I will show various examples that reveal how combining microscopy with other experimental methods can serve to design stimulus-responsive hydrogel interfaces, among others.

Nanoscale Wetting Characterization Using Non-Contact Atomic Force Microscopy in Ambient Conditions—Spectroscopy and Imaging Jaime Colchero and Pranav Sudersan; Universidad de Murcia, Spain

Precise knowledge and control of tip-sample interaction is fundamental for Atomic Force Microscopy to optimize data acquisition on the one hand and for correct data interpretation on the other. A variety of forces may act between tip and sample, in particular in ambient conditions, where not only Van der Waals and electrostatic interactions may act, but also forces induced by liquid menisci [1]. Moreover, since a priory only the total force is

measured, it is often quite difficult to discriminate between contributions of different kind of forces.
In the present work we will discuss on the one hand how tip-sample interaction can be accurately determined by measuring tip-sample multi-dimensional interaction data sets; in particular “Force-Volume” type data I(x,y,z) as well as “Interaction Images” I(ξ,z) as a function of tip-sample distance z and some other parameter ξ. These data sets contain a wealth of information compared to classical 1d spectroscopy. In particular, it allows for a precise separation of Van der Waals and electrostatic forces as well as forces related to the formation of liquid necks in humid environments.
On the other hand, we will focus on how nano-scale liquid menisci forming between tip and sample allows to access nanoscale wetting using non-contact Dynamic Atomic Force Microscopy (nc-DAFM). Here, we demonstrate that nc-DAFM is a valuable tool for characterizing the wetting of water on surfaces at the nano-scale. In humid conditions tip-sample interaction is caused by the spontaneous condensation of liquid water necks when the AFM tip is close to the surface [1], resulting in an attractive capillary interaction that depends on the nano-scale contact angle of water with the surface. The frequency shift of the cantilever oscillation (essentially proportional to the force gradient of the interaction) is directly related to the nano-scale wetting property of the surface. This approach is tested by characterizing gold surfaces (Interdigitated Au-Electrode; Au on Glass, 200nm height, 5 mm periodicity) fictionalized with thiols, forming micro-scale patterns used as a model surface. This surface is imaged using on the one hand nc-DAFM to acquire the frequency shift induced by the interaction of liquid necks, and Jumping Mode [2] to acquire Adhesion maps. Both give essentially equivalent results. In addition, the nano-scale contact angle was obtained from AFM data and is compared with the macroscopic contact angle of the gold-thiol surface. This technique also allows for imaging nanoscale wetting properties also on more complex surfaces interesting for biological and material science [3].

Surface Properties of Two-Dimensional Materials with In-Depth Nano Surface Characterization Madeline Buxton[1], Justin Brackenridge[1], Valeriia Poliukhova[1], Dhriti Nepal[2], Yury Gogotsi[3] and Vladimir Tsukruk[1]; [1]Georgia Institute of Technology, United States; [2]Air Force Research Laboratory, United States; [3]Drexel University, United States

Low-dimensional materials are evolving fast as nanofillers in lightweight structural materials and electronic and sensing applications. Their low cost, scalability, and wide availability of surface functional groups improve composite interfacial mechanics, conductivity, and mechanical performance. Here, we show the use of multimode atomic force microscopy (AFM) to comprehensively characterize two-dimensional (2D) material surface phenomena. From $Ti_3C_2T_x$ MXene nanoflakes and graphene oxide, thin layers via Langmuir Blodgett deposition. We compare the chemical surface modification of these 2D flakes for tunable surface interactions. We have used various AFM techniques, including topography, quantitative nanomechanical measurement (QNM), Kelvin-Probe microscopy (KPFM) and Nano-IR AFM. These quantitatively illustrate the mechanical, electrical, and chemical disparities between and within 2D flakes. Fundamentally describing heterogeneous nanoscale surface properties and distinguishing between individual flakes allows for a multifaceted understanding of interface performance within complex composites and heterostructure arrangements.

Employing Scanning Probe Microscopy to Directly Probe Mitochondrial Physical Properties and Function

Sidney R. Cohen[1], Ekaterina O. Zorikova[1], Irit Rosenhek Goldian[1], Semyon Nesterov[2] and Atan Gross[1]; [1]Weizmann Institute of Science, Israel; [2]NRC Kurchatov Institute, Russian Federation

Mitochondria play a central role in the metabolism and energy production of eukaryotic cells, through several chains of events entailing many protein complexes. Mitochondrial function is governed by all parts of its structure – the outer membrane which transports ions and metabolites as well as housing active enzymes; the inner membrane which contains proteins that mediate electron transport, ATP synthesis and metabolite passage; the region between the two membranes, the intermembrane space, which contains proteins that signal the transport activities. The majority of the mitochondrial proteins reside inside the inner membrane, in a volume called the matrix. Notwithstanding the desire to understand mitochondrial function at the microscopic level, the multitude of simultaneous and sequential activities occurring in the overall process can be studied functionally by measuring physical signals under different stimuli. The size of mitochondria range from diameters of several hundred nanometers up to several micrometers. Various forms of microscopy have been used to study mitochondria. Whereas electron microscopy provides the highest resolution of their inner structure, it cannot observe their function in real time. Optical microscopy including various fluorescent techniques is able to indirectly capture electrochemical activity and function of live mitochondria but with limited resolution. In this talk I will present a multi-faceted scanning probe microscopy-based approach to the study of mitochondrial function. SPM offers several advantages in such studies: Firstly, the measurements can be made in buffer solution with viable mitochondria, so that their response to different additives can be directly observed in real time. Secondly, the high resolving power allows us to obtain 3D images of individual mitochondria, which can simultaneously be characterized mechanically through fast force measurements. Finally, by measuring “noise spectra” of the mitochondria under the influence of different additives, we can follow the organelle’s activity, and how it changes when specific mitochondrial complexes are inhibited/activated, as well as under pathologic conditions. In this talk, I will summarize this work, emphasizing the application of these different SPM measurements and how combining them gives a nice picture of healthy mitochondrial function.

3:30 PM CH03.07.02

AI Virtually Stains AFM Images, Revealing Cell Phenotype at Subcellular Detail

Mikhail Petrov and Igor Sokolov; Tufts University, United States

Atomic force microscopy (AFM) has recently emerged as a powerful tool for identifying the malignancy of cells with high precision. A recent study utilizing AFM Ringing mode imaging of human colorectal epithelial cells demonstrated the ability to distinguish cells with varying degrees of cancer aggressiveness through machine learning (ML) analysis. However, traditional ML methods analyze entire AFM images, lacking the ability to pinpoint specific cell surface features associated with increased cellular aggressiveness. To address this limitation, we propose a novel machine-learning approach capable of identifying discrete geometrical features on the cell

surface that are indicative of highly aggressive cell classifications. By applying our ML algorithm to AFM Ringing mode images, we enable the virtual staining of cells, highlighting phenotypic differences with subcellular resolution. This targeted approach provides valuable insights into the morphological characteristics linked to cancer aggressiveness. The biological implications of the identified cell surface features are discussed, shedding light on potential mechanisms underlying aggressive cancer cell behavior. The application of this technology to other type of cancer cells is also presented. Our findings demonstrate the utility of combining AFM imaging with advanced machine learning techniques to enhance the characterization and understanding of cellular abnormalities at the subcellular level. This innovative approach holds promise for improving diagnostics and contributing to personalized medicine.

3:45 PM *CH03.07.03

Imaging and Sensing with Glass Nanopores Georg E. Fantner; École Polytechnique Fédérale de Lausanne, Switzerland

Scanning ion conductance microscopy (SICM) has been around for decades [1], yet it has not received as much attention as other forms of scanning probe microscopy. Recently, this true non-contact technique has kindled renewed interest among biophysicists and biologists because it is ideally suited for label-free imaging of fragile cell surfaces where it achieves exquisite resolution down to the nanometer regime without distorting the cell membrane. SICM uses a glass nanopipette as a scanning probe and measures the current through the glass nanopore as a proximity detection of the sample surface [2]. The challenge to harness this technique for time resolved 3D nanocharacterization of living cells lies in the relatively slow imaging speed of SICM. In this presentation I will show how we apply what we have learned from high-speed AFM to the field of SICM. By reengineering the SICM microscope from the ground up, we were able to reduce the image acquisition time for SICM images from tens of minutes down to 0.5s while extending the imaging duration to days [3].

SICM, however, is much more versatile than just an imaging tool. I will also discuss our recent results using SICM as a single molecule characterization tool. We term this method scanning ion conductance spectroscopy (SICS) [4]. Using capillaries with exceptionally small nanopores, we can detect and manipulate single molecules in a repeatable and high throughout manner. Compared to other nanopore sensing techniques SICS has inherent temporal and spatial control of the DNA translocation through the nanopore. This greatly increases the SNR and enables detection of even single base gaps in a dsDNA strand. The ability to read the same molecule multiple times makes this technique well suited for biophysics and diagnostic applications.

Nanomechanical Spectroscopy for Single-Entity Imaging—Resolving Biological Particles Through Optomechanical and Thermomechanical Coupling Ana Diaz-Dochado and Daniel Ramos; Consejo Superior de Investigaciones Científicas, Spain

Understanding the cell wall is of paramount importance in biological and medical research, as it plays a crucial role in maintaining the structural integrity and functionality of cells, particularly in bacteria [1]. The cell wall acts as a protective barrier, regulating the interaction between the cell and its external environment, and is essential for processes such as growth, division, and response to stress. Detailed knowledge of the cell wall's composition and mechanics can provide insights into how pathogens invade host organisms, how antibiotic resistance develops, and how to design more effective drugs and treatments [2]. Hence, studying the cell wall not only enhances our fundamental understanding of cell biology but also drives innovations in healthcare and biotechnology.

Several techniques have been developed to measure and analyze the bacterial cell wall, each offering unique insights into its structure and properties. One common method is atomic force microscopy (AFM), which provides high-resolution images of the cell wall surface and allows for the measurement of mechanical properties like stiffness and elasticity [3]. Another technique is electron microscopy (EM), including both scanning electron microscopy (SEM) and transmission electron microscopy (TEM), which offers detailed visualizations of the cell wall's ultrastructure at nanometer resolution [4]. Additionally, X-ray diffraction (XRD) and nuclear magnetic resonance (NMR) spectroscopy are used to investigate the molecular composition and arrangement of cell wall components; whereas, fluorescence microscopy can be employed to observe the distribution and dynamics of cell wall synthesis and remodeling in live cells [5].

In this work, we have developed a spectrometric technique capable of resolving single biological entities, such as bacteria. This innovative approach will facilitate the creation of a novel imaging technique based on the mechanical frequency shift of a nanomechanical resonator, enabling the generation of mechanical images of individual particles and bacteria. The underlying principle of this technique involves the modulation of light absorption by the particle, which induces a thermo-mechanical effect on the nanomechanical resonator. This concept was recently demonstrated using 100 nm plasmonic gold particles and is now being applied to mechanically image viruses and bacterial cells of approximately 700 nm in diameter [6]. The optical absorption varies based on the scatterer's material, allowing for the unambiguous differentiation between different dielectric particles and bacteria cells of the same size by simply analyzing the mechanical frequency shift under laser illumination.

Characterization of Nanostructured Thin Films Using Atomic Force Microscopy and Scanning Electron Microscopy

Zeqi Li, Dominic Caracciolo, Guojun Shang, Lidia G. Gebre, Craig Mu, Jin Luo and Chuan-Jian Zhong; Binghamton University, The State University of New York, United States

Nanostructured thin films (NSTF) represent an advanced class of surface and interfacial materials which have found a wide range of applications, including coatings, sensors, biosensors, catalysts, batteries, and fuel cells. We have been investigating various NSTFs for sensor/biosensor and fuel cell applications. Examples include developing functional metal/alloy nanoparticles and assemblies as sensing or biosensing interfaces, engineering nanoscale catalysts on different support materials, and constructing catalyst layers on membrane electrode assembly for hydrogen production and fuel cell conversion. A key challenge for these applications is the ability to control the nanostructures in terms of the nanoscale components or filaments. In this presentation, recent results from characterizations using atomic force microscopy (AFM) and scanning electron microscopy (SEM) to determine the morphology, structure, and composition of selected NSTFs in correlation with their chemical sensing and fuel cell operation will be discussed. Approaches to use AFM and SEM to quantitatively determine the thickness and roughness of nanoparticle-filamented thin films will also be discussed in correlation with their performance in sensor detection of chemical species and fuel cell operations.

Local Dielectric Spectroscopy as a Scanning Probe Method for Nanoscale Crystallinity Mapping in Semicrystalline Polymers and Polymeric Nanocomposites

Margherita Montorsi and Massimiliano Labardi; Consiglio Nazionale delle Ricerche, Italy

Determining crystal size, typology, and distribution in the amorphous matrix in semicrystalline polymers becomes challenging when the crystal size is reduced to the nanometric scale. Spatially resolved diffraction techniques, like electron diffraction in transmission electron microscopy, demand high crystalline order, often not present in polymers, where crystalline structures can be somewhat disordered. Furthermore, functional properties of crystals in contrast to those of the surrounding amorphous material can be of interest, for instance, the dielectric constant and the role in establishing Maxwell-Wagner-Sillars or interfacial polarization that is at the base of nanodielectrics [1]. Another relevant issue is how the properties of the polymer are perturbed at the interface with inclusions in nanocomposites. Measurement methods to access directly to these properties, at least at the outer surface of specimens, are represented by scanning probes with sensitivity to electrical properties. Notably, Local Dielectric Spectroscopy (LDS) [2] allows obtaining local dielectric spectra with the same spatial resolution as electrostatic force microscopy, that is, a few nanometers [3], with a frequency range of up to 8 decades [4], not far from that of Broadband Dielectric Spectroscopy (BDS). In this work, we illustrate progress in the application of LDS to discriminate crystalline regions from surrounding amorphous ones in semicrystalline polymers like poly (vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) as well as natural polysaccharides as chitosan. On materials with specific spectral features that can be derived from studies of the bulk, discrimination of different phases can be possible, for instance, by exploring the dependence on temperature of such spectral features, related, e.g. to the amorphous or the crystalline state.

Morphological and Mechanical Properties of *Schistosoma Mansoni* Tegument by AFM

Adriane M. Carvalho[1], Raissa L. Oblitas[1], Fernanda d. Teixeira[1], Wagner W. Araújo[1], Maria C. Salvadori[1] and Josué d. Moraes[2]; [1]University of São Paulo, Brazil; [2]Guarulhos University, Brazil

The intravascular parasitic worm *Schistosoma mansoni* is a significant causative agent of schistosomiasis, a neglected tropical disease with immense global public health implications. The parasite's tegument (outer layer) plays a crucial role in its protection, facilitates interaction with the host, and ensures parasite survival. This study aims to characterize the morphology and mechanical properties of the parasite's tegument using Atomic Force Microscopy (AFM). Male and female helminths were analyzed using the PeakForce Quantitative Nanomechanical Mapping (PF-QNM, *Bruker*) operating mode in air, a novel approach not previously explored in the literature for this purpose. The PF-QNM operating mode enables simultaneous acquisition of 3D topography and mechanical property contrasts, such as adhesion and elastic modulus. Furthermore, the tegument of female helminths was assessed through nanoindentation measurements (array of force curves - AFC) using the AFM contact mode, after AFM tip calibration, in the same regions as the images obtained by PF-QNM. As a result, the elastic modulus average of the analyzed regions for both PF-QNM and AFC was determined. These findings suggest that the elastic modulus of the *S. mansoni* helminth falls within the range of fractions or units of GPa. A pattern of alternating bright and dark bands with a certain periodicity was observed in the adhesion maps, which was not detectable in the topography. The spatial period of this fringe pattern was measured, resulting in an average of (715 ± 37) nm. These measurements were carried out on 33 adhesive contrast images of 14 female worms, with a scan size of 10 μm. The tegument of female helminths has annular furrows, with a depth measured of (128 ± 10) nm. Based on these results, we found that the AFM technique proved to be a suitable tool for characterizing the topographical and mechanical properties of the *S. mansoni* helminth. This characterization is of significance for future research, enabling implications studies for parasite biology and survival under immunological or pharmacological pressure.

Nano and Meso Scale Measurement of the Conductivity of Thin Liquid Water Films as a Function of Relative Humidity—Non-Contact Dynamic Force Microscopy and Conductivity of Interdigitated Electrodes

Jaime Colchero and Eva Osuna Bris; Universidad de Murcia, Spain

As shown already in the beginning of Scanning Probe Microscopy, thin liquid films of water, adsorbed in equilibrium with humid air may result in small but measurable current. In the present work, we use meso-scale and nanoscale measurement to explore the conductivity of very thin liquid films as a function of relative humidity. On the one hand, we use interdigitated electrodes [2] of noble metals (gold or platinum) evaporated onto glass to measure the conductivity of these thin films. These inter-digitated electrode have a typical height of 200nm height, and a separation of 5μm between electrodes, which can be put at different potentials to induce currents through

the molecularity thin water layer on the glass substrate. The area covered by these inter-digitated electrodes is 8x8mm, which implies a huge effective square resistance, since current flows through many electrodes essentially in parallel, each pair of electrodes being very close (5µm) and very wide (8mm), enhancing therefore the sensitivity of the device. We note however, that these electrodes have to be cleaned thoroughly in order to obtain GOhm resistance, needed for the measurement of the tiny currents through the water layers.
The macroscopic measurements are performed simultaneously with nanoscale Electrostatic Force Microscopy imaging as a voltage is applied to the electrodes and the dynamics of charge transport through the thin water film is monitored.

Analysis of the Homogeneity of a Thin Ceramic Polymer Composite Film by Atomic Force Microscopy Infrared Spectroscopy (AFM-IR) and Other Complementary Techniques

Danilo B. Janes[1,2], Carolina N. Reis[1], Otávio Berenguel[1], Icamira C. Nogueira[3] and Edson R. Leite[1,2]; [1]CNPEM-Brazilian Center for Research in Energy and Materials, Brazil; [2]UFSCar, Brazil; [3]Universidade Federal do Amazonas, Brazil

Producing thin films by tape casting is well known for manufacturing multilayer electronic components. In the present work, this process was used to manufacture a scintillator made of YAG:Ce with a thickness of a few hundred micrometers, for application in the fourth-generation particle accelerator located at the National Center for Energy and Materials Research (CNPEM) in Brazil. Tape casting consists of a directed spreading of the ceramic suspension through the space between the blade and the substrate at a constant velocity, producing a tape with uniform height. Because of the oriented flow and shear forces, there is a preferential direction of both the ceramic filler and the polymer chains resulting in anisotropy of orientation in the film and consequently different behavior and properties between x- and y- axis. During film drying, the polymer and solvent tend to migrate from the surface in contact with the substrate (base) to the surface exposed to the atmosphere (top), resulting in anisotropy in the distribution of polymer in the z-axis of the film (cross-section). Therefore, it is expected that a non-isotropic film will be formed, and possible warping will occur during the next sintering stage. These phenomena described above are well-known and have been widely reported in literature. Typically, the characterization techniques used to verify these anisotropies are, for example, scanning electron microscopy, polarized light microscopy, and thermogravimetric analysis. We propose a new method of analyzing film homogeneity through topography and infrared mapping using the AFM-IR technique. To produce the YAG:Ce thin film, a stirred ball mill was used with 5 mm diameter zirconia spheres at a rotation of 360 rpm and a chemical formulation composed of ethanol and toluene (solvents); Menhaden Fish oil (dispersants); polyvinyl butyral (binder); diethylene glycol, benzyl butyl phthalate and polyethylene glycol (plasticizer). To characterize the film surfaces (top, base, and cross-section), the AFM-IR technique with thermomechanical response was used. Topography images and infrared spectra were obtained in a nanoIR2-s atomic force microscope (Bruker™) in contact mode. A ContGB-G probe (BudgetSensors™) with a nominal spring constant of 0.2 N/m and <50.0 nm. tip end radius was used for the scanning. Through topographic and infrared mapping (constant wavenumber value of 1728 cm-1) of 2 µm x 2 µm regions of the sample, differences in topography and regions with apparent polymer accumulation were noted. Scanning electron microscopy analyses were complementary to this.

Towards a Quantitative Analysis of the Mechanical Properties of Soft Materials at the Nanoscale—When AI Meets Materials! Francois Fievet, Kilian Bertrand, Romain Caro, Pierre Nickmilder and Philippe E. Leclere; University of Mons, Belgium

Understanding the properties of materials at the nanoscale is fundamental to predict their macroscopic behavior, thus allowing the design of materials adapted to specific applications.
This work explores the use of Machine Learning to improve the analysis of the mechanical properties of materials at the nanoscale, focusing on measurements made by the Atomic Force Microscope (AFM) in Peak Force Tapping and nano Dynamic Mechanical Analysis modes.

Both modes generate detailed sample maps, providing information on the topography, and the mechanical and viscoelastic properties. However, the quality of these measurements depends on the acquisition parameters, which must be adapted for each sample. To address this important issue, we have developed some Machine Learning-based tools to evaluate and score the quality of acquisitions, in particular via a force curve scoring module using supervised learning algorithms to predict three distinct classes (Unusable, Noisy, Excellent).

Another challenge is the determination of the rigidity modulus of materials, usually obtained by fitting a mathematical function to the force-separation curves. The nature of this function may vary (i.e. sometimes from one pixel to another pixel) depending on the local mechanical properties of the sample and the selected contact mechanics model. Most of the time, this crucial point is not considered by most of the SPM manufacturers. Therefore, our work proposes a novel method based on the Tabor coefficient to select the most suitable mechanical model for each pixel of the map, thus providing more accurate data.

To illustrate the power if this original approach, we have successfully applied it to different polymeric systems including hydrogels, multi (up to four) polymer blends, and nanocomposites. The obtained results show that the force curve scoring module has an accuracy of more than 90%, and that the rigidity module recalculation process offers a higher accuracy than the usual models.

In conclusion, our code, called PyCAROS (Python Code for Approach and Retract curve analysis of Organic and hybrid Soft materials), consists in three main modules: a module for reading the acquisition files, a module for scoring the quality of force curves, and a module for recalculating the mechanical properties aiming at helping the SPM users to be more confident in the data acquisition and analysis thanks to AI processes.

CH03.08.08

Nanoendoscopy-AFM—A Novel Technique for Intracellular Imaging and Measurement of Mechanical Properties Mohammad M. Hosain, Yohei Kono, Keisuke Miyazawa, Takehiko Ichikawa, Takeshi Shimi and Takeshi Fukuma; Kanazawa University, Japan

Direct imaging of nanostructures and their dynamics inside living cells has been a great challenge. We have developed nanoendoscopy-AFM (Atomic Force Microscopy), a label-free, non-harmful imaging technique that allows us to see the intracellular structures of a living cell without breaking it apart. A long ultrathin nanoprobe is inserted into living cells to perform 2D and 3D imaging by AFM. We proved that such an imaging method based on ultrathin nanoprobes does not significantly affect cell viability and proliferation. We also investigate the optimal measurement conditions that minimize cell disturbance and avoid inducing significant stress responses.
Besides, measuring the mechanical properties of cells throughout the cell cycle is fundamental to understanding cellular behavior in both physiological and pathological conditions.
Our next aim is to investigate elasticity variations of cellular and nuclear membranes through the cell cycle using

the nanoendoscopy-AFM technique. Combining nanoendoscopy-AFM with FUCCI marker-transfected cells allows precise, real-time mechanical measurements and clear visual identification of cell cycle stages. Our preliminary results indicate substantial variations in the stiffness of the cell membrane and nuclear membrane during different stages of the cell cycle. These findings suggest that cell and nuclear membrane stiffness dynamically changes in correlation with the different phases of the cell cycle, providing novel insights into the mechanical properties of cancer cells as they progress through their growth stages.

Resonant Ultrasound Spectroscopy (RUS) for Determining Elastic Moduli of Soft Materials William Adams and Oleksiy Svitelskiy; Gordon College, United States

The elastic moduli give important information needed for engineering applications. Simple techniques for finding them can greatly aid in developing designs by understanding material properties. Based on the classical RUS design [1] we have built an instrument for exploring materials elasticity. In our setup the excitation signal is driven with a Rohde & Schwarz signal generator (SMY-01) connected to a piezoelectric transducer. Having passed through the sample, the signal is received by another transducer and cleaned up with a Stanford Research Systems (SR810-DSP) lock-in amplifier. The advantage of our setup is that it allows for work at low frequencies, which implies possibility of studying soft materials. Performance of the instrument was tested on recording the resonances of aluminum and magnesium samples with the purpose of elucidating their elastic moduli. Another benefit of our design is that it does not require expensive components and can be adopted for undergraduate education.

Nanoscale Magnetic Stray Field Estimation with Non-Ideal Reference Sample by Quantitative Magnetic Force Microscopy Zhengyang Lyu, Miti Shah, Tony Chiang, John T. Heron and Parag Deotare; University of Michigan, United States

Magnetic force microscopy (MFM) has the ability to provide quantitative information of the magnetic stray fields close to the surface of a sample with nano-scale resolution. A common approach to quantitative MFM is the Tip Transfer Function (TTF) method, which generates a parameter-free description of the scanning magnetic probe tip, which is then used to estimate the magnetic field. However, it requires a well grown and patterned calibration sample, which is not commercially available. On the other hand, magnetic hard drives, one of the most commonly used reference samples, have vaguely defined spatial profiles that hinders TTF generation. We overcome this challenge by using advanced optimization methods to obtain desired parameters from the hard drive while keeping the TTF parameter-free. The computed phase information (utilizing different error functions) is compared with experimentally obtained phase data of hard drive samples until the difference converges and relevant parameters are obtained. We further verify the method by patterning a ~170 nm Iron (Fe) thin film grown on a magnesium oxide (MgO) substrate and applying the TTF. Our preliminary stray field estimation values on a structure with a critical dimension of ~145 nm resemble simulation results within two orders of magnitude. While further development is in progress, the results provide a promising approach for easier access to quantitative magnetic properties at nanoscale that will aid in building pathways to more precise on-chip magnetic field control.

Multimodal and Spectral AFM Applied to Problems in Biomedical Device Compatibilization Greg D. Haugstad; University of Minnesota, United States

We describe industry-collaborative research applying multimodal/photothermal AFM-IR to soft-material technologies that aid the body's acceptance of biomedical devices. Much of our work has been in polymer-drug coatings (e.g., for dexamethasone elution from poly n-alkyl methacrylates) or polymeric fabric (polyethylene terephthalate) engineered to "buffer" a body/metal interface. In the process we are developing understandings of AFM-IR analytical methodology, such as the extent of depth-integration of (chemical) signal, as well as issues of signal/noise (s/n), heating via the IR laser, sample shape/geometry relative to irradiation direction, and more. We present a subset of these topics, both to inform newcomers to AFM-IR and foster discussion among advanced users.

In our core AFM-IR methodologies we utilize pulsed IR irradiation, and resultant AC photothermal expansion (from absorbance), to excite (i) the fundamental contact resonance while under contact-mode Z feedback or (ii) either the fundamental or next higher free eigenmodal resonance while under AC Z feedback, the latter implemented at either the fundamental flexural eigenfrequency or the next higher eigenfrequency. Method (ii) further utilizes *heterodyning*, by pulsing the IR laser at the *difference* of the two eigenfrequencies and taking advantage of the nonlinear tip-sample interaction, which causes frequency mixing. In separate submethods of (ii), the IR laser is either (a) pulsed to excite the next highest eigenmode while the fundamental eigenmode is mechanically driven for Z feedback (the latter being traditional AC/"tapping" mode) – what we dub "forward heterodyning"; OR (b) pulsed to excite the fundamental eigenmode while the next higher eigenmode is mechanically driven for Z feedback – what we dub "reverse heterodyning". In either of these submethods it has been reported that the depth-integration of signal can be much shallower than the case of contact resonance (i), these depths being further a function of parameter settings such as "duty cycle": the exact IR pulse length in time relative to the pulse repetition period. As such, the depth integration of signal can range from micron-scale at the high end down to tens of nanometers, albeit with accompanying differences in s/n.

We choose to take advantage of these differences in depth integration of signal per *research context* – whether for polymer-drug coatings, or biomedical device fabric. For the former, the depth-location of drug is an important engineering variable (e.g., to affect "burst" versus longer-term release). Thus depth integration as an *analytical variable* is useful. For the latter, problems of fabric curling relate to bulk/internal composition, such that we seek to suppress the analytical impact of surface contamination and favor a large signal integration depth. There are also differences in the availability of multimodal tribo-mechanical contrast via images of friction, contact resonance frequency (whereby stiffness), and AC phase (i.e., under conventional tapping). Indeed our selection of method (i) or (ii) is strongly impacted by the presence or absence of sliding friction: highly useful for surface contrast in some cases (favoring method i), while deleterious in other cases, such as very soft materials (favoring method ii). A further consideration in case (ii) is the greater propensity for tip contamination in the net repulsive regime (though yielding higher s/n) compared to the attractive regime. To exemplify, we include a brief example of excellent AFM-IR performance in the AC attractive regime using forward heterodyning, in a comparison of polyethylene spherulitic content (which aids oxygen barrier performance) for the cases of HDPE, LLDPE and blending thereof.

Unraveling Lipid Membrane Dynamics and Phase Behavior Using AFM Lorena Redondo-Morata; Aix-Marseille Université, France

Synthetic lipid bilayers are crucial for modeling cell membranes, as they enable the controlled study of membrane properties and interactions in a simplified, reproducible environment. AFM-based force spectroscopy, in turn, is an ideal technique to investigate the mechanical properties of lipid bilayers at the nanoscale, their elastic mudulus [1], but also their deformation and rupture [2].

In lipid membranes, the ultimate lipid phase coexistence to be fully understood is transient nanodomains, often (confusedly) referred to as lipid rafts [3]. Based on current knowledge, microdomains in equilibrium are no longer considered suitable models for the biological structure that rafts represent. Multiscale spatiotemporal measurements of membrane mechanical properties can help to experimentally address different scenarios where membrane micro- and nanodomain formations provide theoretical support. AFM-based force spectroscopy can resolve the coexistence of domains at concentrations where height differences at domain boundaries are not detectable [4], providing an ideal approach for investigating the mechanical properties of lipid bilayers at the nanoscale. High-speed AFM imaging provides information about the dynamics of domain boundaries. Here, we will discuss several examples of non-equilibrium membrane fluctuations. First, the in situ conversion of sphingomyelin to ceramide. Ceramide is produced in cells from sphingomyelin by means of the enzymatic activity of endogenous sphingomyelinase, impacting the physicochemical properties of the membrane and inducing changes in the curvature, phase, segregation, and order. Then, we will discuss the effect of antimicrobial compounds. Mag2 and PGLa are two antimicrobial peptides that, upon their interaction with biomembranes, have been shown to gradually insert into the lipid bilayer as heterodimer clusters inducing several membrane perturbations, such as alterations in lipid packing, pore openings, and membrane disintegration. Finally, we will address microbial glycolipids, surfactants that can integrate into the microbial cell membranes due to their amphiphilic nature, disrupting the integrity of the membrane. Using these examples, we will conclude that AFM measurements to explore the nanoscale mechanical properties and dynamic behavior of lipid bilayers enhance our understanding of membrane structure and function.

AFM for Studying Geometrical Constraints of Diatoms Silica Cell Wall Irit Rosenhek Goldian, Diede de Haan, Ron Rotkopf, Yoseph Addadi and Assaf Gal; Weizmann Institute of Science, Israel

Unicellular organisms are known to exert tight control over their cell size. In the case of diatoms, abundant eukaryotic microalgae, two opposing notions are widely accepted. On the one hand, the rigid silica cell wall is thought to enforce geometrical reduction of the cell size by the need to fit any new silica element into the previously formed structure. On the other hand, numerous exceptions that include long-term culturing without noticeable size changes cast doubt on the generality of the geometrical size reduction theory.
To gain a deeper insight into the growth mechanism of the diatom rigid silica cell wall in various regions, namely

Valve and Gridle band, we have employed the AFM technique to study their flexibility. To accurately calculate the shell wall Elastic modulus, it is necessary to take into account the shell geometry. As opposed to classical contact mechanics models (i.e Hertz model), where the deformation measured is solely the indentation of the tip into the material, hollow cylindrical shells can bend, buckle or collapse. By using a thin shell cylindrical model that takes into account the geometry of the shell we show that the primary factor contributing to the higher deformability of the girdle bands is their distinct geometry, characterized by a thinner shell wall. These results show that the mechanical properties of *Stephanopyxis turris* girdle bands are flexible enough to accommodate geometrical fluctuations that can override the deterministic prediction of the geometrical model.1

Linking Electronic and Structural Disorder Parameters to Carrier Transport in a Modern Conjugated Polymer

Gaurab J. Thapa[1,1], Mihirsinh Chauhan[1], Rosemary R. Cranston[2], Boyu Guo[1], Benoit Lessard[2,2], Daniel B. Dougherty[1] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]University of Ottawa, Canada

Understanding charge transport in conjugated polymers is crucial for the development of next-generation organic electronic applications. It is presumed that structural disorder in conjugated polymers originating from their semi-crystallinity, processing, or polymorphism leads to a complex energetic landscape that influences charge carrier transport properties. However, the link between polymer order parameters and energetic landscape is not well established experimentally. In this work, we successfully link statistical surveys of local polymer electronic structure with paracrystalline structural disorder, a measure of statistical fluctuations away from the ideal polymer packing structure. We use scanning tunneling microscopy/spectroscopy to measure spatial variability in electronic band edges in PM6 films, a high-performance conjugated polymer, and find that films with higher paracrystallinity exhibit greater electronic disorder. In addition, we show macroscopic charge carrier mobility in field effect transistors and hole-only diode devices are positively correlated with these microscopic structural and electronic parameters.

11:15 AM CH03.09.06

Magnetism and Morphological Effects of Iron Oxide Nanoparticles in Enhancing Antibiofouling Activity of Polyphenol-Coated Surfaces

Faris Aldossari; The University of Toledo, United States

Biofouling is the process of adhesion and proliferation of biological or organic entities that may result in the formation of biofilm consisting of microbes and extracellular polymeric substances (EPS). Biofilm formation on solid surfaces significantly impacts various industries, such as desalination plants, medical devices, water pipelines, heat exchangers, and ship hulls. Microbial fouling involves the physicochemical interactions between microorganisms and solid surfaces. An electromagnetic field (EMF) may change the diffusion rates of microbial cells and the electrical double layer around the cells and contacting surfaces. In the current study, polycardanol (PC) exhibiting antibiofouling activity was modified with ferromagnetic iron oxide (IO) to investigate the EMF effects on bacterial adhesion. Two different types of IO were used to magnetize PC coatings: 1) iron oxide ionic solution (IOIS) and 2) iron oxide nanoparticles (IONPs). When there was a flow of electrolyte that contained bacterial cells across the coating slides, flow-induced EMF generated according to Faraday's principle of induction. It was observed that the IOIS-modified surfaces, with an induced current of 44, 53, 66 nA, showed decreases in the adhesion of bacteria cells more than the unmodified (polycardanol) and IONP-modified ones. In addition to the EMF effects, the nano-scale uniform roughness of the modified surfaces appeared to play an important role in the reduction of cell adhesion. Atomic Force Microscopy (AFM) revealed that incorporating magnetic agents into PC

coatings increased surface roughness. The extent of this increase depended on the concentration and size of the magnetic particles, thereby altering the antibiofouling activity. The IOIS-modified surfaces showed the needle-like spiky peaks rising around 11.8-27.5 nm while the IONP-modified ones had a smaller number of peaks, but the size of them is much larger (89.2-272.3 nm) than those in the IOIS surfaces exhibiting taller, but a lower number of peaks, with irregular spacing between the peaks. The IOIS surface displayed more regularly spaced nano-scale peaks compared to the submicron irregularly spaced spikes seen in the IONP surfaces. Both the surface roughness and the flow-induced EMF were observed to play important roles in antibiofouling activity.

SESSION CH03.10: General Methods and Applications
Session Chairs: Philippe Leclere and Francesca Zuttion
Friday Afternoon, December 6, 2024
Hynes, Level 3, Room 300

1:30 PM *CH03.10.01

Exploring Nanoscale Viscoelastic Properties of Acrylate Copolymers as Models Systems for Future Eco-Friendly Cosmetic Materials Francesca Zuttion[1], Thi Quynh Tran[2], Veronique Valero[1], Simon Taupin[1], Julien Portal[1], Gustavo Luengo[1] and Philippe E. Leclere[2]; [1]L'Oréal-Advanced Research, France; [2]University of Mons, Belgium

The cosmetic industry is actively seeking new eco-designed formulations that maintain optimal performance. Acrylic polymers and their derivatives are widely used due to their diverse physicochemical properties, serving as emulsion stabilizers, dispersants, and film-forming agents. When dried, acrylic polymers create a transparent and flexible coating on the skin, contributing to a smooth feel, water-resistance, and adhesion. These films exhibit excellent wear resistance, color stability, weathering, and prolonged usage in perspiration conditions. However, the lack of sufficient biodegradability in acrylic polymers necessitates the exploration of alternative options. Understanding the structure of these coatings and their impact on cosmetic performance is crucial for identifying suitable replacements.

This study presents how environmental conditions can affect the viscoelastic properties of polymeric films used for cosmetics applications. To mimic skin, polymer coatings were deposited on ex-vivo stratum corneum, the outermost layer of the skin and by using Atomic Force Microscopy- based mechanical modes, the viscoelastic behavior of the material was elucidated. Viscoelastic parameters E', E'', and $\tan \delta$ of the films using nanoDynamic Mechanical Analysis Atomic Force Microscopy (nDMA-AFM) were studied under varying temperatures and humidity levels to simulate skin physiological conditions. Results revealed an enhanced miscible capacity under heated and moist conditions, accompanied by a significant decrease in stiffness.

Future developments in polymer formulations will prioritize eco-design, emphasizing naturalness, bio-sourcing, and environmental impact. The proposed mechanical and structural AFM evaluation protocol presented in this study will contribute to the advancement of alternative acrylate materials. By comprehensively understanding the mechanical and nanostructural properties of acrylic films, we can lay the foundation for the development of environmentally friendly substitutes.

2:00 PM CH03.10.02

Investigation of the Photo-Responsive Electrochemical Activity of van der Waals Heterostructures by Multiple Scanning Probe Microscopies Heyun Du[1,1,2], Kuei-Hsien Chen[3,4] and Li-Chyong Chen[4,4,4]; [1]Ming Chi University of Technology, Taiwan; [2]Chang Gung University, Taiwan; [3]Academia Sinica, Taiwan; [4]National Taiwan

University, Taiwan

Excessive use of fossil energy by human activities leads to global warming and climate change. To address this issue, it is necessary to develop new renewable energy materials using earth-abundant and low-cost resources. Here, we focus on two-dimensional(2D) materials, which are single atoms or molecules thick and have an ideal planar structure. 2D materials such as graphene and molybdenum disulfide (MoS_2) are widely used in hydrogen reduction reactions and water splitting. MoS_2 is considered an ideal photocatalyst material due to its suitable band structure in the visible light region. Furthermore, Van der Waals (VdW) heterostructures are fabricated by dry transfer method from chemical vapor deposition grown MoS_2 flakes, and their structures are analyzed using Raman spectroscopy, photoluminescence (PL), and scanning transmission electron microscopy (STEM). To understand the photocatalytic reaction mechanism of VdW heterostructures, we have developed active site mapping techniques including combined atomic force microscopy-scanning electrochemical microscopy (AFM-SECM) and scanning electrochemical cell microscopy (SECCM). These techniques investigate the light-responsive electrochemical current on single-crystal VdW heterostructure samples, which can further establish the mechanism of photocatalytic carbon dioxide/hydrogen reduction reaction catalysis corresponding to their electronic structures.

2:15 PM *CH03.10.03
Advanced Analysis of the Mechanical and Viscoelastic Properties of Polymeric Materials Mathieu Cognard; Digital Surf, France

In the last few years, the use of SPM techniques in many areas of research has greatly increased. Scanning Probe Microscopy (SPM) is one of the main tools responsible for the emergence of novel soft functional materials and for the characterization of their physical properties at the nanoscale.
Advanced analysis at the nanoscale helps us to solve various challenges we face with materials in the fields of energy harvesting, organic electronics, biosensors, self-assembly, biotechnology, life sciences, and nanomedicine to name but a few.
The quantitative mapping of the actual mechanical properties of materials at the nanoscale constitutes a real challenge for professionals.
The number of collected observables is rapidly increasing and software programs are now mature enough to analyze data user-independently. Most of the existing imaging modes proposed by the manufacturers consider one of the contact mechanical models (among the few analytically available) for the entire acquisition.
In this growing field of research, the contribution of the Laboratory for Physics of Nanomaterials and Energy (LPNE) at the University of Mons (UMONS), Belgium and Digital Surf, France mainly consists of finding the most appropriate contact mechanics model for each pixel using data clustering and mapping of material properties based on the approach–retract force curve analysis. MountainsSPIP® paired with the PyCAROS (Python Code for Approach and Retract force curve analysis of Organic and hybrid Soft materials) for addon was able to recalculate the mechanical properties such as the rigidity modulus and coefficient of correlation for deeper analysis, particularly statistical analysis, and to benefit from the software's rendering capacities.
During the talk, we will illustrate the capabilities of this approach on a polymer blend made of polystyrene (30%) and polycaprolactone (70%) using Peak Force Tapping (PFT) and nano Dynamic Mechanical Analysis (n-DMA) techniques. The polystyrene (PS) forms circular-shaped objects within the semi-crystalline matrix of the polycaprolactone (PCL).
This process has been extended with success to many other materials including nanocomposites, hydrogels, block copolymers, cosmetics and bacteria.

The Effect of Phospholipids Dehydration on Lubrication Nir Kampf[1], Yihui Dong[1], Yaelle Schilt[2], Wai Cao[3], Uri Raviv[2] and Jacob Klein[1]; [1]Weizmann Institute of Science, Israel; [2]The Hebrew University of Jerusalem, Israel; [3]Tel Aviv University, Israel

In our previous studies (i.e. 1-2), we demonstrate the efficiency of PC lipids in reducing surface friction, with the understanding that highly hydrated PC head-groups participating in the *hydration lubrication* mechanism. In the biological context, the robustness of phosphatidylcholine (PC) lipids at biological surfaces is very much effecting its functional properties such as pressure resistance and friction, in particular, at articular cartilage surfaces where low friction is crucial for joint wellbeing. The puzzling question is: how the removal of water from the lipids layer will affect the lubrication? We used DMSO dehydrating material and several approaches, including atomic force microscopy, small- and wide-angle X-ray scattering and all-atom molecular dynamics simulations to elucidate this. Our results show that DMSO clearly removes hydration water from the lipid head-groups, this is offset by both higher areal head-group density and by rigidity-enhancement of the lipid bilayers. Remarkably, and unexpectedly, nanotribological measurements, made by surface force balance technique, show (3) that the dehydration has little effect on the friction. This sheds strong light on the robustness of lipid-based hydration lubrication in biological systems, despite the ubiquitous presence of bio-osmolytes which compete for hydration water.

3:00 PM CH03.10.05
Candida Antarctica **Lipase B-Modulated Top-Down Visualization of Semicrystalline Morphology of Poly(caprolactone)/Poly(ethylene oxide) Blend Films** Bingbing Li, Adam J. Bauer, Hiruni K. Pallage and Yeon H. Kim; Central Michigan University, United States

The properties of semicrystalline polymer-based materials strongly depend on their phase separation morphologies, the spatial distributions of amorphous and crystalline phases, as well as their interlamellar chain topologies. In addition to the unique chemistry and formulation of a given polymer system, its morphology features are often controlled by laboratory or industrial processing conditions. The relaxation of polymer chains often takes a longer time than that required to process the semicrystalline materials, giving rise to polymer morphologies that are far from equilibrium. Thus, through the design of processing pathways, various desired properties can be achieved for the same polymer system held at different nonequilibrium status. In the meantime, the process-controlled nature of nonequilibrium polymer morphology poses challenges for understanding the processing–morphology-property-function relationship at both microscopic and macroscopic levels. Our recent studies have demonstrated that Candida antarctica lipase B (CALB) exhibits high degradation selectivity toward amorphous chains of biodegradable poly(e-caprolactone) (PCL) when used at low concentrations (e.g., ~0.01-0.075 mg×mL^{-1}). The highly selective degradation process provides an easily accessible route to visualize the semicrystalline morphology of PCL, including crystalline skeletons and the hierarchical self-assembly of nanoscale lamellae. The direct visualization method by using a scanning electron microscopy (SEM) can clearly capture the topological features of crystalline skeletons of neat PCL nanofibers and microfibers, PCL-based composite fibers, as well as neat PCL films.

In this presentation, the above-mentioned direct visualization method was utilized to study the phase separation and semicrystalline morphology of biocompatible PCL and poly(ethylene oxide) (PEO) blends. Even though phase behaviors of various PCL/PEO-based binary or ternary blends have been previously documented using information extracted from traditional in-direct characterization methods, top-down direct visualization of phase separation and semicrystalline morphology from the surface to bulk of PCL films has not been reported. In this study, a series of enzymatic degradation experiments were designed to examine the phase separation morphology of PCL/PEO spin-coated films with various blend ratios and thicknesses. Low concentration CALB aqueous solution was utilized to selectively dissect interlamellar amorphous PCL chains and therefore to reveal the crystalline regions of PCL phase. Water soluble PEO can be simultaneously removed by the aqueous solutions, allowing one to envision the topological features of phase-separated PCL/PEO films. The transition from nucleation and growth to spinodal decomposition types of phase separation was fully mapped out, along with the spatial distribution and topologies of PCL crystalline skeletons. The morphological characteristics of PCL/PEO were then correlated to their previously reported physicochemical properties, further demonstrating the impact of microscopic internal structures on the macroscopic properties of semicrystalline polymer systems. The significance of the method utilized in this study is twofold: (1) it can rapidly screen PCL-based films to tailor the semicrystalline morphology toward targeted applications, especially when other sophisticated polymer characterization methods are not available or timewise not feasible. (2) The method is also suitable for a high-throughput laboratory set-up for screening PCL's semicrystalline topologies to understand a processing-morphology relation, which is crucial for optimize the mechanical and biodegradation properties of PCL-based materials, especially in the context of plastic circular economy transition.

Session Chairs: David Halat and Mengya Li
Monday Morning, December 2, 2024
Sheraton, Third Floor, Commonwealth

10:30 AM *CH04.01.01
Linking Structure to Function at Electrochemical Interfaces—Li-Ion and Beyond Lauren Marbella; Columbia University, United States

Despite the fact that the solid electrolyte interphase (SEI) on Li metal was described 45 years ago, it is still the only aspect of the battery that has ambiguity in function. As a community, we have struggled to establish structure-property-performance relationships for the SEI because it is a nanoscale composite that contains chemical compounds whose properties deviate from their bulk counterparts. In this talk, I will describe how we have used nuclear magnetic resonance (NMR) spectroscopy to characterize the structure and dynamics of interfacial phenomena in Li-ion and beyond Li-ion batteries and correlate these features with battery performance. In particular, I will focus on the use of NMR to quantify the source of Li inventory loss, the mechanism of transition metal dissolution, structural evolution at the electrode/electrolyte interface, and the function of the SEI. Insight from these methods allow us to determine the precise mechanisms of failure that arise inside of functional devices as well as develop new approaches to mitigate performance decline.

11:00 AM *CH04.01.02
Understanding Li Ions Diffusion in Sulphide- and Oxide-Based Ionic Conductors from NMR Spectroscopy Frederic Blanc; University of Liverpool, United Kingdom

Li-containing materials providing fast Li ion transport pathways are fundamental in Li solid-state electrolytes and next-generation energy storage materials by implementing Li all-solid-state batteries. Collaborative computationally-guided materials discovery[1] has provided a workflow for identifying unexplored selection of elements containing Li ions[2,3]and designing new superionic Li solid-state electrolytes $Li_7Si_2S_7I$[4] (and derivatives)[5] defined by two-anion packing.
Li ions transport is the key sought physical properties and, in this contribution, we will reveal several efficient NMR methods to probe directly the Li ions dynamics in a range of recently discovered sulphides[2-6] and oxides[7]-containing materials. We exploit a range of variable temperature multinuclear (^{6}Li and ^{7}Li) and multidimensional NMR approaches, such as line shape analysis, exchange phenomena, relaxometry measurements and spin-alignment echo, to determine the Li ion mobility pathways, including the dimensionality of the diffusion processes, and quantify Li ions jump rates. For example, these approaches deployed on (1): Li_3AlS_3[2] identify that Li ion diffusion is fast within the tetrahedral and tetrahedral/octahedral layers but slow between these layers limiting long range translational Li ion mobility;[8] these provide a framework for the further development of more highly conductive Li solid-state electrolytes such as $Li_{4.3}AlS_{3.3}Cl_{0.7}$;[6] (2) $Li_3P_5O_{14}$ determine that the low coordinating Li site exchange with one another between adjacent layered $Li_6O_{16}^{26-}$ chains and through the centre of the $P_{12}O_{36}^{12-}$ rings forming a three-dimensional Li diffusion pathway.

***Operando* NMR Studies on Si Anode Calendar Aging and the Reactivity of Electrochemically Formed Trapped Li_xSi_y** Evelyna Wang, Marco-Tulio F. Rodrigues and Baris Key; Argonne National Laboratory, United States

Replacing graphite anodes with Si anodes can greatly increase the energy of current Li-ion batteries. Detailed characterization of Si lithiation reactions, solid-electrolyte interphase (SEI) formation, and lithium silicide reactivity are therefore active areas of research. Solid-state ^{7}Li nuclear magnetic resonance (NMR) spectroscopy is particularly useful for characterizing different lithium local environments within Si anodes. Here, we developed an operando NMR methodology to characterize aging mechanisms in novel pouch cells by tracking the lithium silicides within the Si anodes. Our operando NMR pouch cells improve upon previous in-situ NMR studies by enabling reliable and long-term electrochemical performance, comparable to commercial cells, whilst retaining NMR compatibility. We investigated several Si anode materials, comparing the lithiation mechanisms and the accumulation of trapped lithium silicides before and after cycle and calendar life aging. Using the operando NMR methodology, we were able to observe the chemical reactivity of trapped lithium silicides at rest as well as compare the state of charge effects on chemical reactivity. Furthermore, we investigated electrode degradation with cumulative long-term calendar and cycle aging and the effects on electrochemical performance.

11:45 AM CH04.01.04

NMR Analysis of Weak Solvating Ester Electrolyte for High Voltage Sodium-Ion Batteries Allen Zheng[1], Lin Ma[2], Steven Greenbaum[1], Oleg Borodin[3], Travis Pollard[3], Rishivandhiga Jayakumar[2] and Vadim Shipitsyn[2]; [1]Hunter College, United States; [2]University of North Carolina at Charlotte, United States; [3]U.S. Army, United States

As part of the development of lithium-alternative battery systems, ester electrolytes have been revealed to be promising for sodium-ion batteries. Various ethyl acetate (EA) solvated electrolytes of $NaPF_6$ salt and propylene carbonate (PC), PC/ethyl methyl carbonate (EMC), and PC/functionalized carbonate were developed by collaborators at University of North Carolina/Charlotte (Lin Ma and coworkers). Self-diffusion analysis using pulsed field gradient nuclear magnetic resonance spectroscopy elucidated transport properties of Na^+ and $PF6^-$ diffusion with promising ionic transference numbers at room temperature. NMR results have closely corroborated molecular dynamics (MD) simulations. In work conducted at UNC/Charlotte and the U.S. Army Research Laboratory, pouch cells with these electrolytes showed promising performance and capacity retention.

SESSION CH04.02: X-Ray Methods I
Session Chairs: Regina García-Méndez and Duhan Zhang
Monday Afternoon, December 2, 2024
Sheraton, Third Floor, Commonwealth

1:45 PM CH04.02.01

Understanding the Morphological, Structural and Redox Behavior of Metal Sulfides as Cathode Active Materials in Solid-State Batteries Katherine Mazzio[1,2], Changjiang Bai[1] and Philipp Adelhelm[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Understanding the charge storage process and material changes in solid-state batteries (SSBs) under realistic operating conditions is challenging due to the high stacking pressures applied during cycling when evaluating new materials. We have recently been developing a variety of incisive tools that enable us to evaluate the morphological, structural, and redox behavior of our CAMs under operating conditions in SSBs through computed X-Ray tomography, X-Ray diffraction, and X-Ray absorption and photoemission spectroscopies. In this talk I will discuss our recent work on understanding charge storage and structural changes in metal sulfide-based cathode active materials (CAMs) for SSBs through a combination of in-situ and ex-situ analysis. We are investigating sulfide-based CAMs because oxide-based CAMs are quickly approaching their limits in terms of capacity. Sulfides offer an intriguing direction for further research because they are high-capacity conversion-type cathodes that can help enable lithium metal anodes in SSBs, while simultaneously offering additional benefits by their reversible charge storage through stable anion redox ($2S^{2-} \rightarrow (S_2)^{2-} + 2e^-$), which can help further boost capacity despite their low operating voltage windows. I will detail our findings on CuS, which undergoes a macroscopic displacement reaction during lithiation, whereby micron-sized Cu networks form, which we were able to follow by in-situ synchrotron-based X-Ray tomography.[1] Despite the large volume expansion of 75% and unique displacement mechanism, CuS-based cells show surprisingly stable cycling behavior, maintaining a capacity of 305 mAh/g over 100 cycles.[2] We investigate further structural stabilization through implementation of ternary compositions such as Cu_3PS_4 and $CuFeS_2$ and find that in both cases we are able to promote stable cycling behavior (maintaining a capacity of 508 mAh/g over 60 cycles for Cu_3PS_4 and 436 mAh/g over 150 cycles for $CuFeS_2$) through favorable chemo-mechanical properties and the formation of finely-dispersed redox centers.[3]

Function and Failure of Energy Materials Explained by Changes in the Crystallographic and Electronic Structure

Kleiner Karin[1], Bixian Ying[1], Honghong Tian[1] and Burkhard Beckhoff[2]; [1]University of Münster, Germany; [2]German Metrology Institute, Germany

In electrochemical devices energy is stored in chemical bonds – that this is not only true for fuel cells and electrolysers but for Li-ion batteries as well will be discussed [1,2]: Reversible charge compensation in NCMs ($LiMeO_2$ with *Me* = Ni, Co, Mn), for example, proceeds from ionic Ni^{2+} to covalent Ni^{3+} while electron density is shifted from O towards Ni forming covalent Ni-O σ-bonds, as revealed with near edge x-ray absorption spectroscopy (NEXAFS) and charge transfer multiplet (CTM) calculations. Mn and Co are not redox active. At the point, where no ionic Ni^{2+} is left, irreversible reactions such as oxygen release and surface morphology changes are observed. Recent advances in the field show that redox processes above this point (> 60% state of charge) involve the oxidation of *Me*-O π-states. However, the reversibility of these redox processes remains challenging.[3,4] The established relation between the electronic structure and the electrochemical performance is used to design superior cathode materials using substitution, doping, and high-pressure modifications which offer higher energy densities, fulfill higher safety standards, and/or provide a higher degree of sustainability.

2:30 PM CH04.02.03

In Situ Synchrotron Characterization on Solid-State Synthesis of Ni-Rich Sodium Layered Oxide Cathodes

Xianghui Xiao[1], Wenhua Zuo[2], Guiliang Xu[2] and Khalil Amine[2]; [1]Brookhaven National Laboratory, United States;

[2]Argonne National Laboratory, United States

Layered transition metal oxides (LTMO) are appealing cathode materials in alkali-batteries. However, the performance degradation due to gradually accumulated microstrains within the materials during battery cycling is a limiting factor to the practical applications of these materials. Various approaches have been developed to control microstrain evolution during battery cycling. Nonetheless, controlling microstrains in pristine materials during calcination process, which are critical initiators for the performance degradation, has not been systematically studies. In this work, we developed a diagnose approach for evaluating microstrain evolution during solid-state calcination of LTMO materials based on in situ synchrotron XRD and TXM 3D XANES. We studied the effects of synthesis temperature, heating ramp rate, and chemical composition gradient on microstrain distributions. Based on the findings, an optimal synthesis condition is found for $NaNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ that shows significantly enhanced cyclability and structural tolerance.

2:45 PM BREAK

SESSION CH04.03: Materials and System Design
Session Chairs: Mengya Li and Duhan Zhang
Monday Afternoon, December 2, 2024
Sheraton, Third Floor, Commonwealth

3:15 PM *CH04.03.01
On Transport and Strain Effects in Solid Ionic Conductors and Solid-State Battery Composites Wolfgang Zeier; University of Münster, Germany

In this presentation, we will show that it is not only important to find fast ionic conductors, but that fast ionic conduction is paramount within solid state battery composites. Measuring the effective ionic transport in electrode composites provides an avenue to explore transport and stability limitations that in turn provide better criteria for solid state battery performance. These transport limitations will be explored as a function of materials composition, particle sizes and processing.
In a second part of this presentation, we will show that fast ionic conductors exhibit low thermal conductivities that may be detrimental to solid state battery operation. The low thermal conductivity stems from large anharmonicities and diffuson-based thermal transport, all of which extends into solid-state battery composites. Finally, we will explore strain effects in solid electrolytes and how pressure affects microstructure, transport, and electrochemical properties of solid ionic conductors.

3:45 PM CH04.03.02
Structural Connectivities and Li (De)intercalation in Vanadium Molybdates Kausturi Parui and Megan Butala; University of Florida, United States

Intercalation battery cathode material a-V2O5 has a high theoretical capacity, but in practice has multiple phase transformations during Li intercalation, poor electronic conductivity, and lack of structural stability. Mitigation of irreversible phase transformations may improve the performance in V2O5, similar to what has been seen for Wadsley-Roth phases. Structurally related to ReO3, Wadsley-Roth materials stabilize against octahedral rotations during cycling due to crystallographic shear planes. According to our previous findings, Wadsley-Roth and V2O5

structures are ‘bridged’ structurally through metastable R-Nb2O5. The ‘idealized’ V2O5 structure of R-Nb2O5, with perpendicular shear planes, resulted in minimal structural evolution, reduced polyhedral distortions, symmetric cycling profiles, and enhanced structural stability during (de)lithiation.
With an interest in mitigating phase transformation in V2O5, we investigated a series of Mo-doped V2O5, V2-xMoxO5, (0.05 = x = 0.8). Using synchrotron X-ray diffraction and battery cycling we probed the degree to which this ‘idealization’ of V2O5 is possible with a transition metal ion substitution. With increasing Mo-content, we find an overall improvement in capacity retention and Coulombic efficiency. Although significant changes in electrochemical behavior are observed, the consistent presence of specific impurities indicate that idealization of the structure is not feasible, which reflects on the metastability of these compounds. With an interest in more general relationships between structural connectivity and battery cycling behavior, we are using data science to establish structure-property-performance relationships in Wadsley-Roth and related materials. Using reported structure and cycling data for a subset of transition metal oxide electrodes and machine learning algorithms, we correlate inter- and intra-polyhedral connectivities and electrochemical behavior. These data and approaches can be used to identify structure-property relationships and inform future synthetic targets and next-generation battery materials.

4:00 PM *CH04.03.03

Design of Sustainable Layered Oxide Cathodes for Na-Ion Batteries Xiaolin Li, Fredrick Omenya, Marcos Lucero and David Reed; Pacific Northwest National Laboratory, United States

Na-ion batteries are expected to deliver high performance comparable to some of the Li-ion batteries for grid energy storage and electric vehicle applications. Among the various chemistries, layered oxide cathodes provide high energy density and excellent flexibility in material design for sustainability. In our journey of sodium-ion battery development at Pacific Northwest National Laboratory, we have demonstrated the viability of the technology using high-Ni layered oxides and have developed various types of layered oxides towards low-cost cathodes with reduced amounts of critical materials. Fading mechanisms of these materials in the bulk structures and at the interfaces also are investigated. In this talk, I will reveal our effort on both fundamental understanding of the cathode material design and practical research on the material scaleup and pouch cell fabrication.

4:30 PM CH04.03.04

Nanoscale Sn-Based Protective Layers with Calendaring Process Enhanced the Longevity of Aqueous Zn-Ion Batteries Sunghee Shin[1,2], Hyo Jin Lim[2], Yewon Kim[1,2] and Hyung-Seok Kim[1,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]KIST school, Korea (the Republic of)

Aqueous Zn-ion batteries (AZIBs) are drawing interest for their potential to address two challenges: the ever-increasing need for safe batteries and the demand for affordable costs. Even though AZIBs make it possible to utilize Zn metal as an anode for high volumetric capacity (5854 mAh cm^{-3}), they still endure low Zn utilization. Above all, one of the effective ways to increase low Zn utilization is by employing a Zn powder electrode as the anode. Despite being less researched, the Zn powder electrode offers more significant potential for controllable utilization than adopting Zn foil as an anode in the battery system. In spite of the high utilization, the large surface area of powder electrodes produces massive side reactions like hydrogen evolution, corrosion, and dendrite growth. Therefore, it is crucial to solve these side reactions.
In this study, we employed two strategies to address these concerns: implementing the calendaring process to improve the uniformity and compaction of the electrode and applying the atomic layer deposition (ALD) process to coat the nanoscale protective layer and inhibit undesired side reactions. Uniformity and compactness were reinforced through the calendaring process, directly impacting Zn utilization in the bare Zn powder electrode

through depth of discharge (DoD). Meanwhile, hindering side reaction from Zn powder electrode-electrolyte, we selected SnO_2 as an artificial layer to restrain the side reaction. In order to form a uniform and thin protective film on the powder surface, the ALD process was employed. Transmission electron microscopy (TEM) analysis was conducted to investigate the formation of a thin protective film at the nanometer scale, exhibiting uniformity across the surface. Combining with two tactics, we endeavored to resolve the decrease in polarization from contact loss and the reduction of side reactions. Following the application of the SnO_2 coating to the Zn powder electrode samples, symmetrical cell testing in accordance with the calendaring process was conducted, resulting in overpotentials as low as 3 mV after 150 hours with a discharge depth of 40% and the occurrence of the bare Zn powder electrode short-circuit at the same time. Furthermore, a full cell test was carried out using zinc vanadium oxide (ZVO) as the cathode, showing that an uncoated Zn powder electrode exhibited a capacity of 40.93 mAh g^{-1}, corresponding to 29.14% after 500 cycles, while a Zn powder electrode coated with SnO_2 had a capacity of 138.4 mAh g^{-1}, equivalent to 54.46%. To analyze the governing side effects like hydrogen evolution reaction, we also adopted differential electrochemical mass spectrometry (DEMS). According to the data, the powder electrode with the SnO_2 coating layer was verified to produce hydrogen gas at a rate that was less than half of the bare Zn powder electrode. Our research findings indicate that coating SnO_2 on Zn powder and combining it with the calendaring process may be an effective method for reducing side reactions, enhancing uniformity, and compacting within the battery system.

SESSION CH04.04: Neutron Methods
Session Chairs: David Halat and Mengya Li
Tuesday Morning, December 3, 2024
Sheraton, Third Floor, Commonwealth

8:30 AM *CH04.04.01
Neutron Scattering Study of Battery Materials Jue Liu; Oak Ridge National Laboratory, United States

Neutron scattering offers unique advantages for battery research. It is highly sensitive to light elements such as hydrogen (H), lithium (Li), carbon (C), and oxygen (O), which are crucial components of rechargeable Li/Na-ion batteries. Additionally, neutron scattering can differentiate between adjacent transition metal (TM) cations like manganese (Mn), iron (Fe), and nickel (Ni) in battery cathodes, particularly during isotope substitution experiments. This capability enables precise investigation of how cation arrangements influence the electrochemical performance of various rechargeable battery cathodes. Neutron scattering is also useful for probing dynamics, such as ligand anion vibrations, lattice dynamics, and ionic diffusion in both electrode and electrolyte materials. Moreover, its strong penetration and non-destructive nature make neutron scattering an ideal tool for characterizing battery materials without damaging the sample or interfering with electrochemical reactions. Despite these advantages, the application of neutron scattering techniques (e.g., diffraction, quasi-elastic, and inelastic scattering) in battery research has been overshadowed by synchrotron X-ray scattering. This is mainly due to the historically limited interaction between the neutron scattering and battery research communities. In this talk, I will briefly review the history of neutron scattering in battery material studies, focusing on our recent efforts using neutron diffraction and total scattering to study battery electrodes and solid-state electrolyte materials. I will also present our recent advancements in developing high-throughput and fast operando neutron diffraction study of conventional Li-ion batteries, as well as the breakthrough of achieving the first operando neutron diffraction study of all-solid-state batteries using SNS's NOMAD instrument.

9:00 AM CH04.04.02

An Investigation of Local-Scale Distortions in Perovskite Solid Electrolytes via Neutron Total Scattering.

Frederick Marlton[1] and Siegbert Schmid[2]; [1]University of Technology Sydney, Australia; [2]The University of Sydney, Australia

The perovskite structured oxides of composition ABO_3 are considered strong candidates for solid-state electrolytes in all-solid-state batteries due to their chemical and structural flexibility. However, further improvements must be made before they become commercially viable, and this requires a clear understanding of the structure-property relationships. In this study, the local structure of the perovskite sodium-ion solid electrolyte series $Na_{1/2-x}La_{1/2-x}Sr_{2x}ZrO_3$ (NLSZ, x = 1/4, 1/6, 1/8, 1/16) was investigated via neutron total scattering. Small-box modelling against the neutron pair distribution function with the orthorhombic *Pbnm* structure showed local-scale features that deviate from the average structure. Big-box modelling quantified significant differences between the bonding configurations of the different A-site cations, which impacts the ionic conductivity of the material. This study demonstrates how understanding local-scale disorder is important for tuning the structure-property relationships of inorganic solid-state electrolyte materials in sustainable battery technologies.

9:15 AM CH04.04.03

Neutron Total Scattering as a Tool for Battery Electrolyte Design Camilla Di Mino[1], Thomas Headen[2] and Mauro Pasta[1]; [1]University of Oxford, United Kingdom; [2]ISIS Pulsed Neutron and Muon Source, United Kingdom

The future of battery science promises groundbreaking innovations, from the development of all-solid-state lithium metal batteries, set to revolutionise battery-powered aircrafts, to novel battery chemistries designed to meet growing demands.[1] While transitioning from liquid to solid electrolytes brings unique challenges, in terms of reduced ionic conductivity and interfacial contact, the intrinsic absence of long-range order in amorphous electrolytes further complicates our fundamental understanding of their degradation.

Neutron total scattering (NTS) is a powerful tool for addressing these challenges due to its high sensitivity to light elements, such as lithium, and its atomistic resolution. The varying neutron scattering lengths of isotopes of the same element enable the acquisition of multiple isotopically distinct patterns that will constrain the derivation of the material structure, permitting us to separate key features. Combined with Monte Carlo simulations, NTS allows us to achieve an experimental, atomistic picture of the systems, where a wide range of intermolecular interactions take place.[2]

Here, we use NTS and Monte Carlo simulations to understand and design next generation battery electrolytes. Starting with known systems, such as lithium phosphorus oxynitrate, we provided new insights into the local atomic structure experimentally with previously unobtainable precision, showing key observed differences from previously established models, such as the presence of a rich glass network in which lithium plays a key stabilising role. With this information in hand, we directly linked material properties (e.g., ionic conductivity) with our measured nanoscale structures to develop a machine learning model that can be predictive in the optimisation of composition, structure, and diffusivity for material discovery.[3]

Concurrently, total scattering offers a unique opportunity for understanding new chemistries, such as fluoride ion. By shuttling an anion instead of a cation, fluoride ion batteries are a promising alternative to lithium, as they rely on earth abundant materials. However, the commercialization of fluoride ion batteries is hindered by the limited solubility of fluoride salts. By comparing three different promising liquid electrolytes for fluoride ion batteries, we used neutron total scattering on an instrument such as the NIMROD diffractometer at ISIS, the UK neutron and muon source, to understand the molecular mechanisms behind their solubility. The wide Q range of NIMROD, that spans from the molecular to the mesoscopic scale, allowed us to shed a light on the solvation of anions and cations, that directly links to charge diffusion and conductivity, as well as on the formation of the hazardous HF.[4]

In summary, we present new advancements in NTS and its use in battery technologies. Our state-of-the-art NTS techniques reveal how these innovations can be directly applied to both understand and optimize disordered electrolyte materials, paving the way for next-generation battery technologies.

Design of High-Performance Solid Electrolytes Inspired by Advanced Characterizations Zhantao Liu[1], Shuo Wang[2], Jue Liu[3], Yifei Mo[2] and Hailong Chen[1]; [1]Georgia Institute of Technology, United States; [2]University of Maryland, United States; [3]Oak Ridge National Laboratory, United States

Solid electrolytes (SEs) are crucial components that significantly impact the performance of all-solid-state batteries. In recent years, many Li^+ and Na^+ solid-state ionic conductors, primarily oxide- and sulfide-based, have been extensively studied. Halides, such as those in the Li_3MX_6 family (where M can be Y, In, or Sc, and X can be Cl or Br), are an emerging group of SEs offering several advantages over oxides and sulfides. However, the mechanisms of ionic diffusion in halides are not fully understood. Experimentally and theoretically, a type-II superionic transition has been observed in several halide SEs, but the structural changes causing this transition remain unclear.
In this study, we conducted in-depth synchrotron and neutron characterizations to understand the superionic transition in Li_3YCl_6. Variable temperature diffraction refinements revealed significant changes in critical bond lengths and diffusion pathway bottlenecks around the transition temperature (Tc). These changes result in markedly different diffusion energy barriers in both the ab-plane and c-direction. Further analysis indicates that these changes are due to variations in the vibration modes of anions.
Based on these findings, we propose a strategy to lower Tc to maintain the low activation energy barrier above Tc, thereby achieving high room-temperature conductivity. We designed a series of compounds by tuning anion compositions, successfully lowering Tc to 70 °C. Another compound was designed to further reduce Tc, achieving a very low Tc of -10 °C and resulting in an ultra-high room-temperature ionic conductivity of 12 mS/cm.
This work provides insights into the type-II superionic transition in halide SEs and presents successful examples of materials design guided by these insights. It demonstrates the critical role that crystal structure characterization plays in materials design and development.

Towards Magnetic Cluster Expansion Monte Carlo Simulations of Battery Electrodes Graciela E. Garcia Ponte, Sesha S. Behara, Euan Bassey, Raphaële Clement and Anton Van der Ven; University of California, Santa Barbara, United States

Non-invasive characterization techniques such as magnetometry, nuclear magnetic resonance (NMR), and electron paramagnetic resonance (EPR) spectroscopies are invaluable for interrogating the working principles and failure mechanisms of Li-ion battery cathodes. Interpreting these magnetic changes demands a physics-driven understanding of the spin dynamics underlying the low-energy magnetic configurations in these cathodes. Such comprehensive simulations can equip us with a robust toolkit to analyze experimental data acquired both *ex situ* and *operando*.
In this work, we utilize first principles computational and statistical mechanical methods such as cluster expansions and Monte Carlo, implemented *via* the CASM software package, to model magnetic interactions in the high-voltage $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) spinel battery material. Density functional theory (DFT) calculations of several Ni-Mn orderings, including the ordered ground state (space group $P4_332$), reveal a preference for an antiferrimagnetic arrangement of the Ni and Mn sublattices due to strong antiferromagnetic superexchange interactions between Mn^{4+} and Ni^{2+} ions. Magnetic cluster expansions of these structures further verify these results, with strong antiferromagnetic Ni-Mn magnetic exchange coupling constants and ferromagnetic Mn-Mn and Ni-Ni exchange interactions among adjacent transition metals. We also study how the magnetic properties are tuned by Li composition.
Further simulations of the LNMO magnetic system were conducted using Metropolis Monte Carlo to investigate finite temperature magnetic properties, through various magnetic models. While these simulations effectively replicate experimental magnetic states at both high and low temperatures, the Ising model fell short in accurately predicting the experimental transition temperature between ordered and disordered magnetic states. In this work, we demonstrate that the Heisenberg model, which aligns better with actual spin behavior, addresses this discrepancy, and very accurately predicts experimental transition temperatures observed in magnetometry measurements. Additionally, we implement a “Semi-Quantum-Semi-Classical” Monte Carlo sampling method, which better represents spins at low temperatures by incorporating quantum behavior. Our results provide invaluable insights into the complex magnetic interactions underpinning these cathode materials, with applications that extend to the broader materials science community.

10:30 AM CH04.05.02

Charge-Clustering Induced Fast Ion Conduction in $2LiX-GaF_3$—A Strategy for Electrolyte Design Erica Truong[1], Sawankumar v. Patel[1], Valentina Lacivita[2], Haoyu Liu[1], Yongkang Jin[1], Yan Eric Wang[2], Lincoln Miara[2], RyoungHee Kim[3], Hyeokjo Gwon[3], Rongfu Zhang[1], Ivan Hung[4], Zhehong Gan[4], Sung-Kyun Jung[5] and Yan-Yan Hu[1]; [1]Florida State University, United States; [2]Samsung Advanced Institute of Technology-America, United States; [3]Samsung Advanced Institute of Technology, Korea (the Republic of); [4]National High Magnetic Field Laboratory, United States; [5]Ulsan National Institute of Science and Technology, Korea (the Republic of)

$2LiX-GaF_3$ (X = Cl, Br, I) electrolytes offer favorable features for solid-state batteries: mechanical pliability and high conductivities. However, understanding the origin of fast ion transport in $2LiX-GaF_3$ has been challenging. The ionic conductivity order of $2LiCl-GaF_3$ (3.20 mS/cm) > $2LiBr-GaF_3$ (0.84 mS/cm) > $2LiI-GaF_3$ (0.03 mS/cm) contradicts binary LiCl (10^{-12} S/cm) < LiBr (10^{-10} S/cm) < LiI (10^{-7} S/cm). Using multinuclear ^7Li, ^{71}Ga, ^{19}F solid-state nuclear magnetic resonance and density functional theory simulations, we found that $Ga(F,X)_n$ polyanions boost Li^+-ion transport by weakening Li^+-X^- interactions via charge clustering. In $2LiBr-GaF_3$ and $2LiI-GaF_3$, Ga-X coordination is reduced with decreased F participation, compared to 2LiCl-GaF_3. These insights will inform electrolyte design based on charge clustering, applicable to various ion conductors. This strategy could prove effective for producing highly conductive multivalent cation conductors such as Ca^{2+} and Mg^{2+}, as charge clustering of carboxylates in proteins is found to decrease their binding to Ca^{2+} and Mg^{2+}.

10:45 AM CH04.05.03

Measurement of Electrolyte Self-Diffusion in Laser Structured Electrodes Sacris Jeru Tambio[1], Michael Deschamps[2] and Wilhelm Pfleging[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Université d'Orléans, France

It is generally stated that a limiting factor in fast charging and high-power discharging of lithium-ion batteries (LiB) stems from the diffusion kinetics of Li^+ in the electrode pore network. Numerous approaches in enabling fast charging of LiBs include active material development, electrolytes with high ionic conductivity and the management of the charging and discharging temperature. Another promising method is laser micro structuring to modify the electrode architecture regarding an enhanced lithium-ion diffusion kinetics. An increased high-rate capability and boost in cell lifetime have been demonstrated with such 3D electrodes [[i], [ii]] but the related mechanisms leading to a substantial impact to diffusion kinetics are still poorly understood. Furthermore, it is imperative to find an optimal ablation pattern with regard to the desired application scenario that minimizes active mass loss in order to create the economic basis for efficient upscaling of the process.

Chemical Exchange Saturation Transfer Nuclear Magnetic Resonance (CEST-NMR) is a technique that exploits spin magnetization saturation for Magnetic Resonance Imaging (MRI) [[iii]]. The generated images allow the best contrast for detecting chemical biomarkers. The image contrasts are a result of saturation exchange between the biomarker and water and is detectable through changes in longitudinal relaxation times (T_1). Through the Torrey-Bloch Relaxation, T_1 can be related with the magnetization profile to extract the effective self-diffusion coefficient. In this work, a modified CEST experiment, is conceptualized to study the impact of laser generated 3D patterns in pore self-diffusion of electrolyte species.

Exchange NMR and T_1 measurements were realized at various soaking times and electrolyte amounts for the following electrolyte species: Li^+, PF_6^-, ethyl carbonate (EC), and ethyl methyl carbonate (EMC), using laser structured, graphite-based electrodes casted on non-metallic substrates (to reduce RF interference). Magnetization profiles show the presence of confined species as well as the approximation of the diffusion properties. Using isotope exchange experiments with ^6Li enriched electrolyte, concentration maps revealed the rate of $^6LiPF_6$ intrusion into $^7LiPF_6$ rich pre-soaked electrodes. The impact of laser generated 3D patterns in pore diffusion will be discussed in detail.

Understanding Charge Compensation Mechanisms Using Hard X-Ray Core-Shell Spectroscopy Methods

Mahalingam Balasubramanian and Mengya Li; Oak Ridge National Laboratory, United States

Understanding the charge compensation mechanisms during electrochemical cycling of battery materials is of both fundamental and applied interest. X-ray absorption near edge spectroscopy (XANES), a bulk-sensitive probe of the unoccupied projected density of states, has been a workhorse technique that sheds light on oxidation state changes of the metal ions. However, the rising edge at the metal K-edge — the energy of which is often used in assigning oxidation state — is also affected by other factors such as ligand identity, covalency, coordination number, and metal spin state. In this talk, we will highlight the application of these hard X-ray spectroscopy methods to understand fundamental structure-function relationships of materials and systems relevant to electrochemical energy storage.

2:00 PM CH04.06.02

Simplifying Access to X-Ray Absorption Spectroscopy with Laboratory-Based X-Ray Spectrometers

Paul Aronstein, William Holden, Zachary Lebens-Higgins and Devon Mortensen; easyXAFS, United States

Identification of oxidation state and coordination environment is often challenging, requiring arduous preparation and destructive analytical techniques which inhibit rapid analyses. X-ray absorption spectroscopy (XAS) is a non-destructive alternative often requiring fewer sample constraints, however access to this analytical technique is often restricted by infrequent beamtime availability and the highly competitive nature of access proposals. Advancements in laboratory-based XAS are addressing this issue, facilitating consistent access to routine element-specific analysis of oxidation state and coordination environment in users' own labs. Intended to simplify and expand access to this powerful technique for both new and existing members of the XAS community, everyday analysis is a game-changer which enables researchers to control their experiment like never before. For non-dilute samples synchrotron quality data is achievable in transmission-mode within minutes facilitating measurement of time-sensitive reactions. Analysis of trace elements (few hundred PPM) is permitted by employing fluorescence-mode XAS with the same synchrotron-quality energy resolution. With a broad energy range (4.5-25 keV) capable of XAS analysis of over 50 elements ranging from titanium through the actinides laboratory-based X-ray absorption spectrometers provide a rapid means for advancing electrochemical research.

2:15 PM CH04.06.03

Observing Interfacial Reactions in Solid-State Li-Ion Batteries with X-Ray Spectroscopies

Trevor B. Binford[1], Joshua Gibson[2], Leanne Jones[1], Tugce Erlap-Eden[3] and Robert S. Weatherup[1]; [1]University of Oxford, United Kingdom; [2]The University of Edinburgh, United Kingdom; [3]Johnson Matthey, United Kingdom

Although lithium-ion batteries (LIBs) are a key technology for enabling the transition to renewable energy sources, they remain limited back by capacity and stability issues. A better understanding of LIB degradation processes will allow more rational design to improve LIBs in terms of energy density, safety, cost, and cycle-lifetime. However, many of the key reactive areas are buried deep within LIBs, making them difficult to access with surface-sensitive techniques. In particular, the cathode-electrolyte interface (CEI) is thought to be particularly important as a site of degradation reactions, but has hitherto been mainly acessed by *ex-situ* disassembly. Such approaches inevitably change the CEI by releasing pressure and exposing the interface as a new surface, inevitably introducing a range of

changes and contamination. To improve upon this issue, we introduce a novel all-solid-state *operando* battery architecture to enable access to the CEI. This design centres on a suspended thin-film cathode made via radio-frequency magnetron sputtering. This cathode, typically layered transition-metal oxide such as $LiCoO_2$, is combined with a solid electrolyte such as argyrodite Li_6PS_5Cl to provides a simple interface between the pure active material of the cathode and electrolyte. Avoiding the conductive or binding additives typically used in cathodes drastically simplifies the system and the number of possible interfaces, while the thinness of the cathode (tens of nanometers) allows measurements with X-ray spectroscopic techniques that would typically be restricted to surface measurements. Synchrotron-based soft X-ray absorption may be used in fluorescence yield (FY) and total electron yield (TEY) detection modes to monitor either species either in the “bulk” of the thin film (via FY) or specifically at the CEI (via TEY). Information on the chemical species and oxidations states at these different regions may therefore be observed as a function of time and the cell’s state of charge. Throughout the process, the cell is maintained in an ultra-high vacuum environment to minimise outside influences that would typically interfere with measurements. Overall, this work provides insight and approaches toward understanding the fundamental degradation mechanisms at the CEI, paving the way for longer-lasting and stable batteries.

2:30 PM CH04.06.04

Revealing Evolution in Electrochemical and Thermal Battery Materials with Synchrotron X-Ray Microscopy and Multimodal Analysis <u>Yu-chen K. Chen-Wiegart</u>[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Synchrotron X-ray microscopy and multimodal analysis offer critical tools for deepening our mechanistic understanding of electrochemical and thermal battery materials for energy applications and future sustainability. X-ray microscopy provides direct visualization and quantification of morphological changes and associated chemical transformations in these materials. By combining X-ray microscopy with complementary synchrotron X-ray analyses, including diffraction, scattering, and spectroscopy, as well as other microscopy techniques like electron microscopy, we can gain a holistic view of the morphological, structural, and chemical changes through this multimodal approach. This presentation aims to discuss the applications of such approaches across a range of electrochemical and thermochemical batteries, connecting diverse systems with common characterization needs and approaches, which could be applicable to a wider scientific community.

We will emphasize electrochemical energy storage, including aqueous Zn ion batteries, non-aqueous sodium metal batteries, and the model system of Cu pulse deposition, which can be used for designing novel battery electrodes. Synchrotron microscopy reveals the complex mechanisms of chemical conversion, dissolution/redeposition, and plating/stripping. Operando synchrotron X-ray fluorescence microscopy, along with X-ray nano-tomography conducted by transmission X-ray microscopy, illustrates the dissolution-deposition mechanisms and the evolution of interfacial morphology and chemistry in these batteries. Additionally, Grazing-Incidence Wide-Angle X-ray Scattering and Soft X-ray Absorption Spectroscopy offer further capabilities to analyze electrochemical interfaces, including the surface of the metal deposits and the solid electrolyte interphase (SEI) layer. The development of X-ray microscopy methodologies involving machine learning has led to super-resolution imaging and mitigated issues for radiation-sensitive systems, which will also be discussed.

Extending X-ray microscopy studies to materials that transform at high temperatures, we will discuss our research on molten salts and thermochemical materials. These are vital for energy applications, including thermal energy storage, also known as thermal batteries. Our research investigates the chemical and structural evolution processes of metals and alloys in molten salts, as well as the redox processes of thermochemical materials undergoing thermal cycling. By employing operando synchrotron X-ray nano-tomography, X-ray Absorption Near Edge Structure (XANES) imaging, and X-ray absorption spectroscopy, coupled with electron microscopy analysis, our research sheds light on the morphological and chemical changes, illuminating degradation mechanisms with the aim of improving the longevity of thermal batteries.

2:45 PM BREAK

3:15 PM *CH04.06.05
Success and Caution in Using Synchrotron to Characterize Advanced Battery Materials Enyuan Hu; Brookhaven National Laboratory, United States

Synchrotron facilities provide a significant flux of x-ray photons across a broad range of energies, making them exceptional tools for characterizing battery materials. This presentation will showcase several successful case studies where synchrotron radiation was used to examine batteries at various length and time scales, revealing unique and valuable information about the materials. These studies include insights into the interphases on both the anode and cathode sides, phase transitions under far-from-equilibrium conditions, and the structural evolution of amorphous materials during synthesis and electrochemical cycling. Additionally, the second part of this talk will address the potential beam damage to samples caused by synchrotron x-rays. We will present examples, discuss the possible origins of this damage, and propose solutions to mitigate the issue.

3:45 PM CH04.06.06
Design of Fluoride-Ion Battery Insertion Electrodes Based on Stereochemically Active Lone Pairs Shruti K. Hariyani[1], George Agbeworvi[1], Anindya Pakhira[1], Conan Weiland[2], Cherno Jaye[2], Lu Ma[3] and Sarbajit Banerjee[1]; [1]Texas A&M University, United States; [2]National Institute of Standards and Technology, United States; [3]Brookhaven National Laboratory, United States

Lithium-ion insertion batteries have revolutionized modern consumer electronics due to their unmatched power densities, yet their large-scale demand and production is giving rise to new concerns on materials criticality. One less explored method to advance energy storage technology while remaining environmentally cognizant is to utilize fluoride-ion batteries. While still in their nascent stage, certain design rules have emerged to help expedite the discovery of new electrodes capable of fluoride-ion insertion. For example, the host crystal structure should contain large tunnels with vacant interstitial positions and be composed of a redox-active transition metal and a p-block cation with stereochemically active lone pairs, which help facilitate anion diffusion. Unfortunately, these design rules have only been applied to materials that crystallize in the Schafarzikite type, which has hindered the development of new electrodes. This work aims to explore the generalizability of these design rules by investigating $PbPdO_2$ and Sn_2TiO_4 as new fluoride-ion insertion electrodes. $PbPdO_2$ and Sn_2TiO_4 were synthesized and fluoridated upon reaction with a molar excess of XeF_2, which was confirmed using X-ray absorption and variable X-ray emission spectroscopies and magnetism. Crystal orbital Hamilton population (COHP) calculations and the measurement of the valence band of $PbPdO_2$, $PbPdO_2F_x$, Sn_2TiO_4 and $Sn_2TiO_4F_x$ using X-ray absorption spectroscopy yields a comprehensive bonding analysis to understand the mechanism of fluoridation within these materials. We show that host structures containing cations with a formal ns2np0 electronic configuration and stereochemical active lone pairs underpin the formation of large one-dimensional tunnels that contain interstitial positions for fluoride ion insertion and the interactions between the active lone pair electrons and fluoride facilitate reversible anion diffusion. This work verifies the applicability of these design rules to new structure types, which drastically expands the structural and compositional spaces of interest and can expedite the discovery of new electrodes capable of reversible, room-temperature fluoridation.

4:00 PM CH04.06.07
Characterization of Stacking Faults in Many Battery Materials Using FAULTS Software Jon Serrano-Sevillano[1],

Marine Reynaud[1], Damien Saurel[1] and Montserrat Casas-Cabanas[1,2]; [1]CIC energiGUNE, Spain; [2]IkerBasque, Spain

Defects significantly influence the physicochemical properties of materials, but characterizing faulted structures can be challenging.[1] Stacking faults are detectable using HR-STEM images; however, as this is a local technique, extrapolating the findings to the bulk material may not be straightforward. Conversely, XRD provides an average overview of the structure, making it possible to extract information that offers a more comprehensive description. Nevertheless, most characterization models are based on ideal structures. Refinement results may be poor if the actual structure deviates significantly from the ideal one due to numerous stacking faults. As a result, stacking faults are often overlooked, leading to potential misunderstandings of structure-property correlations.
In this study, we present the structural characterization of a series of faulted materials which are commonly used in batteries (e.g., Li-rich layered oxides, graphite, etc.). HR-STEM images revealed stacking faults in all samples, affecting their XRD patterns. The FAULTS software[2,3] was used to extract information from the XRD patterns to describe the structure accurately. This software constructs the structure with layers, stacking vectors, and probabilities, allowing for the inclusion and refinement of stacking faults. The refined data were then used to correlate structural details with electrochemical performance.

4:15 PM CH04.06.08

Microstructure Dependent Sodium Storage Mechanisms in Hard Carbon Anodes Luis Kitsu Iglesias, Samuel Marks, Kayla Sprenger and Michael F. Toney; University of Colorado Boulder, United States

Sodium storage mechanisms within hard carbon (HC) anodes for sodium-ion batteries are strongly dependent on the HC microstructure. The capacity curve of HC is composed of a high voltage slope and a low voltage plateau region.The HC microstructure ultimately determines the total capacity and the ratio between the capacities of the slope and plateau regions. It has been established that sodium can be stored via three processes: adsorption, intercalation, and pore filling with the consequent sodium cluster formation in the pores. However, the actual sequence and details of the sodium storage mechanisms still a subject of debate. Using X-ray pair distribution function analysis, this study clarifies how microstructural variations in HC influence sodium storage across both the slope and plateau regions of the capacity curve. During the slope region, sodium ions initially adsorb at high-energy defect sites and subsequently intercalate between graphene layers to adsorb in defect sites, which correlates with distinct electrochemical gradients observed during initial sodiation. In the plateau region, our findings reveal simultaneous intercalation and pore filling, dictated by the microstructure's characteristics such as pore size distribution, interlayer spacing, and defect concentration. This is especially notable in HC synthesized at higher pyrolysis temperatures, where larger sodium clusters form, indicating a preference for filling larger pores. The proposed 'surface adsorption – defect-assisted intercalation – intercalation/pore filling' mechanism highlights the critical role of microstructure engineering in optimizing HC performance. These insights are crucial for advancing HC anode design in sodium-ion batteries, particularly for large-scale energy storage applications, making a significant stride toward sustainable energy solutions.

Multidimensional Contact Potential Difference Measurements at the Nanoscale in Inorganic Oxides

Bugrahan Guner and Omur E. Dagdeviren; Université du Québec, Canada

Inorganic oxide-based sample systems are popular for applications in catalysis, sensing, renewable energy, and fuel cells in which electronic properties play important roles. Environmental conditions, e.g., temperature, can greatly impact the electronic properties and thereby the performance. The lack of basic knowledge of the local variation of electronic properties as a function of temperature limits the fundamental understanding of systems and hampers their robustness. Here, we demonstrate the multidimensionality of contact potential difference (CPD, i.e., the difference in the work functions of the gold-coated probe and the sample when they are in proximity and under thermodynamic equilibrium, a.k.a., volta potential) at the nanoscale in inorganic perovskites and metal-oxides with scanning probe microscopy (SPM) measurements [1, 2]. We concentrated on single-crystal, inorganic perovskites (*e.g.*, strontium titanate, $SrTiO_3$) and metal-oxides (*e.g.*, titanium dioxide, TiO_2) to have the least amount of uncertainty of sample properties. We employed an undoped $SrTiO_3$ and TiO_2, as they are vastly utilized due to their ideal lattice match for similar systems, cost efficiency, stability, and technological and scientific importance. Our experiments reveal three important results: (I) the CPD of both $SrTiO_3$ and TiO_2 evolve with temperature, (II) the measured CPD is dominated by the local surface state at small tip-sample separations (*i.e.*, tip-sample distance < 10 nm), and (III) the thermodynamically driven intrinsic doping of the material is the governing mechanism of the variation of the CPD for these sample systems. These results clearly show that care must be given to identify the temperature-dependent change of electronic properties to attain and preserve the desired performance of inorganic oxide-based sample systems.

Chemo-Mechanical Analysis of Stress Evolution in Solid-State Batteries with High Areal Capacity Cathodes

Liam McMullin, Madeline Weihs and Regina García-Méndez; Johns Hopkins University, United States

Solid-state batteries (SSBs) have the potential to improve energy density, safety, and cycle life when compared to traditional Li-ion batteries. The energy density of the battery is highly dependent on the amount of charge that can be stored in the cathode, which is correlated to the areal capacity of the cathode. Therefore, maximizing energy density necessitates high areal capacity cathodes and a deep understanding of their operation and degradation mechanisms.

Investigation of the stress evolution in high-areal capacity, all-solid-state composite cathodes remains an important challenge in the implementation of SSBs. This work focuses on full cells that are composed of a Lithium/Indium anode, argyrodite solid electrolyte, and composite cathode. It examines two active materials, $LiFePO_4$ and $LiMn_2O_4$, and two halide catholytes. The areal capacity loading of the composite cathode was varied between 1-4 mAh cm^{-2}, and the cycling rate was varied between 0.1C to 0.5C. The stress evolution in the cell was approximated by measuring the change in mechanical force produced by the cell stack upon cycling. The stress evolution was correlated to the mechanical properties of the components, cathode loading and observed capacity retention. Micro-CT, SEM/EDS, and FIB-SEM were conducted to observe chemo-mechanical changes and correlate them to cycling conditions and stress evolution. This work provides insights to optimize SSB systems by highlighting the critical importance of understanding electro-chemo-mechanical phenomena.

CH04.07.03

Defect Clustering and Vacancy Ordering in Gadolinium Doped Ceria—A Combined Reverse Monte Carlo Study

Jing Ming[1], Marcin Malys[2], Maciej Woicik[2,3], Marcin Krynski[2], Wojciech Wrobel[2], Jan Jamroz[2], Stephen Hull[4], Franciszek Krok[2], Marzena Leszczynska-Redekb[2] and Isaac Abrahams[1]; [1]Queen Mary University of London, United Kingdom; [2]Warsaw University of Technology, Poland; [3]Institute of Physics Polish Academy of Sciences, Poland; [4]Rutherford Appleton Laboratory, United Kingdom

Lanthanide-doped cerias exhibit fast oxide ion conduction, making them an effective electrolyte for solid oxide fuel cells operating at intermediate temperatures (*ca*. 500-700 °C).[1] Among all the lanthanides, ceria doped with gadolinium (GDC, $Ce_{1-x}Gd_xO_{2-x/2}$) offers the best conductivity system and has already been adopted commercially.[2] This high ionic conductivity arises from the creation of high concentrations of oxide ion vacancies along with 3-dimensional conduction pathways within the cubic fluorite structure when Ce^{4+} substituted by Gd^{3+}. However, a lack of homogeneity or disruptions in local atomic arrangements in these systems, can impede O^{2-} ion diffusion, potentially suppressing ionic conductivity.

To address the structural complexity, recent advancements in neutron total scattering data analysis now allow for a detailed atomic arrangement through the combination of Bragg and diffuse scattering, providing a more complete picture of both long-range and short-range structures, respectively.[3] In this study, samples prepared with isotopically enriched ^{160}Gd were used to overcome the high neutron absorption coefficient of naturally abundant Gd, enabling us to access previously inaccessible local details in the defect structure of GDC by analysing total neutron scattering data. The total scattering data of $Ce_{0.8}{}^{160}Gd_{0.2}O_{1.9}$ sample were successfully modelled through reverse Monte Carlo (RMC). The variation from the average structure, a complex local structure, including different defect clusters or associations and vacancy ordering patterns, was observed in the final RMC configurations. Dopant cation-oxide ion vacancy association is thought to play an important role at lower temperatures, leading to higher activation energies for conductivity. These findings will also help to uncover local details of the conduction mechanism in other doped ceria systems.

Effect of the Anion Disorder on Lithium Conductivity of Argyrodite $Li_{6-x}PS_{5-x}ClBr_x$ Solid Electrolytes

Seho Yi[1], Taegon Jeon[1], Gyeong Ho Cha[1], Young-Kyu Han[2] and Sung Chul Jung[1]; [1]Pukyong National University, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of)

Li-argyrodite Li_6PS_5Cl is considered a promising solid electrolyte for all-solid-state batteries due to the low cost of raw materials, mechanical flexibility, and high ionic conductivity. Halide-rich argyrodites obtained by replacing S in

Li_6PS_5Cl with Br have been reported to exhibit significantly improved conductivity compared to Li_6PS_5Cl. In this study, using density functional theory calculations and *ab* initio molecular dynamics simulations, we systematically investigated more than 300 Li_6PS_5Cl structures and 500 Br-substituted $Li_{5.75}PS_{4.75}ClBr_{0.25}$ structures and found that anion disorder greatly enhances the stability and conductivity of $Li_{6-x}PS_{5-x}ClBr_x$. The most stable Li_6PS_5Cl and $Li_{5.75}PS_{4.75}ClBr_{0.25}$ structures have the highest level of anion disorder, with S, Cl, and Br anions evenly occupying the Wyckoff 4a and 4d sites. The anion disorder significantly increases Li conductivity in both Li_6PS_5Cl and $Li_{5.75}PS_{4.75}ClBr_{0.25}$ by activating all three types of Li jumps, i.e., doublet, intracage, and intercage, in Li-cage structures of argyrodite. The overlap of Li-cages in $Li_{5.75}PS_{4.75}ClBr_{0.25}$ creates a continuous diffusion path for Li ions, leading to about two times higher conductivity of $Li_{5.75}PS_{4.75}ClBr_{0.25}$ than Li_6PS_5Cl.

***Operando* Optical Microscopy of Battery Materials for Transport Coefficients** Yug Joshi[1,2], Nadine Kerner[2], Monica Mead[2], Robert Lawitzki[2], Roham Talei[2], Sebastian Eich[2] and Guido Schmitz[2]; [1]Max Planck Institute for Iron Research, Germany; [2]Universität Stuttgart, Germany

Diffusion coefficients of electrode materials are often determined using galvanostatic (GITT) or potentiostatic intermittent titration technique (PITT), electrochemical impedance spectroscopy (EIS) or cyclic voltammetry (CV). However, these methods require special care, as each of their formal derivations use quite restrictive assumptions. As an alternative, an operando optical microscopy method is proposed for studying lithium transport. Two material systems are presented namely, Li4Ti5O12 (LTO) and LiMn2O4 (LMO). In both cases, a huge concentration-dependent Li kinetics can be observed. Moreover, phase propagation in the initial stages follows a linear growth rather than the conventional assumed parabolic growth. This is characterized by a "barrier coefficient" which restricts the phase transformation behavior. For the case of LTO this barrier coefficient seems to be size dependent. This is due to the fact that the fast kinetics in Li-poor spinel phase hinders the nucleation of the Li-rich rock-salt phase. For the case of LMO, the method had been extended due to the presence of multiple phases in the solubility range of 1≥x≥0 LixMn2O4. Therefore, no monotonic dependence of optical intensity was recorded by the microscope on lithium concentration. For this purpose, a python code is developed that determines concentration profiles from RGB images using support vector regression (SVR), a flexible machine-learning tool. To evaluate the diffusion coefficient, an inverse Boltzmann-Matano concept is applied. Representing the diffusion coefficient with generalized Redlich-Kister polynomials, concentration profiles are predicted and fit to the measured data.

CH04.07.06

***Operando* Visualization of Electrochemical Evolution in Lithium Batteries** Xinying Sun, Shengbo Lu and Chenmin Liu; Nano and Advanced Materials Institute, Hong Kong

Through the Electro-Chemical reaction visualizing Confocal System (ECCS), we revealed the electrochemical evolution of both graphite-based anodes in lithium-ion battery and lithium metal anodes in lithium metal battery. (i) An innovative solid polymer electrolyte (SPE) coated separator was found to be able to facilitate lithium ion transport, thereby promoting anode lithiation during charging at various C-rates with lean electrolyte. (ii) The graphite/silicon composite anode exhibits a 20.1% expansion during charging at various C-rates. Color analysis of the anode materials reveals that the average lithiation degree is significantly higher in proximity to the separator in comparison to the region near the current collector, particularly at high charge rates. (iii) Through observation of the lithium metal anode, it has been deduced that there is a notable expansion occurring during the 1C cycling process. This expansion results in the displacement of the reaction interface towards the current collector, accompanied by the accumulation of side-products.

Insights Into Na-Ion Battery Conductivity from Mossbauer Spectroscopy Hillary Smith, Aaron Dubois, Alex Wuttig and Shintaro Inaba; Swarthmore College, United States

The motion of active ions in a battery is critical to all major issues facing electrochemical battery systems. A battery's energy density, operating potential, and charge/discharge rate are determined by the ionic conductivity in the cathode. This work uses Mossbauer spectroscopy to assess the activation energy and electron dynamics in sodium-based Prussian blue analogs. The onset of polaron motion in each material is assessed through Mossbauer measurements at increasing temperatures and indicated by spectral distortions that occur when Na atoms become mobile and the iron atoms experience a fluctuating local environment. The critical role of Mossbauer spectroscopy in completing our understanding of conductivity in battery materials will be discussed alongside results for a series of sodium-iron Prussian blue analogs.

CH04.07.08

Correlative SEM, EDX and Raman for Battery Characterization Nikolay Zhelev, Nuria Garcia-Araez and Philip N. Bartlett; University of Southampton, United Kingdom

Battery characterization often requires the combination of various techniques to disentangle their complexity, and it is particularly advantageous when the techniques are applied to exactly the same sample and recorded nearly simultaneously, as it is the case of the new correlative SEM, EDX and Raman instrument recently acquired by the University of Southampton.
The benefits of this new instrument are demonstrated via the characterization of a composite electrode containing a mixture of LCO ($LiCoO_2$), NMC ($LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2$) and carbon particles, showing how the Raman characterization enables the assignment of the chemical composition (and confirmed by EDX elemental analysis) of the different particles detected by the high-resolution SEM.
The instrument is also built with a windowless EDX detector (in addition to a conventional one) able to detect elemental lithium, which is used to investigate the chemical and morphological changes of Li metal anodes in Li-S batteries, taking advantage of a transfer-shuttle system that enables the transfer of samples from the glovebox to the SEM chamber without exposure to air.
Overall, the new instrument enables the nearly simultaneous morphological (SEM), elemental (EDX) and chemical (Raman) characterization of the same sample spot with high spatial resolution, thus bringing new opportunities to address complex questions in battery research.

Quantification of Chemical Heterogeneity in Battery Cathodes—Where Should We Look? Jordi Cabana[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

The evolution of local chemistry determines the performance of electrodes and electrolytes used in batteries because limitations can be tracked to slow kinetics and transport, and irreversibilities in the storage reaction. Tools that provide insight into local chemistry are critical for identifying the underpinnings of electrochemical function. This information must be resolved within architectures, from individual particles to microscale domains, to pinpoint the relationship between local phenomena and their role in macroscopic metrics and degradation. Technical developments in X-ray microscopy and mapping have built a flexible suite of tools that combine the desired spatial resolution and 3D capabilities with a suite of possible contrasts mechanisms, such as diffraction and spectroscopy. In this talk, we will discuss our recent research that demonstrates the diversity of length scales at which important chemical heterogeneity can be induced in battery electrodes, from their synthesis to their operation. For this purpose, the systems of study will be the leading cathodes for Li-ion batteries. We will highlight the new fundamental insight generated by the tools, but also showcase the value of continuously seek to extend analytical capabilities into outcomes of high statistical significance. The insight generated by our approaches will be related to their impact on material and architecture properties. Along the way, we will discuss the prospects of probing time-resolved phenomena using operando measurements to avoid uncertainty due to relaxation under open circuit conditions. We will also provide a glimpse into the future by showing how emerging synchrotron techniques can enhance the impact of X-ray microscopy in fundamental battery science.

Elucidating the Role of Crystallographic Orientation in Atom Probe Analysis for Anisotropic Metal-Ion Battery Cathode Materials Jr Wen Lin, Dajie Xie, Hyewon Jeong, Alexander Littlefield, Beniamin Zahiri and Paul Braun; University of Illinois at Urbana-Champaign, United States

Li-ion batteries (LIBs) have played a pivotal role in electrochemical energy storage and have garnered extensive research interest since their emergence. Layered transition metal oxides (LTMOs), widely adopted Li-ion battery cathode materials, are crucial for enhancing overall energy density. To gain deeper insights into nanoscale material changes during cycling which could lead to capacity loss, atom probe tomography (APT) offers promise due to its sub-nanometer, three-dimensional (3-D) resolution, and high chemical sensitivity. However, challenges related to Li migration under the required intense operational electric fields of APT have limited APT's applications. Here we utilize air-stable lithium cobalt oxide (LCO) as a model system to elucidate the role of crystallographic orientation in APT analysis for the typically anisotropic battery materials. Our findings reveal that the Li/Co ratio detected by APT is highly dependent on applied laser pulse energy, ranging from stoichiometric (1pJ pulses) to 6.4 (10pJ pulses) when the orientation favors Li transport (Li-ion fast diffusing direction is parallel to the applied electric field). In contrast, even under 10pJ pulses, when the LCO is orientated such Li ion transport is impeded, the Li/Co ratio is 1.8 (near stoichiometric). Additionally, we discuss the effectiveness of an extrinsically deposited metallic capping layer in stabilizing localized Li migration for air-stable LTMO materials, reducing the Pearson coefficient from 0.98 to 0.43. The observed effects of sample orientation on APT could explain the inconsistent stoichiometry reported by APT for structurally similar LTMO materials. Our results emphasize the necessity of reporting crystallographic orientation in APT analyses, not only for battery materials but also for a broader class of materials with anisotropic atomic and ionic transport characteristics.

8:45 AM CH04.08.03

μ-Computer Tomography of Cathode Materials for All Solid-State Na Metal Batteries with Na-β"-Alumina Electrolyte Berik Uzakbaiuly, Gi Hoon Cha, Andre Borchers, Sabrina Pechman and Silke Christiansen; Fraunhofer Institute for Ceramic Technologies and Systems, Germany

Lithium-ion batteries have long been the go-to choice for energy storage in mobile applications, thanks to their efficiency and reliability. However, as the global push for renewable energy intensifies and more power plants transition away from fossil fuels, concerns about lithium's limited availability have surfaced. Simply put, if all existing power plants were to switch to renewable sources, there wouldn't be enough lithium to go around for decarbonizing them all. This scarcity underscores the need to explore alternative storage solutions, with sodium batteries emerging as a promising contender.

Researchers are increasingly turning their focus to sodium batteries due to their potential to overcome the limitations posed by lithium availability. This study delved into this area by conducting in-depth X-ray μ-computer tomography assessments on a specific type of sodium battery known as the sodium-nickel chloride ($Na\text{-}NiCl_2$) battery.

The study's primary objective was to gain insights into the complex dynamics within the battery's cathode, which consists of a mixture of $NaCl_2$ and $NaAlCl_4$. The tomography findings unveiled a fascinating pattern of particle size distribution within the cathode material. Notably, the analysis revealed a concentration of fine-structured particles towards the side adjacent to the Na-β"-alumina electrolyte, while coarser particles were predominantly found near the current collector.

This observed particle size distribution hints at the intricate interplay between the battery's various components during charge and discharge cycles. Specifically, it suggests that the electrolyte plays a crucial role in influencing the particle thinning process throughout these electrochemical reactions. Understanding and controlling this phenomenon are vital, as it could lead to challenges such as cathode cracking, especially during prolonged cycling periods.

The possibility of cathode cracking is a significant concern, as it directly impacts the long-term performance and durability of sodium batteries. Addressing such challenges through ongoing research and technological advancements will be essential in ensuring the viability and widespread adoption of sodium batteries as part of a sustainable energy storage infrastructure. These efforts are crucial not only for meeting current energy demands but also for building a greener and more resilient energy ecosystem for the future.

9:00 AM CH04.08.04

Investigating Varied Growth Behavior of Lithium Metal in Solid-State Batteries Using *Operando* X-Ray Tomography Stephanie E. Sandoval[1,1,2], Douglas L. Nelson[1] and Matthew T. McDowell[1,1]; [1]Georgia Institute of Technology, United States; [2]University of Münster, Germany

Lithium metal exhibits complex growth and stripping behavior in solid-state batteries, manifesting as dendrite formation, void generation, and varied lithium growth patterns depending on electrochemical conditions and solid-state electrolyte properties. Previous studies utilizing optical microscopy, *in situ* TEM, cryogenic focused ion beam and X-ray computed tomography have contributed substantially to understanding lithium growth mechanisms.[1-4] However, many investigations concentrate on singular instances or restricted regions. In this work, we leverage *operando* X-ray computed tomography to comprehensively track and quantify lithium evolution across 2 mm interfaces under diverse deposition and stripping conditions. Specifically, three distinct scenarios were examined in half cells featuring varying solid-state electrolyte (SSE) characteristics: uniform deposition and stripping in a low-impedance cell, extensive dendritic growth in a high-impedance cell, and uniform deposition followed by dendrite growth triggered by higher current densities. The low impedance cell enabled favorable conditions for uniform deposition and stripping across three half cycles. Segmentation revealed expected volume evolution in the working and counter electrode. In stark contrast to uniform lithium growth, the high-impedance cell featured highly dendritic growth dispersed throughout the SSE. This cell utilized a coarse-grained SSE that resulted in poor interfacial contact at the solid-solid interface and in a porous SSE pellet. Throughout deposition, dendritic lithium was observed to grow around pre-existing cracks/pores, often closing them as deposition continued. Segmentation methods were used to track and quantify the evolution of lithium throughout the first cycle, finding that ~20% of the mechanical damage was irreversible after the first cycle. Finally, we also observed that dendritic networks grow near the edges of another cell at higher current densities after initially growing uniformly, indicating different chemo-mechanics at the cell boundary. Collectively, the lithium growth behavior captured and reported here enhance our understanding of the diversity of evolution of lithium in SSBs.

Customization of an Atomic Force Microscope for Multidimensional Measurements Bugrahan Guner and Omur E. Dagdeviren; Université du Québec, Canada

Atomic force microscopy (AFM) is an analytical surface characterization tool that reveals the surface topography at a nanometer-length scale while probing local sample properties. Advanced imaging techniques, such as frequency modulation, to achieve high resolution and quantitative surface properties are not implemented in many commercial systems. In this presentation, we illustrate the step-by-step customization of a commercial atomic force microscope [1]. The original instrument was capable of surface topography and basic force spectroscopy measurements while employing environmental control, such as temperature variation of the sample/tip, etc. We demonstrate the capabilities of the customized system with (automated) frequency modulation-based experiments, *e.g.*, voltage and/or distance spectroscopy [2], time-resolved AFM, and two-dimensional force spectroscopy measurements under ambient conditions. We also illustrate the enhanced stability of the setup with active topography and frequency drift corrections. We think that our methodology can be useful for the customization and automation of other scanning probe systems.

Characterization of Aqueous Iron Anode Passivation Angel Burgos, Xiao Zhao, Evan Z. Carlson and William C. Chueh; Stanford University, United States

Metallic iron is an attractive anode material for aqueous batteries due to its mild voltage, low cost, and non-toxicity. However, cycling-induced passivation precludes it from being widely used, especially when cycled beyond Fe (II). Oxidation to Fe (III) leads to irreversible formation of resistive phases, yet the mechanism by which these phases form is poorly understood. In this talk, the evolution of the phase and morphology of this passivation layer is investigated. Iron oxides in the passivation layer are characterized by Raman spectroscopy and conductive AFM, while morphology evolution is studied by SEM and in-situ electrochemical AFM.
Uniquely, this work combines in situ characterization with iron thin films, allowing the growth of oxide phases to be deconvoluted from particle morphology. This enables characterization of individual particles and gives enhanced

understanding of their growth mechanisms. Understanding the phase transformations of iron oxides in aqueous batteries provides insights into the Fe (II)/(III) conversion and will aid the engineering of iron anodes to achieve increased capacity and cyclability.

Elucidating the Structure and Function of the Electrode-Electrolyte Interface by New Solid State NMR Approaches Michal Leskes; Weizmann Institute of Science, Israel

The development of high-energy, long-lasting energy storage systems based on rechargeable batteries relies on our ability to control charge storage and degradation processes in the bulk of the materials and at their interfaces. NMR spectroscopy is exceptionally suited to follow the electrochemical and chemical processes in the bulk of the electrodes and electrolyte, providing atomic scale structural insight into the charge storage mechanisms and ion transport properties. However, interfacial properties, such as the processes governing charge transport between the electrode and the electrolyte, are much harder to study. These processes typically involve thin, heterogeneous and disordered layers that are formed chemically/electrochemically in the battery cell or artificially through coating the electrode material. While NMR is in principle an excellent approach for probing disordered phases, its low sensitivity presents an enormous challenge in the detection of interfacial processes.
I will describe recent approaches to overcome this limitation by the use of Dynamic Nuclear Polarization (DNP). In DNP, the large electron spin polarization is used to boost the sensitivity of NMR spectroscopy by orders of magnitude. I will show how we can use this approach, using exogenous and endogenous sources of polarization, to detect buried solid interphases (such as the SEI), electrode coatings as well as the electrode's bulk, with unprecedented sensitivity. Furthermore, I will present new approaches to probe ion transport properties of metal electrodes interfaces in solid and liquid electrolytes. These allow us to get insight into the functional role of interfaces, which along with the chemical and structural insight, can provide design rules for beneficial interfaces, an essential aspect for developing long-lasting energy storage systems.

10:45 AM *CH04.09.02
Lithium, Speed & Interfaces—Designing Next Solid Battery Materials Real Fast with High Control of Chemistry Jennifer L. Rupp; Technische Universität München, Germany

Next generation of energy storage devices may largely benefit from fast and solid Li^+ ceramic electrolyte conductors to allow for safe and efficient batteries. For those applications, the ability of Li-oxides to engineer their interfaces and be processed as thin film structures and with high control over Lithiation and phases at low temperature is of essence to control performance. Still, till date it takes globally for all academic and industry scientists and engineers between 7 to 15 years to enable any synthesis of Li-based oxide and sulfide battery compounds towards the optimized performance characteristics. With climate change on the rise and translating more shares to storing renewable energy in batteries and using sustainable materials, we have to reconsider the

ways we select elements, synthesize at low CO_2 footprints and shorten time-spans in translation of new materials to reach highest performances. Through this presentation we provide perspective on how high throughput synthesis and also machine learning (ML) enables fast sceening of properties and optimizing synthesis of solid battery material compounds at best performance characteristics. Also, we will critically review and discuss options of performance engineering at interfaces towards charge transfer and vs. current densities.
In the first part we will look at various options on high throughput synthesis of battery materials and charactrisation routes to resolve bottlenecks and optimize performances. In the second part we propose ways to eingineer interfaces and dopants in the materials swiftly such as local chemistries at grain boundaries as a way to control majority and minority charge carriers at interfaces and within space chages to ultimately alter critical current densities of batteries. Or, in the opposite third part synthesize and design a new class of 'high entropy" Li amorphous conductors without any grain boundaries. Through our analysis of the high throughput and ML assisted ceramic synthesis and characterization we provide a blueprint and demonstrate that it is not always the best ceramic battery material fabrication for production that is the best in ML-assisted screening in high throughput and give guidance. Moreover, the insights on solid state energy storage provide evidence for the functionalities that those Li-solid state material designs can have in new materials and synthesis for cost and mass manufacturable solid state and hybrid battery prototypes.

Nanophase Evolution, Local Water Content Distributions and Protonation Levels in SPEEK—A Vibrational

Spectroscopic and Molecular Dynamics Approach Moon Young Yang[1], Dan J. Donnelly III[2], Nicholas Dimakis[3], William A. Goddard III[1] and Eugene S. Smotkin[2,2]; [1]California Institute of Technology, United States; [2]Northeastern University, United States; [3]The University of Texas at Rio Grande Valley, United States

Perfluorinated sulfonic acid (PFSA) ionomers like Nafion have dominated as membranes for low-temperature fuel cells and electrolyzers for nearly 50 years, because of their high chemical-mechanical stability and high protonic conductivity. PFSAs are expensive and are poor conductors beyond 90 °C, however, in addition to being environmental hazards at the end of their lifetimes. PFSAs are often coated with expensive catalysts (e.g., Pt, Ru, Ir, etc.), whose recovery demands inherently toxic incineration processes. Hydrocarbon based ionomers, like sulfonated poly(ether ether ketone) (SPEEK), are synthesized via relatively green synthetic pathways, and lend themselves to catalyst recovery with less environmental impact upon incineration. The advancement of SPEEK and other sulfonated polyaromatic ionomers requires a thorough understanding of their bulk $H_2O/SO_3(H)$ ratio (λ) dependent protonation levels (i.e., SO_3^-/SO_3H ratios).
We report the use of reactive force field (ReaxFF) molecular dynamics (MD) simulations on SPEEK at the following hydration levels: $\lambda = 0, 1, 2, 3, 5, 7, 10, 15, 20$. Each SPEEK system comprises 58 chains with 10 equally spaced sidechains terminated by $SO_3(H)$ groups (i.e., exchange sites). SPEEK protonation levels, inner- and outer-sphere water proportions, and nanophase evolution are contrasted to those of Nafion's across every considered λ value. Moreover, the ReaxFF generated protonation levels are correlated to changes in SPEEK's transmission IR band intensities. We focus on the IR bands related to SO_3H and SO_3^- vibrations, and conduct density functional theory based vibrational assignments of these bands across different λ values, local to each exchange site (λ_{loc}). We show that SPEEK's overall membrane spectra results from a distribution of λ_{loc} spectra.

Machine Learning with Bluesky for Automated Setup, Acquisition and Analysis of Synchrotron Experiments
Mark Wolfman, Chengjun Sun, Rishabh Ranjan, Luca Rebuffi, Runyu Zhang and Xianbo Shi; Argonne National Laboratory, United States

The increased flux resulting from the Advanced Photon Source Upgrade (APS-U) allows high-quality data to be collected faster than ever. Since battery experiments often seek to probe the dynamic behavior of materials, they are well suited to take advantage of this new generation of synchrotron sources. However, beam-time productivity is increasingly limited by the human time required in between measurements, limiting the extent to which the increased X-ray flux is useful. In an effort to overcome these limitations, the Spectroscopy group at APS has developed several tools to automate as much of this process as possible.

Operating a spectroscopy beamline across multiple X-ray edges can be a tedious process that requires re-configuration of multiple components when moving between elements of interest. Machine learning can now be used to automate much of this work, paving the way for more sophisticated operando experiments, or enabling higher-throughput measurements at multiple X-ray edges.

During data collection, real-time decisions must be made that influence data quality, such as acquisition time and step size. The Bluesky orchestration framework provides tools to making these decisions on-the-fly. These tools have been integrated into our beamline control system, and can be used to set data acquisition parameters in order to reach a certain level of data quality.

With increasing data rates come additional burdens on the researcher to analyze the results. This is especially true for X-ray emission experiments, where multiple emission lines must be identified and extracted from area detector images. The Spectroscopy group has developed several tools to automate this analysis and compare the results to physical models in order to extract richer insight into electronic structure.

These tools aim to remove much of the burden of operating a spectroscopy beamline at APS, leaving researchers free to focus on novel scientific discoveries.

11:45 AM CH04.09.05

Elastic Strain Effects on Li-Ion Transport in Garnet-Type LLZO Solid Electrolytes Shikha Saini, Pjotrs Zguns, Subhash Chandra and Bilge Yildiz; Massachusetts Institute of Technology, United States

Solid-state batteries offer better safety and higher energy density than liquid organic counterparts. However, the relatively low Li-ion conductivity of solid electrolytes limits battery charging rates and power density. This issue is primarily due to the complex electro-chemo-mechanical interactions at the electrode/electrolyte interfaces, where mechanical stresses can reach 1-10 GPa due to volumetric changes in the electrodes and interfacial reactions, substantially affecting the conductivity of solid electrolytes. Disentangling the impact of strain from other factors, such as space charge effects and interfacial reactions, poses a substantial experimental challenge. This work aims to quantify and elucidate the mechanisms by which elastic strains influence Li-ion transport in garnet-type LLZO ($Li_7La_3Zr_2O_{12}$) solid electrolytes using *ab initio* molecular dynamics (AIMD). We find that both Al- and Ta-doped LLZO exhibit higher occupancy in Li2 octahedral sites as compared to Li1 tetrahedral sites when accounting for the disorder in these sites. AIMD analysis shows that Ta-doped LLZO exhibits higher Li-ion diffusivity and conductivity than Al-doped LLZO, attributed to more accessible Li sites and higher Li^+ concentrations. Ta doping, which replaces Zr sites, facilitates Li^+ migration, while Al doping hinders transport by occupying Li sites and limiting migration pathways. Next, we have explored the effect of isotropic elastic strains on Li-ion diffusion, revealing that isotropic expansion (+2%) significantly increases Li^+ diffusivity, while isotropic compression (-2%) decreases it. This effect is due to increased Li-Li and Li-O distances under isotropic expansion (+2%), resulting in a larger bottleneck size and facilitating diffusion between Li1 tetrahedral and Li2 octahedral sites, with compression having the opposite effect. Furthermore, we have started applying anisotropic strain tensors, as these conditions can occur in realistic microstructures and can be strategically used to design solid electrolytes with specific strain profiles. Our results indicate that compressive biaxial strains (b-c, a-c) decrease the Li-ion diffusivity (D_{Li}), whereas tensile biaxial strain has a lesser impact on Ta-doped LLZO. This non-monotonic response under biaxial strain cannot be solely explained by changes in bottleneck size. Therefore, understanding the response of elastic strains is crucial for guiding the engineering of high-performance all-solid-state batteries.

***Operando* Visualization of Li Metal Anodes—From Liquid to Solid Electrolytes** Neil P. Dasgupta; University of Michigan, United States

In recent years, there has been an explosion of research into Li metal anodes for high-energy-density batteries. However, despite tremendous progress in the field, the reversible plating and stripping of Li has been hindered by the complex interplay between electrode morphology, surface chemistry, and mechanics. This has led to many empirical observations of improved performance, but our ability to rationally design solutions to solve the challenges of reversibility remain limited by our fundamental understanding of the complex electrodeposition and dissolution processes involved [1]. Moreover, the emergence of solid-state batteries has created new opportunities to enable Li metal anodes, but the unique chemo-mechanical coupling at solid-solid interfaces also brings new challenges for Li metal anodes.

To address these challenges, *in situ/operando* analyses are of paramount importance to the community. However, given the dynamic nature of Li plating and stripping, challenges arise with respect to tradeoffs in spatial and temporal resolution. To address these challenges, we have recently integrated our optical visualization cells with a digital microscope capable of focus variation microscopy. This enables 3-D visualization of the electrode morphology with high temporal resolution, allowing for video capture of Li plating and stripping [2].

In this talk, I will discuss the application of *operando* 3-D microscopy for visualization of Li metal anodes using both liquid and solid-state electrolytes. In the case of Li metal anodes, we observe significant anisotropy in the geometric shape of individual pits during stripping [2]. The nucleation density and anisotropy are shown to be strongly influenced by the surface microstructure and underlying crystallographic texture of the Li metal surface. As a results, pits can exhibit strong faceting, which influences the nature of nucleation at pit edges in subsequent cycles [3].

The dynamic morphological evolution of Li metal anodes for solid-state batteries will also be demonstrated using 3-D microscopy. This enables visualization of nucleation and growth in anode-free architectures, where the Li metal anode is formed *in situ* at a solid electrolyte/current collector interface [4]. The similarities and differences between liquid and solid systems will be discussed in the context of electro-chemo-mechanical coupling, pointing towards new opportunities to enable reversible plating and stripping.

***In Situ* Magnetic Resonance Characterizations of Rechargeable Batteries** Yan-Yan Hu; Florida State University, United States

Magnetic resonance techniques, including nuclear magnetic resonance spectroscopy (NMR), magnetic resonance imaging (MRI), and electron magnetic resonance (EPR), are non-invasive techniques used to examine both surface chemistry and bulk properties. These techniques employ nuclear or electron spins as probes for interrogating structures and dynamics. We have employed these techniques in situ to understand the working and failing mechanisms of rechargeable batteries. Utilizing in situ ^{7}Li NMR, we determined the lithiation and delithiation sequence and rates at different structural sites in high-voltage transition metal oxide cathodes. Via *in situ* ^{17}O NMR, we evaluated the reactivity of various oxygen species in these high-voltage transition metal oxide cathodes and the reversibility of these O redox reactions. In conjunction with *in situ* EPR, we discovered the synergy of the hybridized O_{2p} and TM_{3d} orbitals to deliver additional capacities in Li transition metal oxide materials and the subsequent stabilization of the structures to ensure reversibility. Combined *in situ* NMR and EPR also prove beneficial to elucidating redox mechanisms in organic cathode materials. Our recent work has demonstrated the efficacy of *in situ* 7Li MRI in identifying new dendrite formation mechanisms in solid-state batteries and new phenomena in the dendrite formation process. *In situ* tracer-exchange NMR is useful for mapping out ion transport pathways in complex ion conductors and distinguishing dendrite formation mechanisms at different charge states. In summary, *in situ* magnetic resonance techniques are useful for uncovering structural and dynamic aspects of energy materials with spatial and temporal resolution.

Can You Make Batteries for *Operando* Optical Measurements Without Sacrificing Performance?

Arvind Pujari, Byung-Man Kim, Neil Greenham and Michael De Volder; University of Cambridge, United Kingdom

In recent years, there has been an increased focus on studying light–battery interactions in the context of *operando* optical studies and integrated photoelectrochemical energy harvesting. A variety of optical cell designs have been used for this purpose, but they often suffer from poor electrochemical performance due to their device architecture, which differs significantly from conventional designs. This limits the conclusions that can be drawn from such experiments as well as the cycling protocols (such as high rates) which can be used.

Here, we propose two battery designs to enable light-battery interactions with reasonable electrochemical performance: the windowed coin cell which draws on conventional cell design, and the planar cell, which is inspired by dye-sensitized solar cells. We identify [1] suitable “light-accepting” current collectors for this class of batteries, namely, fluorine-doped tin oxide, indium-tin oxide, and silver nanowire-graphene film, along with carbon paper, carbon nanotube paper, and stainless-steel mesh.

We categorize these current collectors into two classes – transmissive and non-transmissive, based on the orientation of the light–electrode interaction. Various methods to prepare the electrode are highlighted, including drop casting and the fabrication of free-standing electrodes. The optical and electrical properties of these current collectors as well as their electrochemical stability are measured using linear sweep voltammetry against zinc and lithium anodes. The rate performance and long-term cycling stability of lithium manganese oxide ($LiMn_2O_4$) cathodes are measured against lithium anodes with these current collectors and their performance is compared. These results show which current collector to choose depends on the application and cell chemistry.

Finally, we highlight the utility of these cell designs for studying colour changes in battery cathodes through optical microscopy, as well as changes in the band gap of materials during electrochemical intercalation through diffuse reflectance spectroscopy (DRS) [2]. These guidelines will assist in the design of future optical cells for in-situ measurements and photoelectrochemical energy storage.

Towards *Operando* Secondary Ion Mass Spectrometry Imaging of Lithium Redistribution in Solid-State Lithium-Ion Batteries—Correlation of Structural, Chemical and Electrochemical Characteristics Santhana Eswara, Sayantan Sharma and Tom Wirtz; Luxembourg Institute of Science and Technology, Luxembourg

Innovations in lithium-ion batteries rely crucially on the availability of advanced characterization techniques. High-resolution chemical imaging of low-Z elements e.g., lithium (Li) is often difficult in many conventional chemical analysis techniques such as Energy-Dispersive X-ray Spectroscopy. High-resolution Secondary Ion Mass Spectrometry (SIMS) imaging is a well-known technique for the analysis of all elements including isotopes. For this reason, SIMS imaging is used in numerous studies related to Li-ion battery research. While direct imaging of Li in post-mortem battery components is helpful to understand parts of the degradation mechanisms, a complete dynamic view of the evolution of the Li distribution at high resolution during operation (‘*operando*’) of batteries is required to fully understand the local interfacial processes, charge transport characteristics and the degradation mechanisms. A few reports presenting *operando* Time-of-Flight SIMS imaging of batteries have recently been published [1], but the lateral resolution demonstrated in these reports is not adequate to study local processes that occur at nanoscale.

In order to demonstrate *operando* SIMS chemical imaging with sub-20 nm lateral resolution, we developed a novel *operando* methodology suitable for Focused Ion Beam (FIB)-SIMS imaging and analysis. An in-house designed magnetic-sector mass spectrometer [2] attached to a ThermoFisher SCIOS Ga^+ FIB is used for SIMS chemical imaging. A special *operando* sample holder was designed to enable electrochemical cycling of batteries within the FIB-SIMS instrument. The micromanipulator inside the FIB (typically used for preparing thin lamellae for Transmission Electron Microscopy) is used to contact one of the battery electrodes through the *operando* sample holder and complete the electrical circuit. An external potentiostat is then connected to the instrument to drive the charging/discharging of batteries. The proof-of-concept experiments were performed using $Li|Li_7La_3Zr_2O_{12}|Li$ symmetric half-cells. Galvanostatic cycling was performed *in-situ* inside the FIB-SIMS instrument until the sample failed. SIMS chemical mapping revealed a redistribution of Li during cycling. Lithium rich phases appeared during cycling which likely percolated through grain-boundaries and pores of the solid electrolyte causing a short-circuit failure. These results validate our methodology for *operando* analysis of Li-ion batteries with the possibility to obtain SIMS chemical images with sub-20 nm lateral resolution [3, 4].

This work was funded by Horizon Europe project OPINCHARGE and by the Luxembourg National Research Fund (FNR) through the grant INTER/MERA/20/13992061 (INTERBATT).

Exploring Point Defects in Battery Materials with Electron Microscopy and Multislice Ptcyhography James M. LeBeau; Massachusetts Institute of Technology, United States

In this talk, we will discuss how aberration-corrected scanning transmission electron microscopy (STEM) and multislice electron ptychography can be used to probe the atomic scale dynamics and structure of point defects in materials for battery applications. As a prototypical example, we will report on directly quantifying point defect formation and migration in MgCr2O4. In this system, we observe the dynamics of interstitial formation through STEM imaging, which is found to depend on electron dose and energy. The interstitials are observed to reversibly migrate back and forth from the bulk crystal structure to the interstitial positions. Spectroscopy and ptychography will provide evidence of preferential mass loss of the lighter species, i.e. forming vacancies within the structure.

We will also highlight how phase contrast methods, such as iDPC STEM and electron ptychography, can be used to observe the distortion of cation-anion tetrahedra and octahedral during imaging. For example, with the formation of interstitials in MgCr2O4, the atoms bend away from the mid-plane in response to the presence of charged point defects. Furthermore, we will use the intensities of the point defect positions to infer the exchange with neighboring vacancies or migration deeper into the crystal. Through the depth sensitivity of multislice electron ptychography, we will explore where within the sample the defects are formed by the electron beam, both at 300 kV and 60 kV. Finally, we will discuss how STEM imaging and ptychography provide direct insights into mechanisms of ionic conduction, particularly in non-stoichiometric material.

4:30 PM CH04.11.04

Machine Learning Enabled Operando Optical Microscopy for Determination of Lithium Transport in Battery Electrodes Nadine Kerner[1], Yug Joshi[2,1], Monica Mead[1], Sebastian Eich[1], Roham Talei[1] and Guido Schmitz[1]; [1]Universität Stuttgart, Germany; [2]Max Planck Institute for Iron Research, Germany

Diffusion coefficients of electrode materials are often determined using galvanostatic (GITT) or potentiostatic intermittent titration technique (PITT), electrochemical impedance spectroscopy (EIS) or cyclic voltammetry (CV). However, these methods require special care, as each of their formal derivations use quite restrictive assumptions. As an alternative, a machine learning model is presented to extend a previously proposed optical method of studying lithium transport by operando microscopy. The herein reported model enables the measurement of concentration-dependent diffusion coefficients in a wide solubility range. For this purpose, a python code is developed that determines concentration profiles from RGB images using support vector regression (SVR), a flexible machine learning tool. To evaluate the diffusion coefficient, an inverse Boltzmann-Matano concept is applied. Representing the diffusion coefficient with generalized Redlich-Kister polynomials, concentration profiles are predicted and fit to the measured data. The method is demonstrated here on the example of delithiation of $LiMn_2O_4$, but it can, in-principle, be extended to any other battery material showing significant optical response on lithiation, which most of them do.

4:45 PM CH04.11.05

Expanding the Boundaries—Exploring the Impact of Temperature on Electrochemistry in Liquid Cell Scanning Transmission Electron Microscopy Tim B. Eldred, Katherine M. Stephens, Franklin S. Walden, Nelson L. Marthe, Patrick S. Wellborn and John Damiano; Protochips, United States

In-situ, or operando, transmission electron microscopy (TEM) has proven itself to be an invaluable tool for correlating bulk-scale electrochemical measurements to nanoscale phenomena while simulating real working conditions. The introduction of closed-cell holders allows microscopists to perform liquid experiments isolated from the high-vacuum of the microscope, protecting the sample from the vacuum as well as the microscope from the liquid. These cells, consisting of micro-electromechanical systems (MEMS) based silicon nitride chips (or E-chips) have allowed a variety of experimental stimuli to be introduced, including temperature control and electrostatic potentials.[1-2] This has enabled researchers to make strides in understanding the behavior of batteries, including the analysis of the solid-electrolyte interphase (SEI) layer during lithium-ion battery cycling to dendritic growth and analysis of failure mechanisms at room temperature.[3]

Recent studies have focused on expanding the life cycle and efficiency of automotive batteries in more extreme climates, resulting in the need for these next generation batteries[4] to have their formation, failure mechanisms, and material properties studied at varying working temperatures.[5] As such, the in-situ systems used to study these phenomena must be adapted through modifications of the E-chips, holder, and experimental design, in order to push these systems to similar extremes; in not just the chemical or electrostatic conditions of operation, but also by the full range of temperatures they may experience. By studying these materials in-situ, valuable information can be determined about the structural changes that are reflected in the material performance observed in bulk testing.

In this presentation, we will discuss experimental refinements as well as the hardware and E-chip design improvements that have allowed researchers to push the temperature boundaries during electrochemical testing in operando, as well as the challenges and solutions to working at these extreme conditions. We will discuss the impact of temperature on redox kinetics and electrochemical measurements such as cyclic voltammetry, comparing bulk results to nanoscale experiments to demonstrate the applicability of the in-situ TEM technique to real working conditions. We will additionally discuss the implications of this technique on further expanding the range of real world conditions that users can explore in the microscope, including spectroscopic analysis, experimental stimuli, and sample design.

Imaging the Composition and Structure of Battery Materials at High Resolution and Low Dose Using Cryo-Electron Energy Loss Spectroscopy and Ptychography David A. Muller; Cornell University, United States

Battery materials are by design incredibly sensitive to radiation damage by an electron beam – after all they are designed to allow ion motion in response to an applied electric field, and a high-brightness electron beam can certainly provide strong, localized fields. Cryogenically freezing the sample not only reduces the diffusion of radiation-damage products, but makes it possible to prepare site-specific electron-transparent cross-sections of liquid-solid interfaces such as the electrolyte/SEI/electrode [1]. With advances in direct detector technology, more sophisticated image reconstruction methods have been made practical. Multislice Electron ptychography is a highly-dose-efficient approach [2] to imaging the internal arrangement of lithium ions and vacancies at atomic resolution with 3D information inside battery electrodes. Electron energy loss spectroscopy (EELS) provides chemical information, even in disordered materials. As the dose efficiency of EELS is much lower, we apply non-linear dimensionality reduction methods to reveal the structure, reaction products and chemical gradients inside the SEI layer and in contact with the liquid electrolyte and lithium dendrites.

Work in collaboration with Dasol Yoon, Michael Colletta, and in memory of Lena Kourkoutis who started our projects on the cryoEELS of battery materials.

Direct Observations of Dendrite Growth in Ceramic Electrolytes Cole D. Fincher[1], Colin T. Gilgenbach[1], Rachel D. Osmundsen[2], Christian Roach[2], Michael Thouless[3], W. Craig Carter[1], Brian Sheldon[4], James M. LeBeau[1] and Yet-Ming Chiang[1]; [1]Massachusetts Institute of Technology, United States; [2]Thermo Fisher Scientific, United States; [3]University of Michigan, United States; [4]Brown University, United States

Although solid-state batteries with metal anodes promise to enable safer, higher energy density batteries, metal protrusions (dendrites) grow when charging faster than a critical current density. It is generally believed that dendrites grow when plating-induced stresses exceed that required for fracture of the solid-electrolyte. It is commonly assumed that the threshold stress for failure depends on the electrolyte's fracture toughness—commonly taken as a material constant. However, because the dendrite-electrolyte interface is buried, characterization of dendrite growth has proved challenging. Here, we study plan-view solid-state cells with solid electrolytes thinned to the point of translucency, allowing us to analyze dendrites growing through the electrolyte plane. We develop *operando* birefringence microscopy to directly measure dendrite-induced stresses. During propagation, dendrite-induced stresses appear to evolve with time in a fashion that depends on the current density or dendrite velocity. We find that increasing current densities increase the dendrite velocity. At all times, the measured stress associated with dendrite growth is below the critical stress expected for fracture of the electrolyte—dendrite propagation occurs under subcritical conditions. Cryogenic Scanning Transmission Electron Microscopy (Cryo-STEM) reveals decomposed electrolyte phases at the dendrite tip. This decomposition is associated with a volume contraction. All experiments were conducted on the most electrochemically stable Li-ion conducting solid electrolyte (tantalum-doped lithium lanthanum zirconium oxide). Together, these experiments allow separate study of electrochemical and mechanical phenomena underlying dendrite growth in ceramic electrolytes.

Li-Ion Distribution and Local Structure in the Li-Ion Conductor $LiTa_2PO_8$ Peng Ren and Isaac Abrahams; Queen Mary University of London, United Kingdom

In recent years there has been an increasing interest in lithium ion conducting solid electrolytes for use in lithium batteries, due to safety concerns with the flammable liquid electrolyte system. A new phosphate $LiTa_2PO_8$ (LTPO) has been found with Li-ion conductivity in the order of 10^{-4} S cm^{-1} at room temperature.[1] The crystal structure of LTPO has been identified by Kim *et al.* in space group $C2/c$ with cell dimensions a = 9.716 Å, b = 11.536 Å, c = 10.697 Å and b = 90.04°. The structure contains a framework of corner sharing TaO_6 and PO_4 polyhedra, generating various voids with Li^+ ions distributed over three crystallographically distinct sites.[1] Based on results from a recent neutron diffraction experiment, we have now identified between four and five sites for Li^+ ions in the structure depending on the synthesis conditions. Using a 2-step method for the synthesis of LTPO, we have managed to reduce the grain boundary resistance, yielding a total conductivity of 1 × 10^{-3} S cm^{-1} at room temperature, with an activation energy of 0.35 eV.

Interestingly, although the crystallographic analysis indicates the presence of a single crystallographic position for phosphorous in the average structure, the ^{31}P MAS-NMR data indicate multiple resonances, suggesting a number of different local structure motifs.[2] 2D-NMR and neutron total scattering experiments were conducted to study the local structure. ^{31}P-^{6}Li dipolar heteronuclear multiple-quantum coherence (D-HMQC) experiments reveal a broad ^{6}Li peak made up of at least two Li species that couple with two ^{31}P species, one is coupled to both P species while other Li species is coupled to only one phosphorous. This appears to correlate with our neutron diffraction results which reveal Li^+ ions are disordered over 4 crystallographic sites; one of these sites has relatively short contacts to two neighbouring phosphate tetrahedra, while the other 3 sites neighbour only a single phosphate tetrahedron.

Our analysis of total neutron scattering data on the LTPO system has shown the possibility of accurately establishing the Li^+ ion distribution and local structure. Details of these are presented and the difference between samples prepared using different synthesis routes is discussed in light of the local structure.

Non-Destructive Performance Comparison of Li-Ion 2032 Coin Cells for Extreme Temperature Applications

Shintaro Inaba[1], Alex Dubois[1], Alex Wuttig[1], Simon Ji[2] and Hillary Smith[1]; [1]Swarthmore College, United States; [2]Princeton University, United States

Rechargeable lithium-based coin cells are now commercially available, offering an eco-friendly alternative, but their use is not as widespread. The primary concerns of consumers are safety and reliability in a range of applications. Persistent safety concerns plague lithium-ion battery technology, and batteries of small size are susceptible to rapid heat conduction and physical impacts from dropping and puncturing the battery. Reliability, especially under non-ambient temperature present performance concerns, thus detailed performance tests for coin cells are an urgent matter. We report on a non-destructive, temperature-dependent performance comparison of six different commercially available, rechargeable 2032 coin cell models through galvanostatic cycling: LIR2032 (CT-Energy), LIR2032H (CT-Energy), LIR2032 (EEMB), LIR2032H (EEMB), LIR2032 (LoopaCell) and ML2032 (Maxell). Batteries were cycled over 100 cycles at temperatures ranging from 60°C to 0°C. Performance at room temperature was consistent with the manufacture-provided datasheet for all cells. At high temperatures, all cells except for LIR2032 (EEMB) performed in a stable manner. At cold temperatures, all LIR2032 showed stable performance, yet LIR2032H cells performed poorly. During hot and room temperature cycling we also observed an increase in initial capacity, which may be due to a gradual elimination of concentration polarization between the interface and bulk electrolyte as identified from dQ/dV analysis and EIS. Most cells showed an initial ohmic resistance decrease, then loss of both electrode's active material at mid-cycles, and faradaic rate decrease of cathode until end-cycles. Both XRD results and dQ/dV analysis allowed prediction of electrode composition:LIR cells were identified as LCO/GIC, and ML2032 (Maxell) being LMO/Mg2Si. Results of scanning electron microscopy and energy dispersive spectroscopy will also be presented to observe interfacial reactions that may be causing the initial capacity increase and cell deterioration.

CH04.12.03

A New Air-Free Solution for Li Ion Battery SEM/FIB Characterization by Air-Free Shuttle Binbin Deng and Binbin Deng; Scientific Bridge LLC, United States

Li ion battery has been the most promising solution for power sources for electronics, electric vehicles, and medical devices. Understanding the microstructure of Li ion batteries is critical for designing better performance Li ion batteries. However, Li quickly oxidizes in the air, which makes it impossible to image the original sample surface embedded by an unexpected grown oxide layer during sample transfer. To keep the sample from being exposed to air while transferring from the glovebox to the SEM, the air-free shuttle has been developed. The Air-Free Shuttle is filled with Ar-gas, which prevents materials from being oxidized in the air. When put in the Air-Free Shuttle, the pristine metal surface of Li is protected and keeps its original status during transferring and analysis. Without the protection of an air-free shuttle, the surface structure of the lithium sample shows increased roughness after one minute of exposure to air. At a higher magnification, the differences are distinct. The pattered design guarantees non-obstruction platform working mode for sample handling and analysis, which is no problem for SEM imaging, EDS/EBSD analysis and FIB sample preparation (52° sample tilt). The compact design (50 mm x 100 mm x 40 mm, <400g) makes it fit with most commercial SEM/FIBs. The air-free shuttle is a robust maintenance free, cost-effective solution for Li ion battery microstructure study.

CH04.12.04

A Portable Powder X-Ray Diffractometer (XRD) with the Power of a Conventional XRD System Binbin Deng and Binbin Deng; Scientific Bridge LLC, United States

Powder X-ray Diffractometer (XRD) is an analytical device that is widely used for material characterization in geology, environmental science, material science, biology and mechanical engineering. The traditional XRD is a powerful tool for material identification, but the design is bulky and requires a dedicated space and infrastructure, which limits the efficiency and flexibility of its applications. A newly invented device Illumination XRD combines powerful analytical capability with compact design. It is lightweight and portable. The self-developed software provides quick and robust data interpretation. The high-quality data can be obtained in one minute. A large amount of data analysis demonstrates the device's robust working flow and its capability of precise and accurate identification of structures. The portable design allows Illumination XRD to be used for on-site sample analysis in energy, oil, gas and mining industries, and quality control in manufacturing processes. The outstanding fast analytical power and straight forward data interpretation capability make Illumination XRD an idea device for outreach activities, such as classroom presentations, workshops, public talks and lab visits. Combining analytical power with a portable design is a significant advancement in material analysis technology. It enhances the versatility and efficiency of the application of traditional XRD.

CH04.12.05

Disordered Battery Materials and Systems—Insights via Extended X-Ray Absorption Fine Structure Analysis Zhongling Wang, Amy Marschilok, Esther S. Takeuchi and Kenneth J. Takeuchi; Stony Brook University, The State University of New York, United States

Batteries based on highly ordered intercalation materials such as graphite and lithium cobalt oxide undergo well defined and specific crystallographic changes upon electrochemical cycling and are suitable for characterization via diffraction-based methods. In contrast, conversion batteries based on nanocrystalline materials possess less long-range order and may be too amorphous for diffraction based study. Understanding the local coordination environment of such materials and their evolution upon electrochemical cycling can be very beneficial for the materials designer. This presentation will highlight the benefits of extended x-ray absorption fine structure analysis for determining specific coordination environment changes within disordered battery materials. For example, determination and differentiation between octahedral and tetrahedral coordination sites, idealized and distorted environments (i.e. Jahn-Teller) can be deciphered in a specific way using this approach. As conversion batteries provide the opportunity for higher capacities and incorporation of more earth abundant elements, these methods can help support progress toward a green energy future.

CH04.12.06

Probing Local Conductivity of Crystalline and Amorphous Phases in PEO:LiTFSI Electrolyte Yu-Chi Wang and Chia-Chin Chen; National Taiwan University, Taiwan

Poly(ethylene oxide) (PEO) incorporated with LiTFSI salt has emerged as a cost-effective, chemically stable, and lithium-ion-conductive solid electrolyte. However, the low ionic conductivity (~10^{-6} S/cm) and low transference number (averaged at ~0.1) of it restrict the practical application[1]. To overcome these challenges, a deeper understanding of Li^+ transfer mechanism within PEO:LiTFSI matrix is crucial. Below 60 °C, PEO:LiTFSI tends to crystallize, resulting in the coexistence of crystalline and amorphous phases within it, which respectively impact the ionic conductivity and transference number of the entire electrolyte film. Despite this, the precise effects of these two phases on the ion transport within the overall system have remained unknown.
The coexistence of crystalline and amorphous regions complicates the transport of Li^+, due to their different conductivities[2] and complex distribution. Therefore, to elucidate the transport mechanism, it is vital to characterize the local conductivity values of these two phases, separately. In this study, utilizing two-point probe measurement and finite element simulation, we characterized the local resistance value and corrected the boundary effect, thereby directly determining the local conductivity of the crystalline and amorphous phases, respectively, in the single-layer semi-crystalline $P(EO)_{21}$:LiTFSI electrolyte film at room temperature. Our finding provides insights into the local Li^+ transport pathway within PEO:LiTFSI solid-state electrolyte systems, and offers the potential to address critical issues in lithium-ion battery technology.

Electrolyte for Optimal Low-Temperature Performance in Lithium-Ion Batteries Using $Li_3V_2(PO_4)_3$/C as a Cathode Active Material Yoonju Oh, Seunghyun Song, Man Li and Joonho Bae; Gachon University, Korea (the Republic of)

Currently, it is essential to develop batteries that exhibit stable performance at low temperatures because of their widespread use in various fields, such as polar and space exploration, where reliable operation under frigid conditions is critical. Unfortunately, commercial lithium-ion batteries have poor stability, even at -10 °C. The electrolyte is a crucial factor affecting the low-temperature performance of batteries. In this study, we compared the low-temperature performances of 1 M $LiPF_6$ in DEC: DMC: EMC (1:1:1 in volume) (1 M-COM) and 1 M $LiPF_6$ in EC: DEC: DMC: EMC (3:5:4:1 in volume) (1 M-EDDE) using carbon-coated $Li_3V_2(PO_4)_3$/C (LVP/C) as the cathode active material. The 1 M-EDDE LVP/C half-cell has 43.4% capacity retention, which is approximately three times higher than that of the 1 M-COM LVP/C half-cell at 243 K. Additionally, the diffusion coefficients of the 1 M-EDDE and 1 M-COM LVP/C half-cells are on the order of approximately 10^{-10} and 10^{-11} orders, respectively. However, as the temperature decreased, the polarization of the 1 M-COM LVP/C half-cell became wider than that of the 1 M-EDDE LVP/C half-cell. This study highlights the superior performance of LVP/C half-cells with 1 M-EDDE electrolyte at low temperatures, emphasizing the critical role of the electrolyte in low-temperature applications.

Uncover Transport, Mechanics and Failure in Solid Electrolytes Through Atomic and Dynamic Visualization

Xin Xu; Arizona State University, United States

Solid electrolytes with superior ionic conductivity, fast interfacial kinetics, and high mechanical strength are promising for renewable energy storage and conversion systems such as batteries and fuel cells. However, fundamental mechanisms of charge transport and the related electro-chemo-mechanics are not well understood. In this talk, I will highlight my recent work on two types of solid electrolytes: an oxygen-ion conductor CeO_2 for fuel cells, and a Li-ion conductor $Li_7La_3Zr_2O_{12}$ for solid-state batteries. First, I will present a unique approach to study the charge transport at grain boundaries in polycrystalline CeO_2: a combination of electron holography and atom probe tomography. The atomic visualization of electric fields and chemical species reveals the chemical origins of resistive grain boundaries. These insights suggest chemical tunability of grain boundary transport properties which can potentially benefit the design of low temperature solid-oxide fuel cells, solid-state batteries and sensors. Second, I will discuss the Li intrusion phenomena in $Li_7La_3Zr_2O_{12}$, a failure mechanism in solid-state batteries involving both electrochemistry and mechanics. Using *operando* electron microscopy and statistical analysis, I will discuss the mechanical origins of Li intrusion and highlight the mechanical tunability of electrochemical plating reactions in brittle solid electrolytes. I will also show how surface engineering with ultra-thin 3 nm metallic coatings can significantly toughen solid electrolytes and reduce detrimental lithium intrusions.

Chemo-Mechanical Characterization of V2O5 Single Crystals via Nanoindentation and *In Situ* Lithiation

Victor H. Balcorta, Rachel Lee, Raj S. Patel, Samantha Kotze, Arnab Maji, John Ponis, Christopher Walker, Kelvin Xie, George Pharr, Sarbajit Banerjee and Matt Pharr; Texas A&M University, United States

Certain single-crystal materials have shown great promise as next-generation cathodes of lithium-ion batteries due to their high energy density and structural stability. However, single-crystals have anisotropic mechanical, electrochemical, and transport properties that can affect the performance and durability of the battery that must be careful characterized. Furthermore, the impact of mechanical defects, such as cracks, dislocations, twin boundaries, residual lattice stress, and residual lattice strain remains poorly understood and could result in decreased performance during electrochemical cycling. This study aims to provide such understanding in V2O5 single crystals of different phases (alpha, zeta, and gamma) by probing chemo-mechanical interactions during lithiation/delithiation.

Specifically, this study first characterized nano-scale mechanical properties of these single crystals, including hardness, elastic modulus, and fracture toughness, using Berkovich nanoindentation and micro-pillar compression. Additionally, scanning electron microscopy (SEM), electron backscatter diffraction (EBSD), and focused ion beam (FIB) sectioning were implemented to capture details of crystal reorientation, texture evolution, and stress-induced lattice rotation associated with the nanoindentation process. This study also explored the impact of plastic deformation (accomplished via nanoindentation) on chemical lithiation/delithiation of the V2O5 single crystals through in-situ optical microscopy and RAMAN spectroscopy. Finally, SEM, FIB, and EBSD were utilized to analyze the interactions between lithiation-induced effects and the defects and plastic zones caused by previous loading (via nanoindentation).

Surface Characterization of High-Performance Battery Materials—XPS, AES and TOF-SIMS Insights Sarah Zaccarine, Kateryna Artyushkova and Christopher K. Brown; Physical Electronics, Inc., United States

The development of advanced battery materials relies on a deep understanding of their surface and interface properties. To achieve this, researchers need information about a surface’s physical topography, chemical composition, chemical structure, atomic structure, electronic state, and a description of bonding molecules at the surface. No single technique can provide all these different pieces of information. A comprehensive investigation of a surface will always require several techniques.

This presentation highlights the application of three surface sensitive analysis techniques—X-ray Photoelectron Spectroscopy (XPS), Auger Electron Spectroscopy (AES), and Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS)—in the characterization of battery materials to offer unparalleled insights into the composition and behavior of materials critical for high-performance batteries.

In addition to the advanced characterization techniques available, modern instrumentation also includes sample handling options such as *in situ* heating, cooling, and polarization studies to measure how properties change under various operation conditions. This combination is a powerful suite of analytical tools for the development of battery materials, particularly for analyzing anode passivation layers, solid electrolyte interfaces (SEI), and dendrite characterization. Examples illustrating the application of these techniques will be presented, including lithium chemical mapping from all-solid-state battery materials.

9:30 AM CH04.13.04

Induced Stress Evolution at Argyrodite Sulfide/Li-Metal Interface—Tension or Compression? Changmin Shi[1], Pradeep Guduru[1], Yue Qi[1], Yan Yao[2], Jun Lou[3], Siyuan Song[1], Akshay Pakhare[1], Gregory Pustorino[1], Qing Ai[3], Cristina Lopez Pernia[1], Lihong Zhao[2] and Brian Sheldon[1]; [1]Brown University, United States; [2]University of Houston, United States; [3]Rice University, United States

Argyrodite sulfide (Li_6PS_5Cl) has demonstrated great potential as a solid electrolyte (SE) for high-energy-density all-solid-state batteries (ASSB). However, Li dendrite penetration in Li_6PS_5Cl causes electrical short circuits, which has heavily limited the development of ASSBs using Li_6PS_5Cl. It is evident that Li_6PS_5Cl undergoes interfacial chemical reactions and decomposition when in contact with Li metal, forming a solid electrolyte interphase (SEI).

Currently, there is controversy over whether this chemical-reaction-induced SEI causes compressive or tensile stress at the interface, thereby mitigating or facilitating Li dendrite penetration Li_6PS_5Cl, respectively. To answer this question, a customized multiple-beam Optical Stress Sensor (MOSS) system was used to measure curvature changes that occur are induced by the Li_6PS_5Cl reaction with Li metal. These were evaluated with a finite element modeling to determine the stress. The composition of the SEI was also investigated with XPS and ToF SIMs and compared with predictions from atomistic modeling. The results show that the SEI formation generates tensile rather than compressive stress, which is expected to facilitate Li dendrite propagation. We believe this finding provides critical guidance for cycling ASSBs using Li_6PS_5Cl as a SE and for engineering the interface between Li_6PS_5Cl and Li metal.

9:45 AM CH04.13.05

Investigation of Reactivity and Degradation Mechanisms of Na_2Ndc Organic Negative Electrode Material by TEM and *Operando* XRD Maxandre L. Caroff[1], Carine Davoisne[1,2] and Matthieu Becuwe[1,2]; [1]Université de Picardie Jules Verne, France; [2]Réseau Français pour le stockage électrochimique de l'énergie (RS2E), France

The growing demand for electric batteries poses the challenges of resource scarcity. The use of organic electrode materials could release the strain on metal extraction in addition to being easily recyclable and having low-cost chemically adaptable structures [1].
The sodium salt of 2,6-naphthalene dicarboxylic acid (Na_2NDC) is a promising material as negative electrode for sodium-ion battery owing to its low potential of 0.4V *vs* Na and high-rate capability [2]. Recently, Na_2-NDC was integrated in a sodium-ion hybrid full cell (associated with NVPF) displaying 155Wh/kg after 400 cycles. However, it was shown that both electrolyte and electrode material were degrading during cycling which led to long term capacity fading due to unclear phenomenon [3]. Hence, in-depth investigation of Na_2NDC degradation and electrochemical reactivity during cycling is necessary to improve the cell performance.

Cryogenic Transmission Electron Microscopy (Cryo-TEM) and its associated techniques (electron diffraction, EELS) are powerful tools to provide structural, microstructural and chemical data that can be used to elucidate reactivity mechanisms and identify material and interface degradation **[**4]. Coupled with *operando* X-Ray Diffraction, we carried out investigation on electrode material at different state of charge during the first cycles. Thanks to this approach, we observed structural, microstructural and morphological changes during cycling allowing us to understand the degradation mechanisms involved.
To understand the impact of the structure on Na_2NDC electrochemistry, the synthesis procedure was adapted to obtain amorphous particles. Their electrochemical behaviour was then investigated and suggested electrochemical performance can be modulated and improved as a function of textural properties.

Frontier Challenges with Characterization of Solid-State Batteries Kelsey B. Hatzell; Princeton University, United States

Lithium reservoir-free solid state batteries can offer exceedingly high energy densities for a range of emerging applications related aviation and electric vehicles. However, reversible operation of reservoir-free cells are plagued by a range of degradation mechanisms. The morphology of lithium metal film and subsequent evolution during operations can be highly variable and is dependent on the type of solid electrolyte, current collector, and operating conditions (current density, temperature, pressure, etc.). Tailoring studies which can capture cathode an anode dynamics in a solid state batteries simultaneously is challenging because of the diverse array of materials used in a battery and the subsequent resolutions (temporal and spatial) need to understand and unravel dynamics in a solid state batter. This talk will highlight a few examples of ongoing challenges with x-ray, neutrons, and electrons for advanced operando characterization of solid state batteries. Combining multiple techniques (e.g. spectroscopy with imaging) can provide value but requires careful design of operando cells. A discussion of the differences in cell design for neutrons and x-ray wills also be included.

11:00 AM CH04.14.02
***In-Situ* Quasi-Simultaneous Neutron and X-Ray Tomography of Current Collector-Solid Electrolyte Interfaces in Anode-Free Solid-State Batteries** Maha Yusuf[1,2], Alessandro Tengattini[3,4], Anna Fedrigo[3], Lukas Helfen[3], Ove Korjus[3], Patrice Perrenot[5], Mohd Shaharyar Wani[1], Claire Villevieille[5] and Craig Arnold[1,2,6]; [1]Princeton University, United States; [2]Andlinger Center For Energy And Environment, United States; [3]Institut Laue-Langevin, France; [4]Université Grenoble Alpes, France; [5]Université Grenoble Alpes, Université Savoie Mont Blanc, CNRS, France; [6]Princeton, United States

Anode-free solid-state batteries (AF-SSBs) consisting of a metallic current collector (CC) (e.g., stainless steel) as the anode are a promising next-generation battery technology for sustainable electric vehicles (EVs).[1] In comparison to conventional Li-ion batteries, AF-SSBs can potentially provide high energy and power densities, improve battery safety and recyclability, and lower manufacturing costs.[2] However, they suffer from significant anode/interfacial instabilities that have impeded their practical realizations.[3] Particularly, a key challenge facing AF-SSBs is poor chemo-mechanical stability of the CC|solid electrolyte (SE) interface.[3-4] More specifically, the 3D morphological behavior of the CC|SE interface and bulk SE upon Li plating is unknown. The localized and buried nature of the CC|SE interface makes it extremely challenging to characterize.[5]

In this work, we leverage the sensitivity of neutrons to Li and X-rays to metallic CC to conduct in-situ 3D characterization of interfacial degradation of CC|SE interface in AF-SSBs using quasi-simultaneous neutron and X-ray micro-computed tomography (μCT). Here, we used the word "quasi" as we conducted X-μCT first, then a high-resolution neutron-μCT from the exact same sample location at the same imaging beamline. Weperformed our experiments at the NeXT-Grenoble beamline[6] at Institut Laue-Langevin, France. Our effective spatial resolution for the neutron-μCT was ~ 5 um — state-of-the-art in the world. We imaged three batteries in the following states: (1) pristine, and after plating at (2) low current density (0.5 μA) and (3) high current density (5 μA). High current density was chosen as it results in high overpotential, leading to Li dendrite formation during battery cycling.

Our X-μCT data shows interfacial contact loss between the stainless steel (SS) CC and the Li_6PS_5Cl electrolyte as well as void formation at the CC|SE interface. Additionally, our X-μCT data reveals pre-existing cracks in the SE pellet in the pristine cell. Though the cracks in the pristine cell were smaller as compared to those observed in the cells cycled at low and high current densities. Using the neutron-μCT data, we are characterizing the 3D morphological behavior and spatial heterogeneities of plated Li on CC at low and high current densities. Overall, these results will help us understand the chemo-mechanical instabilities of the CC|SE interface caused by poor Li^+ ionic transport. We believe these insights will guide the design of chemo-mechanically stable CC|SE interfaces for AF-SSBs for sustainable EVs.

Correlative SEM/AFM/EDS Microscopy—Combining High-Performance Methods for Nanoscale Measurements

Hajo Frerichs, Marion Wolff, Lukas Stuehn, Sebastian Seibert, Darshit Jangid and Christian H. Schwalb; Quantum Design Microscopy, Germany

In modern material characterization, the combination of analytical methods for qualitative and quantitative evaluation has become essential. Correlative microscopy, in particular, has emerged as a potent technique for acquiring complementary information simultaneously. This study focuses on the integration of two of the most potent microscopy techniques – SEM (Scanning Electron Microscopy) and AFM (Atomic Force Microscopy) – to gain novel insights into the micro- and nanoscale features of samples with the highest resolution. [1-2] However, coupling these two methods presents significant challenges, particularly in terms of the required instrumentation. Typically, SEM and AFM are used separately, leading to difficulties in achieving true spatial correlation of the obtained results.

This study introduces the potential of a combined inspection device – the FusionScope – that seamlessly combines SEM and AFM for the characterization and process control of micro- and nanostructures. Utilizing self-sensing piezoresistive cantilever technology for the AFM scanner, we achieved complete electrical measurement of the cantilever deflection signal. [3] A shared coordinate system between SEM and AFM enables the simultaneous acquisition of data directly at the region of interest. This capability is further enhanced by the integration of Energy Dispersive X-Ray Spectroscopy (EDS), which allows the direct correlation of EDS and AFM data with nanometer precision. Traditional optical methods fail at this point, a challenge effectively addressed by the SEM/AFM combination.

We will present a series of novel case studies demonstrating the advantages of this innovative tool for interactive, correlative *in-situ* characterization of various materials and nanostructures at the nanoscale using SEM and AFM. Additionally, we will showcase how EDS integration advances measurement capabilities by correlating chemical information with AFM data. Specifically, we will present results from the *in-situ* characterization of nanowires, 2-D thin film materials, and multilayer samples, highlighting their electrical, magnetic, topographic, mechanical, and chemical properties. The SEM facilitates the easy localization of single or multiple surface features, while *in-situ* AFM characterizes various "visible" and "hidden" surface and bulk properties. EDS integration further enhances the ability to link chemical information directly to AFM data.

Moreover, we will briefly discuss advanced tip fabrication techniques, such as focused electron beam induced deposition (FEBID), to illustrate how correlated measurements can benefit from fine-tuning the tip properties. [4] Given its broad range of applications in the inspection and process control of various materials and components, we expect that this new inspection device will become a key tool for future correlative SEM, AFM, and EDS analysis.

The characterization of mechanical and electrical properties linked together with EDS data can give innovative insights into the properties of materials in many research fields like material development, battery research or life science. Our SEM/AFM/EDS tool can provide detailed insights into the properties, thereby advancing our understanding and development of next-generation materials.

Comprehensive Approach to Material Design and Testing Enables Rapid Development of Electrolyte Formulations Liu (Amy) Zhou, Monica L. Usrey, Sarah L. Guillot, Brian Kerber, Tobias Johnson, Peng Du and Suresh Sriramulu; Orbia Fluor & Energy Materials, United States

Lithium-ion batteries are complex systems with multiple components that must be optimized to obtain the necessary performance capability. Conventional electrolytes limit the long-term cycling stability, high voltage stability, and thermal stability.[1] As a consequence, there is significant research in the battery field towards optimizing high-stability electrolyte formulations by developing new solvents, additives, and/or salts. In order to rationally design better electrolytes, a fundamental understanding of how electrolyte components drive specific performance attributes, including bulk reactivity and surface interaction mechanisms, is required.

Orbia Fluor & Energy Materials has developed a suite of tools and best practices optimized to gain this type of fundamental electrolyte understanding. As experts in the design and synthesis of fluorinated materials, we specialize in the synthesis of fluorinated electrolyte component materials, including solvents and additives. We use a comprehensive approach that combines rigorous performance testing with complete post-test analysis of the electrolyte, electrodes, and gas to quantitively track salt, solvent and additive reaction pathways and solvation behavior. X-ray photoelectron spectroscopy (XPS), scanning electron microscope (SEM), energy dispersive X-ray (EDX) analysis, and X-Ray diffraction analysis (XRD) are utilized for active material and surface layer analysis. Gas composition is investigated by gas chromatography (GC) with a thermal conductivity detector (TCD). Bulk electrolyte composition is analyzed by nuclear magnetic resonance (NMR) spectroscopy. Based on the results, we optimize electrolyte formulations for specific cell chemistries and performance requirements based upon our rigorous development process.

In this presentation, we will detail our process for elucidating performance-function relationships as applied to a new highly fluorinated additive (OS6), a new fluorinated solvent (403), and a popular $LiPF_6$ salt alternative (LiFSI). This presentation will show how these principles and practices can be broadly applied in the development of novel advanced functional electrolytes.

11:45 AM CH04.14.05

***Operando* Observation of Heterogeneous Electrochemical Reaction in Single-Crystal $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ Particles Using Full-Field Transmission X-Ray Spectromicroscopy** Hideshi Uematsu[1,1,2], Nozomu Ishiguro[1,2,1], Kosuke Kawai[3], Yuhei Sasaki[1,1,2], Oki Sekizawa[4], Masashi Okubo[3] and Yukio Takahashi[1,1,2]; [1]Tohoku University, Japan; [2]RIKEN SPring-8 Center, Japan; [3]Waseda University, Japan; [4]Japan Synchrotron Radiation Research Institute, Japan

Single-crystal $LiNi_xMn_yCo_{1-x-y}O_2$ cathode active materials (NMC) have attracted attention for their superior cycle life and structural stability over conventional polycrystalline NMC. The disadvantage of the single-crystal NMC is that Li^+diffusion path is longer than that of polycrystalline NMC, leading to poor rate capability [1]. To address this issue, observing the electrochemical reactions and Li+ diffusions in the particles and the relationship with the particle morphology under battery working conditions is crucial. *Operando* full-field Transmission X-ray Microscopy (TXM)–X-ray Absorption Near Edge Structure (XANES) technique is a promising tool for visualizing chemical state distribution changes of the target materials [2]. In addition, combined with computed tomography (CT) methods, the three-dimensional reaction distribution can be obtained. In this study, we have investigated the Ni valence distribution of single-crystal $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ (NMC622) during the working condition of a lithium-ion battery cell using *operando* TXM–XANES and CT measurement. We have designed a dedicated electrochemical cell for multi-modal X-ray measurements, including transmission-XAFS spectroscopy, two-dimensional X-ray imaging, and CT measurements. Two-dimensional (2D) and three-dimensional (3D) Ni valence distribution of single-crystal NMC during voltage operations were observed to investigate the relationship between the reaction behavior and the particle morphology.

We developed an *operando* electrochemical cell that has glassy-carbon X-ray transmission windows. The electrode slurry was prepared by mixing NMC622, carbon black, and PVDF binder at a weight ratio of 5:3:2 in NMP solution. The slurry was applied on a 10 μm Al foil. The electrode in the field of view for CT measurement was formed into a columnar shape using the focused ion beam process. The *operando* cells, including Li foil and polyethylene separator, were assembled using electrolyte (1 M $LiPF_6$ in EC:DEC 1:1 v/v%) in a glovebox filled with Ar.

TXM–XANES measurements were performed at SPring-8 BL37XU (Hyogo, Japan). In 2D TXM–XANES measurements, absorbance images were acquired at 60 points from 8200 to 8450 eV including Ni *K*-edge, with an exposure time of 1 s. We performed 2D TXM–XANES measurements at the initial, 3.76, 4.00, and 4.30 V vs. Li/Li^+charge state. Then, we performed TXM–CT measurements at eight energy points from 8344 to 8354 eV with an exposure time of 35 s while holding at 4.30 V vs. Li/Li^+. The projection images were collected in the range of -65° to 65°. By stacking the absorption images and CT reconstructed data sets over energy direction, we obtained spatially resolved 2D and 3D XANES data, respectively. We used curve-fitting analysis to extract the XANES peak energy related to the Ni valence.

From the 2D Ni valence distribution, it was successfully observed that the particles reacted from the surface with increasing voltage. Even when charged at 4.30 V vs. Li/Li^+, the electrode was in a heterogeneous Ni valence state between and within particles. The 3D Ni valence distribution showed that the reaction propagates from the particle closest to the Li metal. Then, we analyzed the distance from the Li metal, the mean and deviation of Ni valence, and the surface area/volume ratio of each particle. The results showed that the particles reacted during the charging process tended to be in a heterogeneous Ni valence state and had a relatively large surface area/volume ratio. Analysis of the Ni valence distribution from the particle surface showed that the Ni valence gradient around the surface ~0.5 μm was larger than the gradient inside the particles.

Operando Gas Analysis to Unpin the Root Reactions Triggering Degradation in NMC-Graphite Cells

Bernardine L. Rinkel[1], J. Padmanabhan Vivek[2], Antonia Kotronia[2], Liam Lu[2], Nuria Garcia-Araez[2] and Clare P. Grey[1]; [1]University of Cambridge, United Kingdom; [2]University of Southampton, United Kingdom

The evolution of gases from batteries is a consequence, and also, a trigger of degradation, as well as an important safety issue. Here we show that the combination of operando gas analysis methods and advanced NMR measurements brings new understanding on previous discrepancies about the interpretation of the mechanism of degradation of NMC-graphite cells [1]. Shao-Horn and coworkers identified the formation of VC from EC dehydrogenation on NMC electrodes [2], whereas Berg, Gasteiger and coworkers observed the evolution of gases (CO_2, CO and O_2) as a result of oxygen loss from NMC [3,4]. Here, we demonstrate that both reactions indeed occur as two distinct pathways of NMC degradation at low and high potentials, respectively, and show that the formation of water as co-product in the second pathway leads to a complex chain of side-reactions initiated by the hydrolysis of the salt ($LiPF_6$) or co-solvent (DMC) [1].

The formation (or re-formation after disruption) of the graphite SEI also involves the formation of gases (primarily, C_2H_4 and CO), but detailed gas analysis comparing reactions in half-cells and full cells with an inert $LiFePO_4$ electrode (which does not consume or produce gases) reveal that lithium plating on graphite can, unexpectedly, lead to gas consumption reactions [5]. This, in turn, also shows that gases can be reactants, as well as products, of SEI formation reactions.

Finally, methodologies to explore and rank the stability of the graphite SEI against various disrupting degradation products, which currently limit the lifetime of NMC-graphite batteries, will also be discussed [6].

Unraveling the Structure and Electrochemical Mechanism in $TiNb_2O_7$ via *Operando* Studies and Theoretical Calculations Siddhartha Nanda, Doosoo Kim and Hadi Khani; The University of Texas at Austin, United States

Understanding the fundamental charge storage and conversion mechanism is of utmost important for developing and designing energy storage devices with exceptional electrochemical performances. In the quest for anodes, graphite and silicon are favored in the high-energy density application. However, they face challenges like overpotentials and lithium plating at high current densities. Recently, Nb-based oxides with a Wadsley–Roth crystallographic shear structure have been proposed as new anode materials for high-energy and high-power lithium-ion batteries (LIBs). The insertion of Li ions into Nb-based oxides mainly occurs at a voltage of about 1.6–1.7 V vs Li^+/Li, preventing the electrolyte decomposition and lithium-dendrite formation. Among this class of materials, $TiNb_2O_7$ (TNO) is the most promising. Its theoretical capacity is 387.6 mAh g^{-1} due to multielectron redox reactions involving several redox couples (Ti^{4+}/Ti^{3+}, Nb^{5+}/Nb^{4+}, Nb^{4+}/Nb^{3+}).

Unraveling the charge storage mechanism in the TNO is a challenging task because of complex crystal structure and the similar potentials for redox reactions of the transition metals. To investigate this a combined approach of experimental and theoretical analysis has been conducted.

Reversible charge–discharge capacity of the as-prepared TNO measured in a galvanostatic mode in the 1.0–3.0 V range at the 0.1C rate was 250 mAh g^{-1}. Cyclic Voltammetry during lithiation shows one large broad peak between 1.2V to 1.8V (vs Li^+/Li) which corresponds to multiple reduction reactions of Nb^{5+} and Ti^{4+}, because Ti 3d and Nb 4d states overlap in energy.

Operando Raman experiment reveals the order of redox reactions happening between Ti^{4+} and Nb^{5+}. In the uncycled state, the Raman peaks at 998 cm^{-1} and 884 cm^{-1} are assigned to edge shared and corner shared NbO_6 octahedra. Similarly in the mid frequency region, the strong peaks at 647 cm^{-1} and 538 cm^{-1} are assigned to edge shared and corner shared TiO_6 octahedra. As soon as the discharge starts, the peak corresponds to corner shared NbO_6 disappears and the peak corresponding to edge shared NbO_6 undergoes red shift indicating the reduction of Nb^{5+}/Nb^{4+} in the edge sharing octahedra site. At the same time both the peaks for TiO_6 undergo red shift confirming the reduction of Ti^{4+}/Ti^{3+}. At around 1.5V (vs Li^+/Li), the peak position for edge sharing NbO_6 remain the unchanged, while the peak correspond to corner sharing NbO_6 keeps undergoing red shift revealing the further reduction of

$Nb^{4+/3+}$ at the corner shared octahedra site. On the other hand, almost all the peaks corresponding to TiO_6 disappear starting at 1.7V and remain the same till the end of discharge. Quantum computational calculation has been performed to study electronic structure and to calculate the Raman modes with DFT using PBE functional. To understand the Raman behavior and structural changes, in situ X-Ray diffraction has been performed. From Rietveld refinement, 5 distinct transitional metal sites (M1-M5) were identified. It has been observed that with the lithiation of $TiNb_2O_7$, the M5 site which has lowest Nb^{5+} occupancy and hence predominantly occupied by Ti^{4+}, undergoes severe distortion. It can be comprehended that, due to this large distortion, the Raman peaks have disappeared once Ti^{4+} reduces to Ti^{3+}. The refinement reveals the phase changes which supports our operando Raman analysis.

2:15 PM CH04.15.03

Understanding Crystal and Electronic Structure of Battery Electrode Materials Using *In Situ,* Variable-Temperature SQUID Magnetometry Joshua Bocarsly; University of Houston, United States

Designing the next generation of high-performance rechargeable batteries will require a detailed understanding of the electrode materials. In particular, the changes in crystal structure and electronic structure experienced by the electrodes during charge and discharge directly control the voltage, capacity, and reversibility of the cell. Therefore, there has been great interest in the development of new tools to efficiently characterize these processes. Here, we demonstrate a new *in situ* variable-temperature SQUID magnetometry probe for electrochemical cells, allowing for the quantitative monitoring of electrode reduction/oxidation in a functioning battery. This probe can be used to continuously measure the room-temperature magnetic moment of a charging and discharging battery cell as the metal oxidation states (and therefore number of unpaired electrons) changes and can also be used to obtain full variable-temperature magnetic data down to 2K at discrete points of charge without battery disassembly. This technique provides quantitative measurements of transition metal reduction/oxidation while also revealing electronic structure transitions including charge ordering and insulator-metal transitions. We employ *in situ* SQUID magnetometry alongside *in situ* high-resolution synchrotron diffraction (beamline I11, Diamond Light Source) to understand the simultaneous evolution of crystal and electronic structure in Nickel-rich battery electrodes, revealing bulk irreversibility in the first charge cycle. Furthermore, we introduce new open software tools that make it easier to process, interactively visualize, and automatically analyze the large sets of data produced by these *in situ* techniques.

***In Situ* Electrochemical Raman Spectroscopy of MXenes in Confined Electrolytes** Kateryna Shevchuk, Kyle Matthews, Ruocun Wang and Yury Gogotsi; A.J. Drexel Nanomaterials Institute, United States

MXenes, a large family of two-dimensional materials, have attracted interest due to their large chemistry space and diverse chemical, electrical, mechanical, and optical properties. MXenes follow the general formula $M_{n+1}X_nT_x$ (n = 1-4) with M representing an early transition metal, X—carbon and/or nitrogen, and T—surface terminations (=O, –OH, and –F). In particular, MXenes' metallic conductivities and redox-active surfaces make them attractive for electrochemical energy storage. Like with many other 2D materials, Raman spectroscopy has proven to be a crucial tool for MXene characterization. More recently, in situ Raman was used to elucidate structural changes in MXene electrodes during electrochemical cycling with a subset of aqueous electrolytes. Confined electrolytes (water-in-salt, PEG, etc.) have shown promise in various electrochemical systems, with recent results pointing to new charge storage mechanisms in MXenes. Further exploration is needed to understand the effect of the cations, anions, and concentrations of confined electrolytes on charge storage mechanisms. This work focuses on using in situ electrochemical Raman spectroscopy to analyze different confined electrolyte systems in MXene cells. The findings demonstrate the potential of using MXenes in aqueous electrochemical devices.

Of Density and Destiny—Progress and Limitations of Acoustic Analysis in Battery Systems Daniel Steingart; Columbia University, United States

The conservation of mass and charge within a closed-form electrochemical energy cell (”battery”) is fundamental to our standing of chemical transport and reaction kinetics with a system. Since the volume of a battery must be constrained (though not conserved, necessarily), the density and density distribution of the evolving battery must contain state information about the system. In this talk, I will discuss our group’s effort in uncovering and exploiting this perspective to understand better battery state of charge, state of health, and chemo-structural evolution and heterogeneity.<!-- notionvc: 266a4ebb-ae2d-427f-839d-11e13a53418a -->

Charge Photometry—A High-Throughput Tool for Operando Studies of Battery Electrodes Akshay Rao, Clare P. Grey, Alice Merryweather and Christoph Schnedermann; University of Cambridge, United Kingdom

In this talk I will introduce Charge Photometry, a technique we have recently established [1-3]. Charge photometry is a optical light scattering microscopy technique that visualizes state-of-charge changes in individual active particles during battery cycling. It exploits the principles of optical interference reflection microscopy to detect scattered light from the active particles. Ion insertion and extraction in the active particles give rise to changes in the detected optical contrast, reporting on the local state-of-charge. Critically, this universal principle means that the charge photometry is agnostic to the underlying battery chemistry and can be applied to a wide range of materials.

I will show examples of how Charge Photometry can be used to gain insights into the mechanisms on charge and discharge within single particles or across the electrode, the nature of phase changes at the single particle level, determine rates of ion diffusion at the single-particle level, monitor degredation of eletrodes down to the singlet particles level and understand electrode-level charge heterogeneity between active particles.

4:15 PM CH04.16.03
***Operando* Thermal Wave Sensing of Lithium Dynamics in Architected Battery Electrodes** Aaron Khan, Anton Resing, Joerg G. Werner and Sean Lubner; Boston University, United States

The quest for optimizing the balance between power density and energy density has led many researchers to explore new battery chemistries and geometries. However, the increasing complexity of these systems presents significant challenges in experimental validation, particularly in non-invasively measuring the subsurface properties of electrochemically active, optically opaque systems during operation. To address this challenge, we are employing thermal wave sensors (TWS) on representative next-generation 3D architected battery electrodes. Using minor surface temperature perturbations, TWS allow for virtual probing of opaque, multi-layered systems during cycling. Unlike optical techniques that require high-energy x-rays to penetrate such systems, relatively small heat pulses readily permeate any interconnected system.

At its core, TWS measure the thermal transport properties of a sample with spatial resolution. These properties can be correlated with any of numerous factors that influence thermal transport. However, due to the sensitivity of TWS to a wide array of properties, careful modeling and calibration are required to discern which observed effects are attributable to changes in the property of interest. Applying TWS to 3D batteries, we aim to model and validate lithium transport through low-tortuosity, interdigitated electrodes. TWS also have the potential to detect morphological and chemical defects caused by cycling, such as pulverization, cracking, interfacial separation, lithium plating, and dendritic growth. This novel sensing approach can support development of novel, more efficient battery designs in the future, and is adaptable to other energy storage systems such as fuel cells and thermal energy storage materials.

4:30 PM CH04.16.04
Understanding the Mechanical Dynamics of Lithium-Metal Battery Formation Protocols Using *Operando* Spatially-Resolved Ultrasound Aamani Ponnekanti[1], Gunnar Thorsteinsson[1], David Wasylowski[2] and Daniel Steingart[1]; [1]Columbia University, United States; [2]RWTH Aachen University, Germany

Formation, the initial cycles of an SEI-forming battery system, is well understood to affect the cycling behavior of the system. This is particularly crucial for anode-free lithium metal batteries due to the significant effect of Li plating morphology and SEI on long-term cyclability. Low-cost, operando tools that spatially map heterogeneities are important for the study and validation of formation protocols. Here, we use spatially-resolved ultrasound transmission and reflection during formation to study variations in gas formation and morphology of Li metal anode-free cells as a function of temperature, pressure, and current density. These non-invasive results are validated with ex situ optical and SEM imaging, and XPS is used to determine the SEI speciation. Formed cells underwent increased-rate cycling coupled with one-dimensional acoustics to understand the effect of formation protocol on mechanical and electrochemical cycling performance.

Advanced Nanoindentation Assisted Acoustic Characterization Techniques for Battery Materials Antanas Daugela[1], Jurgis Daugela[2,1] and Maria Daugela[1]; [1]Nanometronix LLC, United States; [2]Johns Hopkins University, United States

Monitoring of acoustic waves during nanoindentation has been attracting the attention of material scientists since

the inception of nanomechanical test instruments. The conventional acoustic wave signal treatment via RMS or integrated energy values proved that quantitative acoustic wave properties correlate well with the local contact materials‘ phenomena such as yield point initiation for W(100) [1, 2], crystolograpic planes for Sapphire [3], phase transformations on SMA, and thin film fracture modes. A nanofatigue phenomenon can be observed on ultrasonically excited thin films by examining the resulting multi-cycle nanoindentation loading-unloading curves [4]. However, the true potential of the acoustic characterization method is unleashed in a synergy of joint time-frequency domain signal decomposition and machine learning [5].
The Transfer Learning is a subclass of Machine Learning. It is utilized in this work for acoustic signal classification of nanoindentation assisted ultrasonic nanofatigue tests. Both passive and active acoustic monitoring can be conducted during nanoindentation with the integrated utrasonic tip [6].
The status of Lithium-ion baterry components such as uncharged, progresivelly charged can be characterized by the nanonofatigue cycles and corresponding acoustic signatures classified by the Transfer Learning.

Realtime Battery State of Health Diagnosis via Sensing of Cell Thermal Conductivity Tensor Mohammad Shoghi Tekmedash, Rituparna Mohanty and Amin Reihani; Rutgers, The State University of New Jersey, United States

Real-time state-of-health (SOH) and state of safety (SOS) diagnosis of battery cells is crucial for applications in electric vehicles as well as efficient recycling or repurposing of aged cells. We present a novel approach for SOH and SOS estimation by sensing the thermal conductivity tensor of lithium-ion battery (LIBs) cells using a thin-film sensor mounted on the exterior surface of a cell. Our method captures the highly anisotropic thermal conductivity of LIB pouch cells, which present a significantly higher thermal conductivity in the in-plane (x and y) direction compared to the cross-plane (z) direction due to the presence of multilayer internal structure.
The key mechanisms of LIB degradation including lithium plating, dendrite formation, solid electrolyte interphase growth, structural decomposition, and transition metal dissolution are all expected to alter one or more elements of the thermal conductivity tensor unevenly. Therefore, a radiometric measurement of thermal conductivity tensor elements can be used as an indicator of structural and compositional changes inside the battery, and with an appropriate calibration can be employed for SOH and SOS estimation. This correlation provides a non-invasive, rapid, and reliable diagnostic tool, enhancing real-time monitoring of remaining useful life of the cell and early detection of battery failure.
Our thin-film sensor consists of a 45 nm-thick Pt film deposited using electron-beam evaporation on a 25 μm-thick flexible thermally-conductive polyimide film. Subsequently, the Pt film was patterned to produce three serpentine-shaped resistors with dimensions on the order of 1 mm^2 and resistances in the range of 1-10 kohm. These three resistors were arranged in an L-shaped architecture with the first resistor placed at the center, the second resistor displaced in the x-direction, and the third resistor displaced in the y-direction by a few millimeters. Each of the resistors can act as both a local heater and a thermometer. For measurement of diagonal elements of thermal conductivity tensor, we employed the following approach. The central resistor deposits a localized modulated

heat input while the temperature gradients established in *x*, *y* and *z* directions are measured simultaneously by conducting temperature measurements on all three resistors. Subsequently, using the measured temperature gradients, we look up a calibration dataset generated by conducting a series of finite element heat conduction simulations. By interpolating the calibration dataset, we obtained the diagonal values of thermal conductivity tensor. Next, to demonstrate the feasibility of the current sensor for LIB state estimation, we conducted charge/discharge cycling on a nickel-manganese-cobalt (NMC) LIB cell and showed that a correlation exists between the SOH and the ratio of in-plane to cross-plane thermal conductivity. The proposed non-invasive and cost-effective sensing technique aims to provide information on the internal structure and composition of battery cells which can be incorporated into battery management systems for online SOH and SOS estimation.

Elastic Strain Effects on Li-Ion Conductivity in LiPON Solid Electrolyte Subhash Chandra and Bilge Yildiz; Massachusetts Institute of Technology, United States

The solid-state lithium-ion batteries holds a promising future for high energy density applications. In last decade, there have been lot of progress in development of fast lithium solid ion conductors. However, the stress generated at the solid-state interfaces dues to (un)desirable (electro)chemical reactions can lead to build of large local stresses, which could go as high as 10s of GPa. [1] The electro-chemo-mechano coupling to the performance of these batteries is an emerging field enabling us to elucidate the strain effects. The mechanical strain coupling of oxygen ion transport is relatively widely known in solid oxide fuel cells (SOFCs) community, where 4 % elastic strain is could change ionic conductivity by ~4 orders of magnitude. [2] On the other hand, it is relatively new for solid Li-ion conductors with a few earlier studies. [3], [4], [5], [6], [7] In this study, we introduce a custom 3-point bending to apply elastic strain on model systems and simultaneously characterize using electrochemical techniques. We studied model lithium phosphorous oxynitride (LiPON) solid electrolyte for strain effects on Li-ion conductivity. Our data shows that the conductivity of LiPON enhances ~15 % with only ~0.4 % tensile strain. This is remarkable because, given the elastic constant of LiPON of ~77 GPa [8], and interfaces in solid state cells could experience local tensile stresses as of the order of >3 GPa [1], this means that strain of even >4% becomes relevant for LiPON. With addition of the fact that for typical ion conductors' ionic conductivity could experience an exponential dependence on the strain [9], we could expect much larger local Li-ion conductivity modulation at the interfaces of all solid-state batteries utilizing LiPON as solid electrolyte.

Acknowledgements: The work is supported by the Mechano-Chemical Understanding of Solid Ion Conductors, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Science, contact DE-SC0023438. This work was carried out in part through the use of MIT.nano's facilities. We would also like to acknowledge Yen-Ting Chi and Andrew I Ryan for helpful feedback for designing the experiment platform.

Advanced X-Ray and Electron Based Techniques for Material and Cell-Level Battery Analysis

Zijun Wang[1], Simon Bates[1], Tim Bradow[1], Meredith Shi[1], Lee Daniels[1], Angela Criswell[1] and Hikari Takahara[2]; [1]Rigaku Americas, United States; [2]Rigaku Corporation, Japan

Rigaku will discuss its newly developed instruments and approach for Next-Gen battery study at both material and cell level. It includes mechanism study, degradation analysis using XES, XRF, XCT, XRD, and electron diffraction. This includes aspects that have been previously overlooked by researchers, such as the spreading of diffracted peaks in 3D reciprocal space from cycled cathode materials. Additionally, some techniques that were once only possible with synchrotron sources have now been miniaturized into lab-based instruments, offering comparable data quality (lab-based XES).

CH04.17.03

New Technological Advances Enable Portable Powder X-Ray Diffractometer to Collect Data in Seconds

Binbin Deng and Feng Shen; Scientific Bridge LLC, United States

The Illumination Powder X-ray Diffractometer (XRD) is an innovative tool in material characterization by merging high analytical performance with exceptional portability and speed. Traditional XRD systems, while effective in identifying material structures, are large, immobile, and require dedicated infrastructure, making them impractical for field use or smaller laboratories. This limits their application to stationary setups, restricting versatility and making real-time, on-site analysis challenging.

The Illumination XRD overcomes these limitations by offering a lightweight and compact design that allows for easy transport in various environments. Its portability opens a wide range of applications that were previously inaccessible to traditional systems. Researchers and professionals can now carry the device directly to the field or manufacturing sites for immediate material analysis, eliminating the need for transporting samples to a central laboratory. This makes it particularly useful in industries like energy, oil, gas, and mining, where on-site decision-making based on rapid data collection is critical for operational efficiency.

One of the key features of the Illumination XRD is its ability to deliver high-quality data within seconds. The Illumination XRD is designed for rapid data collection with accuracy. This fast data acquisition is supported by advanced technology and self-developed software, which together enable real-time data processing and robust interpretation. This speed is essential for industries requiring quick material identification to optimize processes, improve safety, or ensure product quality.

Beyond its industrial applications, the Illumination XRD is highly beneficial for educational and outreach purposes. Its portability and ease of use make it a valuable tool in classrooms, workshops, and lab visits. Students and attendees can experience hands-on demonstrations of material characterization, making it a perfect fit for educational outreach programs and public engagement. Furthermore, the device's intuitive interface and software reduce the learning curve, allowing non-experts to operate it with minimal training, thereby broadening its accessibility.

Combining speed, portability, and precision, the Illumination XRD not only addresses the challenges of traditional XRD systems but also enhances the efficiency and flexibility of material characterization across a range of industries and applications. This advancement marks a significant leap forward in the field of X-ray diffraction, empowering researchers and professionals with a versatile, portable solution capable of delivering rapid, high-quality data in any setting.

CH04.17.04

An Autonomous Platform for Electron Paramagnetic Resonance Spectra Shengchun Wang[1], Shufei Zhang[2], Manuel Tsotsalas[3], Timothy Cernak[1], Yi Luo[3] and Aiwen Lei[4]; [1]University of Michigan–Ann Arbor, United States; [2]Shanghai Artificial Intelligence Laboratory, China; [3]Karlsruhe Institute of Technology, Germany; [4]Wuhan University, China

The comprehensive characterization of spin species continues to be a formidable challenge in the fields of chemistry, materials science, and biology. Traditional methods for Electron Paramagnetic Resonance (EPR) spectroscopy, while offering high precision, are impeded by significant time requirements and a dependency on extensive expert knowledge, which restrict their practicality and widespread application. Here, we introduce a hybrid approach that combines conventional computational techniques, machine learning, and an automated measurement system for the analysis and characterization of open shell species. Our methodology incorporates a multi-channel feature transformation alongside a deep learning model and a multi-grain iterative optimization method to accurately identify parameters in EPR spectra. Furthermore, our system utilizes a comprehensive, literature-derived EPR database, enabling rapid and accurate identification of spin species in EPR spectra in real catalytic systems. Our approach not only aligns with the accuracy of human experts, maintaining a margin of error within 0.1 Gauss, but also greatly enhances analysis speed by automating parameter adjustments and species identification. By integrating our spectral recognition system into an automated EPR measurement setup, we have successfully achieved the measurement and characterization of 36 samples within one hour, thereby streamlining the workflow and increasing throughput significantly. This advancement represents a pivotal development in EPR spectroscopy, bridging the gap between high-throughput demands and the need for precise, reliable analytical techniques.

CH04.17.05

Investigating the Surprising Electrochemical Dynamics of Zinc Battery Systems' Lithium Vanadium Phosphate Electrodes Kiki R. Lestari, Muhammad H. Alfaruqi and Jaekook Kim; Chonnam National University, Korea (the Republic of)

The low cost and high safety of zinc-ion batteries (ZIBs) have attracted significant attention as a potential alternative to lithium-ion batteries (LIBs). Nevertheless, the commercialization of ZIBs continues to face obstacles, principally because to the lack of electrode materials that provide enough energy density. This research aims to investigate the potential of β-$LiVOPO_4$ as a cathode for high-energy and high-power zinc-ion batteries (ZIBs) owing to its strong three-dimensional structural framework and high operating potential. More precisely, we successfully obtained a significant operating voltage of 1.61 V compared to the standard Zn/Zn^{2+} reference electrode for β-$LiVOPO_4$. The cathode exhibited a discharge capacity of 114.1 mA h g^{-1} at a current density of 100 mA g^{-1}, demonstrating significant cyclability and rate performance. The storage mechanism of the β-$LiVOPO_4$ cathode was investigated using a variety of characterization techniques, such as in situ synchrotron X-ray diffraction (XRD), ex-situ X-ray absorption spectroscopy, ex situ XRD, and theoretical calculations. A reversible and stable phase transition was maintained during cycling by recurrent Li^+/Zn^{2+} (de)insertion and capacitive-based surface reactions. This enhanced the electrochemical efficacy of β-$LiVOPO_4$ when employed as a ZIB cathode.

CH04.17.06

Advancing Material Science—AFM-in-SEM for Battery Analysis Veronika Hegrova[1], Radek Dao[1], Ondrej Klvac[2], Peter Priecel[3], Libor Novak[3] and Jan Neuman[1]; [1]NenoVision s. r. o., Czechia; [2]Brno University of Technology, Czechia; [3]Thermo Fisher Scientific, Czechia

Although lithium-ion batteries, as we know them today, are not a new invention, they are still nowhere near the theoretical limit of capacity and energy density. A great amount of research is to be done, delving deeper and deeper into details. Therefore, with the advances in batteries, the measurement and imaging techniques must advance as well.

While the Scanning electron Microscope (SEM) is the go-to instrument for observing battery samples on the microscale, electrical measurements are still mainly done using a large-scale statistical approach. Atomic Force Microscope (AFM) can provide detailed information about the electrical properties, but it is usually hindered by the nature of battery samples. Their fragile surface and challenging geometry (e. g., narrow tape cross-sections) do not lend themselves well to physical imaging with a sharp tip. However, combining AFM and SEM can avoid some of these pitfalls. For example, one can quickly survey a large sample area with SEM and select interesting or hard-to-reach places to be scanned by AFM. Navigating the tip precisely to the area of interest without touching the sample before imaging saves the tip, time and effort.

Analyzing solid-state batteries comes with additional challenges, such as their high sensitivity to humidity. This necessitates using a sample transfer system that protects the sample from the atmosphere or performing most of the analysis in situ.

We present a workflow for analyzing air-susceptible samples in-situ using a combination of AFM-in-SEM. The method is showcased in a study of electron conductivity of a mixed active material cathode, containing Lithium-Nickel-Manganese-Cobalt oxide (NMC) and Lithium-Nickel-Cobalt-Aluminium oxide (NCA).

The sample (a cross-section of a slurry-cast tape) was prepared in a glovebox, then polished using a Broad Ion Beam polisher, and then imaged with AFM inside SEM. All transfers were done in a protective argon atmosphere. Conductivity maps were taken on a single polycrystalline particle of NCM and a pair of neighboring NCA and NMC particles for comparison. The particles were distinguished using Enertg Dispersive Spectroscopy (EDS). Contrary to expectation, the conductivity differed by several orders of magnitude between the particles. The reason was likely not just the material difference but an additional effect, such as separation from the current collector. Similar differences were observed between grains inside the polycrystalline NMC particles. Here, we suspect a combination of grain separation and crystallographic orientation is responsible for the conductivity pattern. The distribution of conductivity can help diagnose possible failure vectors, especially if correlated with EDS or other advanced SEM imaging techniques.

CH04.17.07

Nanoscale Projection Hard X-Ray Microscope for Statistical Analysis of Chemical Heterogeneity in Lithium-Ion Battery Cathodes Sugeun Jo and Jun Lim; Pohang Accelerator Laboratory, Korea (the Republic of)

Spatiotemporal heterogeneity of the state of charge (SOC) in battery electrodes significantly impairs the rate capability and cycle life of Li-ion batteries (LIBs). However, mapping of this heterogeneity is challenging due to the absence of experimental methods that can quantify SOC across the entire electrode scale, while also offering the nanoscale resolution for in-depth analysis of individual particles. Here, we report an advanced projection hard X-ray microscopy (PXM) offering a nanometric resolution with a large field-of-view, and high chemical sensitivity, significantly minimizing beam damage by lowering beam flux 10^{-4} times compared to traditional transmission X-ray microscopy (TXM) while sufficiently maintaining fast X-ray absorption near edge structure (XANES) imaging speed. Employing full-field imaging on hundreds of Ni-rich layered oxide particles during real-time (de)lithiation at various C-rates, we probed the origin of SOC heterogeneities, and revealed that the battery degradation does not occur uniformly across the entire electrode but progresses differently at the level of individual particles.

Electron Microscopy and Spectroscopy of Low-Dimensional Hybrid Materials Kazutomo Suenaga; Osaka University, Japan

Electron microscopy and spectroscopy are widely used to characterize various low-dimensional materials.

Up-to-date as of November 14, 2024

Identifying the atomic structures and/or measurements of local optical/vibrational properties are of great importance in designing nanoscale devices based on hybrid nanostructures. Electron energy-loss spectroscopy (EELS) has been used for elemental identification in transmission electron microscopes (TEM) by using core-level excitations. Recent developments of monochromators after the e-beam guns have enabled us to access optical and vibrational information from the valence EELS ranges of nanometric materials. Here we show our latest studies to develop the possibilities of EELS applied for low-dimensional hybrid materials. Examples for atomic defects in hybrid TMDCs[1], layered structures of alkali metals/metal chlorides intercalated in bi-layer graphene[2, 3], the moire structueres of bi-layer graphene[4], isotopically heterogeneous graphene[5], and some forms of novel 1D/2D hybrid structures[6] will be shown.

Probing Antisite Defects and Their Mobility in Layered $PtSe_2$ with Low-Voltage Aberration-Corrected STEM

Ilias-Panagiotis Oikonomou[1,2,3], Douglas-Henry Danielle[1,2], Mohammadreza DaqiqShirazi[3], Thomas Brumme[3], Zdenek Sofer[4], Thomas Heine[3,5] and Valeria Nicolosi[1,2]; [1]Advanced Microscopy Laboratory, Crann & Amber Centers, Ireland; [2]Trinity College Dublin, The University of Dublin, Ireland; [3]Technische Universität Dresden, Germany; [4]University of Chemistry and Technology, Prague, Czechia; [5]Center for Advanced Systems Understanding (CASUS), Germany

The successful synthesis/exfoliation of Transition Metal Dichalcogenides (TMDs) covered the need for 2D materials with an energy bandgap, which is essential for transistor applications. $PtSe_2$ belongs to Noble-Metal Dichalcogenides, a subcategory of TMDs, consisting of metals from group 10 of the periodic table. It exhibits layer-dependent electronic properties, allowing it to be employed either as a semiconductor or semimetal. $PtSe_2$ has a broad range of applications in sensing, optoelectronics, and photonics [1], while properties can be tuned through defect engineering. The occurrence of magnetism in $PtSe_2$ has been attributed to Pt vacancies [2] while stacking sequences different than the 1T, can also enhance its performance as a piezoresistive sensor [3]. However, till now the research focused on isolated vacancies, and remains unknown the effect of antisite and complex point defects in the electronic structure and corresponding physical properties of $PtSe_2$. In this work, samples were exfoliated using either mechanical or liquid-phase exfoliation methods [4]. The structural characterization of exfoliated samples was performed with low-voltage aberration-corrected scanning-transmission electron microscopy (STEM) imaging using the Nion UltraSTEM operated at 60 kV. Multi-frame averaging was utilized to reduce beam damage, while custom scan patterns minimized beam-induced movements. Electronic properties of defected $PtSe_2$ were calculated using FHI-aims all-electron code, while geometries were optimized using FHI-vibes. Multislice STEM imaging simulations were accomplished with abTEM code [5]. Different point defects, including vacancies, antisites, and as well complex cases were detected in ultrathin flakes of $PtSe_2$. The presence of point defects was validated with Multislice STEM imaging simulations using the same experimental conditions under which images were acquired. The converged beam in STEM imaging induced beam irradiation effects. Fast frame image series were utilized to study the ‘in-situ’ creation of Pt antisite defects and their mobility across hopping into different atomic positions. The energetic pathways of antisite defects was studied using the Nudged

Elastic Band (NEB) method. Finally, the structure-property correlation, regarding the effect of realistic defect cases in the thermoelectrical properties of $PtSe_2$, was also investigated using the Boltzmann Transport Equation.

Detection of Negative Charge Induced by Single Vanadium Dopant Atoms in 2D WSe_2 by 4D-STEM Hanako Okuno[1], Djordje Dosenovic[1], Samuel Dechamps[1], Jean-Luc Rouviere[1], Kshipra Sharma[1], Yiran Lu[2], Jean-Christophe Charlier[3], Simon Dubois[3], Martien den Hertog[2], Matthieu Jamet[1] and Alain Marty[1]; [1]CEA Grenoble, France; [2]Institut Néel, CNRS, France; [3]Université Catholique de Louvain, Belgium

Structural anomalies in 2D materials have been known as the key to locally modify the electrical, optical and magnetic properties. In order to tailor the material properties and to explore their functionalities, the ability to survey the local electric properties together with their structural configuration at the atomic scale is essential. Recently, a new imaging technique called Center of Mass (CoM), sensitive to the local electrostatic field, has been demonstrated in a Scanning Transmission Electron Microscope (STEM)[1-2]. However, the lack of quantitative understanding and interpretation of CoM images is the main reason why this imaging mode is not yet routinely used for the study of 2D materials.

In this work, we explore the use of the CoM technique for atomic scale mapping of the local electrostatic field and potential around single atom V dopants in WSe_2/graphene heterostructure grown by molecular beam epitaxy (MBE). The quantitative analysis is achieved by comparing the experimentally obtained E-field and potential maps to the Density Functional Theory based multislice STEM image simulations taking into account the influence of key microscope parameters such as: convergence angle, defocus and lens aberrations. The residual three-fold astigmatisms were measured using a ptychographic probe reconstruction for each experimental 4D-dataset in order to generate the reliable and directly comparable simulated potential maps. A negative charge around V dopants is then detected as a drop in the electrostatic potential maps.

Finally, the technique is applied for imaging the electrostatic potential landscape in complex structural configurations in the presence of growth related defects such as Se vacancies and inversion domain boundaries. The separation of background signal from the projected total potential map allowed to extract both the quantitative charge field and the local electrostatic potential directly relating to the individual atom components. The latter was used to determine the precise atomic position of dopants and defects. The results showed the formation of potential wells of different forms arising around vanadium substitutes. A strong background variation is observed and which cannot be explained by the independent atom model simulations. Therefore, we suppose that the potential drop is seen as a consequence of charge related phenomena, where the shape and the depth of the potential drops might be determined by a complex interaction between defects, as predicted by the DFT calculations [3].

Our results demonstrate the capability of the CoM method to map the electrostatic potential including charge effect, opening the perspective for atomic scale analysis of charge effects and interactions between charged

defects in synthesized 2D materials.

TEM-EELS of Low-D Materials Combining High Energy and Momentum Resolution Thomas Pichler; University of Vienna, Austria

A major mission of condensed-matter physics is to understand material properties via the knowledge of the energy vs. momentum (q) dispersion and lifetime of fundamental excitations. Recent developments of EELS in TEM with a combined high energy & q-resolution is a perfect tool to determine them. This opens the so-far unexplored possibility to investigate dispersion and lifetime of phonons, plasmons & excitons in nanomaterials including molecules, 1D & 2D materials and heterostructures with few nm of lateral resolution on samples as thin as an atomic monolayer. In this presentation I give an overview on our recent progress in analysing fundamental excitations such as phonons, excitons, and plasmons in 2D materials such as graphene, h-BN and transition metal dichalcegonides (TMDC) using EELS with complementary high energy and momentum resolution in comparison to previous results. I will show how we can understand the full phonon dispersion of an apolar material like graphene [1] and use the ultrahigh momentum resolution to make the link to surface phonon polaritons close to the optical limits in h-BN. For graphene we also show new results on the plasmon dispersion including the gap opening close to the optical limit unravelling the Dirac cone in the excitation spectrum [2] concomitant to the direct observation of a vanishing EELS cross section approaching the optical limit [3]. For monolayer TMDC using ultra high q resolution we determined the exciton dispersion and deciphered the intense postgap absorptions and disentangling plasmon from excitons from their different momentum dependence [4-6].

High Spatio-Temporal Resolution Low-Dose Phase Characterisation in STEM Using Detector Signal Digitisation Julie Marie Bekkevold[1], Jonathan J. Peters[1], Ryo Ishikawa[2], Naoya Shibata[2] and Lewys Jones[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]The University of Tokyo, Japan

The capability of resolving electric and magnetic fields within materials using the differential phase contrast (DPC) technique in scanning transmission electron microscopy (STEM) has been demonstrated thoroughly. Due to the high sensitivity of this technique, it is becoming commonly used to image both long range fields inside samples and the electric fields surrounding atomic nuclei. This enhances STEM materials characterisation beyond the structural characterisation available using high-angle annular dark field (HAADF) imaging. Additionally, DPC detectors are placed within the bright field region and the high collection efficiency achieved results in a much higher dose efficiency than HAADF. For characterisation of beam sensitive materials, reduction of beam current is crucial to avoid sample damage and degradation during imaging, and DPC is a promising low-dose imaging technique since it allows significantly reduced beam currents.

Furthermore, dose fractionation by multi-framing has been previously demonstrated to significantly reduce sample damage. By acquiring multiple frames with a lower dwell time, as opposed to a single frame with a higher dwell time, the dose is delivered to the sample in shorter bursts, delaying sample degradation. However, at very high scan speeds a scintillator detector is typically too slow to keep up, resulting in artefacts from the temporal response of the detector in the final image. In this work we investigate the practicability of in-hardware digitisation of scintillator detector signal from a segmented annular all-field (SAAF) detector used for STEM-DPC. Live digitisation of the detector signal yields a purely digital image where each electron is detected equally, and the noise-floor of the image is true zero. Most importantly, digitisation retains the precision of the temporal position of electron detection events, and as such they show up in one pixel only in the final image.

Using in-hardware, live digitisation of four segments on a SAAF detector, we have demonstrated experimental imaging of STO at a very fast scan speed: with a dwell time of only 50 ns. At this speed the images from using a scintillator detector exhibit significant loss of information in the fast scan direction due to severe streaking artefacts. On the other hand, the digitised images retain precision of the atomic columns. Finally, binning of the multi-frame stacks in the time-direction allows us to sacrifice some of the signal-to-noise ratio for temporal resolution, paving the way for in-situ phase characterisation in STEM.

1:45 PM CH05.02.02

Simultaneous Data Collection and Utilization of DPC/OBF STEM, EDS and EELS Yuhiro Segawa[1], Akiho Nakamura[1], Hiroki Hashiguchi[1], Yuji Kohno[1], Yuji Konyuba[1], Shigemasa Ohta[1], Takehito Seki[2] and Naoya Shibata[2]; [1]JEOL Ltd., Japan; [2]The University of Tokyo, Japan

The use of a segmented detector has become standard for various STEM observations, particularly for Differential Phase Contrast (DPC) STEM and Optimum Bright Field (OBF) STEM. DPC STEM can visualize weak electromagnetic fields such as p-n junction interfaces and magnetic skyrmions. In low-dose experiments with beam-sensitive materials, like zeolites and metal-organic frameworks (MOFs), OBF STEM method achieves noticeably better contrast during live imaging. Direct imaging using a segmented detector extends across various material fields and extremely contributes to research and developments. As an example of the application, this research shows a combined analysis of these advanced imaging techniques with elemental analysis methods, EDS and EELS, simultaneously acquired in our new FEMTUS™ platform.

The sample was a semiconductor memory. The experiment was performed using JEM-F200, equipped with SAAF-Quad detector (an annular four-segmented detector), Dual SDD detector for EDS, CEOS Energy Filtering and Imaging Device (CEFID) with Dectris ELA hybrid-pixel electron detector, and integrated analysis platform FEMTUS™ developed by JEOL. In the FEMTUS™ platform, all detectors and cameras can be synchronized and simultaneous acquisition becomes possible with easy operation. For all experiments we chose an accelerating voltage of 200 kV, STEM mapping was performed with a dwell time of 10ms, convergence semi-angle of 6.6 mrad, and EELS collection semi-angle of 2.2 mrad limited by the central hole of SAAF-Quad detector. All DPC STEM and EDS/EELS elemental mapping data were acquired simultaneously in a single scan.

The result of simultaneous acquisition is described below. EDS mapping detected heavy elements such as tungsten and titanium, which are difficult to access using the phase imaging method (DPC or OBF STEM) and EELS. EELS mapping clearly showed the contrast for light elements (oxygen, nitrogen, and silicon) with the higher S/N ratio compared to EDS. The information from EDS and EELS was used to analyze the origin of DPC STEM contrast. The DPC STEM method has better sensitivity for differences in projected potential, originating from both electromagnetic field and/or local chemical composition. We compared intensity profiles of the same area of the center of mass (COM) DPC STEM and EELS data and revealed the peaks of COM intensity correspond to the increase of oxygen component, whereas the amount of nitrogen decreases in the interface region. This result shows the composition difference between SiOx film and SiNx bulk region. Such combined information is very helpful to investigate the origin of phase contrast images.

In summary, we acquired DPC STEM, EDS, and EELS data of semiconductor samples simultaneously and revealed that the origin of DPC STEM signals was due to changes in the local chemical composition. Without the additional information from EDS and EELS, it was difficult to clarify whether the obtained phase contrast represents chemical composition, electromagnetic field, or just a difference in local thickness. Such simultaneous acquisition of DPC, EDS, and EELS enables us to directly understand the origin of the observed phase image contrast more easily. Furthermore, since compared to EDS and EELS mappings, DPC STEM is very sensitive to changes in the projected potential, it will be possible to clarify compositional differences by integrating the EDS and EELS signals of regions where phase contrast differences could be observed, even under low-dose conditions. This should also be useful for the composition analysis of electron beam-sensitive materials whose structures are destroyed with just a few scans. On the day of the presentation, we will show the details of the experimental results and additional instances of simultaneous data acquisition including OBF STEM.

2:00 PM CH05.02.03

Towards Real-Time Imaging of Atomic Vibrations with a Pixelated Detector Koudai Tabata[1], Takehito Seki[1,2], Yuji Kohno[3], Yuichi Ikuhara[1,4] and Naoya Shibata[1,4]; [1]The University of Tokyo, Japan; [2]JST PRESTO, Japan; [3]JEOL Ltd., Japan; [4]Japan Fine Ceramics Center, Japan

Aberration-corrected scanning transmission electron microscopy (STEM) is a potent technique for the direct observation of atomic structures and local material chemistry. Electrons scattered at high angles are primarily governed by thermal diffuse scattering, which depends on atomic displacements, particularly those due to atomic vibrations [1]. Therefore, quantitative measurement of atomic vibrational properties is achievable by analyzing detailed distributions of thermal diffuse scattering. Recently developed multi-dimensional detectors, such as segmented and pixelated detectors, can detect changes in scattering distribution attributable to atomic vibrations. Utilizing the segmented detector, we have acquired anisotropy of thermal diffuse scattering and observed anisotropic atomic vibrations of the clathrate compound $Ba_8Ga_{16}Ge_{30}$ [2]. In contrast, pixelated detectors, which can acquire more detailed distributions of thermal diffuse scattering, are anticipated to be powerful tools for analyzing physical properties related to atomic vibrations in more detail, such as localized phonons.

Recent advancements in pixel detector speeds have underscored the critical need for in situ processing of live 4D data and the real-time rendering of processed images. In this study, we developed real-time imaging applications to process 4D data captured by the JEOL JEM-ARM300F, equipped with a DECTRIS ARINA detector [3], at speeds reaching up to 100,000 fps. Our application rapidly transfers the acquired raw data to high-performance GPUs, enabling live display of results through highly parallelized processing using CUDA. We explored the potential for the live visualization of atomic vibrations through the anisotropic scattering imaging using this application. The presentation will report the outcomes of adapting this application to atomic vibration observation and other live observation scenarios.

2:15 PM CH05.02.04

Probing Higher Order Topologies in Free Standing Ferroelectric Oxide Thin Films with STEM EELS and 4D-STEM Lukas Worch[1], Yaqi Li[1,2], Pavlo Zubko[2], Quentin Ramasse[3], Mariana Palos-Sanchex[1], Liam Spillane[4], Rahil Haria[1], Geri Topore[1] and Shelly Michele Conroy[1]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]SuperSTEM Laboratory, United Kingdom; [4]AMETEK, Inc., United States

The combination of strain and electrostatic engineering in epitaxial heterostructures of ferroelectric oxides presents numerous opportunities for inducing new phases, complex polar topologies, and enhancing electrical properties. However, the predominant effect of substrate clamping can limit the electromechanical response, often relegating electrostatic effects to a secondary role. By releasing the mechanical constraints imposed by the substrate, the balance between elastic and electrostatic forces can be significantly altered, allowing them to compete equally. This release also activates new mechanical degrees of freedom, such as the macroscopic curvature of the heterostructure. In this work we explore the formation of higher order topologies and emergent phases in free standing ferroelectric and ferroelastic oxide thin films with atomic scale monochromated EELS and 4D-STEM.

Using applied in-situ stimulus such as cooling, biasing and strain we induce the formation of higher order topologies while monitoring these exotic phases using in-situ EELS and 4D-STEM. Multimodal STEM EELS & 4D-STEM is ideal for characterization of the emergent ferroic phases, as the technique enables correlation of local chemistry and bonding information, with crystallographic, strain, polarisation, and magnetic field information determined from identical specimen regions at micro to (near) atomic scale. By automating the acquisition of EELS and 4D-STEM data with applied in-situ holder stimulus via Gatan software python scripting one can easily probe the dynamically formed emergent phases in these free standing thin films.

2:30 PM *CH05.02.05

Fast Beam Blanking for Time Resolution, Dose Control and Optimal Information Return in TEM Bryan Reed[1], Ruth S. Bloom[1], Gonzalo Eyzaguirre[1], Jonathan Victorino[1], Abdolreza Moghadam[1], Curt Henrichs[1], Daniel Masiel[1], Hiroki Hashiguchi[2], Kazuki Yagi[2], Yu Jimbo[2], Jonathan J. Peters[3], Matthew Mosse[3] and Lewys Jones[3]; [1]IDES, Inc., United States; [2]JEOL Ltd., Japan; [3]Trinity College Dublin, The University of Dublin, Ireland

This presentation will focus on how electrostatic beam blanking enables a surprising range of capabilities for precise, time-resolved, dose-controlled, intelligent transmission electron microscopy (TEM).

TEM has progressed enormously in recent decades. Measurements that used to be heroic are now routine, often limited not so much by the microscope as by the sample. Sources are brighter, columns are more stable, aberration correction is widespread, and detectors have advanced to where 4D-STEM is replacing traditional imaging methods. If the sample can survive the intense scrutiny of the electron beam, modern instruments and techniques can draw out truly enormous amounts of information. But if the sample is more fragile, we need to be smarter about how we draw the information out.

This brings us to the linked frontiers of automation, dose control, data analysis, and intelligent microscopy. The TEM is not just a big, expensive camera for taking pictures. It’s a tool for answering questions about the properties

and behavior of materials. The way we probe the sample must be attuned to the questions we want answered. If the sample is fragile, we must allocate the dose where it matters and make the most of every bit of information we can catch. If we have *a priori* knowledge, we should use it not just to analyze the data but to direct the measurement itself, preferably in real time using strategies rooted in information theory. This is especially true if the material state we're interested in only lasts a short time.
Of all the microscope functions that have improved over the years, it's easy to overlook one of the most basic: the way we turn the electron beam on and off. Old-fashioned magnetostatic beam blankers were fine in the days of cameras that could only capture about one frame per second, but by today's standards they're terribly slow and imprecise. Simply replacing this function with an electrostatic beam blanker, able to operate on nanosecond scales with zero hysteresis, yields surprising benefits. The beam blanker should be designed for integration into complex workflows, including both direct high-speed timing control and external software automation interfaces. The speed and lack of hysteresis of an electrostatic blanker means one can turn the beam on and off at essentially any time without affecting focus or alignment (apart from brief transients, negligible on the typical time scale of TEM measurements). This means you can use pulse width modulation (PWM) to turn down the beam current without sacrificing resolution, and you can freely change the PWM settings as often as you like—even for every single pixel in a STEM scan, a mode we call "dose painting." You can blank the beam whenever it would produce poor or useless data, such as during flyback or even the inter-pixel settling time in STEM. You can even respond to signal levels in real time, blanking the beam when either a fast detector indicates you may be striking a high-energy-absorbing part of the sample, or upon reaching a criterion of accumulated signal level sufficient for your purpose. You can allocate dose in time and space so as to take advantage of the nonlinear, time-dependent aspect of beam-sample damage. And you can allocate dose specifically to regions of spacetime that are relevant for the questions you're asking of the sample, no more and no less. These decisions can be made by human operators, high-speed circuitry, machine-learning algorithms operating in either open or closed loops, or any combination thereof.

Advanced STEM Imaging and Spectroscopy for Energy Conversion Materials and Device Research Michael Zachman, Haoran Yu and David Cullen; Oak Ridge National Laboratory, United States

Energy conversion devices will play a critical role in the transition to a sustainable future by enabling, for example, generation and utilization of green hydrogen [1,2]. Key to these devices are often catalytic materials supported on or within a host material to form a heterogeneous catalyst. Improving heterogeneous catalysts often requires understanding their structure, composition, and bonding environment down to the atomic scale, since properties at these length scales can dictate the performance and durability of the devices utilizing them. These properties can additionally vary across the length scales of the electrodes in which they are incorporated (microns or larger), making high-resolution characterization over large length scales necessary to fully understand relevant properties on the device scale. In addition, the atomic-scale structure of many next-generation heterogeneous catalysts, such as single-atom electrocatalysts (SAEs), is highly sensitive to the high-energy electron probes typically used to characterize materials at this scale, making accurate assessment of their native structure challenging. In each of these cases, characterization by conventional high-resolution (scanning) transmission electron microscopy ((S)TEM) is therefore insufficient to fully understand the properties of heterogeneous catalyst materials utilized in devices.

Here, we will discuss automated (S)TEM imaging and spectroscopy techniques that allow high-resolution information to be obtained and across large fields of view and/or large numbers of catalyst sites [3,4], which, when combined with statistical data analyses, allow the properties of heterogeneous catalyst materials to be more fully understood across relevant scales. In addition, we will discuss the use of ultra-low voltage electron ptychography, performed at 30 keV, to enable direct imaging of the native atomic-scale structure of single-atom electrocatalyst sites while minimizing structural modifications [5]. Combined, these techniques will enable a more accurate and complete picture of the properties of heterogeneous catalyst systems to be obtained, aiding in the development of more advanced materials and devices that are essential for a sustainable future.

High-Resolution 3D Imaging of Gate-All-Around (GAA) Devices Using Multislice Electron Ptychography Shake Karapetyan[1], Ta-Kun Chen[2], Duen-Huei V. Hou[2] and David A. Muller[1]; [1]Cornell University, United States; [2]Taiwan Semiconductor Manufacturing Company, Taiwan

Advances in semiconductor technology have highlighted the need for imaging techniques to visualize the intricate atomic structures of buried interfaces and potential defects in Gate-All-Around (GAA) transistors. This is explicitly called out as a grand challenge in the CHIPS Advanced Metrology for Future Microelectronics Manufacturing roadmap. We demonstrate how this need can be met by imaging modern GAA devices with multislice electron ptychography (MEP). Our method provides sub-Angstrom in-plane and only a few nm in-depth resolution, significantly surpassing the capabilities of conventional (S)TEM imaging techniques, and revealing structural details that were previously inaccessible.

Generating a 3D image using conventional Scanning Transmission Electron Microscopy (STEM) imaging modes like annular dark field (ADF) or integrated differential phase contrast (iDPC) requires acquiring a through-focal series from multiple scans of the same area at different defocus values, reducing the available electron dose budget per scan. These methods are susceptible to multiple scattering and tilt artifacts, reducing the reliability and interpretability of features in depth. In contrast, MEP, a relatively new 4D-STEM technique, enables a 3D reconstruction with better resolution in all dimensions from just a single scan and in a more dose-efficient manner.

Experimentally, we utilize MEP to image GAA transistors, revealing channel irregularities and stacking defects in the crystalline silicon channel. These critical features, essential in the performance and reliability of the devices, are not discernible with traditional methods and could easily be missed without MEP. Through simulations, we validate MEP's accuracy under realistic experimental conditions by successfully recovering critical features from a known atomic model of a transistor.
By offering deep sub-Å lateral resolution and a few nanometers of depth resolution, MEP enables detailed visualization and analysis of both crystalline and amorphous materials, interfaces, and buried defects. This level of depth-resolved detail is not only essential for modern device imaging but also necessary for advancing our understanding of defect formation and behavior in materials.

Optimizing Multislice Electron Ptychography for Robust Reconstructions Colin T. Gilgenbach, Xi Chen and James M. LeBeau; Massachusetts Institute of Technology, United States

Multislice electron ptychography is a developing 4D STEM technique that promises three-dimensional, quantitative phase contrast imaging for a wide range of materials science problems. However, it remains difficult to implement because of the large set of acquisition and computation parameters required for a successful reconstruction. In this talk, we discuss the optimization of acquisition parameters for multislice ptychography. We introduce two physically informed metrics, areal oversampling and Ronchigram magnification, which are sufficient to inform the selection of experimental parameters. We evaluate these metrics over a wide range of metrics in simulation and experiment. Through application of these metrics, we achieve reconstructions with large scan step size, which enables large field-of-view reconstructions with minimal redundant data. Finally, we discuss the application of optimized multislice electron ptychography for quantitative phase contrast imaging.

4:30 PM CH05.03.04

Identifying Implantation Damage and Spin Qubits in Three-Dimensions Using Multislice Electron Ptychography Junghwa Kim, Aaditya Bhat, Colin T. Gilgenbach and James M. LeBeau; Massachusetts Institute of Technology, United States

Solid-state spin defects are promising platform for realizing quantum bits (qubits) [1]. Ion implantation is an instrumental method for creating and manipulating these spin qubits. The accelerated ion beam used in implantation transfers most of its kinetic energy to the host matrix via collisions that displace host atoms and/or create vacancies [2]. Subsequent annealing is followed to repair the damage and electrically activate the dopants [3]. However, this process can lead to unpredicted results, such as unknown defect-related photoluminescence peaks, potentially due to the interactions with preexisting implantation damage [4]. Moreover, isolating spin qubits is necessary to minimize decoherence [5]. In this context, it highlights the necessity of directly studying the consequences of ion implantation, including implantation damage and dopant identification.

Conventional high-angle annular dark-field (HAADF) scanning transmission electron microscopy (STEM) imaging has been employed to identify atomic defects, particularly heavy transition metal dopants, owing to Z-contrast. Moreover, through-focus HAADF imaging enables 3D information. However, it has limitations on sample (around/less than 10 nm) and cannot separate the surface damage contrast [6]. In addition, the z-contrast of HAADF has very low sensitivity for light elements, which results in missing their structural information. These limitations challenge the accurate interpretation of the structures, thereby limiting their reliability in providing precise insights into the local environments in the vicinity of point defects.

To address these limitations, we introduce multislice electron ptychography, offering several advantages including enhanced spatial and depth resolution by accounting for dynamical scattering [7]. In this presentation, using Er-implanted 4H-SiC (unannealed) as a model system, we demonstrate that multislice electron ptychography can quantify the consequences of ion implantation in three dimensions at previously inaccessible concentration levels with conventional electron microscopy. Analyzing ptychographic datasets at various depths reveals atomic displacements as a function of ion implantation depth, highlighting significant damage near the implantation surface. Forward modeling and electron scattering simulations help calibrate these displacements on peak phase, ensuring accurate detection of both dopants and vacancies. Additionally, we elucidate the local structure surrounding atomic defects, showing significant lattice distortion around Si vacancy. This work enhances our understanding of implantation damage and provides a framework for investigating spin defects and their local structures. Furthermore, these findings can support the development of simulations, such as Monte Carlo and molecular dynamics, leading to more accurate predictions of the consequences of implantation and helping to achieve better-optimized implantation parameters.

Understanding Defect Dynamics in 2D MoSe2 by *In-Situ* iDPC STEM Paulo Ferreira[1,2,3]; [1]International Iberian Nanotechnology Laboratory, Portugal; [2]University of Lisbon, Portugal; [3]University of Texas, United States

An ubiquitous challenge in the fabrication of 2D materials and devices is the introduction of defects during synthesis and handling, in addition to the challenging production of large-area monocrystalline structures. Since any defect will have a significant effect in such thin structures, investigating the formation and stability of these defects is a critical issue in 2D materials research. The changes caused by the defects can be detrimental for certain applications, but they may also reveal opportunities for tuneable behaviours that extend the relevance of the materials to other purposes, further justifying the need for comprehensive studies on this topic.
In this paper, the purpose is to monitor the type of defects that occur in MoSe2 under exposure to the electron beam, including their dynamics and stability. The MoSe2 samples analysed were mechanically exfoliated flakes from bulk crystals of the material transferred onto holey SiN grids. Subsequently, single-frame HAADF-STEM images were recorded in order to determine the condition of the sample and its overall behaviour under beam exposure. Next, DPC-STEM data was acquired using fast-scanning series image acquisitions, recording several frames to reduce the rate of damage during the total acquisition time and to improve SNR by alignment and

averaging of individual frames. This analysis leverages the heightened sensitivity of iDPC imaging to perform clearer observations of the structure and formation mechanisms of the defects, ultimately providing insights into potential opportunities for defect engineering and structural manipulation of the material at the atomic level.
We have found various types of defected structures, along with observations regarding their formation and equilibrium dynamics, including large vacancy complexes that acted as unstable single-atom switches, 8-fold-ring complexes, point-sharing 4-fold-ring (4|4P) grain boundaries, and the formation of staggered double VSe line (SDVL) defects in the MoSe2 structure due to a large depletion of Se atoms. These SDVLs were observed to have remarkable stability in their shortest form and were identified as a preferential configuration whenever a large loss of Se atoms begins to occur, with a variety of possible formation mechanisms.

SESSION CH05.04: New Electron Microscopy Instrumentation and Techniques
Session Chairs: Ryo Ishikawa and Quentin Ramasse
Tuesday Morning, December 3, 2024

8:30 AM *CH05.04.01
High Energy/Spatial Resolution Electron Microscopy from LaB_6 Nanostructured Electron Source Han Zhang[1,2], Koji Kimoto[1], Yasushi Yamauchi[2] and Kazuhiro Honda[2]; [1]National Institute for Materials Science, Japan; [2]Scientia Concors Inc., Japan

In recent years, tremendous advancement in S(TEM)-EELS has enabled milli-eV energy resolution and sub-angstrom spatial resolution. New instrumentation has led to new microscopy methodology for extracting material information richer than ever before. In a modern EELS-STEM system, the energy resolution is determined by the energy spread of electron beam coming out of the monochromated electron gun; and spatial resolution, on the other hand, is limited by the geometric aberration generated in the gun due to such monochromation processes. To achieve improvement in both resolution pursuits, though conflicting in nature, it is vital to find an electron source with both brightness and monochromaticity as high as possible. Conventionally available electron sources, including thermionic electron source, Schottky electron source and W(310) cold field emission electron source, with their respective limitations, are insufficient to help overcome current technology barrier. In this talk, we will introduce a new type of ultrahigh brightness cold field electron source made of low work function LaB_6 single crystalline nanowire. We will first go over how nanostructured electron source surpasses conventional counterparts as a mechanistic discussion of basic emission properties. Then application examples in commercial S(TEM), SEM and semiconductor inspection instruments will be demonstrated. Finally, we will discuss several new future development schemes for next generation STEM-EELS that is enabled by the unique features of the LaB6 nanostructured electron source.

9:00 AM CH05.04.02
Expanding the Boundaries of Analytical STEM Through Advanced Integration Maria Meledina, Bas Cornelissen, Terry Dennemans, Sander Henstra, Dileep Krishnan, Sorin Lazar, Sjaak Thomassen, Peter Tiemeijer, Wouter Verhoeven, Maarten Wirix and Paolo Longo; Thermo Fisher Scientific, Netherlands

Electron energy loss spectroscopy is a well established technique applied to the advanced materials to investigate their structure, chemistry and electronic properties at the local scale. For EELS investigations the setting of both the TEM and the EELS filter optics plays a crucial role for the reliable high quality of the produced data. The optics of the whole EELS setup is rather challenging: a broad range of electron energies must be simultaneously transferred through the microscope and through the spectrometer, from specimen to detector, without introducing chromatic blur or chromatic distortions. Together with it, when optimising the experimental conditions aiming for the specific results one is constantly modifying the setting of both the microscope, such as the camera length, and the spectrometer, for example, the dispersions – introducing the extra challenges to maintain the accurate transfer.

To ensure the superior performance and the quality of the EELS data, we closely integrated the optics of the TEM and the EELS filter. Together with this, the close integration of the EELS filer and the TEM column expands the possibilities for the multimodal use of the advanced TEM techniques, such as for example simultaneous EELS and EDX. Several innovations, including, for example MultiEELS™ mode allowing the collection of several regions with the high energy resolution, are introdiced.

In this contribution we will talk on the advances of close integration of the TEM column and the EELS filter and highlight it with various practical examples.

9:15 AM CH05.04.03

Towards Atomic-Resolution Electron Energy Loss Spectroscopy (EELS) in an Uncorrected 30kV Scanning Electron Microscope Quentin Ramasse[1], Demie Kepaptsoglou[1], Sean Collins[1], Takeshi Sunaoshi[2], Kazutoshi Kaji[2], Satoshi Okada[2], Yu Yamazawa[2], Michael Dixon[2] and Tsutomu Saito[2]; [1]SuperSTEM Laboratory, United Kingdom; [2]Hitachi High-Technologies Corporation, Japan

As an era-defining technological advancement in the field of nanoscience and beyond, the effective implementation of aberration correction has allowed electron microscopy to routinely reach deep sub-angstrom-level spatial resolution. Among many impactful consequences, these developments have seen the widespread adoption of low-voltage instruments, which can maintain very high spatial resolutions thanks to their aberration correctors, even down to 20kV, especially for applications in 2-dimensional materials at the single atom level [1]. Beyond single-atom sensitivity, low-voltage operation is highly sought-after for reasons such as reduced knock-on damage to samples or increased inelastic cross-sections resulting in a high signal for spectroscopy. However, for a large number of practical materials science applications, the complexity and price of such instrumentation, especially when analytical capabilities are added, can be a drawback. In contrast, high-throughput capabilities with lower entry barriers in terms of cost and complexity, but which maintain a relatively high-resolution, can often be preferable in order to address numerous scientific questions.

One possible solution is the use of (low-voltage) scanning electron microscopes (SEMs) operated in a transmission geometry – or (T)SEMs [2]. When equipped with cold field emission sources, these instruments have been shown to reach 0.2nm information transfer in bright-field STEM imaging [3], and to provide remarkable flexibility for surface and spectroscopic investigations of functional materials [4]. Here, we show how the capabilities of such a high-resolution (T)SEM can be pushed even further towards near-atomic resolution for EELS mapping. We use a Hitachi SU9000EA microscope, a low-kV (≤30kV) uncorrected (T)SEM equipped with a diffraction camera and a Hitachi electron energy-loss spectrometer developed for this instrument, which, thanks to its cold-field emitter, has a native energy resolution of ~0.3eV.

In the optical configuration chosen, and at 30kV acceleration voltage, the estimated probe size was sufficient to observe 0.26nm spots in the Fourier transform of high-angle annular-dark-field STEM images of a $La_{1/3}NbO_3$ A-site deficient perovskite, a candidate high performance thermoelectric ceramic [5]. This made it possible to use EELS to map with atomic-plane resolution the location of the La cations planes in the structure, 0.8nm apart. The observed oscillations, peaks and troughs, of the integrated intensity of the La $M_{4,5}$ edge in the linescan follow exactly those of the simultaneously acquired HAADF signal – with the darker layers corresponding to La-deficient positions, thus demonstrating plane-by-plane mapping in an SEM. The use of an edge with a high 832eV onset also highlights the applicability of EELS in this uncorrected 30kV system, even at relatively high energy losses. Other

EELS applications, such as plasmonics and low primary energy core-loss (down to 3kV) will also be highlighted to further illustrate the versatility of these instruments, whose advanced capabilities as (T)SEM-EELS instruments belie their relative operational simplicity and low cost.

Secondary Electron Induced Current in Scanning Transmission Electron Microscopy—An Alternative Way to Visualize the Morphology of Nanoparticles Sara Bals, Evgenii Vlasov, Robin Girod and Jo Verbeeck; University of Antwerp, Belgium

Electron microscopy is a useful tool to perform a detailed characterization at the level of individual nanoparticles. Although a plethora of electron microscopy imaging modes are available, a rough distinction can be made between scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The difference between both approaches is related to the fact that in SEM mode one is predominantly probing the surface structure of a sample under investigation, whereas in TEM mode, a projection of the entire sample is measured. SEM is quite user-friendly and often accessible in a scientific environment, but the resolution of a typical SEM instrument is on the order of 1–20 nm. On the other hand, (scanning) transmission electron microscopy ((S)TEM) yields (atomic resolution) information on both the structure and composition of a broad variety of nanomaterials, eventually along with signatures of their electronic and optical properties. However, TEM images conventionally correspond only to a two-dimensional (2D) projection of a three-dimensional (3D) object, which often hampers a clear understanding of the morphology of nanoparticles (NPs).

Electron tomography (ET) enables one to determine the 3D structures of nanomaterials from 2D images. These 2D projection images are acquired over a large tilt range and combined in a 3D reconstruction of the structure of interest through a mathematical algorithm. During past decades, ET in high-angle annular dark-field STEM (HAADF-STEM) mode has become a popular technique to investigate the overall morphology of nanomaterials, to determine the nature of surface facets, and even to characterize the atomic structure in 3D. Unfortunately, the acquisition of a conventional tilt series for ET is a time-consuming process that requires at least 1 h for a standard experiment. In addition, after the acquisition, a postprocess reconstruction step is required to evaluate the final 3D shape of the nanomaterial. Consequently, one can typically analyze approximately 10 NPs in a time frame of 1 day. This restriction further limits a thorough understanding of the structure–property relations, especially because the properties of nanomaterials are mostly measured by ensemble techniques.

We thus aimed to increase significantly the throughput of structural investigation of nanoparticles, for which we decided to exploit imaging by secondary electron-based electron beam-induced current (SEEBIC) in STEM [1,2]. This technique uses the generation of secondary electrons (SEs) in a TEM and can be considered as an unusual modification of the electron beam-induced current (EBIC) setup. The measured current in SE-based EBIC (SEEBIC current) arises from holes generated by the emission of SEs from the sample, upon interaction with the primary beam. This measured current is equal and opposite to the generated SE signal and can be mapped pixel-by-pixel to produce an image. Since SEs originate from near-surface regions of the samples, the SEEBIC image intensity is sensitive to variations in surface topography [2,3].

In this contribution, we will show that SEEBIC can be considered an attractive approach to imaging the morphology of nanomaterials with shorter acquisition and processing times in comparison to ET and superior resolution in comparison to SEM. We will discuss the importance of using a closed membrane to minimize imaging artifacts. Direct access to surface morphology obtainable on the order of minutes opens up the possibility to use SEEBIC for high-throughput analysis, e.g. of chiral NPs and to combine 3D imaging with *in situ* stimuli.

Multi-Scale, Multi-Modal Imaging and Spectroscopy for Quantum Materials and Devices Berit H. Goodge[1,2], Samra Husremović[2], Isaac Craig[2] and Daniel K. Bediako[2,3]; [1]Max Planck Institute for Chemical Physics of Solids, Germany; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

The next leap in computing technologies and capabilities will emerge from the integration of novel materials families into nano-scale devices. Spintronics, for example, offer the possibility of extremely low-power computation, but require new materials platforms which can be tuned to provide the desired functional properties. Scanning transmission electron microscopy (STEM) and related techniques offer unique and powerful insights for the synthesis of these compounds and their fabrication into atomic-scale devices, when experimental challenges of beam-sensitive materials can be overcome. Here I will discuss how new strategies and advances for signal-limited STEM, including high-brightness electron sources and low-noise detectors, can inform new approaches for stabilizing coexisting magnetic and charge-ordered phases in intercalated van der Waals (vdW) compounds which host spin-bearing ions in the weak-bonding gap between quasi-two-dimensional layers of the host lattice [1]. In addition to traditional bulk synthesis approaches [2], we leverage a combination of high spatial-resolution structural and spectroscopic measurements through STEM imaging and electron energy loss spectroscopy (EELS) to reveal new synthetic pathways via metal precursor patterning and vacuum annealing pristine vdW flakes [3,4]. Spatially resolved valence analysis shows how the metal intercalants are introduced to the host lattice, inspiring new methods for fabricating bespoke heterostructures and devices with exquisitely tailored properties. Furthermore, atomic-scale structural analysis informs theoretical calculations to show how intercalants can be preferentially introduced in certain stacking configurations of the vdW material. Together, the insights provided by this access to the structural and electronic details of these intercalated compounds provide novel roadmaps for the synthesis and fabrication of entirely unique functional device geometries.

Visualizing Chain Correlations and Their Evolution Across a Ferroelectric Phase Transition in $BaTiO_3$ Yang Zhang and Ismail El Baggari; Harvard University, United States

The nature of certain structural phase transitions is frequently categorized as displacive or order-disorder type. Either of them is typically thought to describe a majority of known ferroelectric phase transition [1]. Although $BaTiO_3$ is a classical ferroelectric, its ferroelectric (FE)-paraelectric (PE) phase transition challenges the purely displacive or order-disorder cases. The displacive model is attributed by the softening of a transverse optical mode caused by relative displacement of Ti and neighboring oxygen within the octahedron [2-3]. However, the diffuse line observed in both FE and PE phases [4-5] suggests the necessary introduction of order-disorder model, which assumes the occupation of Ti on symmetry-equivalent sites along <111> direction, with a chain-like correlated Ti off-center shift [6-8]. Unlike the well-accepted soft mode in displacive case, the chain correlations is primarily evidenced by the investigation of diffuse line in reciprocal space [4, 5, 8]. However, the real-space behavior of the chain correlations and their evolution across phase transition remain elusive.

Here, we directly track the chain correlations of $BaTiO_3$ across the FE-PE phase transition using in situ scanning transmission electron microscopy (in situ STEM) and give atomic evidence of the order-disorder case. We visualize the famous chain-correlated <111> Ti off-center shift in both the FE and PE phase of $BaTiO_3$ and reveal their link to diffuse lines observed in reciprocal space. By quantitatively tracking the chain correlations across FE-PE transition, we demonstrate the order-disorder case is governed by a competition between local ferroelectric correlation and thermal fluctuation. Notably, an inverse enhancement of correlation across the *Tc* is observed. Our visualization and tracking of chain correlations in $BaTiO_3$ emphasize the role of order-disorder case on describing the FE-PE transition of $BaTiO_3$.

Transmission Electron Microscopy of MBE-Grown Self-Assembled InAs Quantum Dots Capped with GaAsSb Layer(s) Abhinandan Gangopadhyay, Samishta Choudhary, Rajib Saha, Raveesh Gourishetty and Subhananda Chakrabarti; Indian Institute of Technology Bombay, India

Single-layer/multi-layer GaAs(001)-based heterostructures consisting of self-assembled Stranski-Krastanov InAs quantum dots capped with GaAsSb layer(s) are attractive materials for long-wavelength (up to 1550 nm) telecommunication applications. The GaAsSb layer acts as strain reducing layer, however the effect of GaAsSb capping on the size and shape of InAs quantum dots is not well-understood. In this work, the single-layer/multi-layer InAs quantum dots capped with 12-nm-thick $GaAs_{0.86}Sb_{0.14}$ layer(s) were grown using molecular beam epitaxy (MBE), which were characterized using various transmission electron microscopy (TEM)-based techniques such as diffraction-contrast two-beam imaging, high-resolution phase contrast TEM imaging and high-resolution scanning transmission electron microscopy (STEM) in conjunction with energy dispersive X-ray (EDX) spectroscopy. Samples for (S)TEM were prepared using focused ion beam (FIB)-enabled in-situ lift-out method using a Helios 5 UC machine which was operated at 2 KV during final thinning to reduce Ga-ion-induced damage in the thin electron-transparent (S)TEM samples. A ThermoFisher Scientific Themis G3 TEM equipped with four quadrant silicon drift detectors was operated at 300 KV for structural and chemical characterization of the epitaxially-grown quantum dot heterostructures. Cross-section (S)TEM images revealed that although the dots were strain-coupled and vertically well-aligned in both bi- and hepta-layer samples, the aspect ratio (height to base) of quantum dots typically reduced with increasing layer number in the hepta-layer sample. The wetting layer contrast was clearly distinguishable in the STEM images, which confirmed that the growth mode was Stranski-Krastanov. More detailed investigation of intermixing in the buried quantum dots is being undertaken using STEM-EDX spectrum imaging with a judicious choice of electron dose, probe size and pixel size as well as dwell time for X-ray collection. The EDX quantification result for the bi-layer sample obtained using Velox software with optimum prefiltering yielded a reliable profile for Indium distribution across quantum dot and capping layer regions. Current efforts to deduce Sb concentration profile at sufficient spatial resolution and analytical sensitivity will be described in detail.

11:30 AM *CH05.05.04

Atomic-Scale Characterization of the High-Pressure Superconductor $La_3Ni_2O_7$ and Topotactically Reduced $LaNiO_2$ Single Crystals Eren Suyolcu, Yu-Mi Wu, Pablo Sosa-Lizama, Pascal Puphal, Masahiko Isobe, Bernhard Keimer, Matthias Hepting and Peter A. Van Aken; Max Planck Institute, Germany

Rare-earth nickel oxides, known for their complex interplay between structure and properties, serve as a pivotal base for novel quantum phases and advanced applications. Recent topotactic transformations of perovskite nickelates have allowed precise control of oxygen vacancies, leading to the discovery of superconductivity in thin films of the infinite-layer (IL) nickelate $Nd_{0.8}Sr_{0.2}NiO_2$. [1] To unravel the potential of these phenomena, it is crucial to gain in-depth insights into the atomic-scale lattice and electronic structure during topotactic reduction. [2] Recently, the discovery of high-temperature superconductivity in $La_3Ni_2O_7$ at high pressures (>14 GPa) has stimulated considerable research efforts. [3] However, the fundamental properties of the superconducting phase are currently the subject of controversial debates, including the interpretation of the possible filamentary character, whereas early investigations consistently postulated a crystal structure consisting of NiO_6 octahedral bilayers stacked along the c-axis on La_3Ni2O_7. In this talk, I will discuss our atomic-scale investigations that link the observed properties of IL and Ruddlesden-Popper nickelates to their underlying microscopic origins.
To investigate the atomic-scale properties of two different infinite-layer nickelate single crystal variants, *i.e.*, $Pr_{1-x}Ca_xNiO_{3-\delta}$ and undoped $LaNiO_2$, synthesized by topotactic reduction of the perovskite phase, and to reveal the unconventional structure of optically floating zone-grown high-pressure superconducting $La_3Ni_2O_7$ single crystals, we employed high-resolution scanning transmission electron microscopy (STEM) imaging and electron energy-loss spectroscopy (EELS). We first studied $Pr_{1-x}Ca_xNiO_{3-\delta}$ crystals, revealing an oxygen-deficient phase with $\delta \sim 0.25$ during topotactic reduction. The novel arrangement of oxygen vacancies within the brownmillerite-like structure differs from previously observed reduced rare-earth nickelates. [4] Next, we investigated the microstructural effects of topotactic reduction on the undoped $LaNiO_2$ single crystals and showed that the reduction process leads to different types of structural deformations. [5] More recently, we focused on the structural and electronic properties of high-pressure superconducting $La_3Ni_2O_7$ single crystals using high-resolution STEM imaging and STEM-EELS. Although we observed multiple crystallographic phases in the $La_3Ni_2O_7$

crystals, the main matrix is dominated by alternating monolayers and trilayers of NiO6 octahedra [6,7] demonstrating a profound deviation from the previously proposed bilayer structures.

Sub-Nanometer Hyperspectral Imaging of Exciton Confinement within a Moiré Unit Cell in a WSe_2/WS_2 Heterostructure Archana Raja; Lawrence Berkeley National Laboratory, United States

Atomically precise heterostructures of two-dimensional crystals like graphene and transition metal dichalcogenides can be prepared without the constraints of epitaxy by stacking monolayers that are held together by van der Waals forces. The optical and electronic properties of such heterostructures are sensitive to the moiré potential created by the lattice mismatch or relative angular alignment between the constituent monolayers. Here, we use transmission electron microscopy and spectroscopy at cryogenic temperatures to simultaneously image the structure and the excitonic response of the lattice mismatched stack of WSe_2/WS_2. We observe structural reconstruction such that the area of the highest energy stacking site is minimized. Together with optical spectroscopy and ab initio calculations, we discern that the intralayer exciton center of mass wavefunction is localized around this highest energy stacking site to a radius of around 2 nm.

2:00 PM CH05.06.02

Revealing the Intricacies of Vibrations in Complex Structures Using Polarization Selective Electron Energy-Loss Spectroscopy Eric R. Hoglund[1], Harrison A. Walker[2,2], Sokrates T. Pantelides[2,2] and Jordan A. Hachtel[1]; [1]Oak Ridge National Laboratory, United States; [2]Vanderbilt University, United States

Vibrational electron energy-loss spectroscopy (EELS) in a monochromated scanning transmission electron microscope (STEM) has proven to be a useful tool to understand how local heterogeneity impacts atomic vibrations. Such vibrations are typically measured with optical spectroscopies that have superior spectral resolution. However, the power of STEM-EELS is to enable high-spatial resolution while maintaining spectral resolvability, which provides a local understanding of defect vibrations.

Much effort has been put into decreasing the energy resolution gap between optical spectroscopies and monochromated STEM in an effort to observe more detailed information about material’s vibrational responses.

Combined with the advent of off-axis EELS, where the delocalized dipole excitations of the optic axis are deflected away from the EELS collection aperture, this has enabled vibrational excitations to be mapped with atomic-resolution, far beyond current optical techniques.[1]

However, optical spectroscopies also offer the ability to polarize the incident and collected light, which provides details about vibration eigenvectors. While directional polarization selectivity has been examined in aloof EELS[2] it has been overlooked in off-axis EELS. Recent efforts have demonstrated that the direction of the off-axis deflection in reciprocal space directly enables sensitivity to anisotropies in the vibrational eigenvectors due to their projective property in the scattering probability.[3,4] Here we demonstrate high-spatial-resolution polarization selectivity in vibrational EELS and its application to spatially varying anisotropic vibrations in nitride interfaces and complex oxides heterostructures. By operating at nanometer-scale resolution, we gain mixed-space insights into the behavior of unique vibrations. We also demonstrate using the polarization selective off-axis geometry and high-momentum-resolution EELS to study the intricacies of unique modes from materials symmetry-vibration relations.[5]

2:15 PM CH05.06.03

Measurement of Heat Flow on Nanometer Length Scales Thomas W. Pfeifer[1], Eric R. Hoglund[2], Jordan A. Hachtel[2], Andrew Lupini[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Oak Ridge National Laboratory, United States

Modern progress in microengineering and nanofabrication have prompted renewed interest in accurate measurement of nanoscale thermal properties, such as thermal conductivity, thermal boundary resistance, and the influence of size and defect effects. Microscale thermal measurements, such as pump-probe thermoreflectance techniques, are typically used for the determination of these nanoscale properties. These techniques operate by focusing lasers to micrometer-sized spots on the sample surface, which results in a fundamental limit in spatial resolution. Questions also remain, such as the nature of the phonon scattering phenomena and the distribution of temperature gradients near interfaces, which would make a truly-nanoscale measurement technique valuable. Ultrafast Transmission Electron Microscopy (UTEM) techniques pair a pulsed laser with a transmission electron microscope (TEM) and have been used to visualize phonon propagation, however no studies have directly used these nanoscale observations as a measure of thermal properties.
We present the development of a modulated laser-pumped electron-probe thermal scanning transmission electron microscopy imaging technique. This does not require the complicated photo-excitation of a field-emission gun as is used in UTEM. In this technique, a continuous-wave laser is used to thermally excite a sample inside a scanning transmission electron microscope (STEM), with the electron beam probing the localized temperature with atomic-scale spatial resolution. The laser is modulated, enabling lock-in signal acquisition with

the high-angle annular dark field detector, allowing the observation of otherwise-undetectable thermally-induced changes.
Several additional experimental considerations are also included, including mitigation of pump-induced defocus artifacts. We also perform extensive modeling to understand the mechanisms behind the acquired signal, such as localized strain and the distances of atomic vibration (Debye-Waller factors). We also use modeling to understand the measurement sensitivity under varying conditions, such as the presence of sample tilt, defocus, or aberrations.

Electron microscopy supported by the U.S. Department of Energy, Office of Basic Energy Sciences (DOE-BES), Division of Materials Sciences and Engineering, and were conducted at the Center for Nanophase Materials Sciences, (CNMS), which is a DOE Office of Science User Facility.

2:30 PM *CH05.06.04
Quantum Insight: Advancing STEM-EELS for Materials Properties Detection Juan Carlos Idrobo[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Scanning transmission electron microscopy (STEM), when combined with electron energy-loss spectroscopy (EELS), has the potential to detect properties associated with quantum materials with unprecedented spatial resolution. These properties include the emergence of magnetic ordering, valley polarization, phonon chirality, and topological characteristics such as Hall effects. In this study, we will show that achieving such measurements requires a configuration that ensures that electron momentum transfer in EELS mimics the role of polarization in light and X-rays.

Here, we will present three examples. [1] The first example demonstrates the detection of ferromagnetic ordering in lanthanum strontium manganite (LSMO) at room temperature. [2] The second example illustrates that orbital angular momentum, through the orbital Hall effect (OHE), can be detected and characterized at the nanometer scale. [3] The third example shows how EELS, though monochromation can be used to detect isotopic changes in oxygen in a Cr_2O_3 thin film, achieving atomic planes spatial resolution. [4]

[1] The EELS part of this research was supported by the Center for Nanophase Materials Sciences, which is a Department of Energy Office of Science User Facility. This research was conducted, in part, using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy. This work was also partly funded under the Laboratory Directed Research and Development Program at Pacific Northwest National Laboratory, a multiprogram national laboratory operated by Battelle for the U.S. Department of Energy.

Recent Advances in Magnetic-Field-Free Atomic-Resolution Transmission Electron Microscopy Naoya Shibata; The University of Tokyo, Japan

Magnetic-field-free environment for samples is indispensable for characterizing magnetic materials and devices at very high spatial resolution by transmission electron microscopy. Recently developed magnetic objective lens system that realizes a magnetic field free environment at the sample position has realized atomic-resolution observation of magnetic materials [1,2]. This magnetic-field-free atomic-resolution electron microscope (MARS) will be a powerful tool for characterizing many magnetic materials and spintronics devices. In this talk, recent developments and applications of MARS with related new techniques such as tilt-scan differential phase contrast imaging technique [3,4] will be reported.

4:00 PM CH05.07.02
Dislocation Charge Density Quantification Using Precessed STEM Differential Phase Contrast Edwin Supple[1], Matt Brubaker[1], Kris Bertness[1], Allison Mis[2], Megan E. Holtz[2] and Alexana Roshko[1]; [1]National Institute of Standards and Technology, United States; [2]Colorado School of Mines, United States

GaN threading dislocations accumulate charge with density and sign varying according to their dislocation type and the dominant charge carrier. Leakage current due to these dislocations has a deleterious effect on the performance of GaN electronic devices. Previ-ous transmission electron microscopy studies have used electron holography to determine electric potential profiles across individual dislocations and the implied charge density. The electron holography experiment, however, requires careful setup and specialized equipment to produce useful results. We demonstrate measurement of local electric field and charge density of GaN threading dislocations using (precessed) 4D-STEM differential phase con-trast (DPC). Electric field associated with the dislocations deflects electrons as they pass through the lamella, causing a corresponding shift in the center of mass of the direct beam. Precessed scanning smooths the dynamical diffraction due to strain associated with the dislocations, improving signal:noise in the DPC signal. 4D-STEM additionally allows near-simultaneous dislocation Burgers vector identification by virtual dark field imaging. This approach can be applied broadly to other material systems such as oxides where dislocation charge is responsible for the speed of ionic diffusion.

4:15 PM CH05.07.03
Exploring Spin-Structure Correlation in van der Waals Ferromagnet $Fe_{5-x}GeTe_2$ Using (4D-)STEM Haoyang Ni[1], Andrew May[2], Jian-Min Zuo[1] and Miaofang Chi[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Oak Ridge National Laboratory, United States

Van der Waals (VDW) ferromagnet $Fe_{5-x}GeTe_2$ has attracted great research interest in recent years as it hosts high and tunable Curie temperatures, topological spin states, and thickness-dependent magnetism down to monolayer, in favor of the next generation spintronic devices. However, the mechanism enabling such rich magnetic behaviors in a single system remains elusive. It has been hypothesized that the complex magnetic structures in $Fe_{5-x}GeTe_2$ are linked to local structural order and disorder induced by the Fe deficiency within an average structure of R-3m. To investigate the correlation between local structure and chemistry, we systematically characterized $Fe_{5-x}GeTe_2$ using a combination of (4D)-scanning transmission electron microscopy (STEM).

From our atomic resolution STEM imaging, we show that the $Fe_{5-x}GeTe_2$ form split-site ordering, coexisting with disordered intralayer structure when viewing along [1-10]. The split-site ordering breaks the inversion symmetry within each layer, and forms √3×√3 superlattice in ab-plane. Stacking faults can be observed in our STEM images as well, suggesting further symmetry breaking combining the split-site ordering and stacking faults. Furthermore, our atomic-resolution core-loss electron energy loss spectroscopy (EELS) shows a strong correlation between local Fe concentration and intralayer ordering and disordering, where disordered layers systematically have lower Fe concentration than ordered layers. We further performed large-scale domain mapping using scanning electron nanodiffraction (SEND), a 4D-STEM technique. We observed phase segregation, where disordered layers forms micron-scale domains within the ordered-layer dominant matrix.

To clarify how the spin is affected by structural ordering in $Fe_{5-x}GeTe_2$, we used Lorentz 4D-STEM to measure the induction field in our sample, as well as its response to external field, temperature and tilting. In the ab-plane, we show $Fe_{5-x}GeTe_2$ hosts stripe domains when cooled below Curie temperature without external field. Increasing the external field drives the magnetic stripe-bubble transition until saturation. When field-cooled, a mixed type-I and type-II skyrmionics bubbles can be observed, and we show that the type of the magnetic bubbles can be controlled by in-plane field strength using tilting. Along axis, on the other hand, ferromagnetic domains form mainly in the ordered-layer dominant matrix, while the domains terminate at disordered domains. Our Lorentz 4D-STEM result indicates that the $Fe_{5-x}GeTe_2$ shows the characteristics of a centrosymmetric, anisotropic magnet. Within the ordered domains, the induction field is not perturbed by stacking faults or coexisting ordered and disordered layers, suggesting a long-range spin interaction across the VdW layers. However, the micron-scale disordered and ordered domains have distinct magnetic behavior, which suggests that the mesoscopic averaged structure of $Fe_{5-x}GeTe_2$ could still play an essential role in determining the magnetic behavior of $Fe_{5-x}GeTe_{2.}$

Altogether, by combining (4D-) STEM and EELS, we reveal the correlation between local structure, chemistry and magnetic properties in a VdW ferromagnet $Fe_{5-x}GeTe_2$. We can clarify that the structural ordering of $Fe_{5-x}GeTe_2$ can be driven by local Fe concentration, and the magnetic structure is impacted by micron-scale ordered/disordered domains. Our findings could greatly advance the understanding of the complex spin ordering in $Fe_{5-x}GeTe_2$ and could lay the foundation for precise tuning of the magnetic properties of $Fe_{5-x}GeTe_2$ by chemistry and structural engineering.

4:30 PM *CH05.07.04

Towards Magnon Spectroscopy in an Electron Microscope Demie Kepaptsoglou[1,2], Jose-Angel Castellanos-Reyes[3], Adam Kerrigan[2], Khalil El Hajraoui[1,2], Julio Alves Do Nascimento[1,2], Stuart Cavill[2], Juan Carlos Idrobo[4], Vlado Lazarov[2], Jan Rusz[3] and Quentin Ramasse[1,5]; [1]SuperSTEM Laboratory, United Kingdom; [2]University of York, United Kingdom; [3]Uppsala University, Sweden; [4]University of Washington, United States; [5]University of Leeds, United Kingdom

In the last decade, the advent of high-resolution vibrational EELS spectroscopy in an electron microscope has revolutionised materials science, enabling the detection of the spectroscopic signature of phonons down to the single atom level , a feat that was for a long time considered impossible. As the technique moves rapidly from proof-of-principle to established methodology, questions about the ‘next-quasiparticle’ that could be probed arise.

Beyond phonons, the next obvious excitation to hunt for is arguably that of magnons, or spin waves, which arise from the collective excitation of the electrons’ spin in ferro- and antiferromagnets. The concept of using electrons as a probe for magnons is not new; they can be efficiently excited by electron scattering in reflection geometry using spin- and non-polarised electron sources (SPEELS, REELS respectively). It is therefore expected that, in direct analogy with phonons, the spectroscopic signature of magnons and their dispersion in momentum space should also be accessible within the remit of vibrational electron-microscopy-based EELS. Nevertheless, the challenges of magnon-EELS spectroscopy are significant; while they qualitatively occupy the same energy range as phonons, their relative intensity is several orders of magnitude lower than that of phonons making their detection extremely challenging.

Here, we explore the prospects of using high-resolution EELS spectroscopy beyond the detection of phonons and propose a combined experimental and theoretical approach for magnon spectroscopy. We explore the conditions to excite and detect magnons in the electron microscope and their dispersion in energy and momentum, and present preliminary experiments in thin layers of ferromagnetic and antiferromagnetic materials grown by pulsed laser deposition. The experiments were performed using a monochromated Nion UltraSTEM MC, which is equipped with an IRIS spectrometer with a Dectris ELA direct electron detector for EELS and is capable of energy resolutions of ~6 meV. The experiments are guided and rationalized by theoretical calculations for the description of magnon excitation and momentum dispersion in an electron microscope and simulation of magnon energy loss spectra. The calculation of magnon diffuse scattering is analogous to thermal diffuse scattering due to atomic vibrations (phonons) and quantum excitation of phonons.

SESSION CH05.08: Nanoscopies

8:00 AM *CH05.08.01

Revealing the Anisotropy of Frequency- and Symmetry-Dependence of Atomic Vibrations in Oxides by Electron Energy-Loss Spectroscopy Xingxu Yan[1], Paul M. Zeiger[2], Yifeng Huang[3], Jie Li[3], Ruqian Wu[3], Jan Rusz[2] and Xiaoqing Pan[1,3,3]; [1]University of California, Irvine, United States; [2]Uppsala University, Sweden; [3]University of California, United States

The underlying dielectric properties of materials, along with intriguing optical, thermal, and elastic phenomena, stem from the anisotropy of atomic vibrations. Traditionally, diffraction techniques have been used to estimate the average thermal ellipsoids of distinct elements, though they lack the desired spatial and energy resolutions. Here, we present a novel dark-field monochromated electron energy-loss spectroscopic approach for momentum-selective vibrational spectroscopy, enabling the cartographic delineation of frequency- and symmetry-dependent phonon eigenvectors. In centrosymmetric strontium titanate, we distinguish between two types of oxygen vibrations exhibiting contrasting anisotropies: oblate thermal ellipsoids below 60 meV and prolate ones above 60 meV, due to their local symmetry, supported by theoretical modeling. Furthermore, the tetragonality of non-centrosymmetric barium titanate and accompanying cation displacements generate an unexpected modulation of thermal ellipsoids between apical and equatorial oxygen sites near 55 meV, along with soft-phonon modes. These frequency-linked thermal ellipsoids offer insights into diverse dielectric behaviors strongly correlated with acoustic and optical phonons. Our method establishes a new pathway to visualize phonon eigenvectors at specific crystalline sites for various elements, delving into uncharted realms of dielectric, optical, thermal, elastic, and superconducting property investigations with unprecedented spatial and energy resolutions.

8:30 AM *CH05.08.02

Exploring Nanoscale Materials with Time-Resolved Electron Spectroscopies Luiz Tizei; Centre National de la Recherche Scientifique, France

The evolution of technology drives the construction of increasingly complex and compact devices. Consequently, comprehending the physics underlying excitations and effectively controlling them in devices necessitates tools with precision at the nanometer or atomic scale. In this sense, spectroscopies in electron microscopes (electron energy loss spectroscopy, EELS, and cathodoluminescence, CL) have strongly impacted advances in nano-optics [1]. These spectroscopies have some penalties in comparison to photon experiments: lack of excitation energy control and polarization degrees of freedom and limited spectral resolution.

In this seminar, I will describe applications of electron spectroscopies to study 2D materials [2-5] and lead halide perovskites [6-8]. With this, I will try to exemplify how correlative measurements of structural, chemical and optical information at the nanoscale can solve problems not accessible to macroscopic explorations.

Following this, I will demonstrate innovative strategies to overcome electron spectroscopies inherent limitations by integrating them with a light injection/collection system, complemented by time-resolved experiments (using a ns-blanking system or a Timepix3 event-based electron detector).

Electron inelastic scattering in matter exhibits a broadband nature. As a result, the exchanged energy during each scattering event can only be determined through the detection of individual electrons with nanosecond time resolution [9]. With this, the energy losses leading to CL photon emission can be determined. This methodology, called cathodoluminescence excitation (CLE) spectroscopy, allows for the probing of excitation pathways leading to photon emission [10], similar to the approach in photoluminescence excitation (PLE) spectroscopy. CLE provides access to materials' relative quantum efficiency with nanometer precision. I will discuss the implications of these time coincidence experiments for phase shaped EELS [11].

Finally, if time allows, I will briefly mention a new spectroscopic method, called electron energy gain spectroscopy (EEGS), that allows for sub 10 μeV spectral resolution by coupling electrons and laser beams [12].

Quantum Aspects of the Interaction Between Free Electrons, Light and Material Structures Javier Garcia de Abajo[1,2]; [1]ICFO-The Institute of Photonic Sciences, Spain; [2]ICREA, Spain

The synergetic combination of electron microscopy and ultrafast optics has given birth to ultrafast electron microscopy as a research area aiming to investigate material excitations with an unprecedented combination of spatiotemporal resolution. In this context, we will overview the fundamental principles ruling the interactions between free electrons, light, and photonic nanostructures, with an emphasis on exploring quantum aspects that include electron decoherence caused by coupling to radiative modes and the generation of quantum states of light. In particular, radiative decoherence could be potentially useful to sense the presence of distant objects and measure the vacuum temperature, while the study of quantum correlations between electrons and surface polaritons enables the generation of single and entangled photons heralded by the detection of electrons that have experienced specific amounts of energy losses and angular deflections.

V. Sakharov[5], A. F. Tsatsulnikov[5], A. E. Nikolaev[5], A. Polman[2], Andrea Balocchi[6], Nikolay Cherkashin[1], Luiz H. Galvao Tizei[3] and Sophie Meuret[1]; [1]Centre d'Élaboration des Matériaux et d'Etudes Structurales, France; [2]AMOLF, Netherlands; [3]Université Paris-Saclay, France; [4]Centre Castaing, France; [5]Ioffe Institute, Russian Federation; [6]LPCNO, France

The development of time-resolved Cathodoluminescence (TR-CL) in a scanning electron microscope has enabled the measurement of the lifetime of excited states in semiconductors with a sub-wavelength spatial resolution [1]–[3]. For example, it was used to measure the influence of stacking faults on the GaN exciton [1], to probe the role of a silver layer on the dynamics of a YAG crystal[2] or to show the influence of stress on the optical properties of ZnO nanowires [3]. These results demonstrate that TR-CL is essential to study the correlation between semiconductor optical and structural properties (composition, defects, strain...). While TRCL is usually done in a scanning electron microscope, the improvement of the spatial resolution and the combination with other electron-based spectroscopies offered by transmission electron microscopes has been a step forward for TR-CL [4], [5]. Our TRCL experiment are performed in a unique electron microscope, based on a cold-FEG electron gun [6]. This technology allows among other things to reach a spatial resolution of a few nanometers, essential for the study of III-N heterostructures. In this presentation we will discuss for example the advantage and inconvenient of TRCL in a UTEM and present our results on the study of charge carrier dynamics in $In_{0.3}Ga_{0.7}N$/GaN quantum well with a resolution below 10 nm. Comparing different heterostructure we will discuss the impact of growth conditions on the optical properties (spectral and carriers dynamics). We will study the QW emission dynamic both along and across the quantum well and correlate the results with the strain maps obtained from the high resolution HAADF-STEM images[7] and temperature dependent time-resolved photoluminescence experiments

Wednesday Morning, December 4, 2024
Sheraton, Third Floor, Fairfax B

10:30 AM *CH05.09.01
***In-Situ* Investigation of the Ferroelectric Phase Transition in Improper Ferroelectric $YMnO_3$ Thin Films by Electron Energy Loss Spectroscopy** Marta D. Rossell[1], Alexander Vogel[1,2], Alicia Ruiz-Caridad[1,2], Johanna Nordlander[3,4], Rolf Erni[1] and Morgan Trassin[3]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]University of Basel, Switzerland; [3]ETH Zürich, Switzerland; [4]Harvard University,, United States

The functional properties of many materials are closely related to symmetry-changing phase transitions. In particular, many perovskite materials undergo a temperature-driven phase transition at the so-called Curie temperature (T_c) from a non-polar paraelectric (PE) phase at high temperature to a lower-temperature, non-centrosymmetric polar ferroelectric (FE) phase. The spontaneous polarization exhibited by ferroelectric materials below T_c has made them promising candidates for non-volatile memories. In improper ferroelectrics, the phase transition is governed by a primary order parameter, which is independent of electrostatics, and ferroelectric polarization arises as a secondary effect of this order parameter. As a result, in contrast to proper ferroelectrics, the ferroelectric properties of improper ferroelectrics are expected to be robust against the detrimental effects of the depolarizing field, which is important for the continued miniaturization of ferroelectric devices, down to the ultrathin limit.
Of the various known improper ferroelectrics, the hexagonal $YMnO_3$ (YMO) has attracted much attention due to its multiferroic properties, vortex-antivortex topological domain configurations, conducting domain walls and magnetoelectric coupling. In its paraelectric phase, it crystallizes in the centrosymmetric $P6_3/mmc$ space group, consisting of corner-sharing MnO_5 bipyramids alternating with Y^{3+} ion layers along the *c*-axis. A structural phase transition to the noncentrosymmetric $P6_3cm$ space group occurs at a T_c of ~997 °C, when the unit cell triples as a result of a zone-boundary K_3 phonon-mode condensation driven by a tilting of the MnO_5 bipyramids around the Y^{3+}

ions and a buckling of the Y layers. However, the exact details of the electronic structure in YMO during the phase transition have remained unclear to date [1-4].
In this talk, we discuss how the electronic structure of YMO epitaxial thin films changes across the PE-FE phase transition, as observed by in-situ heating experiments in the transmission electron microscope. Specifically, our electron energy loss spectroscopy observations clarify some of the remaining uncertainties about the electronic structure of YMO at the PE-FE phase transition. This information is crucial for the control of exotic polarization states and the development of emerging ferroelectric-based electronics [5].

Streamlined *In-Situ* MEMS-Chip Fabrication for Electrical and Electro-Thermal (S)TEM Studies via Optimized FIB Methodology

Vesna Srot[1], Rainer Straubinger[2], Felicitas Predel[1] and Peter A. Van Aken[1]; [1]Max Planck Institute, Germany; [2]Protochips, United States

Transmission electron microscopy (TEM) with in-situ electrical and electro-thermal probing demands pristine, contamination-free electron-transparent samples. Focused ion beam (FIB) milling used for site-specific TEM sample preparation often introduces artifacts that hinder accurate electrical measurements. Here, we present a novel and optimized FIB-based methodology specifically designed for in-situ studies on micro-electro-mechanical-system (MEMS) chips.
Our approach [1, 2] minimizes manipulation steps and Pt deposition, one of the main sources of contamination. Crucially, we introduce an alternative lamellae orientation during the lift-out procedure that enables direct attachment onto the MEMS chip, eliminating the need for a separate attachment/detachment steps and, hence, minimizing potential contamination. This methodology is universally applicable for depositing lamellae on any MEMS chip or flat surface.
We systematically investigated the impact of key sample preparation parameters on the electrical performance of the final lamellae. First, we examined the influence of Pt contact size and position. Samples featuring Pt contacts deposited across the top surface exhibited superior stability and reproducibility compared to those with limited sidewall contacts. This suggests a more robust electrical connection due to increased contact area. Second, we explored the effect of incident Ga beam energies (30 kV vs. 8 kV) during Pt contact deposition. Lamellae prepared with a 30 kV Ga beam displayed cleaner surfaces and sharper contact edges. Furthermore, these differences in surface morphology translated to distinct measured electrical responses, highlighting the critical role of minimizing contamination for accurate electrical characterization. Finally, we investigated the effect of different lamellae thicknesses and the incorporation of specific slit geometries on the electrical measurements. High-resolution STEM imaging and spectroscopy confirm the excellent quality of the prepared samples.
This optimized FIB methodology, based on a novel geometry and streamlined processing, represents a significant advancement for in-situ TEM studies of electrical and electro-thermal phenomena in diverse materials amenable to standard FIB preparation.

***In-Situ* Switching of van der Waals Ferroelectrics with In-Plane Electric Biasing** Xinyan Li[1], Chuqiao Shi[1], Nannan Mao[2,2], Jing Kong[2,2], Ramamoorthy Ramesh[1,1,1] and Yimo Han[1]; [1]Rice University, United States; [2]Massachusetts Institute of Technology, United States

Two-dimensional (2D) van der Waals (vdW) ferroelectrics offer the enticing opportunity of both stabilizing ferroelectricity down to atomic thickness while seamlessly integrating with current complementary metal-oxide-semiconductor (CMOS) technologies [1-3]. Here, we perform *in-situ* in-plane biasing scanning transmission electron microscopy (STEM) imaging to investigate the switching dynamics in vdW (anti)ferroelectrics. By visualizing the metastable intermediate states during switching processes at atomic scale, we reveal the pivotal role of stacking-polarization coupling in governing the switching pathways of SnSe.

Our in-situ biasing experiments utilize a micro-electromechanical system (MEMS)-based holder to apply an in-plane biasing to SnSe. A SnSe flake is transferred to a MEMS chip and subsequently thinned by focused ion beam (FIB). We estimate the applied electric field (ranging from 0 to 50 kV cm^{-1}) by measuring the distance between Pt electrodes and the voltage supplied by a constant voltage source. High angle annular dark-field (HAADF) STEM images reveal the polarization order and interlayer stacking order. Upon applying in-plane electric field to pristine AFE-order SnSe, both AFE-to-FE polarization order transition and AB-to-AC stacking order transition were observed through a 180° switching pathway. In addition, 90° switching can also introduce stacking order transition and concurrently switch armchair to zigzag direction. To quantify the in-plane strain, out-of-plane strain and atomic displacement, we performed strain mapping derived from the atomic-scale images for understanding the switching mechanisms.

In summary, by combining *in-situ* in-plane biasing method and atomic position analysis, we reveal the intrinsic coupling between stacking and polarization order in 2D vdW ferroelectrics and highlight the strain-mediated switching pathways of AFE-to-FE order transition. Additionally, this experimental methodology is adaptable to any in-plane (A)FE materials and *in-situ* heating technology, underscoring the *in-situ* in-plane biasing method for understanding fundamental mechanisms of functional materials.

Subnanometer-Resolution *In-Situ* ADF-STEM Observation of Domain Structure Formation During the MoS$_2$ Lithiation Process Kei Nakayama and Shunsuke Kobayashi; Japan Fine Ceramics Center, Japan

Lithiation reactions are crucial for Li-ion batteries. In many cases, the migration of Li ions into electrode materials is accompanied by atomic-scale and nanoscale structural changes. Therefore, their in-situ observation is necessary to comprehensively understand the dynamic processes of lithiation reactions. High-resolution transmission electron microscopy (HRTEM) has been leading in this field, particularly using transition metal dichalcogenides such as MoS$_2$ as model electrode materials. However, interpreting the atomic positions in the images obtained by in-situ observations remains challenging because the HRTEM image contrast often becomes too complicated to interpret straightforwardly, limiting detailed discussions on the local structural changes during lithiation processes. In this study, using annular dark-field (ADF) scanning transmission electron microscopy

(STEM), which is expected to provide more directly interpretable image contrast, we performed in-situ observation of the MoS_2 lithiation process. Using a tungsten probe equipped in a sample holder, Li (exposed to air during transport to the electron microscope) was brought into contact with single-crystalline MoS_2 inside an electron microscope. In-situ ADF-STEM observation at low magnification, followed by electron energy-loss spectroscopy analysis, confirmed that a lithiation reaction occurs. When in-situ observation was performed at high magnification, contrast changes at subnanometer resolution were observed. Although the visibility of the contrast in the raw data was very low due to a low signal-to-noise ratio, a stepwise appearance of new peaks in the Fourier transform pattern suggested that microstructural changes occurred in stages. By applying a threshold filter in reciprocal space and a moving average filter, the contrast changes became more clearly visible in real space. As a result, a stepwise formation of a nanoscale domain structure was found, which is likely to relax the internal stress during the lithiation process. This work was supported by JST PRESTO (JPMJPR23J9), JSPS KAKENHI (JP23K13567, JP23H00241), ISTF (0341198-A), NSGF (no grant number), and ATLA (JPJ004596) in Japan.

***In-Situ* Biasing TEM Analysis of Resistive Switching in Amorphous GaOx for Next-Generation Memory Applications** Sanghyo Lee[1], Jinseok Ryu[2], Hein Philipp[3], Manfred Martin[3] and Miyoung Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Diamond Light Source, United Kingdom; [3]RWTH Aachen University, Germany

There has been growing interest in next-generation memory semiconductors, particularly those exhibiting resistive switching phenomena. Recent advancements in AI have accelerated this trend, drawing more attention to the potential of these materials. Among the various materials being researched, recent studies have shown that amorphous GaOx exhibits non-filamentary memristive switching behavior when sandwiched between two ion-blocking electrodes. This behavior is believed to be related to the movement of oxygen ions within the material when an electric field is applied. Previous studies have included electrical property measurements, structural analysis, and numerical simulations, but TEM studies on the material have not been actively conducted beyond structural analysis.

In-depth TEM analysis of atomic and electronic structures can provide insights into the relationship between resistive switching and changes in the bulk oxygen concentration profile, directly imaging how these phenomena are interconnected. In this study, we induced resistive switching in an a-GaOx layer using in-situ biasing TEM. We employed a TEM holder from Nanofactory to induce changes in the oxygen concentration in the film and quantitatively confirmed changes in electrical conductivity by measuring resistance before and after switching. 4D-STEM and STEM-EELS analyses provide the spatial distribution of short-range ordering, stoichiometry, and electronic structures. Particularly, the drift of oxygen vacancies under applied bias redistributes the local composition of the a-GaOx film. Given that the disproportion occurs below a critical value of x, local mapping of the radial distribution function and the radial variance profile by 4D-STEM, in correlation with different values of x, is crucial for understanding the switching behavior. This is further examined in conjunction with the electron-loss near edge structures.

Our study provides direct insights into how changes in atomic and electronic structures influence resistive switching, advancing the understanding of the switching mechanism and highlighting its potential for next-generation memory device applications.

SESSION CH05.10: *In Situ* EM II—Beam Damage

1:30 PM CH05.10.01

Atomic-Scale Investigation of Electron Beam-Induced Phase Decomposition of Cu-Doped $CsPbI_3$ Shaona Bose[1], Somnath Mahato[1,2], Baidyanath Roy[1], Tukai Singha[3], Sanjeev Kumar Srivastava[1] and Samit K. Ray[1]; [1]Indian Institute of Technology Kharagpur, India; [2]Lukasiewicz Research Network - PORT Polish Centre for Technology Development, Wroclaw, Poland, Poland; [3]Saha Institute of Nuclear Physics, India

The investigation of lead halide perovskites at the atomic level has recently gained significant attention due to their potential applications in the optimization of perovskite-based photovoltaic and optoelectronic devices. Although transmission electron microscopy (TEM) is a powerful tool for analysing these electron beam-sensitive materials at the atomic scale, it can also introduce structural and chemical changes along with other undesirable artefacts. In this study, we examine how electron irradiation at different beam doses affects the phase stability of nominally Cu-doped $CsPbI_3$ nanocrystals with enhanced structural stability compared to their pristine counterparts, using high-resolution TEM at ambient conditions.
Our results demonstrate a notable transition of $CsPbI_3$ from the cubic to the orthorhombic phase at an electron beam dose of $\sim 3\times10^3$ $e^-/Å^2$. A meticulous analysis of the energy delivered by the electron beams per unit cell, corroborated by the energy kinetics and lattice dynamics of the electron-affected $CsPbI_3$ nanocrystals, obtained using density functional theory, offers valuable insights into the mechanism governing the process of beam-induced phase decomposition. A critical dose of $\sim 1.68\times10^6$ $e^-/Å^2$ results in complete and irreversible degradation of the lattice.
In summary, our study presents for the first time, *in situ* observation of electron beam-induced phase decomposition in Cu-doped lead halide perovskites. Furthermore, we estimate the electron dose thresholds below which beam-induced alterations are minimal, enabling accurate imaging and analysis of the samples.

1:45 PM CH05.10.02

Electron Beam Sensitivity in Perovskite Nanocrystals as Compared to Bulk Perovskites Pritish Mishra[1,1], Linh Lan Nguyen[1], Yeng Ming Lam[1] and Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Agency for Science, Technology and Research, Singapore

Perovskite materials has been very well studied a lot in the past 10 years due to its outstanding optoelectronic properties leading to various applications such as LED, Photovoltaics etc. But characterization of halide perovskite materials have been very difficult due to their air, water, laser and electron beam sensitivity. The quantitative sensitivity to these external factors depend on both physical form of the crystals as well as synthesis process. In this work, the affects of size has been studied on the electron beam sensitivity of halide perovskite materials. Same composition has been synthesized in both bulk and nanocrystal (quantum dots) forms and their degradation to electron beam has been measured and analysed. Negative spherial abberation Transmission Electron Microscopy (TEM) with calculated dose and dose rates have been used to compare the change in electron diffraction of the samples, thereby giving a quantitative difference between beam damage in both the types. The differences have been correlated to surface effects and presence of surface ligands in the lower dimension crystal.

Machine Learning-Driven Automated Aberration Correction on Scanning Transmission Electron Microscopes

Zijie Wu, Matthew G. Boebinger and Rama K. Vasudevan; Oak Ridge National Laboratory, United States

Scanning Transmission Electron Microscopy (STEM) has become an indispensable tool for material science, enabling high resolution imaging and analysis of condensed materials on atomic scale. However, achieving optimal image resolution is often hindered by aberrations in the electron optics, and aberration correction is an unavoidable prerequisite step in the beginning of almost every STEM experiment. While physics-based algorithms are generally available in modern STEM control software to auto-correct high-order aberrations, significant human input is still required to manually correct low-order aberration parameters such as defocus and astigmatism, presenting a tedious labor for STEM experts and a significant barrier for those new to STEM. In this talk, we discuss a novel approach leveraging machine learning (ML) techniques to automate aberration correction in STEM. We build baseline neural networks (NN) to predict aberration coefficients by learning from large datasets of simulated ronchigrams; we then combine the trained NN models with optimization techniques to automatically adjust the aberration coefficients on microscope for optimal resolution. By automating the challenging and repetitive process of aberration correction, our method has the potential to lower the technical barrier of STEM experiments and allow for more efficient material characterization and discovery.

Microscopy research was performed at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory, which is a US Department of Energy (DOE), Office of Science User Facility.

2:15 PM CH05.11.02

Accelerating the Closed-Loop Transmission Electron Microscope via Hardware-Software Codesign of Machine Learning Frameworks Jonathan Hollenbach, Stewart Koppell, Abdulazeez Mohammed Salim and Mitra L. Taheri; Johns Hopkins University, United States

Adjusting processing parameters on-the-fly in response to multi-modal datasets during an *operando* Transmission Electron Microscope (TEM) experiment promises precision control over structure and electronic states of a material. The continued development of multi-dimensional characterization techniques has created an exponential growth in data rates produced from the instrument. Machine learning (ML) has been proven to process, analyze, and respond to the large spatially and temporally resolved datasets, enabling closed-loop response of dynamics within the TEM. However, due to the timescales of the observed changes in an experiment, such as defect formation and crystallization, the latency and throughput of conventional machine learning frameworks lack the response time to act before the change has occurred. Traditional compute architectures for ML are optimized for large data tasks. Alternatively, edge compute devices from commercial vendors and custom designed accelerators on Field Programmable Gate Arrays (FPGAs) offer means to accelerate machine learning frameworks and optimize latencies for closed loop microscopy. We demonstrate how deploying ML frameworks on edge devices can reduce processing times and lessen the bottleneck of processing data within the closed-loop. To optimize the performance on edge and computation precision, hardware-software codesign is necessary for ML frameworks to use dedicated hardware accelerators in a System-on-a-Chip or FPGA. We also illustrate how codesign can be achieved by a domain scientist without extensive knowledge of computer architectures through tools and strategies available and capabilities developed in this work. Bridging the gap between microscopist, data scientist, and hardware engineer is a critical step towards achieving real time closed-loop control of materials within the TEM.

3:30 PM *CH05.12.01

Structure Determination from S/TEM Images and Theoretical Analysis of Complex Nanoscale Materials

Venkata Surya Chaitanya Kolluru[1], Eric Schwenker[2], Yuxin Chang[1], Guiliang Xu[1], Soohyun Im[3], Piyush Haluai[4], Peter A. Crozier[4], Paul M. Voyles[3] and Maria K. Chan[1]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States; [3]University of Wisconsin–Madison, United States; [4]Arizona State University, United States

The knowledge of atomistic structure of complex nanomaterials is needed to fully leverage the theoretical capabilities to gain insights into the atomic scale phenomena. However, often it is challenging to determine the underlying 3D atomistic structure corresponding to a S/TEM image due to one-to-many problem. We developed Ingrained software package [1], which can construct the atomistic structure of grain boundary interfaces from S/TEM images using only the observable experimental parameters as inputs. We apply the Ingrained package to determine the structures of domain boundaries, from STEM images, and analyze the oxygen instability during charge-discharge cycles [2].

Complex interfacial structures with local disorder result in low resolution regions in the S/TEM images. To determine atomistic structure of such regions, we further integrate local structure optimization routine using DFT calculations with the Ingrained package and developed a multi-objective evolutionary algorithm called FANTASTX (Fully Automated Nanoscale To Atomistic Structure from Theory and eXperiments). We apply FANTASTX to create models of the interface structure in Al-Si hetero-interfaces from STEM images to study the structural origin of two-level systems for quantum applications. Finally, denoised phase contrast TEM images of Pt nanoparticle on ceria substrate in CO gaseous environment are used to create experimentally observed Pt nanoparticle structures to study the atomistic phenomena behind the observed surface dynamics. Both Ingrained and FANTATSX software serve as computational tools to invert the experimental TEM images of interfaces, nanoparticles or 2D materials to create high-fidelity atomistic structures for further theoretical analysis.

Exploiting HAADF-STEM to Determine the Surface Coverage and Distribution of Immobilized Molecular Complexes Eric A. Stach[1], Sungho Jeon[1], Hannah Nedzbala[2], Brittany Huffman[2], Adam Pearce[3], Carrie Donley[2], Xiaofan Jia[3], Gabriella Bein[2], Jihoon Choi[1,4], Nicolas Durand[5], Hala Atallah[5], Felix Castellano[5], Jillian Dempsey[2], James Meyer[3] and Nilay Hizari[3]; [1]University of Pennsylvania, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Yale University, United States; [4]Sungkyunkwan University, Korea (the Republic of); [5]North Carolina State University, United States

The immobilization of molecular transition metal catalysts on solid supports, particularly semiconductors like silicon (Si), combines the advantages of homogeneous and heterogeneous catalysis for applications such as photo-electrocatalytic CO2 reduction. While spectroscopy and other methods provide averaged information about surface structures, they lack insight into catalyst distribution and coverage. Aberration-corrected high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) offers potential for locating immobilized molecular catalysts with sub-Ångstrom resolution, by exploiting the strong scattering of the single metal atoms in the catalysts. However, applying HAADF-STEM to molecular catalysts on Si presents challenges due to organic ligands' vulnerability to electron beam. Furthermore, the high magnifications used to form the images leads to a small sampling area, hindering quantification. To overcome the limitation of small image regions, we use a convolutional neural network (CNN) to analyze numerous images quickly, enabling statistical analysis of a representative surface percentage. Our study characterizes molecular catalysts immobilized on Si using HAADF-STEM combined with a CNN model, focusing on catalysts used in either CO2 reduction or hydrogen evolution reaction (HER). Once trained, the CNN model can readily detect the single atoms, allowing detailed statistical analysis of surface coverage, catalyst distribution, and exploring how electron irradiation effects different catalytic systems. This approach explored clustering and dispersion behaviors of immobilized molecular catalysts, showing that surface distribution and coverage vary depending on attachment group, ligand type, and reaction conditions. The work demonstrates that HAADF-STEM, in conjunction with CNN models, is an optimal tool for understanding the distribution of molecular catalysts on surfaces, providing unprecedented opportunities to connect linker types, coverage/dispersion, and catalytic activity.

4:15 PM CH05.12.03

Machine Learning-Driven 3D Sectioning and Analysis in Electron Microscopy Jinho Byun[1], Keeyong Lee[1], Daesung Park[2], Hyobin Yoo[2], Geun Ho Gu[1] and Sang Ho Oh[1]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]Sogang University, Korea (the Republic of)

Transmission electron microscopy (TEM) is pivotal in determining atomic-scale structures in materials science. Two primary methods for 3D sectioning in electron microscopy are electron tomography and multi-slice ptychography. While electron tomography is powerful, it often falls short with beam-sensitive nanomaterials due to the long acquisition time required for numerous tilt series images. Multi-slice ptychography, on the other hand, uses iterative algorithms to find probe-specimen interactions in samples, offering improved resolution but poor depth accuracy. We introduce a machine learning-driven approach to electron tomography without acquisition of tilt series images, specifically tailored for twisted bilayer transition metal dichalcogenides (TMDCs). This technique reconstructs high-resolution 3D images from defocused diffraction patterns obtained via scanning transmission electron microscopy, similar to multi-slice ptychography. By integrating machine learning, our method surpasses traditional multi-slice ptychography and electron tomography, enhancing both in-plane resolution and depth accuracy. This advancement in atomic resolution tomography significantly improves the structural determination of a wide range of beam-sensitive nanomaterials.

4:30 PM CH05.12.04

Machine-Learning-Assisted Statistical Analysis of Electron Microscopy Data for Nanocrystal Synthesis Min

Gee Cho[1,2], Katherine Sytwu[1], Luis Rangel DaCosta[2,1], Myoung Hwan Oh[3] and Mary Scott[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Korea Institute of Energy Technology, Korea (the Republic of)

The emerging domain of nanomaterials holds the potential to revolutionize crucial industrial technologies, particularly in the areas of nanocatalysis, sensor technology, and devices for energy storage and conversion. This study focuses on the controlled synthesis of nanoparticles, particularly in tailoring their morphology to enhance the efficiency of catalysts made from noble metals such as platinum and palladium. Changing the morphology of nanoparticles alters the surface facets exposed, directly impacting their catalytic performance. Traditionally, the analysis of active sites on nanoparticles has been limited to a few representative particles in a sample. This approach neglects the variance in characteristics within a batch, leading to incomplete understandings of nanoparticle behavior. Our research addresses this gap through a comprehensive, population-wide statistical characterization using high-resolution transmission electron microscopy (HRTEM) images, encompassing a vastly larger dataset of nanoparticles.
We synthesize cubic-shaped cobalt oxide nanoparticles, varying in size and shape descriptors such as circularity and face convexity. We then obtain HRTEM images of hundreds of thousands of these nanoparticles produced under various synthetic conditions. The large scale of this analysis requires automated image processing. Conventional computer vision techniques, such as thresholding or K-means image segmentation, are insufficient for high-resolution images with complex contrast and texture, which exhibit detailed surface boundaries crucial for identifying particle surface characteristics. To resolve these challenges, we apply a convolutional neural network (CNN) for image analysis. This approach allows for precise, pixel-by-pixel segmentation of particles from backgrounds in several hundred 4k TEM images, each containing hundreds of nanoparticles. This method efficiently detects particles, facilitating the correlation of statistical distributions of their size and shape with synthesis conditions. This machine-learning-assisted statistical methodology will open new opportunities for the designed synthesis of nanomaterials with advanced functionality.

4:45 PM CH05.12.05

Reward Driven Image Analysis Workflows in Automated Electron Microscopy Kamyar Barakati[1], Utkarsh Pratius[1], Richard Liu[1], Austin Houston[1], Gerd Duscher[1] and Sergei V. Kalinin[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Pacific Northwest National Laboratory, United States

Automated experiments in scanning transmission electron microscopy (STEM) require rapid image segmentation to optimize data representation for human interpretation, decision-making, site-selective spectroscopies, and atomic manipulation. Currently, segmentation tasks are typically performed using supervised machine learning methods, which require human-labeled data and are sensitive to out-of-distribution drift effects caused by changes in resolution, sampling, or beam shape. We develop an approach based on the concept of a reward function, intricately linked to the experimental objectives and the broader context, yet quantifiable upon experiment completion. Once defined, these reward function allow optimization of the workflow, including both combinatorial analysis selection and continuous parameter optimization via Bayesian Optimization, thereby ensuring the attainment of results that are both precise and aligned with the human-defined objectives. We demonstrate the applicability of reward-based workflows for tasks such as atom finding, identification of the amorphized regions due to the radiation damage on a single sublattice, and mapping of phases and ferroelectric domains. We further operationalize and benchmark reward-driven workflow for on-the fly image analysis in STEM. We establish the timing and effectiveness of this method, demonstrating its capability for real-time performance in high-throughput and dynamic automated STEM experiments. This unsupervised approach is much more robust, as it does not rely on human labels and is fully explainable. The explanatory feedback can help the human to verify the decision making and potentially tune the model by selecting the position along the Pareto frontier of reward

functions. The reward driven approach allows to construct explainable robust analysis workflows and can be generalized to a broad range of image analysis tasks in electron and scanning probe microscopy and chemical imaging.

***In-Situ* Investigation on Reversible Polar-to-Nonpolar Phase Transition in Fluorite Oxide Ferroelectrics** Xinyan Li[1,2], Qinghua Zhang[2], Chen Ge[2], Lin Gu[3], Yimo Han[1] and Ramamoorthy Ramesh[1,1,1]; [1]Rice University, United States; [2]Chinese Academy of Sciences, China; [3]Tsinghua University, China

Switchable spontaneous polarization of ferroelectrics enables stable storage of two reversible polarization states applicable to next-generation electronic devices. As exemplified by $Hf_xZr_{1-x}O_2$ (HZO), fluorite oxide thin films demonstrate great silicon compatibility and robust FE polarization down to the thickness of several unit cells, which is beneficial for silicon-compatible and scalable electronics. However, fluorite oxides exhibit various polymorphs and the desirable ferroelectric orthorhombic (O) phases is metastable. Therefore, stabilizing O phase instead of nonpolar ground-state monoclinic (M) phase in thin films remains a significant challenge [1] and understanding the mechanisms that govern phase transitions and FE switching at the atomic scale [2] is crucial for rational design of fluorite oxide devices.

In this study, we investigate the reversibility of O-M phase transition in ZrO_2 nanocrystals by *in-situ* visualization of the martensitic transformation at atomic scale. We reveal that the reversible shear deformation pathway from O phase to M state is protected by 90° ferroelectric-ferroelastic switching. Nevertheless, as the M state gradually accumulates localized strain, a critical tensile strain can pin the ferroelastic domain, resulting in an irreversible O-to-M transformation and the loss of ferroelectricity. Additionally, four-dimensional scanning transmission electron microscopy (4D-STEM) analysis shed light on the crystal relationship in the thin film on a larger scale [3]. These findings demonstrate the key role of ferroelastic switching in the reversibility of phase transition, and also provide a tensile-strain threshold for stabilizing the metastable ferroelectric phase in fluorite-oxide thin films.

CH05.13.02

Electron Microscopy Study of Solute Segregation Process in an Oxide Grain Boundary Jason Tam[1], Bin Feng[1], Atsutomo Nakamura[2], Shun Kondo[1], Naoya Shibata[1] and Yuichi Ikuhara[1]; [1]The University of Tokyo, Japan; [2]Osaka University, Japan

Yttria stabilized zirconia (YSZ) is a technologically important ceramic with diverse applications. However, the structure and chemistry at the atomic scale need to be well-controlled to optimize the macroscopic properties and behaviour. In YSZ, Y^{3+} tends to segregate to grain boundaries in a substitutional manner as in the bulk. Currently, little is known on the segregation process and the conditions that trigger segregation. A novel bicrystal fabrication process was developed to fabricate specimens without Y^{3+} segregation. As a model system, the grain boundary geometry selected for this study is Σ3 {111}<110>. To induce grain boundary segregation, the specimen was annealed at various temperatures and their structure and chemistry were tracked by atomic resolution scanning transmission electron microscopy (STEM) imaging and energy dispersive X-ray spectroscopy (EDS). The results of this study can be used as a guideline to control the decoration of solutes at the grain boundary to enable desirable physical and functional properties.

CH05.13.03

Carbon Contamination Mitigation for STEM Imaging of Chemically Synthesized Beam Sensitive Materials

Pritish Mishra[1,1], Yee Yan Tay[1] and Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Agency for Science, Technology and Research, Singapore

Chemically synthesized materials such as colloidal nanoparticles have been studied a lot in the past decade owing to their ease of synthesis and enhanced properties as compared to their bulk counterparts. Halide - perovskite quantum dots (h-PQDs) are one of these widely researched class of materials due to their near unity Photoluminesence Quantum Yield (PLQY). But due to the presence of organic ligands and highly ionic nature of composition, the material faces extreme carbon contamination and radiolysis damage on exposure to electron beam during Scanning Transmission Electron Microscopy (STEM) imaging and analysis. In this work, we build a methodology for atomic resolution imaging and analysis of such materials with high beam dose at room temperature. One section of the sample is exposed to stationary STEM beam which damages the exposed area of the sample while reducing contamination for the immidiately neighbouring area, thereby improving contrast and reducing astigmatism compensation and image aquisition time. The process has been optimized with different beam voltages and calculated dose rates. The resulting images appear noise free and can be analysed without any need for post processing, filters or image treatments. These results show promise in atomic resolution imaging of all chemically synthesized materials without beam damage and contrast reduction due to carbon contamination.

CH05.13.04

High Resolution (S)TEM Analysis of the Chemical Solution processed $PbZrO_3$ Thin Films—Defect Occurrence on Different Scales

Vasily Lebedev[1,2], Kristina Holsgrove[3], Sarah Stock[1,2], Milan H. Haddad[4], Amit Kumar[3], Sergey Lisenkov[5], Inna Ponomareva[5] and Lewys Jones[1,2]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Trinity College Dublin, Ireland; [3]Queen's University Belfast, United Kingdom; [4]Georgia Institute of Technology, United States; [5]University of South Florida, United States

Lead zirconate $PbZrO_3$ (PZO) belongs to the perovskite structural type and is well-known as an archetypal antiferroelectric material, however, it is expected to demonstrate a complex picture of a polarization behaviour at the nanoscale. The emergence of ferroelectricity and the possible co-existence of FE-AFE ordering has been predicted using first-principles density functional theory (DFT) for the case of size/dimensional confinement [1]. The reduction of film thickness to achieve this has been attempted in $PbZrO_3$ with the expectation that the substantial changes in electrical and mechanical boundary conditions would tilt the energy balance towards the FE phase.

For this purpose, continuous PZO thin films ranging from ~120nm to ~650nm of thickness were grown via repeated chemical solution deposition (CSD) of organic precursors on Pt/Ti/SiO_2/Si wafers with the subsequent drying, pyrolysis, and crystallization. According to the outcome of X-ray diffraction (XRD), phase pure $PbZrO_3$ thin films

with the $[001]_O$ orientation were successfully obtained. The proposed layer-by-layer synthesis method poses high flexibility and the scalability potential, however, the spatial continuity of crystallites within the films and their chemical homogeneity has to be thoughtfully analyzed to confirm the suitability of the exact processing conditions. To assess this, the spatial continuity has been analysed with high-resolution scanning transmission electron microscopy (STEM) and energy dispersive X-ray spectroscopy (EDS), focusing on the microscopic structural changes within the films.

Lamellae from representative areas of samples were prepared using gallium focused ion beam (Ga-FIB) with subsequent argon ion milling to remove residual gallium and amorphous layers, and to reach the suitable lamellae thicknesses. Thickness was estimated using electron energy loss spectroscopy (EELS) t/λ mapping, the ratio of elastic and inelastic electron scattering.

STEM-EDS and STEM-EELS analyses have been performed using a ThermoFisher Talos F200X and Titan-G2 microscopes in QUB and the Advanced Microscopy Laboratory (AML) respectively. High spatial-precision imaging at atomic resolution was performed using the Nion UltraSTEM 200 instrument at the AML. In order to reduce the beam damage and sample drift effects, low-dose multi-frame non-rigid registration approaches were employed [2].

To assess and verify the proposed explanations of the features observed in the STEM images, in addition to the routine FFT-based analysis, the ab-initio simulations were performed to create the idealized image of the proposed model structures at the experimental conditions in use.

It has been confirmed that the obtained films demonstrate high structural and compositional continuity with a minor amount of nanometer-sized inclusions and defects. The results obtained enable further investigation to advance the fundamental understanding of antiferroelectricity in $PbZrO_3$ thin films and nanostructures.

In Situ Biasing STEM Investigation of Mg-Based Electrochemical Ionic Synapses (EIS) Devices

Alexandre Foucher, Miranda Schwacke, Bilge Yildiz and Frances M. Ross; Massachusetts Institute of Technology, United States

Developing and understanding innovative electronic components are essential for next-generation computing devices. In this work, we used in situ STEM techniques to measure Mg-based electrochemical ionic synapse (EIS) devices with a soft electrolyte layer. We first developed a focused ion beam (FIB) sample preparation procedure to minimize structural damage to the prepared lamella. The thin lamella was then deposited on a TEM chip for dedicated *in situ* biasing STEM experiments. We observed the dynamics of these Mg-based devices with atomic resolution imaging and spectroscopy when voltage was applied. The electron dose of the STEM probe was adjusted to create minimal structural damage to the device, especially the beam-sensitive electrolyte layer composed of MgF_2. We also demonstrated how electron energy loss spectroscopy can be adjusted to obtain critical information about dynamics in sensitive materials during *in situ* biasing experiments. This work underlines a pathway to characterize beam-sensitive materials with *in situ* STEM that can be expanded to a larger class of materials.

CH05.13.06

Development of a Method to Understand Morphological Changes in Materials at Ultrahigh Pressures Using Electron Microscopy George Hollyer[1], Dmitri Zakharov[2], Calvin A. Parkin[3], Daan Hein Alsem[3] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States; [3]Hummingbird Scientific, United States

High-pressure chemical reactions are critical to a wide range of industrial processes, such as mining operations, catalysis, manufacturing, power generation, carbon sequestration and energy storage. Understanding the high-pressure nano-scale dynamics of material interfaces (gas/liquid, liquid/solid) at the nanoscale will permit the optimization of these reactions based on their fundamental physics. This knowledge can also lead to the discovery of cleaner and more sustainable processes. The technological challenges to obtaining the necessary information to pursue these optimizations are significant because the relevant features are extremely small (tens of nanometers or smaller), and the reaction kinetics under investigation only activate at extremely high pressures (10-100 bars). Precise concentrations of multiple reagents or precursors and reaction temperatures are required to recreate the exact conditions found in nature and industry. Atmospheric transmission electron microscopy (TEM) has been important for understanding some of the processes mentioned above, but these experiments are confined to one or at most two atmospheres of pressure. Here we will describe our development of a new experimental apparatus that allows us to achieve ultrahigh pressure materials characterization using the transmission electron microscope. The experiments we will describe rely upon changes to the existing methods that allow a closed-cell TEM holder to withstand higher pressures without breaking the confining membranes and exploit the extra pumping of an environmental transmission electron microscope (ETEM) to protect the electron source. We will describe how we have determined spatial resolution using both scanning transmission electron microscopy and energy-filtered high-resolution transmission electron microscopy as a function of gas pressure and composition, how we have explored the limits to structure determination via electron diffraction, and the difficulties associated with spectroscopy using this approach.

CH05.13.07

Advancing Liquid Phase Electron Microscopy—Low Voltage Electron Microscopy Paired with Graphene Liquid Cells Emad Shahnam[1,2], Daniela Vieira[1] and Jared Lapkovsky[1]; [1]Delong America, Canada; [2]McGill University, Canada

High-contrast imaging of soft materials in transmission electron microscopy has always been challenging —made even more complicated for dealing with such samples in liquid environments. While Graphene Liquid Cells (GLCs) have been a valuable tool for liquid phase electron microscopy (LPEM) over the past few years due to the high electron transparency of the graphene, their integration with Low Voltage Electron Microscopy (LVEM) represents a novel advancement, opening new doors for high-contrast and high-resolution imaging of hydrated samples. However, the current trend in using the GLCs is in the realm of high-voltage electron microscopy (above 80 keV), which limits the contrast and might introduce beam damage especially in low atomic weight elements including life-science applications. The LVEM-GLC combination addresses such long-standing challenges in the field. GLCs provide an ultra-thin, electron-transparent environment for imaging liquid-phase samples, while the lower operating voltages of LVEM enhance electron scattering in light-element materials, resulting in significantly improved contrast. This dual approach allows for the visualization of hydrated samples in their native state without the need for staining or other potentially disruptive preparation steps. Additionally, the conductive

properties of graphene prevent beam-induced damage, extending the imaging duration and preserving the sample's integrity.

The novelty of this work lies in the ability to apply LVEM—operating below 30 keV—to GLC-encapsulated samples, offering significantly enhanced contrast and resolution compared to traditional high-voltage TEM approaches. The GLCs used in this study were prepared using an automated preparation technique with Naiad's commercial GLC fabrication system. This automized approach further enhances reproducibility and throughput, making this technique accessible for routine use in various research fields such as biological research, drug delivery, and nanotechnology. The combined application of GLC and LVEM allows for real-time monitoring of dynamic processes such as bubble formation, which is otherwise challenging to achieve with conventional high-voltage TEMs.

In this study, we used the Delong Instruments' compact LVEM 25 under TEM mode (1.0 nm resolution), and STEM (1.3 nm resolution). The accelerating voltages for TEM and STEM modes were 25 keV and 15 keV, respectively. Two GLCs containing ferritin and gold nanoparticles were prepared using Naiad instrument's automatic loop-assisted transfer method (by VitroTEM) wherein the GLC is supported by TEM grid with a porous polystyrene film. Ferritin (an iron storage protein in blood) and gold nanoparticles were chosen due to their relevance in biological and material science applications.

Both TEM and STEM microscopy of the GLCs produced high contrast enabling the differentiation between the particles of interest, liquid pockets, graphene layers, and gas bubbles dynamics. With the prolonged beam illumination on a single area, hydrogen bubbles begin to form slowly due to radiolysis. This was observed because of the gradual formation and movement of these bubbles, a process only observable at LVEM as this occurs too quickly at higher voltages, increasing the likelihood of liquid pockets bursting. Moreover, the liquid pockets demonstrated robustness under low-voltage beams and tolerated the increasing internal pressure due to the gradual gas formation.

In conclusion, the observation of GLCs using LVEM represents a significant leap forward in liquid phase electron microscopy, providing researchers with a powerful tool for imaging hydrated samples with unprecedented clarity and minimal sample disruption. This novel approach is set to unlock new insights into the behavior of particles in liquid environments, offering opportunities across a wide range of disciplines.

Tunable Optical Response of Phase-Change VO_2 Nanostructures Probed by Electron Energy-Loss Spectroscopy Andrea Konecna, Peter Kepic, Michal Horak, Jiri Kabat, Filip Ligmajer and Vlastimil Krapek; Brno University of Technology, Czechia

Low-energy excitations in matter, such as phonons, excitons, or plasmons, can be significantly influenced by defects, material phase, interfaces and boundaries. For instance, by nanostructuring bulk metallic materials, it is possible to engineer localized plasmonic resonances both spectrally and spatially, which is vital for light manipulation at the nanoscale. However, a detailed analysis of the plasmonic and other low-energy optical excitations in nanostructures requires probes that can provide high spectral (meV) and spatial (~ nm) resolution. Focused electron beams in scanning transmission electron microscopes (STEMs) in connection with electron energy-loss spectroscopy (EELS) can perfectly fulfil these requirements [1,2].

We use the advantages of STEM-EELS with in-situ thermal biasing to probe the local optical response of nanostructured vanadium dioxide (VO_2) across its reversible insulator-to-metal phase transition [3]. Our experimental results, supported by analytical and numerical modelling, demonstrate that Mie-like and plasmonic resonances emerge in nanoparticles below and above the transition temperature. We reveal that the size of the VO_2 nanoparticles strongly influences their optical response, hysteretic behaviour of the phase transition and the possibility of phase coexistence [4]. We further exploit the phase coexistence in a theoretical study of the optical properties and applications of gradually switching VO_2 nanoparticles. We also predict the existence of localized phononic modes that could be probed with EELS in the mid-infrared spectral range. Our results provide valuable insights into the general properties of phase transition in VO_2 nanostructures and highlight their impact on potential applications in nanophotonics.

Atomic-Scale *In Situ* STEM Investigation of Complex Fe Oxide-Ru Nanostructures Alexandre Foucher and Frances M. Ross; Massachusetts Institute of Technology, United States

Continued development of catalysts is essential to improve the synthesis of chemicals and reduce the cost of industrial processes. To this end, bimetallic nanoparticles are of great importance as the synergy between the two metals creates unique catalytic properties. However, changes in morphology and composition in a reactive environment can significantly alter the chemical properties of the catalysts. In this work, we studied Fe oxide-Ru nanoparticles as catalysts in reactive conditions (oxidative and reductive) to understand the dynamical restructuring effects that affect their catalytic potential. We recorded aberration-corrected *in situ* scanning transmission electron microscopy (STEM) images while simultaneously acquiring secondary electron (SE) images using the dual detectors available in a Hitachi HF5000-IS environmental transmission electron microscope. Atomic-scale STEM imaging combined with SEM and spectroscopy provided an overview of changes in the materials as a function of the conditions (temperature and gas environment). In particular, the surface-sensitive SE images and the projected Z-contrast sensitivity of dark field STEM allowed us to conclude that both segregation and mixing of Ru occur under different conditions along with changes in facet geometry. In an oxidative environment, Ru tends to mix with Fe_2O_3 at the surface of the nanoparticles. In contrast, a reductive environment causes the aggregation of Ru atoms into larger clusters, causing fewer Ru atoms to be exposed to the surface and mixed with Fe. Based on these results, we suggest protocols for maximizing the exposed expensive Ru and its potential for surface chemistry applications. Hence, this work underlines the advantages of combining atomic-scale STEM imaging with other techniques to track surface structure and compositional changes of bimetallic nanocrystals upon oxidative or reductive treatment.

Structural Transformations at the Atomic Scale in Vanadium Oxides upon Mg^{2+} Intercalation Danial

Zangeneh, Anwesa Semanta, Arashdeep Thind, Robert F. Klie and Jordi Cabana; University of Illinois at Chicago, United States

The advancement of mobile energy storage systems depends on the development of rechargeable batteries with higher energy densities.[1] Despite the widespread use of lithium-ion batteries in portable devices, there is growing research into alternative battery chemistries, including those using more abundant elements or electrodes that may also offer higher energy densities.[2] Mg-ion batteries are one such candidate, showing advantages such as greater material abundance, enhanced safety, and reduced cost compared to Li-ion batteries.[3]

In this contribution, we will study two possible Mg^{2+} intercalation cathodes, MgV_2O_4 and α-V_2O_5, using scanning transmission electron microscopy (STEM), electron energy-loss spectroscopy (EELS), and energy dispersive spectroscopy (EDS). We analyze structural changes with atomic resolution, quantify changes in the local bonding structures and valence states, and quantify variations in chemical distribution of these multi-valent cathode materials during charge/discharge cycles at elevated temperatures. A previous study demonstrated morphological changes in α-V_2O_5 during chemical cycling at elevated temperatures. [4] It was found that the charge-discharge cycle induces structural transformation and the formation of an amorphous layer with a distinct bond structure compared to the crystalline region. [5] Here, we will focus on identifying the reduction of the local crystalline order and morphological changes caused by electrochemical cycling to elucidate the Mg (de)intercalation pathways. [6]

Investigating the Thermal and Environmental Causes of Particle Migration in Pt/Al_2O_3 Catalysts

Jacob Smith[1] and Miaofang Chi[1,2]; [1]Oak Ridge National Laboratory, United States; [2]Duke University, United States

Emission control catalysts are an important environmental protection technology that eliminate harmful gases from hydrocarbon combustion reactions. Pt nanoparticles supported on alumina (Pt/Al_2O_3) are among the most common catalysts for this purpose. However, catalytic activity is lost over time to sintering processes facilitated by a combination of particle migration and coalescence, and also Ostwald ripening, that are driven by chemical and thermal interactions. These interactions are quite complicated and can produce substantially different dominant sintering mechanisms across the typical range of operating temperatures. Investigating these transient effects at atomic resolution under realistic environmental conditions requires the use of in situ atmospheric scanning transmission electron microscopy (STEM).

We have performed a series of in situ atmospheric and vacuum STEM experiments to understand the origin of particle migration in Pt/Al_2O_3 catalysts. Within a vacuum environment, Pt nanoparticles become mobile at 700 °C. However, the presence of oxygen and water vapor enhance the mobility of Pt nanoparticles so that motion becomes possible at temperatures as low as 500 °C. This motion is undulating in nature, wherein the nanoparticles extend and contract as they move across the Al_2O_3 surface. Through density functional theory calculations, it has been determined that enhanced particle migration in Pt is driven by nanoparticle-oxygen interactions. The adsorption of oxygen atoms increases the stability of anisotropic morphologies, permitting nanoparticle extension, while the release of PtO_2 molecules results in the contraction of the nanoparticles. Experimentally observed particle migration at 500 °C is not immediately followed by coalescence in neighboring nanoparticles. Instead, coalescence is gradually facilitated at higher temperatures. This delayed and temperature specific sintering behavior demonstrates the importance of understanding the complex environmental and thermal interactions that exist under realistic operating conditions.

9:45 AM CH05.14.05

Observing Early-Stage Zn Oxidation Using Environmental Transmission Electron Microscopy Hanglong Wu and Frances M. Ross; Massachusetts Institute of Technology, United States

Zn oxidation is a fundamental process in fuel cells, aqueous Zn batteries, and catalytic applications such as methanol synthesis. Understanding the oxidation of zinc is of critical importance in developing the broad applications of zinc and zinc oxide in energy, catalysis and electronics. Although Zn oxidation has been studied for over a century, the atomic mechanisms behind early-stage oxidation remain elusive. For instance, the native Zn oxide layer on Zn (0001) has been interpreted through the Volmer–Weber (VW) mechanism. However, the early electron spectroscopy studies indicated that the initial zinc oxide film growth (< 2 nm) was controlled by a different growth mechanism.

Environmental transmission electron microscopy (ETEM) is well known as a powerful technique for elucidating metal oxidation mechanism at the atomic scale. The capabilities of ETEM can be enhanced through the addition of a secondary electron (SE) detector which enables surface information to be obtained simultaneously with the STEM signal during gas reactions. To date, the application of SE-STEM in metal oxidation studies has been limited. Despite comprehensive conventional ETEM studies on the oxidation of metals such as Cu, Ni, and Al, the Zn system has not been studied, possibly due to the challenges in preparing an oxide-free starting Zn surface and the potential for Zn contamination inside the TEM column.

In this work, we investigate the initial stages of zinc oxidation using an aberration-corrected ETEM equipped with an SE detector. We first fabricate pristine, oxide-free Zn surfaces by electron irradiation in the TEM. We show movies of the decomposition of zinc oxide and the formation of the oxide-free Zn surface at elevated temperatures. These movies show sublimation-induced faceting and surface reconstruction of the Zn surface, and we discuss the mechanisms at work. Subsequently, by exposing the newly formed Zn facets to different O_2 concentrations, we observe the initial stages of Zn oxidation at various temperatures. Simultaneous SE-STEM imaging enables the evolution of sample surface morphology to be compared with the changes in the bulk during the processes of Zn surface formation, sublimation and oxidation. On higher oxygen exposure, an epitaxial oxide forms with a moiré structure arising from mismatch. We conclude that ETEM provides new insights into the Zn oxidation mechanism, and we anticipate broader applications of SE-STEM in studying the oxidation processes of other metals.

***In Situ* Microscopy and Spectroscopy Study on Dynamics of Nanostructure in Catalysis for Sustainable Energy** Gengnan Li[1], Dmitri Zakharov[2] and Jorge A. Boscoboinik[2]; [1]Argonne National Laboratory, United States; [2]Brookhaven National Laboratory, United States

Understanding the atomistic structure of the active site during catalytic reactions is of paramount importance in both fundamental studies and practical applications, but such studies are challenging due to the complexity of heterogeneous systems. Using Pt/CeO_2 as an example, we reveal the dynamic nature of active sites during the water-gas-shift reaction (WGSR) by combining multiple in situ characterization tools to study well-defined CeO_2 nanoshapes with different exposed facets. In situ near-ambient pressure X-ray photoelectron spectroscopy shows that metallic Pt is present on the $CeO_2(111)$ surfaces, while oxidized Pt species are dominant on $CeO_2(110)$ and (100) surfaces after O_2–H_2 pretreatment. The different concentrations of interfacial $Pt^{\delta+} – O – Ce^{4+}$ moieties at Pt/CeO_2 interfaces are responsible for the rank of catalytic performance of Pt/CeO_2 catalysts: Pt/CeO_2-rod > Pt/CeO_2-cube > Pt/CeO_2-oct. For all the catalysts, metallic Pt is formed during the WGSR, leading to the transformation of the active sites to $Pt^0 – O_v – Ce^{3+}$ and interface reconstruction, which is demonstrated by the in situ environmental transmission electron microscopy. These findings shed light on the dynamics nature of nanostructures under operating conditions and highlight the importance of combining complementary in situ techniques for establishing structure-performance relationships.

10:45 AM CH05.15.02
Investigation of Interfacial Radiolysis of Water at Silicon Nitride and Strategies to Minimize Radiolysis by Utilizing Graphene Hayeon Baek and Jungwon Park; Seoul National University, Korea (the Republic of)

Liquid phase TEM (LPTEM) is competitive tool to investigate formation mechanism, degradation, and nano-scale surface structure of nanomaterials in colloidal state. However, electron beam induced radiolysis of liquid damages the original structure of nanomaterials in colloidal state, which hinders stable TEM imaging. Many efforts have been made to reduce radiolysis effect during LPTEM observation, such as TEM imaging with low electron dose rate and some additives to scavenge radiolysis products. However, radiolysis of adsorbed water at the interface of silicon nitride, which is the window materials for the MEMS based liquid cell, remains less studied. Here, we investigate the radiolysis effect of adsorbed water by observing Pd nanocube dissolution process, and the strategies to mitigate interfacial radiolysis by using graphene which is known to be good electron compensator.

11:00 AM CH05.15.03
A New Way to Visualize Electrochemical Reactions at the Nanoscale–*In Situ* Liquid Phase TEM Zhiyuan Zeng; City University of Hong Kong, Hong Kong

For interfacial reactions, the state-of-the-art In-Situ Liquid Phase TEM is an ideal technique for identifying the phase changes during intercalation process. With self-designed electrochemical liquid cell utilized, we can directly vapture the dynamic electrochemical lithiation and delithiation of electrode in a commercial $LiPF_6$/EC/DEC electrolyte, such as LiF nanocrystal formation, lithium metal dendritic growth, electrolyte decomposition, sodium metal deposition and solid-electrolyte interface (SEI) formation. We fabricated electrochemical liquid cell with a much thinner liquid layer (150 nm) created by thin indium-spacer than that of commercial ones (1000 nm) created by O-ring. The thinner imaging windows (35 nm SiN_x) and thinner liquid layer ensure that the fabricated liquid cell can capture electrochemical reactions with better TEM spatial resolution than commercial products (Hummingbird, Protochips, etc). This technique opened a window for probing dynamic electrochemical reactions in liquid with high resolution. For LiF formation, The LiF nanocrystals show two-dimensional (2D) morphologies on the electrode surface, which can serve as a cathode electrolyte interface (CEI). Furthermore, the merging of LiF nanosheets was also observed, which may underlie the self-healing ability of LiF-based CEIs. Theoretical modeling indicates that there are two types of LiF formation paths on positive voltage-biased Ti electrodes. This work shows the remarkable morphing mobility and self-healing ability of LiF nanosheets and sheds light on strategies of modulating LiF nanocrystals and cathode surface chemistry for improving battery performance and cycle life.

***In Situ* 4D STEM with an Ultrafast Detector to Study Phenomena in Liquids** Carter Francis, Shuoyuan Huang and Paul M. Voyles; University of Wisconsin, United States

Ultrafast direct electron cameras create the opportunity for *in situ* 4D STEM experiments at (spatial) frame rates of order 10 frames per second (fps). We have used this capability to study phenomena in highly supercooled liquids near the glass transition, where dynamics are slow. We have used the scattering angle dependence of various elemental partial structure factors to measure the composition-dependent relaxation times from *in situ* 4D STEM. These data are otherwise accessible only through expensive and inaccessible radiotracer diffusion experiments. We have also used *in situ* 4D STEM to observe two-stage, non-classical nucleation in a metallic supercooled liquid. Instead of forming a crystal embryo with an interface with the liquid, the system first forms a nanoscale, disorder precursor particle. The crystal then form within the disordered precursor and grows to consume it before growing into the liquid. We believe this is the first experimental observation of non-classical nucleation of an inorganic crystal from a liquid of the same composition. Both of these experiments generate multi-TB scale datasets, which require efficient, out-of-memory lazy processing to analyze.

11:30 AM CH05.15.05

Imaging the Nanoscale Dynamic Structuring of Flow-Induced Gold Nanoparticle Superlattices in a Microfluidic Channel Rieke von Seggern[1,1], Jasmin Pongratz[1,1], Gregor Madej[1,2], Christine Ziegler[1,2] and Sascha Schäfer[1,1]; [1]Universität Regensburg, Germany; [2]University of Regensburg, Germany

Liquid cell transmission electron microscopy (LCTEM) has made great progress over recent years, overcoming initial challenges such as sample thickness, vacuum compatibility and the implementation of electrodes for electrochemistry or heating, and offers a unique access to the nanoscale structure of sample systems in an aqueous environment [1].

A large area of interest in LCTEM involves the behavior of nanoparticles (NPs) in a liquid medium, with investigations ranging from particle growth processes to particle diffusion and assembly. However, NPs in solutions are typically not visible in LCTEM due to rapid Brownian motion and only particles bound to the walls of the liquid channels can be imaged.

In our experiments, we have now been able to study the turbulent behavior of a dense cloud of citrate-capped Au NPs in aqueous solution with the adjustable liquid flow as an external control parameter for the NP density. The experiments were conducted in a JEOL JEM-F200 TEM with a cold-field electron source and an Insight Chips liquid-cell sample holder with well-defined microchannel flow geometry [2]. Utilizing the electron-beam induced deposition of NPs, we selectively create a nanoparticle sieve within a liquid cell channel, which effectively filters NPs from the flowing liquid. Up-stream of the sieve, NPs pile up and create a dense particle cloud. The density of the cloud is controlled by temperature dependent particle diffusion and the flow velocity of the liquid through the sieve. Comparison of the electron image contrast before and after the sieve yields a direct measure of the local particle density.

For such an experimental configuration, we observe two intriguing phenomena: Firstly, the particle cloud shows millisecond dynamics akin to the turbulent motion in a smoke cloud with indications of vortex formation. We putatively attribute this behavior to a dynamic rearranging of the sieve structure resulting in a change in the local fluid flow profile across the microchannel. Secondly, at the highest particle densities, the particles within the cloud start to form a stable, spatially periodic arrangement which breaks up once the liquid flow velocity is reduced.

Our experiments yield access to the dynamic nanoscale structure formation in densely packed liquid environments with some similarities to the crowded structures inside cells.

11:45 AM CH05.15.06

Molecular-Resolution Imaging of Ice Crystallized from Liquid Water Jingshan S. Du[1], Suvo Banik[2,3], Henry Chan[2], Birk Fritsch[4], Ying Xia[5], Andreas Hutzler[4], Subramanian Sankaranarayanan[2,3] and James J. De Yoreo[1,5]; [1]Pacific Northwest National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]University of Illinois at Chicago, United States; [4]Forschungszentrum Jülich GmbH, Germany; [5]University of Washington, United States

Despite the ubiquity of ice, a molecular-resolution image of ice crystallized from liquid water or the resulting defect structure has never been obtained. Here, we report the stabilization and angstrom-resolution electron imaging of ice I_h crystallized from liquid water. We combine lattice mapping with molecular dynamics simulations to reveal that ice formation is highly tolerant to nanoscale defects such as misoriented subdomains and trapped gas bubbles, which are stabilized by molecular-scale structural motifs. Importantly, bubble surfaces adopt low-energy nanofacets and create negligible strain fields in the surrounding crystal. These bubbles can dynamically nucleate, grow, migrate, dissolve, and coalesce under electron irradiation and be monitored in situ near a steady state. This work opens the door to understanding water crystallization behaviors at an unprecedented spatial resolution.

SESSION CH05.16: Breaking News
Session Chairs: Ryo Ishikawa and Quentin Ramasse

Thursday Afternoon, December 5, 2024
Sheraton, Third Floor, Fairfax B

1:30 PM CH05.16.01
Ultrafast Energy Transfer and Structural Dynamics of the PTB7 Polymer on a MoS$_2$ Monolayer Ming-Fu Lin[1], Hung-Tzu Chang[2], Andrew Attar[3], Aravind Krishnamoorthy[4], Alexander Britz[1], Xiang Zhang[5], Xiaozhe Shen[1], Pulickel Ajayan[5], Xijie Wang[1], Priya Vashishta[6], Aiichiro Nakano[6] and Uwe Bergmann[7]; [1]SLAC National Accelerator Laboratory, United States; [2]Max Planck Institute, Germany; [3]Vescent Photonics, United States; [4]Texas A & M University, United States; [5]Rice University, United States; [6]University of Southern California, United States; [7]University of Wisconsin-Madison, United States

Energy transfer across a heterogeneous interface is an important topic to understand detailed functioning mechanisms of solar cells and photocatalysts. Here, we used mega-electronvolt ultrafast electron diffraction (MeV UED) as a sensitive time-resolved ”thermometer” to simultaneously measure structural dynamics and energy transfer between a polymer (PTB7) and an atomic thin MoS$_2$ monolayer. Optical excitation of the polymer to the excited state relaxes quickly through the heterojunction interface to the monolayer MoS2. The thermal energy transfers from the polymer to the atomic layer can be described by a thermal transport model. The time-resolved structural dynamics of polymer suggests a bond dissociation located specifically at the C-O sidechain during the flattening motion of the two aromatic conjugated rings in the excited state, providing the fundamental mechanism of the photo-instability of a polymer in the applications of solar cell materials.

1:45 PM CH05.16.02
Imaging the Smallest Living Things with Nanometer-Resolution Without Compromising Viability Ashutosh Kumar, Nicolas Perry, Apurba Paul, Mehmet Ozdogan and Gregory Timp; University of Notre Dame, United States

This work represents a first step towards the illumination of the biological mechanisms underpinning live cell physiology with nanometer resolution. Using low-energy (30 keV), low-dose, probe-corrected, integrated differential phase-contrast scanning transmission electron microscopy (iDPC-STEM) in conjunction with a liquid flow cell, two genetically engineered *Mycoplasma* species, *M. mobile* and *M. pneumoniae,* which are among the smallest, simplest, self-replicating bacteria, were scrutinized with nanometer-resolution without compromising cell viability. The viability was scored at a lethal dose to 50% of the population at LD$_{50}$ > 3600 e^-/nm^2 at a beam energy of 30 keV by expression of an inducible fluorescent reporter following exposure to the electron beam in genetically engineered strains of the bacteria, which is in stark contrast with the LD$_{50}$ < 56 e^-/nm^2 observed at 300 keV. The higher LD$_{50}$ at a beam energy of 30 keV opened a wide window for high-resolution imaging of cell physiology. Within this window, the mechanisms for gliding motility in *Mycoplasma,* which are essential to infection and mediate attachment to a host, were elucidated with < 3 nm resolution.

2:00 PM CH05.16.03
***In Situ* Transmission Electron Microscopy of Light-Induced Processes in Liquid** Andrzej M. Zak[1,2], Olga Kaczmarczyk[1,2], Marta Piksa[1,3], Irena Maliszewska[1] and Katarzyna Matczyszyn[1]; [1]Wroclaw University of Science and Technology, Poland; [2]Massachusetts Institute of Technology, United States; [3]Ludwik Hirszfeld Institute of Immunology and Experimental Therapy, Poland

In situ transmission electron microscopy (TEM) allows real-time observation of dynamic processes. Although stimuli such as strain, temperature, and magnetic or electric fields are commonly explored, the interaction between light and matter is less frequently studied. Nevertheless, recent years have witnessed a notable gain in interest in this aspect of the technique. Historically, the delivery of light into TEM samples has been a complex task, with various methods such as dedicated specimen holders, parabolic mirror mounts, or optical fibers being employed. However, these solutions often have limitations, such as uneven sample illumination, restrictions on sample manipulation, or issues with light intensity calibration [1].

Due to the limitations of commercial solutions, we created our own sample illumination in our TEM systems. Our first setups used the Hitachi H-800 [2], and allowed for precise control over light exposure and dose measurement [3]. They allowed us to perform a series of preliminary studies and define precise requirements for the final configuration of the TEM microscope for light-induced studies.

Our main trials focused on imaging the antimicrobial photodynamic therapy (aPDT) phenomena [4]. aPDT is a modern, noninvasive method for combating infections, including those caused by drug-resistant bacteria. The process relies on photosensitizers (PS) that, when exposed to specific light wavelengths, generate reactive oxygen species (ROS), which damage cellular structures. The primary targets of ROS are cell membranes, leading to functional disorders and bacterial inactivation. However, damage to nucleic acids and proteins can also play a role in this process. To enhance the understanding of the mechanism of therapy, advanced techniques such as electron microscopy are necessary, especially since light microscopy often lacks the resolution required to observe the fine details of microbial damage. For this purpose, we also had to implement liquid cell TEM preparation, based on the SiN + graphene configuration and on sandwitches of amorphous carbon (aC) films. In a study designed to explore the aPDT, bacteria were encapsulated with liquid photosensitizers and irradiated with light in a TEM setup. The system used in the experiments included a top-mounted light source, allowing precise control over illumination. For these tests, Gram-positive Staphylococcus aureus and Gram-negative Acinetobacter baumannii were used, with methylene blue as photosensitizer and 660nm light illumination. One of the major issues in using TEM to observe hydrated samples, such as bacteria in a liquid cell, is the damage caused by the electron beam itself. In preliminary tests, the team successfully demonstrated that light-induced effects could be isolated from electron-induced damage. The results showed that aPDT damage occurred mainly in the outer cellular structures of the bacteria, confirming the central role of membrane disruption in aPDT.

In cooperation with ThermoFisher Scientific, we managed to create a new model of the illuminator on the Talos F200i microscope. The ongoing delivery of the chip-based liquid cell holder will allow us to compare the imaging efficiency of light- and electron-beam-induced processes in different types of liquid cells (SiN/graphene/aC). The newly implemented project will answer the questions of how different photosensitizers act on microorganisms of the ESKAPE group.

This research was made possible by the National Science Center, Poland (2023/51/D/ST11/01490). Andrzej Zak would like to acknowledge the Polish-American Fulbright Commission and Institute of International Education (Fulbright Senior Award) and LightTEM project (7308/IA/SP/2022, Ministry of Education, Poland).

Advancing EELS Applications by Combining New Scan Strategies with Direct Detection Cameras Andrew Thron, Liam Spillane, Ray D. Twesten and Paul Thomas; Gatan Inc., United States

Up-to-date as of November 14, 2024

Advancements in electron optics have pushed the spatial resolution of electron energy loss spectroscopy. This has enabled scientists to study chemical and electronic structure changes at the atomic scale [1]. Traditionally, spectrum images were acquired in one single pass. A typical probe current of 100-200pA and dwell times on the order of 5-10ms were needed to obtain a sufficient signal-to-noise ratio to resolve the features in an EELS spectrum image (SI), leading to a total dose on the order of 10^7 $e^-/Å^2$. Such a large dose is needed due to the relatively small inelastic cross sections of most ionization edges of interest, and the poor collection efficiency of the previous generation CCD cameras. These large doses have prohibited achieving similar resolutions in dose-senstive samples such as Zeolites, which has a total dose thresh hold of <3000 $e^-/Å^2$. In extremely dose-sensitive samples such as polymers and biological samples, whose total dose threshold is between 40-100 $e^-/Å^2$, the spatial resolution is limited to a range of 10’s nm. Such a dose-constrained resolution prevents the investigation of soft-mater interfaces and potential insight into chemical changes in biological samples that occur on the nm scale.

The Continuum GIF, combined with Gatan's Direct Detection Cameras, enables SI pixel dwell times of ~100s of μsec. due to the increased frame rate of the cameras and collection efficiency of the spectrometer’s optics. An increase in speed inherently changes the mode of SI acquisition from a single pass to acquiring the SI in multiple rapidly acquired passes. This has been shown to reduce or eliminate sample degradation through dose fractionation, where a series of fast spectrum image passes spread the total dose over the same accumulated time as a single pass [2,3]. Compared to the traditional raster pattern, alternative scan patterns have also been shown to reduce the level of sample degradation in ADF STEM images by reducing the effect of damage delocalization caused by multiple scattering to the surrounding sample volume [4]. These new scan strategies are now being implemented with Gatan's Digital Micrograph and DigiScan 3. The fast read-out speed, the ability to fractionate the dose over multiple passes, and the reduction of damage delocalization has enabled the advancement of EELS SI into materials applications that were otherwise not thought possible.

We demonstrate how the combination of these new scan strategies enabled by direct direction cameras can push EELS spectrum imaging into new applications. We show that atomic resolution Spectrum imaging can be achieved on a ZSM-5 Zeolite sample. For multipass spectrum image acquisition, we use Digital Micrographs in-situ SI tool to individually save each SI and pass. This allows us to play back the sequence of passes post-acquisition to monitor degradation in the sample. We hope to show that these new scan strategies, combined with direct detection cameras, can help push EELS into new applications, including biological samples.

Nonresonant Control of Materials Aaron Lindenberg; Stanford University, United States

We report on a novel type of mechanism for manipulating solids via non-resonant, below gap photo-excitation, mediated by the real part of the dielectric constant. Typically, light-induced phase-changes are induced through the imaginary part of the dielectric function, associated with above-gap or resonant excitation. Here we describe two application of this non-resonant approach, first in the ferroelectric $LiNbO_3$ where we show evidence for transient reversal of the ferroelectric polarization, and second in the chalcogenide SnSe where we observe evidence for a new type of phase-change to a higher symmetry state with long-lived and significant modulations in the optical properties. We show that both responses can be understood in terms of a non-perturbative impulsive stimulated Raman scattering response. This work defines new routes towards novel types of phase-change materials with reduced energy consumption and ultrafast switching speeds.

Time-Resolved X-Ray Diffraction Studies of CdSe:CdS Semiconductor Nanocrystals Ben L. Cotts[1], Eliza Wieman[1] and Burak Guzelturk[2]; [1]Middlebury College, United States; [2]Argonne National Laboratory, United States

Colloidal semiconductor nanocrystals (NCs) are increasingly used in photonic and electronic applications due to their tunable properties, which can be adjusted by altering their size, shape, composition, or surface chemistry. As such, a thorough understanding of their nanoscale thermal properties is essential for maintaining device performance and stability during operation. Previous studies have reported that the thermal conductivity of nanocrystal films range from 0.1-0.6 W m^{-1} K^{-1}, nearly two orders of magnitude lower than their bulk counterparts. This slow thermal transport in NC thin films can negatively affect device performance, reducing the lifespan and efficiency of NC-based optoelectronics such as lasers or LEDs. Additionally, a better understanding of nanoscale thermal transport could improve the development of NC-based thermoelectrics, which convert thermal gradients into electrical power. Real-time characterization of temperature changes as excited charges relax in device active layers is needed to help unlock these applications.

In this study, we use time-resolved x-ray diffraction (TR-XRD) measurements on CdSe:CdS NC thin films to directly measure thermal conductivity in samples that model a NC laser cavity. We compare experimental results with thermal transport models to determine thermal conductivity. Previous TR-XRD studies of measure thermal conductivity have been focused on bulk materials, epitaxial films, or small flakes of 2D materials, without a focus on NC thin film assemblies. Our work builds upon earlier studies of NC thin film thermal conductivity, which used conventional methods such as 3ω and time or frequency domain thermoreflectance to capture this information in a contact-less approach. Using TR-XRD to study NC thin films will enable direct monitoring of structural dynamics and thermal transport in photoexcited NC thin films and actual NC-based devices.

11:15 AM CH06.01.03

Discerning the Mechanism Behind Photochromism in Rare Earth Oxyhydrides Using Femtosecond Pump-Probe Experiments Jose Montero and Germán Salazar Alvarez; Uppsala University, Sweden

Rare-earth oxyhydrides (REHOs) exhibit photochromic properties, darkening reversibly under blue/UV light and bleaching back thermally when kept in darkness. This property, combined with their inorganic nature and easy fabrication by scalable methods such as sputtering, makes REHOs very promising materials for many technological applications, including smart windows [1]. The darkening/bleaching process in REHOs is accompanied by lattice expansion/contraction [1]. The underlying mechanism of the photochromic behavior in REHOs remains unknown. However, studying the dynamics of the lattice expansion/contraction, and specifically how fast the lattice contraction takes place after light impinges on the material, can be instrumental in unveiling the photochromic mechanism. If we assume that the contraction of the lattice is related to an electronic process, e.g., a pseudo-Jahn-Teller process, we would expect a nearly instantaneous response of the lattice after excitation with a UV femtosecond laser. If the contraction involves anion hopping and/or diffusion of other species, we would expect a response in the nanosecond regime. On this basis, we performed pump-and-probe X-ray diffraction experiments at the FemtoMax beamline at MaxIV, Lund (Sweden) [2]. In the experiments, we studied different photochromic yttrium oxyhydride (YHO) thin films (crystalline structure fcc) using a femtosecond pulsed laser (wavelength 365 nm), while simultaneously monitoring the position of the Bragg peak (111) of YHO with excellent temporal (picosecond) and spatial (0.01°) resolution. In the talk, we will discuss some of the outcomes of these experiments (including the discovery of a discontinuous jump of the diffraction ring, which likely points to a light-induced phase transition), as well as some of the experimental challenges encountered in the study of this particular material and how they could have been avoided.

The ability to understand and ultimately control the transformations and properties of various nanoscale systems, from proteins to synthetic nanomaterial assemblies, hinges on the ability to directly elucidate their dynamics on their characteristic length and time scales. Here, we use MHz X-ray photon correlation spectroscopy (XPCS) to directly elucidate the characteristic microsecond-dynamics of density fluctuations of semiconductor nanocrystals (NCs), not only in a colloidal dispersion but also in a liquid phase consisting of densely packed, yet mobile, NCs with no long-range order. By carefully disentangling X-ray induced effects, we find the wavevector-dependent fluctuation rates in the liquid phase are suppressed relative to those in the colloidal phase and to those in experiments and hydrodynamic theories of densely packed repulsive particles. We show that the suppressed rates are due to a substantial decrease in the self-diffusion of NCs in the liquid phase, which we attribute to explicit attractive interactions. Via comparison with simulations, we find that the extracted strength of the attractions explains the stability of the liquid phase, in contrast to the gelation observed via XPCS in many other charged colloidal systems. This work opens the door to elucidating fast, condensed phase dynamics in a variety of complex fluids and other nanoscale soft matter systems, such as densely packed proteins and non-equilibrium self-assembly processes.

Energy-Filtered Ultrafast Electron Microscopy for Improving the Time Resolution Ye-Jin Kim[1,2] and Oh-Hoon Kwon[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

For the instrumentation in ultrafast electron microscopy (UEM), imaging the ultrafast phenomena at the nanoscale was challenging because the temporal resolution was insufficient to film the onset of the structural change associated with atomic motions. For imaging electron pulses, the duration is determined at the initial stages of photoemission, resulting from the mismatch of photon energy and the work function of the photocathode, inhomogeneities on the surface, and bandwidths of the photoemission-driving pulses, and during the propagation experiencing multiple beam crossovers. This energy spread of electron pulses develops a chirp, which is an energy (E)–time (t) correlation defined as a phase-space slope, resulting in the temporal broadening of the pulses because the leading electrons with higher energies accelerate and those with lower energies are retarded during propagation.

In this presentation, we show the application of an energy filter to UEM to mitigate the temporal broadening of probe electron packets due to coulomb repulsion, and thus energy exchange, among the dense electrons. Energy-filtered TEM is advantageous for enhancing image contrast/resolution by mitigating chromatic aberration effects, which blur images. Likewise, a conventional energy filter gates the chirped photoelectron packets in UEM to select photoelectrons of narrow energy distribution and, therefore, short temporal duration.

With the requisite time resolution, we reveal the mechanism behind the ultrafast photoinduced phase transition of VO_2 and address its heterogeneous nature. For the optically induced phase transition of the polycrystalline VO_2 film, the time-resolved electron imaging with gated photoelectrons revealed the enhancement of instrument response function from 2.8 ps to 700 fs. Utilizing the energy-filtered UEM, we show the heterogenous ultrafast phase transition of VO_2 nanoparticles through a transient low-symmetry metallic phase induced by local strains.

Attomicroscopy—Attosecond Electron Microscopy Dandan Hui, Husain Alqattan, Mohamed Sennary, Nikolay Golubev and Mohammed Hassan; The University of Arizona, United States

Ultrafast Electron Diffraction and Microscopy imaging have been demonstrated to be pivot tools for imaging the atomic motion in real-time and space. The generation of a few hundred femtoseconds electron pulses enabled recording movies for molecular and atomic motion. However, the technical challenges in electron pulse compression have limited the temporal resolution of electron imaging experiments to a hundred femtoseconds. Here, we demonstrate the attosecond temporal resolution in the transmission electron microscope by optical gating to establish what we so-called “Attomicroscopy”. Moreover, we utilized the Attomicroscopy to image the electron motion dynamics in graphene. In a strong field, the electron is moving in the reciprocal space following the waveform of the driver field. The attosecond electron diffraction experiment allowed us to study the electron density distribution in the reciprocal space at different time instants and connect it with the electron motion in real space. The demonstrated Attomicroscopy imaging tool opens the avenue to study electron motion in neutral matter and promises new electron imaging applications in physics, chemistry, and biochemistry.

Opportunities in nanoscale probing of laser-driven phase transitions:

For several decades, optical near-field microscopy facilitated pioneering investigations of photonic excitations at the nanoscale. In recent years, the near-field microscopy of terahertz fields has emerged as an important tool for experiments involving phononic and electronic phenomena, rich spatio-temporal dynamics, and highly nonlinear processes. Building on this foundation, this Perspective illuminates the transformative opportunities provided by terahertz near-field microscopy to probe ultrafast phase transitions, helping to tackle previously inaccessible challenges of condensed matter physics. In many systems, laser-driven phase transitions are accompanied by the generation of terahertz pulses with spatio-temporal features governed by the complex physics underlying the phase transition. Thus, characterization of the emitted pulses using terahertz near-field microscopy techniques could support the investigation of ultrafast phase transition dynamics. This approach could, for example, allow the observation of ultrafast topological transitions in quantum materials, showcasing its ability to elucidate the dynamic processes underlying phase changes.

Structural Dynamics in 2D Materials Revealed by Ultrafast Transmission Electron Microscope Kyoko Ishizaka[1,2]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Visualizing and evaluating ultrafast structural dynamics occurring in a variety of materials and nanostructures are becoming important these days, such as photoinduced structural phase transitions, ion dynamics, coherent phonons, acoustic resonances, and so on. For this purpose, we have been working on developing the ultrafast transmission electron microscope (UTEM) by utilizing the combination of short-pulsed laser and transmission electron microscope technique. This enables us the pump-probe spatiotemporal measurement of nm × ps resolution and wide range (ps – sub-ms), by using a variety of bright/dark field imaging and/or electron diffraction methods [1-4].
In this talk, we will introduce our recent studies on two-dimensional (2D) atomically thin flake materials. We employ the newly developed automated dark-field tomography technique combined with UTEM, which enables us to quantitatively obtain the information of the structural dynamics including the stacking direction of the 2D materials, such as the heights of the constituent atoms, interlayer distances, and so on. First we demonstrate that the interlayer distances for natural-bilayer-WSe_2 and twisted-bilayer moire WSe_2 are both expanded as compared to bulk 2H-WSe_2. We further reveal the optically induced sub-Å interlayer decoupling in the twisted-bilayer moire WSe_2, that appears in the picosecond scale apart from the lattice thermalization effect. Possible mechanisms of this significant interlayer decoupling in the twisted-bilayer moire system will be discussed in comparison with the bulk and natural-bilayer counterparts.

Ultrafast Cathodoluminescence for Exploring Exciton Dynamics in Perovskites Heterostructure and Interfaces

Betty Shamaev and Yehonadav Bekenstein; Technion–Israel Institute of Technology, Israel

Halide perovskites have garnered significant attention for their potential in optoelectronics due to their exceptional photoluminescence quantum yield, fast lifetime, and tunable optical and electronic properties. For halide perovskite, interfaces and heterostructure will affect both structure and function. The presented study investigates vapor-grown CsPbBr3 micro-wires and their relations with competing Cs4PbBr6 phase serving as their nucleation seeds. We show that by controlling growth parameters and surface roughness, we can favor two distinct wire geometries. The first involves out-of-plane growth, where the wires grow at a fixed angle to the substrate. Through angle-resolved cathodoluminescence analysis, the growth angle α can be determined for the first time to be 57°±3°, identifying the contact surface as the {111} cubic CsPbBr3 plane. The second geometry involves the more common in-plane growth, with rectangular well-faceted wires in direct contact with the substrate along their elongated side. The main challenge is determining the effects of such interfaces on these materials' dynamics and excitonic properties. To achieve diffraction-limited spatial resolution, we use an ultra-fast cathodoluminescence microscope. We explore excitonic dynamics in which the Cs4PbBr6 seed influences the emission characteristics, affecting both the emission intensity and the lifetime near the interface. Our results resonate and support previous observations of similar heterostructures that were grown under very different growing conditions, indicating the generality of the observed effect and robustness of the measurement technique. The vision is to further explore the influence of lower temperatures on the interfaces and the various phase transitions and effects on exciton dynamics.

4:00 PM CH06.03.03

Characterizing Quantum Emitters at the Nanoscale with Time-Resolved Cathodoluminescence in a

Scanning Transmission Electron Microscope. Muchuan Hua[1], Thomas E. Gage[1], Hanyu Hou[1,2], Benjamin T. Diroll[1] and Jianguo Wen[1]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Urbana-Champaign, United States

Combining a scanning transmission electron microscope with cathodoluminescence (STEM-CL) allows researchers to simultaneously acquire atomic scale structural and compositional information along with local optical properties of the sample. Such CL systems have been applied for examining quantum dots, color centers in wide bandgap materials, and other quantum emitters (QE), allowing the establishment of direct correlation between the material's structural feature and its optical properties. Our research demonstrates an integration of high temporal-resolution into the STEM-CL system, allowing the research of the fast processes during the QEs' photon emissions. The temporal resolution is achieved with a simple pump-probe mechanism, where fast (ns) and ultrafast (ps) electron pulses are utilized as pump, while the photons generated by the CL processes are sent into a time-correlated-single-photon-counting device to reveal the temporal information. The system is set up on an aberration corrected STEM equipped with the CL module. An initial demonstration experiment was carried out with as short as 5 ns electron pulses generated by the beam blanker to obtain the spatially resolved radiative decay lifetime of Ce-doped YAG nanoparticles. Anticipated upgrades to the system will include an RF module to pitch the electron beam in GHz frequency, creating ps electron pulses, pushing the temporal-resolution to ps region. An HBT interferometer is also integrated to the CL module allowing simultaneous anti-bunching measurements. The details of the system and the preliminary results will be shown in the presentation.

4:15 PM CH06.03.04
Towards µm-Sized Laser Spots in a TEM Christian Monachon, Nicolas Tappy and Maïté Blank; Attolight AG, Switzerland

Utilizing both photons and electrons to characterize a material is emerging as a field, for example when dealing with nanoscale transport properties, or simply to record gain and loss electron spectroscopy signals for higher energy resolution. In both examples, having a very tightly focused spot on the specimen surface is desirable. Tighly focusing a laser beam on a TEM specimen is a challenge, because the sample lies in a tight space between the top and bottom part of the objective lens of the microscope.
Ongoing efforts at Attolight AG are directed at reaching the smallest spot sizes on a TEM sample using the Mönch® add-on mirror, which is inserted between the part of the objective lens closest to the electron source and the sample. While it was initially used for light collection, it is seeing increasing interest for injection.
This contribution will describe the dedicated apparatus and experimental procedure developed to characterize and optimize the light injection spot on a TEM sample surface. This apparatus is based on an Allalin® SEM platform, rigged with a Mönch light collection/injection add-on. This allows the use of the Allalin collection optics to be used in conjunction with the Mönch mirror, both as a reference and collection apparatus for defocused beam conditions.
The advantages and limitations of the Mönch as an injection method will be discussed. In particular, sensitivity to defocus and misalignment will be discussed, both on-axis and off-axis.

SESSION CH06.04: Ultrafast Electron Microscopy II
Session Chairs: Ye-Jin Kim, Volkan Ortalan and Ding-Shyue (Jerry) Yang
Tuesday Morning, December 3, 2024
Sheraton, Third Floor, Fairfax A

8:30 AM *CH06.04.01

Ultrafast Transmission Electron Microscopy—Instrumental Developments and Applications Alexander Schröder[1], Niklas Müller[1], Jonathan Weber[1], Rieke von Seggern[1], Soufiane el Kabil[1] and Sascha Schäfer[1,2]; [1]Universität Regensburg, Germany; [2]University of Regensburg, Germany

Time-resolved variants of transmission electron microscopy have started to provide an unparalleled view into the fast and ultrafast dynamics of solid-state nanostructures. A crucial instrumental pre-requisite for constructing the next generation of time-resolved electron microscopes is the development of novel pulsed electron sources, fast detectors and versatile sample excitation schemes. In the first part of the talk, I will summarize our recent developments and characterization of a laser-driven cold-field emitter source (in collaboration with JEOL Ltd.), including the achieved electron pulse duration, spectral width, and electron beam brightness. Applications of these high-brightness electron pulses for the imaging of wavelength-dependent optical near-fields in transition metal dichalcogenides will be presented [1].

In the second part, I will focus on the application of event-based TimePix3 electron detectors in fast electron imaging. Using a neural network approach trained by experimental data with synchronized femtosecond electron pulses, we can improve the time-resolution of the TimePix3 detector utilizing the intrinsic correlations within event clusters [2]. Finally, as two applications for event-based electron imaging, I will discuss the excitation and phase-resolved mapping of nonlinear Duffing modes in a silicon membrane, demonstrating quality factors exceeding 10^5, and the time-resolved Lorentz imaging of photoinduced charging in metal nanoparticles [3].

Directing Energy Transport at the Nanoscale with Electron Microscopies Prakriti P. Joshi[1], Davis Unruh[2], Nasim Mirzajani[1,1], Thomas E. Gage[2], Luqing Wang[2], Ruiyu Li[1,1], Haihua Liu[2], Joseph L. Spellberg[1,1], Liangbo Liang[3], Ilke Arslan[2], Maria K. Chan[2,4] and Sarah B. King[1,1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]Northwestern University, United States

Spatial direction of energy flow, namely carrier and heat transport, in 2D materials is critical for developing these materials into next-generation optoelectronic and thermoelectric applications. However, current understanding at the single- and few-atom layer limit is largely informed by intrinsic charge and phonon transport mechanisms and does not consider the effects of nanoscale morphological variations, such as material edges and localized strain, which are especially abundant in mechanically exfoliated systems. The resulting modification of the electronic wave functions, band energetics, and phonon dynamics can compete with or even overwhelm intrinsic properties. I investigate this interplay of intrinsic and extrinsic behavior in a model system, anisotropic black phosphorus (BP). Interrogating the nanoscale edge modifications and dynamics requires sub-100 nm spatial resolution, which is prohibitive to conventional optical microscopies but well-suited to electron microscopies. I combine polarization-dependent photoemission electron microscopy (PEEM) and ultrafast transmission electron microscopy (UEM) to investigate the role of edge-modification on the electronic structure and coherent acoustic phonon transport in BP by directly interrogating the above-bandgap optical transitions and photoexcitation-induced lattice dynamics, respectively. Using PEEM, I show that spatially confined wavefunctions at BP flake edges results in a rotated transition dipole moment, which has implications for spatially selective excitation and design of nanostructured 2D materials. With UEM, I show that the bonding anisotropy-driven mixing of longitudinal and transverse acoustic phonon modes results in a strongly reduced group velocity of in-plane coherent acoustic phonons, which cannot be explained by mode-averaged diffusive transport models. These results suggest that intentional design of edge orientations and intrinsic bonding anisotropy offer a novel route towards controlling in-plane acoustic phonon and heat propagation.

9:15 AM *CH06.04.03
Microsecond Time-Resolved Cryo-EM Ulrich J. Lorenz; École Polytechnique Fédérale de Lausanne, Switzerland

While cryo-electron microscopy (cryo-EM) is rapidly gaining in popularity, its time resolution is frequently insufficient to directly observe proteins in action, leaving our understanding of these nanoscale machines fundamentally incomplete. My group has recently introduced a novel approach to time-resolved cryo-EM that improves its time resolution by about 3 orders of magnitude. Our method involves melting a cryo sample with a laser beam, which allows dynamics of the embedded particles to occur in liquid once a suitable stimulus is provided. While the dynamics occur, the heating laser is switched off at a well-defined point in time, causing the sample to rapidly recool, so that it vitrifies. The particles are thus trapped in their transient configurations, in which they can subsequently be imaged. We demonstrate that our approach affords a time resolution of 5 µs or better. Moreover, near-atomic resolution reconstructions can be obtained from revitrified samples, showing that the revitrification process leaves the protein structure intact. Finally, I will present a microsecond time-resolved pH jump experiment, in which we observe the dynamics of the capsid of CCMV, an icosahedral plant virus. These results highlight the potential of our method to fundamentally advance our understanding of protein function through direct observation of the dynamics involved.

10:15 AM *CH06.04.04
Imaging a Photo-Doped Mott Insulator with Ultrafast Electron Microscopy Bolin Liao; University of California, Santa Barbara, United States

Scanning ultrafast electron microscopy (SUEM) is an emerging optical-pump-electron-probe technique that can image spatial-temporal dynamics of photo-induced surface charges with high resolutions and surface sensitivity. In this talk, I will describe our preliminary study of photo-doped Mott insulator ��-RuCl3 using SUEM, where we observed qualitatively different dynamics of photo-induced charge with varying optical excitation fluence. At low fluence, we observe the diffusion of a Gaussian population with a long hot carrier cooling time beyond 1 nanosecond, which is almost one order of magnitude longer than that in conventional semiconductors. At higher fluence above a threshold, we observe a highly nonlinear response in the SUEM images showing a ring-shaped feature and an overall suppressed contrast intensity. By comparing to time-dependent DFT simulations, we attribute the observation to a photo-induced insulator-to-metal transition in ��-RuCl3. Our results demonstrate the rich physics in a photo-doped Mott insulator that can be extracted from spatial-temporal imaging and showcase the capability of SUEM to sensitively probe photoexcitations in strongly correlated electron systems. This work is supported by US Air Force Office of Scientific Research under the award number FA9550-22-1-0468 and US Army Research Office under the award number W911NF2310188.

10:45 AM CH06.04.05
Attosecond Optical Switching by Controlling the Electron Motion of Dielectric Material Dandan Hui, Husain Alqattan, Mohamed Sennary and Mohammed Hassan; The University of Arizona, United States

Modern electronics are founded on switching the electric signal by radio frequency (RF) electromagnetic fields on the nanosecond timescale, limiting the information processing to the gigahertz speed. Recently, optical switches have been demonstrated using terahertz and ultrafast laser pulses to control the electric signal and enhance the switching speed to the picosecond and a few hundred femtoseconds time scale. Here, we exploit the reflectivity modulation of a dielectric system in a strong light field to demonstrate the optical switching (ON/OFF) with attosecond time resolution. Moreover, we present the capability of controlling the optical switching signal with complex synthesized fields of ultrashort laser pulses for data binary encoding. This work paves the way for establishing optical switches and light-based electronics with peta- and exahertz speeds, several orders of magnitude faster than the current semiconductor-based electronics, opening a new realm in information technology, optical communications, and photonic processor technologies.

11:00 AM CH06.04.06

Visualizing Photoemission and Photocarrier Dynamics in Wide Bandgap Semiconductors with UV-Pumped Scanning Ultrafast Electron Microscopy Yujie Quan, Basamat Shaheen, Zeyu Xiang, Ryan Gnabasik and Bolin Liao; University of California, Santa Barbara, United States

Wide bandgap semiconductors have a broad range of applications, including light-emitting diodes, photodetectors, and field-effect transistors. The performance of these devices strongly depends on the ultrafast carrier dynamics, referring to the generation, relaxation, and recombination processes of charged carriers. Therefore, a comprehensive microscopic understanding of carrier dynamics with simultaneously high spatial and temporal resolutions is vital to providing optimization strategies for the design of wide bandgap devices with enhanced performance.

Scanning ultrafast electron microscopy (SUEM) has emerged as a cutting-edge optical-pump-electron-probe technique for visualizing photocarrier dynamics with combined high spatial and temporal resolutions and surface sensitivity. Despite previous studies on the carrier dynamics of a broad range of inorganic and organic semiconductors with SUEM, investigations have been largely confined to narrow bandgap semiconductors due to limitations posed by the relatively long wavelength of the pump light used (typically around 500 nm), which precludes efficient one-photon excitation in wide bandgap materials. In this work, we have implemented an ultraviolet (UV) pump at 257 nm (4.8 eV) that enables the direct visualization of the hot photocarrier dynamics as well as the photoemission process via one-photon excitation in wide bandgap materials for the first time. The photoemission process of wurtzite gallium nitride and the photocarrier dynamics of silicon carbide will be discussed as an example. Our work deepens the understanding of the microscopic hot carrier transport and relaxation process near the surfaces of wide bandgap materials and offers valuable insights for future device design.

This work is based on research supported by AFOSR under the award number FA9550-22-1-0468 and ARO under the award number W911NF2310188.

Leveraging 4D-USEM in Probing Charge Carriers at the Surface of Single Crystal Perovskites Razan O. Nughays[1], Khulud M. Almasabi[1], Sarvarkhodzha Nematulloev[1], Chen Yang[1], Lijie Wang[1], Issatay Nadinov[1], George Harrison[1], Bian Tieyuan[2], Jianfeng Zhao[3], Jun Yin[2], Shadi Fatayer[1], Osman M. Bakr[1] and Omar F. Mohammed[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]The Hong Kong Polytechnic University, China; [3]Chinese Academy of Sciences, China

Perovskite single crystals offer revolutionary light-harvesting technology, showcasing exceptional optoelectronic properties and device performance. Achieving stable perovskite single crystals with enhanced optical properties and device performance is crucial for guiding material scientists, chemists, and engineers in designing superior crystals with very low defect concentration, if any. Despite the extensive investigations on their photo-induced charge-carriers dynamics, most of the time-resolved techniques focus mainly on bulk properties rather than surface characteristic which plays a crucial role for their optoelectronic-device performance. Thus, understanding charge carrier and surface defects at atomic level and femtoseconds scale is necessary. Herein, four-dimensional ultrafast scanning electron microscopy (4D-USEM) have been utilized to probing the photo-generated carrier transport at the first few nanometers of the top surface In this technique, a pulsed primary electron beam generated optically by a UV excitation pulse from a cooled Schottky field-emitter tip produces secondary electrons that are sensitive to the localization of the charge carrier on surfaces and interfaces of the photoactive materials. Additionally, density functional theory (DFT) was conducted to unfold the reasons behind the formation of both defect centers and ions migration. In this work, four different samples of single crystal perovskites were investigated; MAPbI$_3$ (001), MAPbI$_3$ (100), FA$_{0.6}$MA$_{0.4}$PbI$_3$ (FA-rich) and FA$_{0.4}$MA$_{0.6}$PbI$_3$ (MA-rich). Our time-resolved results revealed that the orientations and compositions strongly affect charge carrier behavior. For example, MAPbI$_3$ (100) and MA-rich samples displayed a shorter carrier lifetime and exhibited a dark image-contrast in the SUEM experiments. Whereas the lifetime and concentration of defects were notably improved and reduced, respectively in case of MAPbI$_3$ (001) and FA-rich samples. These findings shed the light on the importance of understanding the role of orientation/termination and the cation's selection on the charge carrier behavior at the first few nanometers to assist engineering high-performance optoelectronic devices based on single crystal perovskites.

The Many Facets of Ultrafast Electron Diffraction and Microscopy—The Development and Applications

Chong-Yu Ruan; Michigan State University, United States

In the past two decades, the rapid pace in the development of ultrafast electron diffraction and microscopy instruments has ushered in a new area of investigating structural dynamics and related material property responses[1]. In this presentation, I will review the multifaceted development that now reaches temporal resolution of 100 fs-level or below with electron density as high as 10^5 particles per pulse for structure dynamics involving nanometer-thin or micro-structured material systems. Prototypical examples for instrument design, data collections, and specialized protocols for structure analysis relevant for photoinduced phase transitions will be outlined in some detail with the hope that they can be reproduced by interested audience in their own studies[2]. The need to simultaneously obtain information about the electronic states, functionalities, as well as structure dynamics motivates the development of ultrafast electron microscopy in which diffraction, imaging, and spectroscopy are united to enable the multimodality observations at the ultrafast timescales for a broad range of material science problems[3]. Examples will be given to illustrate the technologies on two prototypical examples: (1) Scale-dependent self-organization in vanadium dioxide thermally induced and photoinduced phase transitions. (2) Nonequilibrium universal dynamics in the condensation of 2D charge-density waves in 1T-TaS$_2$ and

Investigation of Electrical Pulse-Driven Processes by Ultrafast Tem Suman Kumari, Mason Freund and Volkan Ortalan; University of Connecticut, United States

In the last couple of decades, significant advancements have been made in the development of ultrafast transmission electron microscopy (UTEM). It has enabled the exploration of short-lived transient stages involved in various material processes in time scales ranging from a few femtoseconds to microseconds.[1,2] In a usual UTEM setup, the sample excitation laser pulse is synchronized at a selected time delay with another laser pulse for the photoemission of electrons to probe the material dynamics. To investigate the sample excitation by other means such as electric pulses, a specialized in-situ TEM holder can be utilized in synchronization with the electron probe pulse. It opens many opportunities to investigate various material dynamics driven by electric pulses at high temporal resolution in a TEM.[3,4] Amongst many such processes, failure of electrical contacts is a major concern in the reliability of modern-day electronic devices due to exposure to extreme conditions because of miniaturization. Particularly, the failures caused by pulsed DC excitations occur extremely fast, leaving us with very limited information from post-characterization to determine the evolution of failure. In this study, we have utilized the capability of UTEM to probe the transient stages involved in the failure process via single-shot imaging. To further characterize the intermediate stages, specific experiments were performed to investigate the material morphology using a variety of electron microscopy techniques. In this presentation, we will discuss various aspects of the failure process, including time scales, the evolution of material morphology, and underlying mechanisms.

2:15 PM *CH06.05.03

Dynamic TEM With Nanosecond Pulses in the Study of Fast Thermal Processes in Nanomaterials Florian Banhart; Université de Strasbourg, France

Materials under intense laser pulses are in extreme conditions. Electronic excitations and thermal effects appear at characteristic timescales. The size of the system often determines the timescales of phase transitions or chemical reactions, in particular when the laser-induced excitation (e.g., a sound wave or thermal diffusion) propagates through the system. The different approaches of ultrafast or dynamic TEM (UTEM, DTEM) give access to fast transformations in nanomaterials if they are detectable by imaging, electron diffraction or electron energy-loss spectroscopy (EELS). Reversible transitions are studied by the stroboscopic [1] and irreversible by the single-shot technique [2]. In this contribution, thermal effects in nanomaterials occurring at the nanosecond timescale are described. In a dedicated setup, two coupled nanosecond lasers are used to induce transitions of the specimen and to create photoelectron pulses in the TEM.

The stroboscopic mode is used for studying photoswitchable materials that undergo reversible phase transitions under electronic excitation or temperature changes [3, 4]. Results on spin-crossover (SCO) materials and trititanium pentoxide crystals are shown, where reversible phase transitions at the nanosecond timescale are observable by imaging and electron diffraction. By measuring the time interval between the pump pulse and the onset of structural changes, the characteristic switching time of the materials is determined. Furthermore, rapid oscillations between different phases are observed. After a longer interval, the materials relax back into their initial phases. Due to the high spatial selectivity of TEM, the time-dependent behavior of individual nanocrystals can be studied at the nanosceond timescale.

The single-shot mode is applied to study fast chemical reactions in nanomaterials [5]. As an example, the reduction of nanocrystalline oxides, that is observed at nano- to microseconds, is studied. Since most chemical reactions are irreversible, one intense nanosecond pulse is necessary for recording the signal after a certain pump-probe delay. Mutual repulsion of the electrons within the intense pulse limits the spatial, temporal and energy resolution of the technique. Nevertheless, useful information can be gained about short-lived transient states during the reaction. This allows studying the kinetics of reactions in nanocrystals which often differs from the kinetics in a bulk phase. The complementarity of imaging, diffraction and EELS shows to be highly beneficial for obtaining a complete picture of fast transformations at the nanoscale.

Ultrafast Coherent Control of Structural Orders in a Layered Rhenium Disulfide Ye-Jin Kim[1,2] and Oh-Hoon Kwon[2]; [1]Seoul National University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

The optimal functionalities of correlated matter often appear at emergent structural orders involving entangled changes in the electronic states and the underlying nuclear lattices. Here, we study a layered rhenium disulfide

(ReS_2), an atypical transition metal dichalcogenide with its unique electron-rich nature of Re atoms. This yields the formation of stable, high-order superlattice variants, which emerge from a distinct six-fold stacking order when subjected to photothermal annealing using light pulses ranging from femto- to nanoseconds. Electronically driven coherent melting and reordering of the superlattices in ReS_2 upon photoexcitation is unfolded with time-resolved electron diffraction in ultrafast electron microscopy, mapping the full phase trajectory of the structural orders therein supported by atomic-resolution imaging. We discuss the identity of the high-order structural arrangement and the origin of its emergence. Our discovery on the structure and electron-correlated behavior between active degrees of freedom in a low-dimensional material system gives a rich palette to control emerging multitude of intriguing phases and complex transitions with electronic manipulations and ultimately to boost an extra flexibility to design new quantum phenomena.

3:45 PM CH06.05.05

Observing Phonon Dynamics with Shot-to-Shot Acquisition Ultrafast Electron Diffraction Bruce Weaver[1,2], Remi Claude[1], Francesco Barantani[1,3], Fadil Iyikanat[4], Michele Puppin[1], Alexey Sapozhnik[1], Ivan Madan[1], Thomas Lagrange[1], Javier Garcia de Abajo[4] and Fabrizio Carbone[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Central Laser Facility, United Kingdom; [3]The University of Texas at Austin, United States; [4]ICFO–The Institute of Photonic Sciences, Spain

Ultrafast electron diffraction (UED) uses short-wavelength electrons to reveal structural dynamics triggered by ultrashort laser pulses in materials. Recently, UED has been extended to observe the changes of diffuse scattering [1] brought about by the non-thermal phonon population dynamics, induced by the electron-phonon coupling after electron excitation. Because the diffuse scattering is very weak, very high experimental sensitivity is required.
We present ultrafast electron diffuse scattering achieved by 20 kHz shot-to-shot acquisition in a tabletop UED system [2]. The shot-to-shot acquisition system is synchronized to a chopper in the pump arm, allowing every individual measurement to be normalized to a reference under identical conditions. This leads to excellent signal-to-noise, enabling the measurement of the transient modification of diffuse scattering.
We apply this technique to study of phonon dynamics in graphite. Ultrafast time and momentum-resolved electron energy loss (tr-q-EELS) measurements [3] measured the same system but with access to energy information as well momentum. tr-q-EELS revealed plasmon dynamics in graphite, which theoretical analysis linked to the population of phonons modes via inter- and intravalley scattering that depend on the pump wavelength. We use UED to investigate this hypothesis by directly by observing the formation of phonons in real time. By comparing the results of the two experiments we can reveal the full picture of the phonon dynamics in graphite.

Laser Induced Melting and Coalescence of Nanoparticle Clusters Captured with Ultrafast Transmission Electron Microscopy Mason Freund, Shuai Jiang and Volkan Ortalan; University of Connecticut, United States

Transmission electron microscopy (TEM) is an essential characterization method for obtaining information with high spatial resolution. Combining with *in situ* techniques, information during a dynamic process can be acquired in real time. Increasing the temporal resolution of these techniques allows for capturing ultrafast dynamics and reactions. Ultrafast TEM (UTEM) combines high spatial and temporal resolutions to capture nanoscale snapshots of the dynamics at well-defined delay times and has been applied to various materials and observable rapid dynamic processes [1–3]. The single shot pump probe scheme utilized in UTEM provides capabilities for observing irreversible processes such as laser induced interactions. Laser interactions with metal materials lead to complex heat transfer and transient events including melting, fusion, and other dynamic behaviors. Laser-based fabrication methods have become widespread in a variety of applications and industries and at various length scales [4]. Observing the dynamic behaviors at the nanoscale, temporally and spatially, allows for a more comprehensive understanding of the intricate processes involved in laser-material interactions. In this work, clusters of silver nanoparticles are irradiated by a single nanosecond laser pulse and imaged at precise delay times through single shot UTEM to investigate the dynamics and timescales of nanoparticle melting and coalescence. These dynamic events are shown to be manipulated through cluster location and size. Combined with electron microscopy and energy dispersive x-ray spectroscopy, substrate deformations and subsequent interactions are determined to strongly affect the exposed region and can influence the fusion process. This study provides valuable insights into laser-based fabrication behaviors of nanoparticle clusters for nanoscale structures.

Grains Ain't Misbehaving or Going Wild? The Initiation of Abnormal Grain Growth! Klaus-Dieter Liss; The University of Tennessee, Knoxville, United States

Unconventional white-beam Laue synchrotron X-ray diffraction has been used on rolled magnesium alloys during in-situ heating experiments. At high temperatures, reflections of single grains are superimposed on the halo stemming from matrix grains. Some unique grain reflections spontaneously move, indicating grain rotations in response to torque expedited at grain boundaries. When a grain boundary spontaneously activates, it can begin to rotate, allowing diffusive mass transport and activating the boundaries of its other neighbors. Now the given grain can freely rotate towards coalescence; however, the multitude of grain boundaries compete in torque orientation and magnitude, resulting in zigzag rotations. After coalescence, the larger grain is still active and continues this scenario of growth, while the majority of the matrix grains remain inactive. The first-time experimental observation of such erratic grain behavior supplies the missing puzzle stone leading to anomalous grain growth, long postulated in literature. The sub-second time resolution allows, for the first time, the determination of grain reorientation rates and pathways. This method can be easily adapted for higher time resolutions and faster processes.

SESSION CH06.06: Electron and X-Ray Probes II

Visualizing Ultrafast Energy and Charge Transport in Semiconducting van der Waals Heterostructures
Archana Raja; Lawrence Berkeley National Laboratory, United States

I will discuss two stories from our joint experimental and theoretical work focusing on the prototypical 2D semiconductor interface of monolayer WS_2 and WS_2. In part one, we use ultrafast electron diffraction to visualize lattice dynamics during the charge transfer process at the type-II heterojunction. Following the excitation of lower-gap WSe_2, we measure the concurrent
heating of both layers on a picosecond timescale. This observation cannot be explained by phonon transport across the interface. In conjunction with ab initio theory, we uncover the critical role of layer-hybridized electronic states in enabling ultrafast energy and charge transport across such atomic junctions. In part two, we use optical spectroscopy and microscopy to visualize diffusion of interlayer excitons over a wide range of temperatures. While the measured exciton diffusivity decreases with temperature, it surprisingly plateaus below 90 K. Our observations cannot be explained by classical models like hopping in the moiré potential. Ab initio theory and molecular dynamics simulations suggest that low energy phonons arising from the mismatched lattices of a moiré heterostructures play a key role in understanding this anomalous behavior of exciton diffusion. This indicates that the moiré potential landscape is dynamic even at low temperatures.

9:00 AM CH06.06.02
Cross-Examination of Carrier and Structural Dynamics Reveals Unexpected Behavior of a Bismuth-Iodide Perovskite, Black Phosphorus and Metal Surfaces Ding-Shyue (Jerry) Yang; University of Houston, United States

In this talk, I will describe the use of electron and optical probes under similar experimental conditions and the cross-examination of their data for materials research, using a bismuth-based perovskite $Cs_3Bi_2I_9$, black phosphorus (bP), and metal surfaces as three examples. For $Cs_3Bi_2I_9$ and bP, the correlation between the electronic and lattice structures significantly influences their photoinduced carrier and structural dynamics, which demonstrates crucial structure–behavior relations. It is found that carriers photoinjected into $Cs_3Bi_2I_9$ form self-trapped excitons on an ultrafast time scale. However, most of their energy is retained and their coupling to Fröhlich-type optical phonons is limited at initial times. The long-lived excitons exert an electronic stress via deformation potential and develop a prominent, sustaining strain field as coherent acoustic phonons (CAPs) in 10 ps. In bP, in contrast, most of the photoinjected carriers are annihilated within 1 ps and transfer their energy to optical phonons in a nonthermal, anisotropic fashion. Electronically, the remaining carrier density around the band edges induces a significant interaction that leads to a unique interlayer lattice contraction, prior to the generation of out-of-plane CAPs and thermal lattice expansion starting at ~6 ps. A physical picture with five temporal regimes can be reached for bP's photodynamics. Finally, the surface dynamics of Au(111) and Pt(111) will be discussed to show the unique strength of surface specificity of reflection ultrafast electron diffraction (UED). I will also provide the technical confirmation for the validity of reflection UED and address the long-standing concerns related to laser-induced surface transient electric fields.

The support from the National Science Foundation (CHE-2154363) and the R. A. Welch Foundation (E-1860) is acknowledged.

9:15 AM CH06.06.03

Nonresonant Raman Control of Material Phases Jiaojian Shi and Aaron Lindenberg; Stanford University, United States

Important advances have recently been made in the search for materials with complex multi-phase landscapes that host photoinduced metastable collective states with exotic functionalities, such as high-temperature superconductivity, ferroelectricity, or topological properties. In almost all cases so far, the desired phases are accessed by exploiting light-matter interactions via the imaginary part of the dielectric function through above-bandgap or resonant mode excitation. Nonresonant Raman excitation of coherent modes has been observed experimentally and proposed as a means of dynamically controlling material functions. However, the atomic excursion driven by this approach has been perturbative, and these prospects have been hindered by the concomitant excitation of carriers and subsequent heating-induced sample damage. Here, we demonstrate that it is possible to overcome this challenge by employing nonresonant ultrashort pulses with low photon energies significantly below the bandgap. We first achieve this in a prototypical ferroelectric, lithium niobate, using mid-infrared pulse excitation and concurrently monitoring the lattice dynamics using femtosecond stimulated Raman scattering and second harmonic generation. Large-amplitude ferroelectric soft mode displacements driven by nonresonant Raman excitation can reverse the Raman polarizability sign and the second harmonic phase, indicating a ferroelectric reversal. We extend this to tin selenide, a material with complex energy landscapes requiring simultaneous excitation of multiple modes to trigger phase transformation. Using time-domain Raman scattering and time-resolved X-ray diffraction to monitor mid-infrared-excited tin selenide, we observe the suppression of A_g Raman modes beyond a critical MIR field strength, indicating a new phase formation. Reconstructed atomic displacements from structural factor changes show distinct lattice dynamics compared to heat or carrier excitation. Further corroborated with first-principle calculations, this discovery introduces a novel phase control method that goes beyond the conventional resonant excitation approach and unlocks exciting possibilities for facile manipulation of phases and chemical reactivity with complex energy landscapes at reduced energy consumption and ultrafast operation speeds.

9:30 AM CH06.06.04

Physics-Informed Multimodal Learning for Phase Retrieval from Synchrotron Data Aditya Koneru[1,2,3], Tanny Chavez[1], Anas Nassar[1], Maximilian Jaugstetter[1], Slavomir Nemsak[1,4], Petrus Zwart[1] and Alexander Hexemer[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Illinois at Chicago, United States; [3]Argonne National Laboratory, United States; [4]University of California Davis, United States

Synchrotrons have played an instrumental role in unravelling atomistic to mesoscale details for a variety of material systems. It is through the culmination of several scattering techniques that equipped us with a lens to investigate these surface, bulk and atomistic features of dynamical systems. However, the advancements are limited by two key major aspects, one is the curation of high volumes of data for further analysis and the other is online computation necessary to construct the real space from reciprocal space data. The latter has been addressed by utilization of several phase learning involving both conventional optimization and deep learning (DL) methods. Out of them tools based on DL have shown that they are scalable on the modern edge computing devices. However, they require multiple training cycles and are often not complemented with relevant physics. This makes it difficult to validate the complex-uninterpretable neural network models. We circumvent this by utilizing a multimodal dataset from Small Angle X-ray Scattering and X-ray Photoelectron Spectroscopy. We use PMMA/PA as our representative system for which we first test our workflow on a synthetic dataset and implement the same for a real-time data stream. We further anticipate that this workflow could be utilized to simulate much more physical datasets via noise-learning from real-time data.

Lightwave Controlled Haldane Model in Quantum Material with Hexagonal Symmetry Shubhadeep Biswas; SLAC National Accelerator Laboratory, United States

Stacking and twisting atom-thin structures with matching symmetry creates new superlattice structures with emergent quantum properties [1]. In parallel, coherent electron motion in solid can also be manipulated with strong light fields, leading to potential in quantum electronics for ultrafast switches of quantum properties at room temperature [2]. Here, we present a lightwave-driven analogy to twisted layer stacking in hexagonal materials. Utilizing the alignment between the crystal lattice's three-fold symmetry and the structured spatial waveform of the light field—a novel parameter under sub-laser-cycle precision control we showcase sub-cycle-controlled time-reversal symmetry breaking and valley band gap manipulation in an insulating hBN monolayer, thereby achieving the light-driven equivalent of the Haldane topological model.

Here, I shall demonstrate a tailored lightwave-driven analogue to twisted layer stacking in a hexagonal boron nitride monolayer [3, 4]. We tailor the symmetry of the light waveform to that of the crystal lattice (C_3), which allows for sub-femtosecond control over time-reversal symmetry breaking and thereby band structure engineering. In this way, for the first time, we realize the light-analogue of the topological Haldane model [5] in an insulating material, controlling its parameters with sub-femtosecond precision. Twisting the lightwave relative to the lattice orientation enables switching between band configurations, providing unprecedented control over the magnitude and location of the band gap, and curvature. This also allows us to establish a new regime of valleytronics [6] that uses non-resonant light fields and allows valley polarization control on femtosecond timescales.

Investigating Ultrafast Charge Generation in Y6 Non-Fullerene Acceptor Using Ultrafast Spectroscopies
Nisreen Alshehri[1], Catherine S. De Castro[1], Christopher E. Petoukhoff[1], Olivier Aleveque[2], Eric Levillain[2] and Frédéric Laquai[1]; [1]King Abdullah University of Science and Technology, United States; [2]Université d'Angers, France

In recent years, the development of organic photovoltaics (OPV) has progressed rapidly due to the emergence of non-fullerene acceptors (NFAs), in particular Y6 (i.e., BTP-4F) [1]. This is mainly attributed to the molecular structure of the NFAs and their packing in the solid state. Typically, NFAs are composed of electron-accepting (A) and electron-donating (D) subunits arranged in planar and curved shapes, which leads to large exciton delocalization over one molecule. In addition, strong electronic coupling between two adjacent molecules gives rise to exciton delocalization with charge transfer (CT) character [2]. In fact, there has been evidence that Y6 generates charges immediately upon photoexcitation without the need of a donor/acceptor interface [3, 4]. There is, however, no consensus about the mechanism governing the ultrafast free charge generation yet limiting the fabrication of single-component OPVs based on Y-series NFAs.

This work explores excited-state dynamics from generation, dissociation, and recombination in planar and curved NFAs, namely IT4F and Y6, in diluted and solid states. We investigate these processes using a combination of transient absorption (TA), time-resolved photoluminescence (TRPL), and quasi-steady-state photoinduced absorption (PIA) spectroscopies, among others. We identified the excited state species contributing to the TA signals using a combination of spectroelectrochemistry, and triplet-sensitized NFAs TA and PIA for charges and triplets, respectively.

Our results show that, unlike IT4F, the initial photoexcitations in Y6 are mostly polaronic states upon near bandgap excitation. However, the appearance of these species within our ~120 fs temporal resolution demands further investigation into whether they are primary photoexcitations or generated from exciton dissociation. We show that upon increasing the excitation energy, a higher-laying hot exciton dissociates into free polarons within 0.2 ps. This is supported by the observation of the initial photoexcitation peak shift, which is assigned to the electroabsorption effect caused by the separation of the electron-hole pair. Excitation-density-dependent TA results show these polarons are mobile and recombine quickly via bimolecular recombination within a few hundred picoseconds. Eventually, the long-lived species relax on one molecule, creating intramolecular charge transfer, as reflected by the spectral shape's resemblance to the first derivative of the absorption spectrum. These results give insight into the correlation between the molecular structure and the feasibility of intrinsic charge generation in pristine organic semiconductors; hence, the possibility of fabricating single-component OPVs.

Spectroscopic Investigation of Defect-Enabled Long-Lived Emission in Photoactive Metal-Organic Frameworks

Sean M. Griffin, David Bain, Andrew Musser and Phillip Milner; Cornell University, United States

Novel insights into the photophysical properties of photoactive Metal-Organic Frameworks (MOFs) can be unveiled by applying highly sensitive materials characterization techniques such as time-resolved photoluminescence (TRPL) spectroscopy. TRPL enables the detection of weak, long-lived photon emission in MOFs out to 1 μs, substantially longer than previously reported. The long-lived emission reveals unexpected electronic state population dynamics by tracking the change in emission wavelength and intensity over time. The long-lived emission can be attributed to defect-enabled delayed charge recombination. TRPL can be applied to a range of systems displaying long-lived emission including a tetraphenylethylene based MOF, CORN-MOF-1, & MOF-74. The extent of long-lived, defect-enabled emission can be tuned by engineering the defect density of the material or adjusting the local packings of photoactive linkers in the MOFs. Defect-engineering allows for a tunable and enhanced photophysical response of a range of MOF systems. Tuning these properties aids in tailoring novel materials for improved photoactive devices such light emitting devices or photovoltaics. Precise control and understanding of light-matter interaction is critical for the development of the next generation of light-based devices.

Ultrafast Surface Carrier Recombination in Semiconductors Evaluated by Two-Photon Photoemission Spectroscopy Shuhei Ichikawa and Kazunobu Kojima; Osaka University, Japan

Recently, ultra-small sized optical and electronic devices have actively been developing, and evaluation of ultrafast carrier recombination processes on semiconductor surfaces is important technique to control the device performances. Time-resolved photoluminescence spectroscopy and microwave photoconductivity decay are typically used to characterize carrier recombination lifetime in semiconductors. However, the detected signals include information from both surface and bulk states due to penetration depth of the excitation light. Time-resolved two-photon photoemission (Tr-2PPE) spectroscopy can be a novel technique to directly detect excess electrons as photoelectrons emitted from sample surfaces. In this approach, the first pulsed-light excites electrons from a valence band to a conduction band, and the second pulse ionizes the excited-electrons beyond a vacuum level after controlled time-delay. The detected signals are limited by surface carriers due to the short electron mean free paths (less than several nanometers). In this paper, we report on the analyses of surface recombination of semiconductors based on the Tr-2PPE spectroscopy where GaAs (110) is evaluated as an example, and show a strong impact of unintentional native oxides on the surface on carrier recombination processes.

A mode-locked Ti:Sapp laser (pulse width: ~100 fs, repetition frequency: 80 MHz) was used as an excitation light source, and the fundamental wave (1.55 eV) with photon energy slightly higher than the bandgap energy of GaAs, 1.42 eV, was used as a pump light. The third-harmonic (4.65 eV) was generated as a probe light, and each pulsed light was input into a Mach-Zehnder interferometer. By controlling the time-delay, we constructed a Tr-2PPE system with high time resolution (the cross-correlation width of the pump and probe pulses was ~175 fs). The pump and probe pulses were irradiated on the samples in a vacuum chamber.

Using the Tr-2PPE system, we evaluated carrier recombination lifetimes at un-doped GaAs (110) surfaces varying air-exposure time. After a clean GaAs (110) surface obtained by cleaving an un-doped (001) GaAs substrate in the vacuum chamber were characterized by the Tr-2PPE, the sample was exposed to the atmosphere for 0.1 to 2612 hours (temperature 20°C, humidity 40%). Then, it was re-introduced in the vacuum chamber for measurements. All the measurements were performed at room temperature.

After excitation by the pump light, nonequilibrium excited electrons in the conduction band around Γ-valley were found to relax to the conduction band minimum with 0.6 ps. This relaxation process is attributed to intravalley relaxation associated with electron-phonon scattering due to Fröhlich interaction[1]. Surface carrier recombination processes of the excited electrons after being relaxed to the conduction band minimums were subsequently evaluated. From the long-ranged Tr-2PPE decay curves, the carrier recombination lifetimes were estimated by fittings of the decay curves with a single exponential component. Although the surface carrier lifetime at the as-cleaved GaAs (110) was 5100 ps, those after air-exposure drastically reduced as air-exposed time increased, and it ranged from 1670 to 73 ps. The carrier lifetimes are extremely short compared with the typical recombination lifetime based on band-to-band transitions in GaAs, and they clearly originate from nonradiative Shockley-Read-Hall processes due to surface recombination. Furthermore, we found that the formation of native oxides on the GaAs (110) surfaces significantly promotes nonradiative recombination. These results quantitatively explain that GaAs-based optical devices deteriorate significantly with air-exposure[2], and also demonstrate that the Tr-2PPE can be a powerful spectroscopic method directly evaluating the surface recombination lifetime of semiconductors.

11:15 AM CH06.07.05

Temperature-Dependent Transient Microscopy of Excitons and Free Carriers in Perovskites Seryio Saris[1], Vladimir Bruevich[2], Vitaly Podzorov[2] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]Rutgers, The State University of New Jersey, United States

Recent studies have revealed that exciton transport in low-dimensional perovskite materials deviates significantly from anticipated trends, exhibiting much higher diffusivities, excitation memory effect, and the potential roles of excitonic fine structure and superradiance. These findings raise critical questions about whether such phenomena are inherent to all perovskites, including their bulk (3D) counterparts, or are specific to lower dimensionality. While *charge transport* mechanisms in bulk perovskites are well understood, *exciton transport* remains largely unexplored. In this work, we use temperature-dependent transient photoluminescence microscopy (TPLM) to access distinct transport regimes dominated by excitons and free charges, benchmarking behavior in high-quality epitaxially-grown perovskite single crystals. We compare our results with the predictions from the Saha equation describing the thermal equilibrium between the two species. Anomalous and fast transport behavior of excitons is revealed at cryogenic temperatures, providing insights into the excited state landscape in perovskite materials.

SESSION CH06.08: Ultrafast Electron Microscopy and Electron and X-Ray Probes II

Observation of Dynamics in Materials Using Ultrafast Electron Microscopy Thomas E. Gage, Haihua Liu and Ilke Arslan; Argonne National Laboratory, United States

Ultrafast transmission electron microscopy (UEM) methods have become a new frontier in materials science due to the ability to follow dynamics on time scales down to hundreds of femtoseconds with nanometer spatial resolution. Imaging on ultrafast time scales reveals nonequilibrium metastable states of matter, phonon transport pathways in materials, and plasmon dynamics. Some examples from the UEM at the Center for Nanoscale Materials at Argonne will be presented.

Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

2:00 PM *CH06.08.02

Nanoscale Mapping of Optical Near Fields with Attosecond Electron Microscopy Murat Sivis[1,2]; [1]Max Planck Institute for Multidisciplinary Sciences, Germany; [2]University of Göttingen, Germany

Transmission electron microscopy is essential for observing matter with high spatial resolution down to the atomic scale. In combination with electron energy loss spectroscopy (EELS), fingerprints of material composition as well as optical properties of nanoscale structures [1] can be elucidated. However, EELS can only reveal the intrinsic properties of a sample, such as the geometric electromagnetic near-field modes of a plasmonic nanoresonator, with a spectral resolution given by the electron microscope itself (typically in the sub-100 meV range in monochromated systems). This is due to the excitation of these near-field modes by the swift electrons and the subsequent spontaneous electron energy loss. Recent approaches facilitating stimulated electron-light interaction overcome these limitations by using extrinsically excited near fields, enabling photon-induced near-field electron microscopy (PINEM) and electron energy gain spectroscopy (EEGS). In these approaches, ultrashort laser pulses populate specific modes of a sample and high energy electron pulses interacting with the associated near fields undergo stimulated energy gain and loss [2]. PINEM and EEGS allow the quantitative measurement of near-field strengths with nanometer spatial resolution [3] and also provide a means of mapping the spectral response with sub-meV resolution [4] by scanning the wavelength of laser excitation. In addition, the sensitivity of these methods to the optical phase allows access to the field evolution with sub-cycle time resolution [5,6].

In this presentation, I will give an overview of the Göttingen UTEM project [7], in which we are exploring the capabilities of ultrafast transmission electron microscopy for mapping and controlling optical near-fields [8]. In recent studies, we have demonstrated mode-selective reconstruction of plasmonic near-fields [9] and introduced a free-electron homodyne detection (FREHD) scheme to precisely measure the time evolution of these near-fields with few-nanometer spatial and attosecond temporal resolution [6].

Fast Electrons and Hard X-Rays for Unraveling Atomic-Scale Dynamics in Light-Energy Conversion Renske M. van der Veen[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]University of Illinois at Urbana-Champaign, United States

The conversion of light energy into other forms of energy is of uttermost importance in a vast range of fields, such as natural and artificial photosynthesis, photoelectrochemistry, or optoelectronic device development. Excited-state energy dissipates by a variety of mechanisms, including intersystem crossing, electron-phonon coupling, luminescence, charge/energy transfer, or non-radiative decay in the form of heat. Depending on the specific application, the aim is to optimize one or several of these relaxation pathways, while avoiding others. A fundamental atomic-scale and microscopic understanding of the dynamics after photon absorption is thus important to uncover the mechanisms of bond-breaking and -making in photochemical reactions, to derive intricate structure-property-photoactivity relationships, and to enhance the predictive ability of theoretical atomic-scale models in photovoltaics, photocatalysis, and optoelectronics.

While ultrafast optical spectroscopies are very powerful for probing the electronic population of excited states with attosecond to nanosecond temporal resolution, they often lack the spatial resolution necessary to resolve individual atoms. Our research group at the Helmholtz Center Berlin specializes in the development and application of time-resolved pump-probe techniques based on X-ray and fast-electron probes. The Å-nm-scale de Broglie wavelength of these probe pulses renders them directly sensitive to the atomic-scale structure of materials. In this talk I will present our recent results in the fields of in situ time-resolved electron microscopy and ultrafast X-ray spectroscopy. Using a custom-built ultrafast transmission electron microscope coupled with external laser systems, we followed the transformation of copper and copper-gold nanoparticles under plasmonic excitation. Ultrafast X-ray spectroscopy at synchrotron and XFEL facilities can deliver powerful complementary information on spin-state, charge, and structural dynamics in photoexcited coordination complexes. In this talk, I will show selected results on Ni-based photoredox complexes and mixed-valence Fe-Co complexes. This work enables us to unambiguously confirm the nature of excited states that have been implied by ultrafast optical spectroscopies and density functional theories.

4:00 PM CH06.08.04

Exploring Dynamical Heterogeneity in Layered 2D Materials Within an *Operando* Ultrafast Electrochemical Setup Felipe A. de Quesada[1,2], Philipp Muscher[1], Edbert Sie[1], Eliana Krakovsky[1,3], Daniel Rehn[3], William C. Chueh[1] and Aaron Lindenberg[1,2]; [1]Stanford University, United States; [2]Stanford Institute for Materials and Energy Sciences, United States; [3]Los Alamos National Laboratory, United States

The unique layer-stacking degree of freedom in 2D layered materials facilitates the formation of nearly degenerate and exotic phases of matter that can be easily switched using a variety of static and dynamic external stimuli, thus opening novel routes for the design of low-power reconfigurable devices. Leveraging the gaps formed between stacked layers, electrochemical ion intercalation has emerged as a promising approach to further stabilize metastable phases in these layered materials across the entirety of the bulk and explore the effects of extreme carrier doping and strain on the functionality of the system. However, the prevailing scarcity of opportunities to characterize the in-situ structural evolution of the material during electrochemical intercalation has limited the direct visualization of key transient physical processes that directly affect the material functionality. Here we introduce a novel experimental platform capable of performing electrochemical lithium-ion intercalation, while allowing multimodal ultrafast characterization of the lattice using, for example, ultrashort, femtosecond-long electron bunches and near-infrared light pulses. Centering the study on the layered semimetal WTe2 as a model system, we demonstrate that our unique experimental approach uncovers a previously unnoticed dynamically fluctuating polymorphic structure at room temperature, which can be subsequently homogenized by the introduction of electronic carriers accompanying the positively charged lithium ions. This leads to significant changes in the interlayer shear mode, including increases in the damping time and mode amplitude. We complement and contrast these findings with x-ray structural studies and theoretical calculations, and find that dynamic structural heterogeneity originates from the low energetic separation between metastable states and the presence of thermal fluctuations.

4:15 PM *CH06.08.05

Electron-Photon Interactions for Advanced Electron Microscopy Martin Kozák, Petr Koutenský, Neli Laštovičková Streshkova, Kamila Moriová and Marius Constantin Chirita Mihaila; Charles University, Czechia

In this contribution I will review our efforts on electron-photon interactions in free space based on ponderomotive potential of coherent optical fields. I will discuss the possibilities of complex spatio-temporal electron beam shaping via the interaction with shaped light fields. Such electron shaping may be applied for generation of coherent superposition of electron vortex beams, electron beam monochromatization or for correction of spherical aberration of electron lenses. The possibilities of quantum coherent transverse electron beam shaping

using Kapitza-Dirac effect will be shown. Finally I will discuss the application of 4D STEM technique using TimePix3 detector in time-resolved imaging experiments in an ultrafast scanning electron microscope.

4:45 PM CH06.08.06

***In Situ* Observation of $(PbTiO_3)_{14}/(SrTiO_3)_{16}$[hl1] Superlattice Structural Transition Under Electric Field** WooJun Seol[1], Sixu Wang[2], Qian Li[2], Hyeon Jun Lee[3] and Ji Young Jo[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Tsinghua University, China; [3]Kangwon National University, Korea (the Republic of)

$(PbTiO_3)_m/(SrTiO_3)_n$ (PTO_m/STO_n) superlattice thin film heterostructures exhibit exotic nanoscale domain configurations such as polar skyrmions. A key feature of these nanodomains is that external stimulus such as an electric field can perturb the energy balance consequently resulting in polarization modulation. In-situ X-ray diffraction with an application of electric field can provide the insight into the atomic scale mechanisms of field-driven domain configuration dynamics of polar skyrmions. From a thermodynamic perspective, skyrmions under positive bias are expected to shrink with more coherent distribution, while skyrmions under negative bias expand and coalesce leading to continuous c-domain matrix randomly embedded by stripe-like skyrmions.[1] However, the field-driven domain evolution of polar skyrmions have not been experimentally explored yet. In this study, we probe the evolution of polarization configuration in polar skyrmions in $(PbTiO_3)_{14}/(SrTiO_3)_{16}$ (PTO_{14}/STO_{16}) superlattice thin film by measuring the x-ray reflections under the electric field.

To figure out the electric field induced polar skyrmion evolution paths of PTO_{14}/STO_{16} superlattice system, quantitative analysis of polar skyrmions and c-domain structures under electric field is necessary. In-situ time-resolved x-ray microdiffraction enables the simultaneous probing of in-plane domain structure and out-of-plane superlattice structure while applying electric field. A spatial resolution of few tens of micrometers achieved by focused x-ray beam enables probing the structural evolution below the electrode where electric field is directly applied. Based on the scattering intensity of domain and superlattice structures provided from reciprocal space maps, the domain configuration of polar skyrmions under electric field can be investigated.

We conducted in-situ time-resolved x-ray microdiffraction at 9C beamline of Pohang Accelerator Laboratory. Superlattice peaks from out-of-plane ordering and satellite peaks from in-plane ordering with Q_y ordering of ~0.1 $Å^{-1}$ were observed simultaneously under electric field. Superlattice peaks showed peak shift about 0.3% when ±15 V is applied which corresponds to previous reports, while integrated intensity shows asymmetry with the polarity of the electric field. [1] The position of satellite peaks showed no shift in Q_z direction which indicates no in-plane ordering change under electric field while integrated intensity is decreased to 30% under15 V compared to pristine state, while intensity decreased 15% under -15 V, indicating asymmetric behavior of polar skyrmions with the polarity of the electric field.

In conclusion, we could observe asymmetric intensity behavior of both superlattice and satellite peaks with the polarity of electric field which relates to the size of domain configuration under electric field. We could propose new polar skyrmion evolution model related to polar skyrmion domains that the polar skyrmions maintain its configuration after applying higher voltage than the coercive voltage. By unveiling field-driven domain configuration of polar skyrmions, this study provides new insight into structural manipulation of superlattice.

Non-Destructive Steady-State and Time-Resolved Photoluminescence Characterization of Photovoltaic Devices

Christian Oelsner, Eugeny Ermilov, Volker Buschmann, Felix Koberling, Jürgen Breitlow and Rainer Erdmann; PicoQuant GmbH, Germany

Over the years, luminescence spectroscopy has become one of the fundamental methods for analyzing the photophysical properties of a wide variety of samples, ranging from organic molecules to semiconductor materials and photovoltaic (PV) devices. It should be emphasized that detection sensitivity is a key parameter to meet today's requirements for handling weakly luminescent samples and for short measurement times in the optical evaluation of PV devices. The introduction of single-photon counting based data acquisition has proven to provide a significant increase in sensitivity and a very high dynamic range – it is the ideal method for measuring weak photoluminescence (PL).

The commonly used steady-state luminescence spectroscopy methods provide valuable insight into the photophysics of a sample. However, such results offer only a partial picture of the sample’s behavior after photoexcitation. Another piece of the puzzle is often revealed by performing time-resolved PL spectroscopy, which provides deeper insights into the photophysical processes occurring in the sample under investigation. An even more comprehensive picture is gained by incorporating spatial information. Acquiring time-resolved spectroscopic data at regions of interest (ROI) in the sample can help to infer structural-to-photophysical relationships in PV materials. Gathering such information is an important step towards optimizing the structure as well as the preparation process of such materials in order to increase the performance of PV devices.

Herein, we will demonstrate that the combination of time-resolved microscopy and PL spectroscopy provides a powerful tool for the characterization and analysis of various PV materials, providing spectral, spatial and temporal information on semiconductor samples studied by PL emission. This combination allows the mapping of a broad range of phenomena including time-resolved PL, carrier diffusion, wavelength and power dependent emission with high spatial resolution. We will also discuss the advantages of the MicroTime 100 confocal photoluminescence lifetime microscope combined with the FlexWave software controlled wavelength selection unit for time-resolved imaging of very weakly emitting PV materials such as perovskites up to 1000 nm.

CH06.09.02

Two-Dimensional Coherent Spectroscopy of GaAs/$Al_{0.3}Ga_{0.7}As$ Multiple Quantum Wells Using Acousto-Optic Modulator and Chirp Compensation

Yuka Yamaya, Yuto Tokuyama, Fujio Minami and Kazutaka Nakamura; Tokyo Institute of Technology, Japan

Two-dimensional coherent spectroscopy (2DCS) using femtosecond optical pulses makes it possible to investigate ultrafast dynamics such as energy transfer and dephasing in molecules and solid materials. It has also been reported that the use of acousto-optic modulator (AOM) makes the 2DCS system relatively simple. However, the pulse width is extended due to the large group velocity dispersion of the AOM. In this study, to investigate femtosecond coherent dynamics of solid materials, we constructed a simple 2DCS system using an AOM and chirp-pulse compensation technique. Using GaAs/$Al_{0.3}Ga_{0.7}As$ multiple quantum wells as the sample, 2DCS spectra were obtained using chirp-compensated, negative and positive chirped pulses.

The pulse used in the experiments is an output from Ti:sapphire oscillation with a pulse width of approximately 60 fs (center wavelength of about 800 nm, full width of half maximum of about 25 nm). After passing through the AOM, the pulse width was extended to about 1100 fs (positive chirped). The pulse was compensated using a pair of gratings, which was set before the AOMs, to about 60 fs. In addition, the large negative chirped pulse (about 970 fs) was also used for 2DCS measurements in order to study the effect of pulse chirping. In the experiments, the interval between pulses 1and 2 was varied from 0 to 2 ps in 20-fs steps, and the interval T between pulses 2 and 3 was fixed at 1 ps. The signal light was superimposed on the pulse 3 and observed through the spectrometer.
The heavy hole exciton (X_{hh}) peak and the cross peak ($X_{hh\text{-}lh}$) were observed in the 2DCS spectrum measured with 60-fs pulses under the circular polarization condition of $\sigma_+\sigma_+\sigma_+$ and $\sigma_+\sigma_+\sigma_-$. The X_{hh} and $X_{hh\text{-}lh}$ peaks were also observed in the positive and negative chirp, but the intensity of the $X_{hh\text{-}lh}$ peak was weaker in the negative chirp. In the measurements with chirped pulses, 2DCS spectra were obtained despite the overlapping condition of three pulses. The 2DCS spectrum measured with 60-fs pulses under the circular polarization condition of $\sigma_+\sigma_+\sigma_-$ also showed a heavy biexciton peak.

CH06.09.03

Atomic-Scale Terahertz Time-Domain Spectroscopy Vedran Jelic[1], Stefanie Adams[2], Mohamed Hassan[2], Kaedon Cleland-Host[2], Eve Ammerman[3] and Tyler Cocker[2]; [1]University of Ottawa, Canada; [2]Michigan State University, United States; [3]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Terahertz time-domain spectroscopy (THz-TDS) is one of the central technologies of THz science. By measuring the oscillating THz electric field after it has interacted with a sample and comparing it to a reference field, the complex dielectric function at THz frequencies may be determined. Based on the same concept, in THz scattering-type scanning near-field optical microscopy (s-SNOM), THz pulses focused onto a scanning probe tip may be used to spatially map the local complex dielectric function on the 10-100 nm scale [1]. However, many open questions in surface science require these properties to be determined at yet smaller length scales. For example, THz-TDS of individual atomic sites would allow the role of defects, dopants, and interfaces on charge transport to be studied in unprecedented detail. Here, we introduce an experimental method for atomic-scale THz-TDS in a THz scanning tunneling microscope (THz-STM) junction. Using our technique, we demonstrate atomically resolved THz-TDS of a silicon-doped GaAs(110) sample, revealing a resonator defect with the hallmarks of the elusive DX center [2]. In our THz-STM setup, a strong-field THz pulse is coupled to the STM tip and acts as an ultrafast bias voltage in the tip-sample junction, inducing a current pulse with a rectified component that is measured electronically [3]. To perform atomic-scale THz-TDS, we use this induced current pulse to sample a second, weaker THz pulse through a cross-correlation (THz-CC) measurement that captures the near-field waveform. First, a THz-CC waveform is recorded on an Au(111) surface, which is used as a reference sample because of its flat spectral response. Then, we can perform STM topography of our GaAs(110) sample surface; where atomic rows are visible, as are multiple types of atomic defects (e.g., gallium vacancies and silicon substitutional dopants). We find a region, where a particular defect exhibits a strong THz-STM signal. Near-field THz-CC waveforms were measured 200 pm away from the defect and in the center of the bright feature in the THz-STM scan already observing a high contrast between the two measurements. We further divide the amplitude spectra of the GaAs(110) near-field waveforms by the Au(111) reference spectrum. This reveals distinct responses for the two sample locations due to dielectric contrast. Spectroscopically, the most prominent contrast occurs at 0.96 THz, where the defect exhibits a strong resonance that is absent at the location 200 pm away. From this signature resonance and other STM characteristics, we identify the defect as a silicon-vacancy complex stabilized in a DX center configuration and the resonance as the vibrational motion of the silicon dopant atom. Although DX centers are of significant interest in semiconductor research due to their prominent role in carrier scattering [4], this is the first time one has been observed directly. With atomic-scale THz-TDS we can now study open questions that previously could not be addressed experimentally, such as the simultaneous spatial and spectral description of defect complexes in semiconductors. As a next step, we envision that THz-TDS within a THz-STM junction will enable time-resolved THz spectroscopy of the transient THz dielectric response on the atomic scale.

Capturing Rayleigh-Plateau Instability in Silver Nanowires via Ultrafast Electron Microscopy Shuai Jiang and Volkan Ortalan; University of Connecticut, United States

In recent years, the development of ultrafast transmission electron microscopy (UTEM) has allowed us to observe ultrafast processes occurring in materials, contributing to a fundamental understanding of a wide range of dynamic processes. In UTEM, while samples are excited with a pulsed laser to trigger reactions, a second delayed laser pulse is used to stimulate the photoemission of an electron pulse from the cathode. Depending on the reversibility of the studied dynamics, UTEM can be operated either in stroboscopic[1] or single-shot mode[2]. In this presentation, the application of single-shot UTEM in probing irreversible dynamics of materials will be exemplified for the Plateau-Rayleigh instability behavior of silver nanowires upon laser irradiation. By comparing the laser fluence required to initiate the Plateau-Rayleigh instability in silver nanowires on different substrates, it was found that substrate heating was the main driving force for the Plateau-Rayleigh instability in this study. In addition, the complex motions of silver nanowires under laser irradiation were systematically investigated by combining the results of UTEM with scanning electron microscopy characterizations. They were determined to be related to nanowire-membrane interactions or pre-existing stresses on the nanowires, demonstrating the potential of single-shot UTEM for the characterization of materials under extreme conditions[3].

Coherent Optical Phonons in Diamond Studied with Relative Phase- and Polarization-Controlled Femtosecond Pulses Kazutaka Nakamura, Itsuki Takagi, Itsuki Kasai and Tetsuya Kimata; Tokyo Institute of Technology, Japan

The optical phonon in diamond has 40-THz frequency and a relatively long coherence time and is expected to be used as a qubit operating at room temperature. Coherent optical phonons are induced by a femtosecond pulse and can be controlled by a sequence of the pulses.

We performed transient transmission measurements of a diamond crystal using a pump and probe technique with relative phase- and polarization controlled femtosecond pulses. The laser pulse width was approximately 10 fs and its spectrum was centered at 800 nm, with a bandwidth of approximately 200 nm. Both pump and probe pulses can be divided into two pulses by a home-build interferometer. Their relative phase and polarization were also controlled.
The transient transmission showed coherent oscillation with frequency of 40 THz, corresponding to an optical phonon mode. The amplitude of the coherent optical phonons is controlled by varying the delay between either the pump pulses or the probe pulses. When the pump (or probe) pulses are set to parallel along the (110) crystal axis, the phonon amplitude is enhanced at delays matched to integer multiply of the oscillation period, and suppressed at delays matched to half integer multiply of the oscillation period. On the other hand, at the perpendicular polarization condition, the phonon amplitude is enhanced (suppressed) at a half integer (integer) multiply of the vibrational period. We also discussed the coherent control experiments using four pulses (two pump and two probe pulses).

Investigating Water Behavior on Repellent Self-Assembled Materials via Soft X-Ray Emission Spectroscopy

Yusuke Tomiyori[1,2], Hisao Kiuchi[1], Miho Kitamura[3], Daisuke Asakura[4,5], Eiji Hosono[4,5] and Yoshihisa Harada[1,5]; [1]The University of Tokyo, Japan; [2]AGC Inc., Japan; [3]National Institutes for Quantum Science and Technology, Japan; [4]National Institute of Advanced Industrial Science and Technology, Japan; [5]AIST-UTokyo Advanced Operando-Measurement Technology Open Innovation Laboratory, Japan

Self-assembled monolayers (SAMs) are nanostructured materials that can easily impart various functions by bonding to a substrate[1]. In particular, SAMs containing fluorine are known to be able to impart unique functions to substrates, such as water repellency and slipperiness, due to their low surface tension, which are not found in other elements[2]. Understanding the repellent mechanism of materials at the molecular level is useful for the development of functional materials, but little is known about the influence of the chemical structure of SAMs on water adsorption behavior.
In this study, we employed soft X-ray emission spectroscopy (XES), a powerful tool for examining the occupied electronic structure of light elements including water, to acquire a deeper understanding of water adsorption behavior on SAMs with different water repellency and chain structures. We conducted XES measurements on hydrocarbon and fluorocarbon chain structures of SAMs with different water repellency by using a setup developed by our research group that enables XES measurements under precise humidity control. The results demonstrated that under medium humidity conditions, water molecules were progressively trapped on the surface and within the hydrocarbon chains as the supply of water molecules increased. However, such behavior was not observed in the fluorocarbon chains. In contrast, under low humidity conditions, there was no significant change in the initial adsorption phase of water for both hydrocarbon and fluorocarbon chains.
Based on the results of XES and molecular dynamics simulations, we discuss in detail the behavior of water adsorption on molecular chains with different water repellency.

Direct Observation of Triplet-Pair State of TIPS-Pentacene Film by Electronic Sum Frequency Generation Spectroscopy Weiwang Zeng and Zefeng Ren; Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China

Sum-frequency generation (SFG) spectroscopy is a second-order nonlinear process with unique surface sensitivity, ideal for the nondestructive detection of adsorbed molecules at surfaces or interfaces. As a purely optical detection method, it can probe buried interfaces accessible by light. When incident laser beams resonate with the electronic state of a molecule, we can obtain electronic information about the material's surface. Combined with pump-probe techniques, we can also study surface carrier dynamics.

We used electronic resonant SFG (ESFG) spectroscopy to investigate the electronic structure of 6,13-bis(triisopropylsilylethynyl) pentacene (TIPS-Pc) films. We observed not only the electronic transition of $S_0 \rightarrow S_1$, consistent with the linear absorption spectrum, but also the direct observation of the $S_0 \rightarrow {}^1(TT)$ electronic transition. This marks the first direct detection of triplet pairs. The ${}^1(TT)$ state is an important intermediate in the singlet fission process, and understanding its spectral characteristics aids in comprehensively understanding the singlet fission process. However, it is a dark state in the linear absorption spectrum, with its energy level position determinable only by theoretical calculation.

In TIPS-pentacene molecules, geometric symmetry breaking enhances Herzberg-Teller coupling, causing the dark state of ${}^1(TT)$ to couple with the vibrational energy level of the bright state S_1, thereby exhibiting bright state properties. Although the $S_0 \rightarrow {}^1(TT)$ electron transition intensity remains weak under Herzberg-Teller coupling, it can still be detected in the highly sensitive ESFG spectrum, with further enhancement from the double resonance effect.

Additionally, we inferred the direction of the electronic transition dipole moment through phase-resolved ESFG spectroscopy. The ESFG spectra show that the phase of the $S_0 \rightarrow {}^1(TT)$ electronic transition is opposite to that of the $S_0 \rightarrow S_1$ electronic transition in TIPS-Pc film, indicating that the direction of the electric dipole transition moment is opposite. This suggests that the $S_0 \rightarrow {}^1(TT)$ electron transition direction is from the benzene ring of the TIPS-pentacene molecule to the adjacent molecule. The experiment demonstrates that SFG spectroscopy can also detect forbidden transition levels in the linear spectrum, greatly expanding the application field of SFG spectroscopy technology and promoting its development as a spectral method for dark state detection.

High-Repetition-Rate Extreme Ultraviolet Beamlines at the Artemis Facility Bruce Weaver[1], Yu Zhang[1], Nrisimha Murty Madugula[1], Charlotte Sanders[1], Adam Wyatt[1], Richard Thompson[1], James Thompson[1], Tiffany Walmsley[1], Gourab Chatterjee[1,2], Gabriel Karras[1,3], Greg Greetham[1] and Emma Springate[1]; [1]Rutherford Appleton Laboratory, United Kingdom; [2]SLAC National Accelerator Laboratory, United States; [3]Diamond Light Source, United Kingdom

Artemis is a mid-scale extreme ultraviolet (XUV) laser science laboratory at the UK’s Central Laser Facility (CLF), which provides users access to cutting-edge femtosecond dynamics in gas-phase and solid-state systems via photoemission spectroscopy. We have recently commissioned a 100-kHz 200-W high-repetition-rate Yb-based laser system based on optical parametric chirped-pulse amplification (OPCPA). Whilst providing adequate peak power to trigger high-harmonic generation (HHG) in an argon gas jet, our new Yb-based laser source permits enhanced signal-to-noise ratio, finer energy resolution, and shorter data acquisition times in pump-probe photoemission studies of solid samples [1].

Time- and angle-resolved photoemission spectroscopy (TR-ARPES) has brought new insights into challenging aspects of surface science [2]. Advancements in light sources have improved pulse compression to gain higher time resolution, better spatial resolution, and enhanced signal-to-noise ratio. These improvements, however, lead to vacuum space-charge effects, which compromise energy and momentum resolution and generate peak shifts [3]. To minimize these issues and improve the data collection rate during pump-probe experiments, it is necessary to increase the laser repetition rate.

Our TR-ARPES beamline consists of a Fastlite OPCPA, pumped by a 220-W regenerative amplifier. Post-compression, the OPCPA delivers 50 – 100 fs pulses in the ranges of 1450 – 1850 nm (signal) and 2350 – 3680 nm (idler), with up to 200 μJ of energy per pulse at 100-kHz repetition rate.

HHG is achieved by focusing the signal beam into an argon cell, either directly or following SHG. When driven by the second harmonic of the signal, the HHG output spans energies from 20 to 45 eV, with a maximum flux of ~1010 photons/second at the sample.

The XUV beamline includes a monochromator select probe photon energies. A demagnification unit focusses the XUV spot to 20 μm at the sample, facilitating measurements on small samples and on individual structural domains within inhomogeneous samples. The experimental endstation is equipped with a hemispherical analyzer, and a newly commissioned “Fermi Surface Mapper” analyzer [4], which permits photoelectron momentum mapping sliced in the energy axis [5].

To expand the horizon of experiments, we have recently secured funding for a £17M major upgrade [6] of all the CLF’s ultrafast facilities. Our main goal at Artemis is to increase the repetition rate available for atomic molecular, and optical (AMO) science—which, at present, is still running on our older 1-kHz titanium sapphire laser system—and to take advantage of improved data collection rates, by upgrading the endstations on both the TR-ARPES and AMO beamlines. The upgrade will include the following:

1) TR-ARPES endstation incorporating both a momentum microscope and a hemispherical analyzer.
2) 100-kHz Yb-based laser system, with 1.5-mJ, <50-fs pulses at 1 μm for HHG, and tunable <50-fs pulses from 235 nm to 10 μm.
3) AMO endstation offering a dual-coincidence electron-ion spectrometer, laser-desorption, and supersonic gas-jet sources.

***In situ* XRD Observation of the α-ω Phase Transition in Titanium During Shock Loading**

Sota Takagi[1,2] and Sally Tracy[2]; [1]Tokyo University of Science, Japan; [2]Carnegie Institution for Science, United States

The response of titanium (Ti) under shock compression is of fundamental importance due to its wide applications. Here we carry out a series of time-resolved x-ray diffraction (XRD) measurements for Ti under shock loading and release at the Matter in Extreme Conditions (MEC) beamline of the Linac Coherent Light Source (LCLS). Samples were laser shock loaded to a peak stress above the phase transition boundary between α phase and the high-pressure ω phase. Time-resolved XRD captured a complete transition to the ω phase under shock compression and reversion to the α phase during release process. Some amount of ω phase was retained for tens of nanoseconds (ns). The fraction of back-transformed α phase was observed to increase after the onset of spallation, and ultimately, a complete reversion to the α phase was observed at 85 ns after the onset of release. The time evolution of the phase fractions indicates that spallation promote back transformation, likely due to the rise in temperature and uniaxial tension experienced by the spall region.

Direct Triplet Exciton Generation from the Singlet Ground State in Organic Semiconductors Coupled with Lanthanide-Doped Nanoparticles Lars Van Turnhout, Rituparno Chowdhury, Alexander J. Gillett, Richard H. Friend and Akshay Rao; University of Cambridge, United Kingdom

The ability to control triplet excitons is of paramount importance in and beyond the field of optoelectronics. As molecular triplet excitons are dark states, triplets can generally not be accessed directly nor harvested luminescently. Here we show that upon bringing organic molecules and polymers in close proximity to inorganic lanthanide-doped nanoparticles (LnNPs), the quantum mechanically forbidden singlet ground state to triplet excited state transition gains oscillator strength. This allows us to directly excite into the triplet excited state manifold from the singlet ground state.

These absorptions (T1 <- S0) can be readily measured via simple UV-Vis absorption spectroscopy and as such this method presents a straightforward way to measure triplet exciton energies of organic semiconductors. We show this strategy to be widely applicable to a range of organic semiconductors including acenes, organic donor polymers, organic acceptor molecules, and TADF molecules. Using a mixture of low-temperature absorption measurements and magneto-optic measurements we shine light on the mechanism underpinning this phenomenon.

Furthermore, we use transient absorption spectroscopy to study the excited state dynamics of these directly generated triplet excitons. We find these triplets to have short lifetimes well-below 1 ns, allowing for efficient emission from these triplet-excitons. Current studies are underway looking into the possibilities of utilising these directly generated triplets for processes such as direct triplet-triplet annihilation.

All in all, these results deepen our understanding of coupled organic-LnNPs systems and provide a new way to control triplet excitons, which is essential in and beyond the field of optoelectronics.

Improved Methods for Measuring Charge Carrier Transport Parameters from Microscopy Data Thomas Sheehan and William Tisdale; Massachusetts Institute of Technology, United States

Time-resolved microscopy techniques are frequently used to measure the transport of excited charge carriers and excitons in semiconducting materials. Typically, parameters such as diffusivity are extracted by generating a spatially localized population of excited charge carriers, then measuring the spatial growth of the population profile over time. However, commonly used analysis techniques are highly sensitive to the shape of the initial charge carrier profile, and can result in large errors for even small deviations from an assumed profile shape. Additionally, these measurements may be significantly affected by shot noise under common experimental conditions. Here, we propose a new analysis algorithm that uses convolutions of Gaussian functions with the measured charge carrier spatial profiles to both smooth the effects of shot noise and to measure the growth of the spatial profiles. Using simulated data sets of charge carrier transport, we demonstrate that the diffusivity values obtained from this algorithm are less impacted by shot noise and are almost completely insensitive to the shape of the initial charge carrier spatial profile for one-dimensional transport. Within this framework, we quantify how physical phenomena such as nonlinear recombination terms and multi-dimensional diffusion can skew the extracted diffusivity parameters. To mitigate some of these effects, we introduce strategies for extending our algorithm to measure diffusion in two dimensions, which additionally allows for accurate measurements of anisotropic diffusion. Finally, we validate our algorithm by using it to analyze time-resolved photoluminescence microscopy experiments on exciton diffusion in two-dimensional perovskites.

Probing Thermal Decomposition of Energetic Materials with Fast Imaging Techniques Mason Freund, Mehedi Hassan Dipu and Volkan Ortalan; University of Connecticut, United States

Probing ultrafast dynamics provides fundamental information into the mechanisms that drive the evolution of materials. Numerous methods using various probes to capture the dynamic processes at different scales have been developed for various applications and material systems [1–4]. Energetic materials are known to release large amounts of heat via rapid exothermic chemical reactions [5]. Therefore, the observation of the short-lived transient states and the evolution of the complex processes in energetic materials requires fast in-situ characterization techniques with relevant temporal and spatial resolutions for the investigated dynamic process. Due to their ability to quickly release stored energy, energetic materials are utilized for propellants, explosives, and pyrotechnics applications. The response of these materials upon excitation has been heavily studied to understand the initiation mechanisms [1–3,6]. Experimental and numerical methods have been performed to better control and improve performance and efficiency as well as to gain an understanding of the mechanisms driving the reactions. The ability to observe rapid reactions occurring in energetic materials can provide valuable insights into the initiation and heat dissipation mechanisms. In this presentation, time resolved investigation of laser-initiated decomposition of selected energetic materials with fast probing techniques will be discussed.

Ultrafast Photoexcitations in $Ti_3C_2T_x$ —Sodium Polyphosphate Thin Films Andrew M. Fitzgerald[1], Tom Kohen[1], Laura Londono Fandino[1], Michael Zajac[2], Dawei Liu[1], Tianqi Jin[1], Mary Qin Hassig[3], Kateryna Kushnir[1], Joshua R. Uzarski[4], Michel W. Barsoum[3], Ronald L. Grimm[1], Jeannine Coburn[1] and Lyubov V. Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Rhode Island College, United States; [3]Drexel University, United States; [4]U.S. Army, United States

2D titanium carbide MXene, $Ti_3C_2T_x$, where T_x stands for surface terminations -OH, -F, and -O, exhibits high intrinsic free carrier density, conductivity greater than 1,000 S/cm, unprecedented light-to-heat conversion efficiency and unusually slow heat dissipation after excitation with a short laser pulse [1-4]. In our recent study, we have demonstrated that rapid increase in lattice temperature arising from strong electron–phonon coupling results in long-lived (> 1 ns) changes in optical properties of $Ti_3C_2T_x$ films in near-infrared and THz spectral range: bleaching of the localized surface plasmon at ~ 750 nm and suppression of THz optical conductivity [3]. Monitoring recovery kinetics of those effects thus provides a view into thermal properties of MXene films. Here, we investigate how capping MXene nanosheets with sodium polyphosphate, which has been shown to improve their chemical stability in aqueous solution [5], impacts thermal relaxation following photoexcitation. We find that polyphosphates do not significantly impact thermal relaxation kinetics, suggesting that it is possible to achieve long-shelf life MXene colloidal suspensions that can be used for flexible photothermal devices.

Exploring Fast and Ultrafast Dynamics of Matter with Magnons and Phonons Keith A. Nelson; Massachusetts Institute of Technology, United States

We have an ever-expanding repertoire of methods that enable control over elementary excitations, in some cases launching excursions into far-from-equilibrium regimes that may lead to phase transitions or other collective transformations. We also have a widening range of probes that allow incisive observation of the excursions along degrees of freedom that are excited directly or are coupled to the driven modes. Here we will review recent experiments involving coherent excitation of magnons and phonons and observations of the material behavior near and far from equilibrium.

In canted antiferromagnetic materials such as $YFeO_3$, we are able to drive nonlinear responses of magnon modes. They are measured using 2-dimensional THz spectroscopy in which two THz excitation pulses separated by variable delay times drive the system and time-dependent coherent THz signal fields are read out by variably delayed optical pulses that overlap the THz fields in an electro-optic crystal (*Nat. Phys*. 2024 DOI:10.1038/s41567-024-02386-3; DOI:10.1038/s41567-023-02350-7). The use of 500 readout pulses with variable delays on each laser shot reduces the data acquisition time for a single 2D spectrum from several days to minutes, enabling systematic study (including 2D THz polarimetry in which THz polarizations relative to crystallographic axes are incremented in small steps) that would otherwise be impossible. The use of a recently developed method for THz field enhancement throughout a small macroscopic volume (*Sci Rep* **13**, 15228 (2023)) enables generation of far higher-order magnonic responses up to 9-quantum coherences, well outside the perturbative limit. The results reveal magnon self-interaction at large excursions and suggest approaches for tailoring THz magnetic fields in order to drive magnetization reorientation transitions or domain reversal.

THz driving of “soft” optical phonons associated with the suppressed ferroelectric phase transition in the quantum paraelectric phase of $SrTiO_3$ were reported to have induced a transient ferroelectric configuration in the crystal (*Science* **364**, 1079 (2019)). It was assumed based on tabletop optical measurements that the induced changes were essentially inform in the irradiated sample. However, diffuse x-ray scattering measurements revealed singular responses at off-Bragg wavevectors corresponding to polar nanoregions of ~ 10-nm dimensions, suggesting that the quantum paraelectric material is near an instability with respect to a phase with spatially modulated ferroelectricity, stabilized by strong gradients in the strain and the polarization (i.e. flexoelectric effect), as well as a phase with spatially uniform ferroelectricity (*arXiv*:2403.17203 (2024)).

Recent advances in direct generation of high-wavevector coherent magnons and phonons through excitation with crossed beams (transient grating excitation; *Photoacoustics* **29**, 100453 (2023)) at extreme UV or hard x-ray wavelengths will be discussed. In very recent experiments, hard x-ray transient grating excitation with an interference period of 12 nm generated coherent acoustic phonons at that wavelength. The approach may enable transient grating measurements with periods as short as 1 nm or less.

Finally, a key degree of freedom for coherent control of material behavior is strain. We have recently used focusing nonlinear surface acoustic waves (surface acoustic shocks) to induce the insulator-to-metal phase transition in V_2O_3. The transition is irreversible, driven and observed on a single-shot basis. More generally, we have developed methods for nondestructive optical excitation of focusing and non-focusing shocks that reach pressures on the order of 10 GPa (*Phys. Rev. Appl*. **20**, 044044 (2023)). The approach enables high repetition rate pump-probe measurements with the shock playing the role of the pump, either by itself or supplemented by additional excitation using THz or optical pulses for multimodal collective coherent control.

9:30 AM CH06.10.02

Temperature-Dependent Recombination Dynamics of Photocarriers in $CsPbBr_3$ Microcrystals Revealed by Ultrafast Terahertz Spectroscopy Sheng Hung Lee[1], Kyeongdeuk Moon[1], Muhammad Shoaib[1], Charles Pedorella[2], Kellen O’Brien[2], Meng-Ju Sher[2], Seokhyoung Kim[1] and Tyler Cocker[1]; [1]Michigan State University, United States; [2]Wesleyan University, United States

We study the ultrafast dynamics of photoexcited charge carriers in micron-scale crystals composed of the inorganic perovskite $CsPbBr_3$ with time-resolved terahertz spectroscopy. Exciting with photon energy close to the band edge, we find that a fast (< 10 ps) decay emerges in the terahertz photoconductivity with increasing pump fluence and decreasing temperature, dominating the dynamics at 4 K. The fluence-dependent dynamics can be globally fit by a nonlinear recombination model, which reveals that the primary nonlinear recombination mechanism depends on temperature, with Auger scattering determining the fast decay at 77 K but radiative recombination responsible for the fast decay at 4 K. Spectroscopically, the terahertz photoconductivity resembles a Drude response at all delays, yet an additional Lorentz component due to an above-bandwidth exciton resonance is needed to fully reproduce the data. The coexistence of excitons with free charge carriers impacts the scale of the recombination coefficients, as the absorbed photon density significantly exceeds the free charge carrier density.

9:45 AM CH06.10.03

Experimental Evidence for Bright-to-Dark Exciton Transition in Anatase TiO_2 Andrea Iudica, Gabriele Lovati, Stefano Dal Conte, Giulio Cerullo and Margherita Zavelani-Rossi; Politecnico di Milano, Italy

Up-to-date as of November 14, 2024

Anatase TiO_2 is a well-known indirect bandgap transition metal oxide, featuring high photocatalytic activity and excellent photoelectric properties, together with chemical stability and wide bandgap [1]. Very recently, further interesting properties, so far unexplored, have emerged. In particular, strongly bound excitons across the direct bandgap of the material have been highlighted. Bright, momentum-direct excitonic states have been predicted theoretically and observed experimentally. It was shown that the typical binding energy of these excitons is exceptionally large for a bulk solid, approaching 200 meV [2].

Given the indirect bandgap of anatase TiO_2, a further attractive property resides in the possibility of bound, momentum-indirect dark excitons. Such excitons are characterized by longer lifetimes compared to their bright counterpart, making them a possible platform for quantum information, Bose-Einstein condensation, and energy harvesting [3]. The possibility of momentum indirect excitonic states in TiO_2 has only been investigated theoretically quite recently [3] and remains without any experimental confirmation. An experimental proof of the existence of indirect excitons in anatase TiO_2 would represent a relevant result, providing important information for fundamental research and technological applications.

Here, we report the first experimental evidence of a strongly bound, momentum-dark exciton at the indirect bandgap of anatase TiO_2. In this work, we employ deep-UV pump-probe spectroscopy in transient reflectivity (TR), with 20 fs time resolution and high sensitivity. We populate the bright excitonic state (3.8 eV) near the direct bandgap of the material and collect the transient reflectivity response over a broad photon energy range (from 2.5 to 4.85 eV) across the bandgap of TiO_2. We can thus detect the dark exciton and characterize its temporal evolution.

The TR spectra are characterized by a clear signal corresponding to the bright exciton. The main contributions to its spectral feature are given by a combination of phase space filling (PSF), coulomb screening (CS) and bandgap renormalization (BGR) [4]. Superimposed to this signal, We observe a weak spectral feature with derivative shape at photon energies around 3.4 eV, which is consistent with the theoretical estimation of the dark exciton. Moreover, this feature shows a well-defined rise time of approximately 200 fs. We also observe that this rise time matches the ultrafast decay component of the TR bright exciton signal. This is a clear indication of a transition from the lowest bright exciton at the direct bandgap of the material, to the dark, momentum indirect exciton, due to scattering events of charge carriers with phonons. The experimental timescale of this process agrees well with the theoretical predicitions, highlighting a clear dark-to-bright transition, driven by a strong hole-phonon scattering channel along the Γ-to-X direction taking place in 100 to 300 fs [3]. We postulate that the effects of PSF, CS, BGR on the dark excitonic state are sufficiently large to modulate the cross section of phonon-assisted light absorption, generating a faint spectral feature in the transient reflectivity spectra. The dependence of the scattering rate from the temperature is also considered.

In conclusion, using a high sensitivity setup for ultrafast spectroscopy in the deep UV spectral range, with a sufficiently high temporal resolution, we are able to detect the predicted dark exciton of anatase TiO_2. We thus shed light on the properties of this physically and technologically relevant material. This result also contributes to the general understanding of excitonic states in transition metal oxides, and wide bandgap indirect semiconductors.

Near-Unity Biexciton Quantum Yields and Broadband, Low Threshold Lasing from Colloidal Quantum Shells
Anton Malko; The University of Texas at Dallas, United States

Spherically shaped semiconductor nanoplatelets, called quantum shells (QSs) have recently attracted considerable attention for various optoelectronic applications. We developed a range of CdSe quantum-confined spherical shell sandwiched between wider-bandgap CdS core and CdS outer layers in which separation of charge carriers is defined not only by the mutual attraction or repulsion of the exciton pairs, but also by the core size. At the same time, it allows for a smaller electron-hole overlap, promoting longer radiative times. We demonstrate that such QSs with a large-size core component exhibit excellent multi-exciton emission characteristics with strongly suppressed Auger recombination. By using a combination of photoluminescence (PL) blinking and single-photon statistics measurements, we show that biexciton quantum yield increases from QY^{BX} ~45 % for small-core CdS/CdSe/CdS QSs (D_{core} = 4.5 nm) to an average QY^{BX} of ~ 82 % for large-core QSs (D_{core} = 8.2 nm) with individual particles exhibiting QY^{BX} of up to 100%. Efficient emission and ultralong BX lifetimes (> 15 ns) allowed us to observe low-threshold amplified spontaneous emission (ASE) with modal gain *g* ~ 1000 cm^{-1} in large-core QS films. To utilize broad gain bandwidth, we demonstrated narrow line lasing action using QSs in tunable optical cavity configurations. We design distributed feedback (DFB) cavities using lithographically defined SiO_2 nanopillar arrays etched on Si substrates and filled with close-packed QS films. Using only one QSs size (i.e., confinement), we demonstrate emission coupling and low threshold, narrowband lasing across wide spectral range, from single exciton (l_X~640 nm) to biexciton (l_{BX}~625 nm) to multiple exciton (l_{MX}~615-565 nm) transitions. The ensemble-averaged gain threshold of $\langle N \rangle$~1.4 electron-hole pairs per QS particle and lowest pump fluence of ~ 4 mJ/cm^2 result from almost completely impeded Auger recombination and low optical losses in the nanopillar cavity. Lasing emission tuning shows excellent agreement with calculations as an array period is continuously varied, while maintaining the mode confinement and quality (*Q*) factors. These results represent a significant advance towards the development of future electrically pumped, colloidal nanocrystal lasers.

11:00 AM CH06.11.02
Coherent Multi-Dimensional Spectroscopy Reveals New Physics of System-Bath Interactions in Metal-Halide Perovskite Quantum Dots Patanjali Kambhampati[1] and Maksym V. Kovalenko[2]; [1]McGill University, Canada; [2]ETH Zürich, Switzerland

Coherent Multi-Dimensional Spectroscopy (CMDS) is now well established enough to be experimentally tractable for more groups in materials science. But the contributions of CMDS to materials science is in its early stages as the development work has now matured. With this maturity in the method, we are poised to unravel processes in materials that could not be addressed using one-dimensional ultrafast spectroscopies like transient absorption (TA). Transient absorption (TA) spectroscopy as now mature and has grown ubiquitous due to its scientific power and the availability of commercial solutions for laser systems and now for spectrometers. TA spectroscopy is a one-dimensional spectroscopy in that one probes a single energy axis (the probe energy), as a function of pump/probe time delay. In 2D spectroscopy one obtains 1D TA spectra at various pump energies. 2D is a simplification of Coherent Multidimensional Spectroscopy (CMDS), because the coherence of the measurement process is important and is lost in the hole burning analogy. In moving to CMDS, one has two (or more) energy axes. There is the usual probe axis, and now a pump axis, each at some population time. Being multidimensional, the experiment can have multiple energy axes. Being coherent, the experiment can measure coherent signals and enables 2D measurements of amplitude and phase of coherences. CMDS enables many leaps forward past 1D TA spectroscopy.

We apply CMDS to CsPbBr3 metal-halide perovskite quantum dots spanning weakly confined to strongly confined. CMDS enables a number of totally now and remarkable observations. The CMDS data reveals a previously unobserved excitonic doublet which has remarkable properties. This excitonic doublet is shown to support long-lived excitonic coherence, fulfilling a longstanding search for electronic coherence in the CMDS field. The data reveal splittings in the diagonal and the anti-diagonal spectral that are not possible to observe in 1D spectroscopy. These features in the off diagonals reflect couplings between excitons which we show to be time dependent due to lattice structural dynamics. The CMDS lineshape analysis enables disentangling of all the contributions to spectral broadening from homogenous, to inhomogeneous, from static to dynamic. These CMDS experiments provide a number of remarkable observations on a remarkable material.

Investigations of Dependence of Optical Behavior of β-Ga_2O_3 Substrate on Their Crystallographic Orientations Kishor Upadhyaya, Hadeel Alamoudi, Vijay Kumar Gudelli, Fatimah Alreshidi and Iman S. Roqan; King Abdullah University of Science and Technology, Saudi Arabia

b-Ga_2O_3 has shown enormous potential in various deep UV applications. Due to lack of symmetry in monoclinic structure, the anisotropy in the optical properties of b-Ga_2O_3 is still not sufficiently understood. To address this research gap, we carried out detailed experimental and theoretical investigations of three crystallographic orientations, (100), (010), and (001) of high quality single crystalline b-Ga_2O_3 substrates grown via melt growth method. We correlated the obtained spectroscopic ellipsometry and advanced optical spectroscopy findings with the density functional theory (DFT) calculations. XRD rocking curve analyses exhibits narrow FHWMs in the range of 200-300 arcseconds for all the films demonstrating the superior crystalline quality, confirming very low defect density and hence, ruling out the effect of structural defect influence on the optical properties. In addition, measurements based on the room temperature Raman spectroscopy reveal that different strong vibration modes depend on the film orientation, indicating that it also governs the intrinsic point defect structural configuration (i.e. tetrahedron or octahedron ones). Further, absorption measurements show an anisotropic behavior of bandgap edge, and result in distinct bandgaps, as well as an energy shift from 4.4 eV to 4.5 eV, depending on film orientation. Spectroscopic ellipsometry measurements at 632.8 nm show a similar anisotropic orientation dependence for the refractive index of all films. Moreover, temperature-dependent photoluminescence (PL) spectra and PL excitation (PLE) spectra of all films confirm that the emission produced by all studied b-Ga_2O_3 samples comprises different emission bands, which can originate from self-trapped excitons in shallow defect bands below the conduction band, while the PLE results confirm a similar bandgap shift for different orientations. Advanced temperature-dependent time-resolved photoluminescence (TRPL) findings further reveal that the carrier transition mechanism results in a shorter luminescence lifetime than trap states associated with conventional defects. As our experimental findings are in good agreement with the DFT calculations of the optical and electronic properties, they offer valuable new insights into the origin of the anisotropic behavior in the b-Ga_2O_3 films with different orientations of [100] crystallographic group, thus advancing the understanding of the optical properties of such emerging materials.

SESSION CH06.12: Scanning and Optical Probes and Terahertz Spectroscopy

Photoinduced Surface Oxygen Vacancies and Effect of Methanol on the Charge Carrier Dynamics in TiO_2

Bugrahan Guner and Omur E. Dagdeviren; Université du Québec, Canada

The migration of holes in metal oxides such as TiO_2 plays a vital role in (photo)catalytic applications. The dynamics of charge carriers under operation conditions can be influenced by both methanol addition and photoinduced surface oxygen vacancies (PI-SOVs) [1]. Nevertheless, the existing knowledge of the effect of methanol as a function of PI-SOVs solely concentrates on the chemical reduction process. For this reason, the fundamental understanding of the time-dependent charge carrier-vacancy interactions with the presence of methanol is impaired. To overcome this challenge, we performed time-resolved atomic force microscopy measurements to quantitatively disclose the dynamics of charge carriers in a rutile-terminated, single-crystal TiO_2 (100) sample under the influence of methanol as a function of high-energy ultraviolet (UV) surface irradiation [2-4]. We have three major experimental findings: (I) The addition of methanol decreased the time constant, and hence, the mobility of the charge carriers. (II) The energy barrier within the system was decreased by UV irradiation; however, the presence of methanol did not alter the corresponding barrier. (III) The reversibility of the charge carrier dynamics was observed upon the termination of UV irradiation. Our analysis of methanol's role in hole mobility as a function of surface irradiation contributes to the understanding of surface interactions and charge carrier dynamics, offering valuable insights for (photo)catalytic applications.

2D THz Measurement of Magnon-Phonon Coupling in Multiferroic $BiFeO_3$ Megan Biggs, Claire Rader, Brittany Knighton, Aldair Alejendro and Jeremy A. Johnson; Brigham Young University, United States

Quantum phonon, magnon, and electronic excitations are the building blocks of lattice, spin, and electronic degrees of freedom. Couplings between these modes can lead to new excitations, like electromagnons, and exotic macroscopic properties like colossal magnetoresistance, where a magnetic field dramatically alters the electrical conductivity. Terahertz (THz) frequency light is uniquely suited to resonantly probe collective electronic, phonon, magnon, and electromagnon modes. New developments in 2D THz spectroscopy are enabling the direct measurement of nonlinear excitation of phonon, magnon, and electronic modes, and preliminary measurements are directly showing couplings between them.

$BiFeO_3$ is one of the most studied multiferroic materials. It is a prototypical example of an ABO_3 type I magnetoelectric multiferroic, where the ferroelectric polarization (due to lone-pair-active structural distortions involving the “A” Bi atoms) arises independently from the magnetic ordering (that is due to the spin structure of electrons associated with the “B” Fe atoms). $BiFeO_3$ is ferroelectric below the Curie temperature of ~1100 K and it becomes antiferromagnetic below the Néel temperature of ~650 K, making it multiferroic at room temperature. Because it is a type I multiferroic where spin and ferroelectric ordering arise independently of each other, coupling between magnon, electronic, and phonon subsystems is not expected to be strong. Nevertheless, the 2D THz measurements of $BiFeO_3$ at room temperature reveal that magnon-phonon coupling occurs.

Direct phonon-phonon coupling between two phonon modes at 4 and 2.3 THz are observed. We additionally see direct magnon-phonon coupling between the phonon at 2.3 THz and a magnon at 0.6 THz. This direct measurement of magnon-phonon coupling not only enables us to prove that it occurs even in a weakly coupled multiferroic like $BiFeO_3$, but now we can further consider how to control the fundamental material degrees of freedom by using these mode couplings.

Probing the Ultrafast Dynamics of Phonon Polariton Active Tuning Sarah Sutton, Adam Dunkelberger and Daniel Ratchford; U.S. Naval Research Laboratory, United States

One current limitation of many nanophotonic devices is that once fabricated, the device’s optical response is fixed. Surface phonon polaritons (SPhPs), hybrid excitations of light strongly coupled to the vibrational modes of a polar dielectric, offer a path to create nanophotonic devices whose infrared response can be modulated on the fly. For instance, spectral tuning in nanophotonic materials can be achieved by coupling the free carrier plasma to localized SPhP modes. The photoinjection of charge carriers perturbs the dielectric function, causing the SPhP resonances to shift. Thus, spectral tuning can be achieved by modulating the free carrier density. Resonance shifts are defined by a tuning figure of merit (FOM) that is anticorrelated to the resonance bandwidth, which depends on the free carrier lifetime. Therefore, determining the mechanisms that dictate the free carrier relaxation kinetics in these nanophotonic materials is crucial to extending the tuning range and optimizing the tuning FOM. This presentation details using a pump-probe spectroscopy technique to extract carrier lifetimes and image ambipolar diffusion in nanopillar arrays that support SPhP modes. The results of these experiments provide insight on the impacts of surface defects and diffusion into the substrate that potentially limit SPhP resonance tuning.

Resolving a THz-induced Phase Transition in WTe_2 on the Sub-Atomic Scale with THz-STM Vedran Jelic[1], Stefanie Adams[2], Daniel Maldonado-Lopez[2], Ismail Buliyaminu[2,2], Mohamed Hassan[2], Jose Mendoza Cortes[2,2] and Tyler Cocker[2]; [1]University of Ottawa, Canada; [2]Michigan State University, United States

The discovery of topologically protected states has had a lasting impact on condensed matter research, leading to countless theoretical and experimental discoveries of new topological phases in materials. Amongst these, the transition metal dichalcogenide WTe_2 has been proposed as a candidate type-II Weyl semimetal that hosts Weyl points at the contact points of electron and hole pockets. More recently, an experimental THz pump / ultrafast electron diffraction probe study of WTe_2 has indicated that strong THz fields can drive a structural phase transition from the Weyl semimetal ground state into a trivial semimetal phase through an interlayer shear motion that

restores lattice inversion symmetry. However, this study primarily relied on measurements of the lattice symmetry to deduce the topological transition and did not have access to the electronic properties of either phase.
Here, we show that terahertz scanning tunneling microscopy (THz-STM) can both drive the phase transition of WTe_2 via the enhanced THz fields at the STM tip apex and distinguish the electronic phases. We find evidence for the phase transition through THz-induced changes to the local density of states and real-space imaging, both supported by DFT calculations. The spatial contrast between the phases enables us to perform THz-STM imaging with unprecedented spatial resolution – down to the 10 picometer scale – revealing subtle differences in the surface electronic wavefunctions as the atomic positions distort and the lattice planes shift across the transition. The possibility of finely adjusting the density of states of a material with an ultrafast light field and simultaneously resolving the spatial dependence of the transition on the sub-atomic scale presents a novel way of studying topological phase transitions. Overall, our finding that THz-STM is extremely sensitive to differences between electronic phases is an exciting prospect for further studies of topological materials with THz-driven transitions.

3:15 PM CH06.12.05
Extended Time-Resolved Terahertz Spectroscopy for Photovoltaic Material Analysis KM Ashikur Rahman, Bin Yun, Jack Root and Meng-Ju R. Sher; Wesleyan University, United States

Time-resolved terahertz spectroscopy (TRTS) is a crucial technique to study the lifetime and charge carrier dynamics in materials suitable for photovoltaic applications. This technique, utilizing THz probes generated by fs lasers, provides insights into charge carrier dynamics, including lifetimes and recombination processes, with picosecond resolution. In TRTS, an optical laser excites the sample while THz waves probe its transient conductivity. Although perovskites and organic photovoltaics are known for their long carrier lifetimes, as reported in published literature, the TRTS's capability to study these materials is traditionally constrained to a few nanoseconds due to physical stage limitations. Our current setup includes a pump source with interchangeable laser diodes and electronic synchronization between the pump and probe, extending the observable timeframe from 2 nanoseconds to hundreds of microseconds, with a probe resolution of 30 microseconds. A wider observation window helps analyze the dynamics of these materials, allowing us to probe various depths with the interchangeable diode laser. This enables a detailed investigation of decay dynamics and differentiation between surface and bulk recombination processes through transient pump-probe measurements. By extending the temporal window, we can capture longer-lived processes and obtain a more comprehensive understanding of the material's behavior over time, including how charge carriers move and recombine in different regions of the sample. We utilize transient pump-probe measurements and frequency-dependent analysis to monitor THz signal changes over time and frequency, applying the Drude model to derive parameters like scattering time. By adjusting the laser spot size and the duty cycle of the pump diode laser, we enhance detection signals. Our steady-state measurements also address materials with shorter lifetimes by illuminating the sample. This balances carrier generation and recombination rates, allowing us to study carrier dynamics even below the minimum resolution limit of transient techniques. We are currently focused on conducting further measurements on a silicon wafer, for which we have already generated reference data for parameters such as lifetime and mobility to match with published information. Our next step is to extend these studies to perovskite and organic photovoltaic materials. However, we recognize that there are resolution limitations in our current setup, and we are considering substituting the diode laser with an Nd: YAG nanosecond laser. This modification would enable us to study charge carrier dynamics and overall recombination behavior in photovoltaic materials with longer lifetimes, achieving nanosecond resolution within the hundreds of microseconds observation window.

3:30 PM CH06.12.06
Fast and Slow Timescale Effects of Photoinduced Surface Oxygen Vacancies on the Charge Carrier Dynamics of TiO_2 Bugrahan Guner and Omur E. Dagdeviren; Université du Québec, Canada

The migration of charge carriers (*e.g.*, electrons, holes) in metal oxides, such as TiO_2, plays a vital role in (photo)catalytic applications.<!--[endif]---->[1-4] Nevertheless, photoinduced surface oxygen vacancies (PI-SOV) scan significantly alter the dynamics of charge carriers.<!--[endif]---->[1-6] Here, we study the effect of PI-SOVs (prompted by high-energy ultraviolet irradiation) on fast (*i.e.*, electrons) and slow (*i.e.*, holes) charge carriers via time-resolved atomic force microscopy (TR-AFM) measurements, while simultaneously exploring the effect of gold nanoparticles (Au-NPs). We conducted our measurements on Au-NP-deposited titanium dioxide, *i.e.*, TiO_2. Our measurements illustrate that the induced oxygen vacancy (V_O) defects result in a decrease in time constants associated with the migration of electrons. In addition, we quantified the effect of induced defects on the migration barrier of slow charge carriers, *i.e.*, holes. Our respective measurements show that PI-SOVs lower the migration barrier of holes for both the TiO_2 and TiO_2/Au-NP interface. We believe that the observed statistical difference is caused by the effect of defects over the recombination and trapping mechanisms of fast and slow charge carriers. Our results express the important effect of V_O on charge migration dynamics, which underlines the need for further studies of defects under realistic conditions.<!--![endif]----><!--![endif]---->

Understanding Electronic Inhomogeneity in 2D Layered Materials and Structures via Cryogenic STEM
Miaofang Chi[1,2], Haoyang Ni[1], Joy Chao[1] and Elizaveta Tiukalova[1]; [1]Oak Ridge National Laboratory, United States; [2]Duke University, United States

Two-dimensional quantum materials exhibit unique phenomena and functionalities beyond classical physics. Constructing hetero- and twisted structures from them has emerged as a promising method to induce distinctive local lattice reconstructions and thus induce exotic quantum effects. Critical to this research is studying the spatial inhomogeneity of these materials to finely tune their quantum states. Advances in cryogenic scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) with enhanced stage stability have significantly enabled this research. In this talk, I will present our ongoing research using atomic-scale cryogenic STEM and monochromated EELS to investigate lattice-electronic structure coupling in several representative 2D van der Waals structures for magnetic storage and spintronic applications. Key examples include the discovery of layer-number-dependent phase transitions in $CrCl_3$ during cooling, the elucidation of complex local symmetry breaking in the long-wavelength charge density wave in $EuAl_4$, and the mapping of local excitons in moiré-structured $MoTe_2$. These studies demonstrate that the electronic and magnetic properties of 2D materials can be tuned by manipulating the layer number, introducing lattice displacements, or creating moiré structures. These studies also highlight the power of combining high-resolution cryogenic STEM imaging and spectroscopy for studying quantum materials in general.

This work was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division. Microscopy was performed as part of a user proposal at the Center for Nanophase Materials Sciences (CNMS), which is a US DOE Office of Science User Facility at Oak Ridge National Laboratory (ORNL).

Structural and Electronic Evolution in Metal-Insulating Nickelates Probed by Advanced Cryo-STEM Techniques
Lopa Bhatt[1], Yonghun Lee[2], Xin Wei[2], Noah Schnitzer[1], Michael Colletta[1], David A. Muller[1], Harold Y. Hwang[2], Lena F. Kourkoutis[1] and Berit H. Goodge[3,1]; [1]Cornell University, United States; [2]Stanford University, United States; [3]Max Planck Institute for Chemical Physics of Solids, Germany

Correlated phase transitions offer both a rich playground and unique challenge for real-space imaging and spectroscopic studies down to the atomic scale. With direct access to relevant order parameters such as atomic lattice, charge, and spin, scanning transmission electron microscopy (STEM) can provide crucial information regarding phase coexistence, evolution, and inhomogeneity compared to bulk-averaged probes. Recent technical and analytical improvements are now enabling correlated structural and electronic studies down to liquid nitrogen

temperatures in the STEM. More stable and flexible cryogenic sample holders, for example, slow thermally driven mechanical drift at the sample and provide additional tuning knobs such as variable temperature or biasing control [1]. Fast, low-noise detectors equipped on instruments with high-brightness sources improve the quality of dose-limited signals [2,3,4]. Analytically, new methods of dimensionality reduction can help tease out electronic phases from low signal-to-noise-ratio data [5]. Here, we study the competition and interplay between structural and electronic effects across the metal-insulator transition (MIT) in free-standing rare-earth nickelate perovskites ($RNiO_3$) membranes through a combination of cryogenic four-dimensional (4D)-STEM, multislice electron ptychography (MEP), and electron energy loss spectroscopy (EELS). We observe clear spectroscopic signatures consistent with the temperature-driven MIT which are resolved into spatially separated components templated by the film (membrane) geometry, while imaging and local diffraction reveal the importance of local domain orientation. Mapping the length scales and coupling of such structural and electronic transitions will have important implications for future applications of these materials in micro- and nanoscale devices for e.g. neuromorphic computing.

11:30 AM *CH07.01.03

Imaging the Structural Evolution of Strongly Correlated Order in Oxides with Cryogenic Electron Ptychography and Variable Temperature Cryo-STEM Noah Schnitzer[1], Lopa Bhatt[1], Ismail El Baggari[2], Berit H. Goodge[3], David A. Muller[1] and Lena F. Kourkoutis[1]; [1]Cornell University, United States; [2]Harvard University, United States; [3]Max Planck Institute for Chemical Physics of Solids, Germany

Quantum materials host rich phase diagrams characterized by the competition of electronic, magnetic, and lattice degrees of freedom. The small energy barriers between phases with disparate properties give rise to rich couplings and exotic behavior such as charge and pair density waves and colossal magnetoresistance, as well as nanoscale inhomogeneity including phase coexistence, domain structures, active defects and disorder. Studying the emergence of these nanoscale features and their significance to functional material properties requires high resolution characterization, while stabilizing ground states of interest and tracking the evolution of order parameters under applied stimuli necessitates *in situ* measurement. Here, we apply cryogenic scanning transmission electron microscopy (cryo-STEM) to characterize the emergence and destruction of strongly correlated electronic phases in complex oxides with sub-Angstrom resolution, and demonstrate two emerging cryo-STEM techniques. First, we apply variable temperature cryo-STEM imaging, enabled by *in situ* holder developments, to step through a low-temperature electronic phase transition in a charge-ordered manganite and reveal transient structures which reflect the coupling between the charge ordering and the lattice. Secondly, we leverage cryogenic multislice electron ptychography, made possible by high-speed, high-dynamic-range 4D-STEM detectors, to achieve deep-sub-Angstrom spatial resolution imaging with light-element sensitivity to probe the strain-mediated metal-insulator transitions in Ruddlesden-Popper ruthenate thin films.

SESSION CH07.02: Cryogenic Electron Microscopy and Correlative Characterization Techniques for Quantum Materials II
Session Chairs: Michele Conroy and Ismail El Baggari

Up-to-date as of November 14, 2024

Monday Afternoon, December 2, 2024

1:30 PM *CH07.02.01
Charting New Territory in Materials Science with Cryo Electron Microscopy Juan Carlos Idrobo[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Modern scanning and transmission electron microscopes (S/TEM) have become almost ubiquitous in materials and biological sciences laboratories. They have significantly advanced our understanding of matter at the atomic level, providing unique insights into the structure, chemical composition, and electronic properties of materials. Furthermore, the recent development of stable cryogenic TEM holders, which operate at temperatures ranging from liquid nitrogen (100 K) to 300 K and include electrical contacts, combined with aberration-corrected and monochromated electron optics, has enabled S/TEM to study magnetic, structural, and electronic phase transitions with unprecedented spatial and energy resolutions.

In this talk, I will present two examples of cryogenic STEM measurements done in a set of two-dimensional (2D) transition metal dichalcogenides (TMDs) and hexagonal boron nitride (hBN) samples. In the first example I will address excitonic dephasing in MoS_2, and how local strain can affect the excitonic properties of hetero TMDs bilayers. In the second example, I will present our efforts to try to measure chiral properties in hBN using monochromated EELS in the phonon and core-loss energy regimes. Prospects and limitations of future experiment will be discussed in the detail during the talk. [1]

[1] The EELS part of this research was supported by the Center for Nanophase Materials Sciences, which is a Department of Energy Office of Science User Facility. This research was conducted, in part, using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy. This work was also partly funded under the Laboratory Directed Research and Development Program at Pacific Northwest National Laboratory, a multiprogram national laboratory operated by Battelle for the U.S. Department of Energy. The TMDs TEM sample preparation was supported by the UW Molecular Engineering Materials Center, an NSF Materials Research Science and Engineering Center (Grant No. DMR-2308979).

2:00 PM *CH07.02.02
Advanced Cryogenic Electron Microscopy for Quantum Materials Yimei Zhu; Brookhaven National Laboratory, United States

In this presentation, I will provide an overview of our recent advancements in cryogenic microscopy characterization of quantum materials. I will highlight the interplay of electron, spin, and lattice degrees of freedom, and reveal the significant roles of heterogeneity and disorder at cryogenic temperatures when materials are subjected to external electric, magnetic, and photonic excitations. Specifically, I will present our low-temperature diffuse scattering analysis, which maps the photoinduced dynamics of charge density waves and the associated population evolution of various phonon branches. Additionally, I will discuss the use of cryogenic Lorentz phase microscopy to investigate the transformations among topological chiral spin states, including skyrmions, under applied electric and magnetic fields. Our development of a liquid-helium-free cryogenic sample holder capable of maintaining temperatures below 6K with long holding times and millikelvin temperature stability and control for autonomous electron microscopy will also be discussed.

I would like to acknowledge the electron microscopy group at CMPMS, BNL, for their assistance. This work was supported by the US DOE/BES-MSED under Contract DE-SC0012704.

2:30 PM CH07.02.03

Joint Ptychographic Tomography—From Frozen Hydrated Proteins to Magnetic Vector Potentials Georgios Varnavides[1,2], Yue Yu[3], Berk Kucukoglu[4], Stepanie Ribet[2], Mary Scott[1], Henning Stahlberg[4] and Colin Ophus[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Chan Zuckerberg Institute for Advanced Biological Imaging, United States; [4]École Polytechnique Fédérale de Lausanne, Switzerland

An electron beam passing through a thin sample acquires phase shifts due to sample interactions, including electrostatic and magnetic scattering contributions. Reconstructing three-dimensional scattering sources from two-dimensional phase-less diffraction intensities is a high-dimensional non-convex inverse problem. Iterative electron ptychography is a phase-retrieval technique which attempts to solve this inverse problem using the redundant information in a set of converged-beam diffraction intensities with sufficient real-space illumination overlap [1,2], e.g., using defocused-probe 4DSTEM measurements.

Conversely, single particle analysis (SPA) of frozen-hydrated proteins using cryogenic electron microscopy (cryo-EM) enables the three-dimensional structure determination of biomolecules with ångström resolution. Despite the remarkable advances enabled by cryo-EM SPA, the technique requires extensive data acquisition and processing and suffers from size limitations. Recently, considerable efforts have been employed to apply phase-contrast STEM methods, including electron ptychography, to study biological structures [3,4,5]. Cryogenic electron ptychography has recently been used to obtain sub-nanometer resolution of apoferritin samples using a relatively small number (~11,000) of high signal-to-noise particle reconstructions [6]. This "serial" approach, where one uses the 4D diffraction datasets to reconstruct 2D projection images which are then subsequently used to reconstruct a 3D volume using standard cryo-EM methods, is however, not maximally dose efficient.

In this talk, I will propose an alternative technique we term "joint" ptychographic tomography, where the 3D volume is reconstructed directly from the 4D data. This has multiple advantages of 2D projection-based techniques: first, nonlinearities arising from multiple scattering in the sample can be accurately modeled; second, it enables 3D regularization directly which can more effectively fill-in information from missing projection directions; and finally, it can more accurately capture amplitude and phase variations of the scattering potential. Finally, I will demonstrate how orthogonal tilt-series of diffraction intensities can also be used to directly solve for the three-dimensional nature of vector magnetic scattering sources, to enable antiferromagnetic imaging at atomic resolution [7].

Unveiling Atomic Structure and Excitons in Twisted 2D $MoTe_2$ via Cryogenic STEM-EELS Elizaveta Tiukalova[1], Olugbenga Olunloyo[2], Kai Xiao[1], Andrew Lupini[1] and Miaofang Chi[1]; [1]Oak Ridge National Laboratory, United States;

[2]The University of Tennessee, Knoxville, United States

Moiré heterostructures composed of 2D semiconducting transition metal dichalcogenides (TMDs) have emerged as a rich platform for exploring novel correlated phases [1]. Their physical properties can be precisely tuned through the selection of materials and the manipulation of the twist angle between layers, often leading to the emergence of exotic phenomena. Notable examples include superconductivity [2] and Mott insulating states in graphene [3], and anomalous Hall effect in twisted MoTe$_2$ [4].

Twisted MoTe$_2$ (tMoTe$_2$), with its distinctive electronic properties, holds potential for applications in topological quantum computing [5]. Electronic, optical, and topological properties of 2D moiré materials are highly sensitive to their underlying atomic structure and lattice reconstruction, which significantly impact their electronic band structure. Therefore, real-space information is essential for applications involving 2D materials, as quantum confinement effects, heterogeneities, defects, and interfaces can profoundly influence and modify the emergent properties.

In this study, we utilize advanced electron microscopy techniques, combining atomic resolution scanning transmission electron microscopy (STEM) and monochromated electron energy-loss spectroscopy (EELS) at cryogenic temperatures (~100 K), to investigate moiré heterostructures of MoTe$_2$ with various twist angles. We will discuss interplay between interlayer coupling, excitons, strain, and defects, and their impact on the electronic properties of tMoTe$_2$, providing insights for future advancements in moiré-based devices. Unraveling Magnetic Spin Texture Behavior Using Cryo Electron Microscopy Yue Li[1], Arthur R. McCray[2], Md Rafique U. Nabi[3], Brian Casas[4], Alex Moon[5,4], Suzanne G. te Velthuis[1], Luis Balicas[4,5], Jin Hu[3,3], Amanda K. Petford-Long[1,6] and Charudatta Phatak[1,6]; [1]Argonne National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Arkansas, United States; [4]National High Magnetic Field Laboratory, United States; [5]Florida State University, United States; [6]Northwestern University, United States

Several emergent magnetic phenomena occur at cryogenic temperature, so that the development of advanced cryogenic capability to probe magnetic structures in quantum materials is important. Here, we leveraged cryo Lorentz transmission electron microscopy (LTEM) to map and understand local spin textures and microstructure of ferromagnetic van der Waals (vdW) and ferrimagnetic crystals with high-resolution, and correlate with their behavior. 2D magnetic vdW materials possess unique crystal structures characterized by atomic layers separated by vdW gaps, and hence display strong intra-plane interaction but weak inter-plane interaction [1]. This layered structure and strong intrinsic spin interactions give rise to fascinating phenomena such as rich magnetic spin textures. We have explored magnetic spin textures of $Fe_{5-x}GeTe_2$ crystal as a function of temperature and magnetic field using cryo LTEM. The (anti)merons appear at a high temperature and coexistence of merons and skyrmions is observed in a lower temperature regime [2]. We will present that this behaviour is strongly dependent on Fe content and microstructures. Ferrimagnets, which have both ferromagnetic and antiferromagnetic couplings, are attracting increased attention in the realm of spintronic devices due to advantages such as ultrafast dynamics and a suppressed skyrmion Hall effect. We explored the topological spin textures as a function of temperature and magnetic field in ferrimagnetic $Mn_{2-x}Zn_xSb$ (x=0.85) by using cryo LTEM and magneto-optic Kerr effect (MOKE) microscopy. $Mn_{1.15}Zn_{0.85}Sb$ displays two phase transitions at around 286 K and 170 K and hence possess rich magnetic phases [3]. We discovered unique and diverse magnetic structures as a function of magnetic field and temperature in each phase regime. Importantly, the displacement and randomization of various Mn atoms break the local structure symmetry, which introduces effective Dzyaloshinkii-Moriya interaction and eventually forms Néel spin textures.

4:00 PM CH07.02.06
Imaging Electronic Phase Transitions with Liquid Helium Temperature TEM Suk Hyun Sung[1], Emily Rennich[1,2], Nishkarsh Agarwal[2], Maya Gates[2], Robert Kerns[2], Benjamin H. Savitzky[3], Robert Hovden[2] and Ismail El Baggari[1]; [1]Harvard University, United States; [2]University of Michigan, United States; [3]h-Bar Instruments, United States

Exotic electronic states often emerge at low temperatures in quantum materials. However, these exciting phases are typically inaccessible with modern cryogenic transmission electron microscopy (TEM) due to poor stability and limited temperature range and control. Despite recent advancements in cryogenic TEM techniques, these serious challenges persist, especially below 100 K where correlation-driven quantum behaviors prosper. Here, we present a novel ultra-low-temperature TEM specimen holder capable of atomic resolution near liquid helium (LHe) temperatures. This custom holder enables continuous temperature control over a wide range of cryogenic temperatures (≥ 23 K) in the TEM with ±2 mK thermal stability over a period of 10+ hours [DOI: 10.48550/arXiv.2402.00636]. We show emergence of 3×3 charge order supercell in $2H\text{-}NbSe_2$ (Tc ~30 K) using LHe electron diffraction. The diffraction pattern shows sharp, bright superlattice peaks as well as unexpected, elliptically structured diffuse scattering spanning pairs of superlattice peaks. In addition, we use 4D-STEM to probe the charge ordering structure both locally and over wide fields of view with LHe cooled TEM. Our cryogenic TEM sample holder represents a significant advancement that addresses a longstanding desire to access ultra-cold phases at atomic resolution, offering new opportunities for characterizing challenging quantum materials.

4:15 PM CH07.02.07
Liquid Helium TEM Sample Holder—Swift Cool-Down and Long Holding Time Denys Sutter[1], Penghan Lu[2], András Kovács[2], Yan Lu[2], Joseph Vas[2], Michael Faley[2], Thibaud Denneulin[2], Amelia Estry[1], Damian Bucher[1], Johan Chang[1,3], Dominik Biscette[1] and Rafal E. Dunin-Borkowski[2]; [1]CondenZero AG, Switzerland; [2]Forschungszentrum Jülich GmbH, Germany; [3]Universität Zürich, Switzerland

Quantum materials display a variety of unique electronic and magnetic properties—including superconductivity, charge ordering, and topological states—which are predominantly observed at cryogenic temperatures [1, 2]. Swift progress in cryogenic scanning transmission electron microscopy (S)TEM methodologies has been achieved at liquid nitrogen (LN_2) temperatures. While LN_2-cooled side-entry sample holders and cartridge-integrated microscopes are tailored to suit the demands of the life sciences, the study of phase transitions within materials science typically necessitates adjustable temperatures with a base in the liquid helium (LHe) range [3].

Historically, LHe solutions for electron microscopes were constructed in a cryo-stage setup [4-7], achieving temperatures as low as 1.5 K utilising superfluid helium alongside LN_2-cooled shields, and thus enabling high-resolution imaging over a continuous five-hour span [8]. Despite these achievements, the preference for technically versatile side-entry holders has hindered further advancements in cryo-stage development. Presently, LHe side-entry holders are limited by considerable mechanical and thermal instability, and their base temperature holding times are short due to LHe's low latent heat and the limited cryogen storage capacity of the dewar attached to the holder. Efforts to extend cryogenic holding periods have led to integrating a commercial LHe continuous flow cryostat into a modified 60 mm pole piece gap following the removal of the objective lens [9]. This modification has facilitated temperature control within a range of 6.5 K to 400 K, maintainable over several days. However, the substantial alterations to the microscope structure and the requirement to vent the column for specimen loading present practical challenges for routine operation.

Here, we present recent innovations of a lightweight, ultra-low-temperature LHe TEM sample holder. Starting from room temperature, a base temperature of 5.2 K—measured adjacent to the specimen by a Cernox sensor—can be attained within one minute and sustained for days with a temperature stability of +/- 2.5 mK. Initially designed for X-ray diffraction studies of quantum matter in pulsed magnetic fields, condenZero, a spin-off company from the University of Zurich, has adapted their miniaturisable cryostat design for cryo-TEM usage. Collaborative efforts with the ER-C at the Research Centre Juelich have led to additional enhancements and optimisations. Here, we demonstrate the capabilities of our latest LHe cryo-TEM setup.

SESSION CH07.03: Cryogenic Electron Microscopy and Correlative Characterization Techniques for Quantum and Energy Materials I

Session Chairs: Leopoldo Molina-Luna and Mary Scott
Tuesday Morning, December 3, 2024
Sheraton, Third Floor, Tremont

8:00 AM *CH07.03.01

Cryogenic TEM Sample Holder and MEMS-Chips Development for *In Situ* Cooling, Heating and Biasing Applications Yevheniy Pivak[1], Mia Andersen[1], Tianshu Jiang[2], Andres Alvarez[1], Gijs van der Gugten[1], Vasilis Papadimitriou[1], Christian Deen-van Rossum[1], Eva Bladt[1], Leopoldo Molina-Luna[2] and David Westmoreland[1]; [1]Denssolutions, Netherlands; [2]Technische Universität Darmstadt, Germany

Recent developments in the cryogenic scanning transmission electron microscopy (cryo-STEM) have sparked significant interest from the quantum materials community [1]. Cryo-STEM is becoming an indispensable tool to visualize phase transitions at the atomic scale with improved stability [2-4]. The reduced sample drift comes from the advancements in the cryo-STEM sample holders [5] and the usage of the microelectromechanical systems (MEMS)-based chips [6] which opens up the possibility to locally and continuously change the temperature of the sample in a wide temperature range and, at the same time to measure its electrical response. The ability to understand the structure, electronic and transport properties of materials under an applied thermal and/or electrical stimulus at low temperatures enable applications in the field of quantum materials like superconductors and topological insulators, chare ordering, metal to insulator transitions, magnetic materials, ferroelectrics and many more.

To majority of the in situ cryogenic experiments have been performed employing cooling holders compatible with Thermo Fischer Scientific microscopes. Till now there are only a few reports showing stable cryogentic imaging in JEOL TEMs. In this talk, we will share our new development with respect of a combined in situ cooling and biasing system for JEOL microscopes. The system includes a double-tilt multi contact cryogenic JEOL sample holder that is MEMS-chips based. The holder has no integrated dewar and uses liquid nitrogen for cooling. The specially developed MEMS-chips possess eight electrical contacts, where four contacts are used for accurate resistive heating control using four-point-probe method and the other four electrodes are used for supplying electrical stimuli to the sample. The chips enable simultaneous in situ heating and biasing experiments up to 900°C in the absence of the cooling agent. In a cooled state, the sample can reach temperatures of ~ - 170°C and the microheater of the chip will allow to continuously vary the temperature. By exploiting the high stability of this system and its double tilt capability, we will demonstrate atomic resolution imaging at various intermediate temperatures in a wide temperature range. We will present a number of application examples of cooling, biasing and heating experiments with Focused Ion beam (FIB) lamellas of variety of samples.

Revealing the Microscopic Origin of Electron-Phonon Coupling at the FeSe/SrTiO$_3$ Interface by Atomically Resolved Vibrational Spectroscopy Hongbin Yang[1], Yinong Zhou[1], Guangyao Miao[2], Paul M. Zeiger[3], Francisco Guzman[1], Toshihiro Aoki[1], Xuetao Zhu[2], Jan Rusz[3], Weihua Wang[2], Jiandong Guo[2], Ruqian Wu[1] and Xiaoqing Pan[1,1]; [1]University of California, Irvine, United States; [2]Chinese Academy of Sciences, China; [3]Uppsala University, Sweden

The significant increase in superconducting transition temperature (Tc) at the interface of a one-unit-cell thick FeSe layer on a SrTiO$_3$ substrate (1uc FeSe/STO) has drawn substantial research interest. While this high Tc is believed to be linked to electron-phonon coupling (EPC), the microscopic mechanisms involved and their role in superconductivity remain unclear. In this study, we utilize q-selective high-resolution electron energy loss spectroscopy (EELS) to atomically resolve the phonons across the FeSe/STO interface. We identify new optical phonon modes, strongly coupled with electrons, within the energy range of 75-99 meV. These modes are attributed to the out-of-plane vibrations of oxygen atoms in the unique double-TiOx layer at the interface and the apical oxygen in the STO substrate. Additionally, we discover that both the EPC strength and the superconducting gap of 1uc FeSe/STO are closely tied to the interlayer spacing between FeSe and the TiOx-terminated STO. Our results highlight the critical role of spatial overlap between electron and phonon wavefunctions in modulating the interfacial EPC. These findings elucidate the microscopic origin of the interfacial EPC and provide insights for achieving substantial and consistent Tc enhancement in FeSe/STO and potentially other superconducting systems.

9:00 AM CH07.03.03

Inverse Melting of Polar Order in a Ferroelectric Oxide Yang Zhang[1], Suk Hyun Sung[1], Colin Clement[2], Sang Wook Cheong[3] and Ismail El Baggari[1]; [1]Harvard University, United States; [2]Independent Researcher, United States; [3]Rutgers, The State University of New Jersey, United States

In condensed matter systems, disorder generally gives way to order when temperature is reduced as thermal fluctuations subside. In a rare phenomenon known as “inverse melting”, however, more disordered configurations appear at lower temperatures [1]. This century-old proposal has only been realized in some systems such as polymers [2], metal alloys [3], vortex lattices in superconductors [4], magnets [5] and more recently in ferroelectric domains [6]. Inverse melting in all these cases concerns large mesoscale structures, like microscale domain structures, or changes in the states of matter. To date, inverse melting has not been observed nor visualized in atomic- and nanoscale fluctuations of order parameters.

Here, we discover an inverse melting of the polar order in a ferroelectric oxide with quenched chemical disorder ($BaTi_{1-x}Zr_xO_3$) through direct atomic-scale visualization using in situ scanning transmission electron microscopy (including heating and cryogenic). In contrast to the clean $BaTiO_3$ parent system in which long range order tracks lower temperatures, we observe in the doped system $BaTi_{1-x}ZrxO_3$ that thermally driven fluctuations at high temperature give way to a more ordered state and then, surprisingly, to a re-entrant disordered configuration at even lower temperature. Such an inverse melting of the polar order is likely linked to the random field generated by Zr dopants, which modulates the energy landscape arising from the competition between thermal fluctuations and random field pinning potential. These visualizations highlight a rich landscape of order and disorder in doped materials, and may be key to understanding the colossal and unusual responses of materials with quenched disorder

***In Situ* MEMS-Based Cryo/Heating STEM for Probing Dislocation Dynamics and Domain Evolution in Single-Crystal $BaTiO_3$** Tianshu Jiang[1], Alexander Zintler[2], Yevheniy Pivak[3], Fangping Zhuo[1] and Leopoldo Molina-Luna[1]; [1]Technische Universität Darmstadt, Germany; [2]University of Antwerp, Belgium; [3]Denssolutions, Netherlands

Domain engineering at the nanoscale in ferroelectric materials holds great promise for improving their overall functional properties, particularly in electromechanics and electronics. This method involves creating topological defects in functional materials to enhance their performance[1]. However, progress in developing these ferroelectric functional materials is hindered by our limited grasp of how defects behave and interplay at varying temperatures and how these defects affect domain nucleation and domain wall motion. Bridging this knowledge gap is essential to fully exploit the potential of nanoscale domain wall engineering.

In this work, we introduced well-aligned {100}<100>-type and {101}<101>-type dislocations through high-temperature uniaxial compression along [110] and [001] directions[2]. Using MEMS-based *in situ* heating and cryogenic scanning transmission electron microscopy (STEM) technology[3], we directly probed the temperature-induced structural evolution of the dislocation dipole at the atomic scale over an extensive temperature range spanning from -175°C to 200°C, covering all possible phases of $BaTiO_3$. We investigated the charged dislocation cores by electron energy loss spectroscopy (EELS) at various temperatures. Geometric phase analysis (GPA) was implemented for generating strain maps around dislocation core regions. These comprehensive approaches allowed us to study both the dislocation-enhanced local polarization and the total energy density of ferroelectric $BaTiO_3$ in terms of different degrees of freedom (DOFs), namely the charge, elastic lattice, and strain gradient.

Our research, by revealing the atomic-scale evolution of local lattice structures, not only advances the field of domain wall engineering in ferroelectric materials but also introduces a novel approach for understanding and manipulating nanoelectronics across a broad temperature range. This atomic-level insight provides a foundation for developing advanced functional materials with precisely tailored properties.

Studying the Behavior of Relaxors, Antiferroelectrics and Ferroelectric Materials with Cryogenic/*In Situ* STEM James M. LeBeau; Massachusetts Institute of Technology, United States

Determining the chemical and structural order/disorder within functional oxides is often key to understanding their properties as a function of temperature and electric field. This is particularly true in relaxor ferroelectrics and antiferroelectrics. To achieve this, cryogenic and in situ STEM have emerged as powerful tools for exploring phase transitions in these functional oxides.

In this talk, I will delve into the application of cryogenic aberration-corrected scanning transmission electron microscopy (STEM) to directly discern nanoscale structural changes at the atomic level in relaxor ferroelectric and antiferroelectric materials, complementing diffraction studies and room-temperature information. By acquiring images sensitive to chemistry (angle annular dark-field STEM) and light elements (integrated differential phase contrast STEM) under cryogenic conditions, we establish direct correlations between nanoscale chemical order regions, distorted oxygen octahedra, and local polarization concerning temperature and/or applied biasing.

Additionally, we will discuss the correlation of antiphase boundaries in an antiferroelectric material with local chemical disorder and their behavior as a function of temperature. Further, multislice ptychography will be shown to enable the disambiguation of various structural and chemical boundary models, concluding that the boundary is inclined and disordered compared to the ‘bulk’ thin film. Moreover, antiferroelectric nanodomains reside within the chemically disordered regions of the antiphase boundaries.

10:30 AM *CH07.03.06
Towards Cryogenic Differential Phase Contrast Scanning Transmission Electron Microscopy Naoya Shibata; The University of Tokyo, Japan

Differential phase contrast scanning transmission electron microscopy (DPC STEM) is a powerful technique for local observing electromagnetic field distribution inside materials and devices. Using fast segmented detectors or pixelated detectors, DPC STEM can be imaged in live [1], which may make this imaging method suitable for in-situ applications. Therefore, applying this technique for materials under various external conditions such as low temperatures is much anticipated especially for characterizing quantum and energy materials. In this talk, recent developments and applications along this direction will be reported.

11:00 AM *CH07.03.07
Probing Highly Sensitive Hard-Soft Interfaces in Energy Devices by Low-Dose Cryo-(S)TEM Michael Zachman[1], Juhyun Oh[1], Obeen Kwon[2], Daniela Ushizima[3], Ritu Sahore[1], Xi C. Chen[1] and Iryna Zenyuk[2]; [1]Oak Ridge National Laboratory, United States; [2]University of California, Irvine, United States; [3]Lawrence Berkeley National Laboratory, United States

Energy storage and conversion devices such as batteries [1], electrolyzers [2], and fuel cells [3], are becoming increasingly important as society shifts to renewable energy production and electrification of transportation. Interfaces between materials within these devices often dictate their overall properties, with length scales for relevant features at these interfaces approaching the atomic scale. Electron microscopy is therefore well suited for studying these important features. Many materials used within next-generation energy storage devices, however, are highly sensitive to high-energy electron probes, such as solid polymer electrolytes (SPEs) within lithium metal batteries (LMBs) and thin-film ion-conducting ionomers and electrode materials within water electrolyzers, making high-resolution characterization of these materials challenging or impossible using conventional (scanning) transmission electron microscopy ((S)TEM) methods.

Here, we will discuss cryogenic (S)TEM (cryo-(S)TEM) techniques that allow highly beam-sensitive materials at hard-soft interfaces in energy devices to be characterized at high resolution. First, we will discuss how automated, low-dose cryo-TEM imaging allows heterogeneous thin-film ionomer properties such as morphology and coverage to be measured statistically as a function of position across an electrode structure. We will additionally discuss how low-dose STEM imaging and electron energy-loss spectroscopy (EELS) allow novel nanoscale structural, compositional, and bonding information to be measured at interfaces between SPEs and high-voltage cathodes (HVCs) in LMBs. These techniques provide access to information typically inaccessible to conventional techniques, and as a result, will help generate a more complete understanding of these hard-soft interfaces critical to energy devices, therefore aiding in design of next-generation devices with improved properties.

11:30 AM CH07.03.08

Determination of the Structure of the Solid Electrolyte Interphase Using Cryogenic Scanning Electron Nanobeam Diffraction

Eric A. Stach, Hyeongjun Koh, Yihui Zhang, Jongbeom Kim, T. Jamie Ford and Eric Detsi; University of Pennsylvania, United States

Cryogenic electron microscopy is seeing increasing use in describing solid-liquid interfaces, specifically the solid-electrolyte interphase in battery systems. We have employed cryogenic focused ion beam milling (FIB) in a plasma-focused ion beam/scanning electron microscope system to prepare sensitive lithium metal specimens, allowing us to assess potential ion beam damage, understand the process of lithium oxide formation of the sample surfaces and suppress the formation of ice contamination. As a result, we reproducibly create thin sections of battery materials for subsequent cryogenic electron microscopy observation. This approach has allowed the examination of Li metal batteries with vitrified liquid electrolytes and facilitated the discovery of an elusive solid-electrolyte interphase (SEI) component, lithium fluoride. This has not been observed when using conventional sample preparation techniques involving rinsing. Furthermore, scanning electron nanobeam diffraction data reveals the presence of short-range order at different regions in the SEI structures, influencing and controlling lithium metal growth and ion and electron transport. We can correlate specific SEI structural motifs and layers with enhanced battery performance, providing important insights into the design of batteries with high cycling stability. Furthermore, we show that prior studies that utilize phase-contrast high-resolution electron microscopy likely report incorrect information regarding SEI structure due to the effects of electron beam irradiation. Overall, these results highlight the valuable role cryogenic lift-out and cryogenic scanning transmission electron microscopy can play in enabling nano- to atomic-scale characterization of energy storage devices containing reactive materials or solid-liquid interfaces.

11:45 AM CH07.03.09

Investigating the Nanoscale Solid–Liquid Interface for Next Generation Batteries via Cryogenic APT & STEM

Lukas Worch[1], Neil Mulcahy[1], Ramin Jannat[1], James Douglas[1], Baptiste Gault[1], Valeria Nicolosi[2] and Shelly Michele Conroy[1]; [1]Imperial College London, United Kingdom; [2]Trinity College Dublin, The University of Dublin, Ireland

Improving lifetime and performance of liquid-electrolyte based batteries, especially the commonly used Li-ion batteries, requires an understanding of the interactions at play at the solid-electrolyte interphase (SEI) between the electrode and the electrolyte. However, the liquid phase and volatile nature of these electrolytes makes characterising this region challenging. Current methods either provide insufficient information at the microscopic scale or require steps such as washing of the electrode that damage the sensitive SEI. In order to investigate these materials, a new fully cryogenic workflow must be developed, combining APT measurements with 4D-STEM and electron microscope-based spectroscopy such as EELS. These will allow characterisation of the composition, morphology, atomic structure, and bonding environment at the SEI. Due to the volatile and reactive nature of lithium, preparation of the samples must also be done at cryogenic temperatures through use of a plasma FIB. The final goal is to take APT and TEM-based measurements of the same sample, maintaining cryogenic vacuum conditions throughout the entire process from the point of sample extraction. This will not only prevent loss of lithium and air-based degradation of the sample, but also combines the two techniques in a way that allows for both structural insight into the SEI, and a detailed atom by atom breakdown of its development and degradation through battery cycling. Initial experiments on MXene based electrode materials demonstrate the ability of this method to image both electrolyte and material, and indicate the usefulness of this method for observing non-reversible changes in the electrode that lead to loss of capacity during cycling.

SESSION CH07.04: Cryogenic Electron Microscopy and Correlative Characterization Techniques for Quantum and Energy Materials II
Session Chairs: Michele Conroy and Ismail El Baggari
Tuesday Afternoon, December 3, 2024
Sheraton, Third Floor, Tremont

1:30 PM *CH07.04.01
Interfacial Manganese-Ion Dissolution in Cycled Li-Ion Cathodes Dependent on Electrolyte Chemistry—A Cryo-Electron Microscopy Study Katherine L. Jungjohann[1], Nikita S. Dutta[1], Madison S. King[2], John Mangum[1], Bingning Wang[3], Renae Gannon[4] and Chen Liao[3]; [1]National Renewable Energy Laboratory, United States; [2]Northern Arizona University, United States; [3]Argonne National Laboratory, United States; [4]Thermo Fisher Scientific, United States

In lithium-ion batteries, the pivot from scarce cobalt to earth-abundant elements for cathodes (composed of 0.3 Li2MnO3 and 0.7 LiMn0.5Ni0.5O2 w/w) has caused destabilization of the cathode interfaces during Li-ion cycling, losing manganese into the electrolyte. Electrolyte engineering is combating this interfacial destabilization using a combination of additives in the common Generation 2 (Gen2) electrolyte, 1.2M LiPF6 in EC:EMC (3:7 w/w). This study is focused on a mixture of additives targeting the interfaces on the cathode and anode. This work aims to understand how the combination of these additives has yielded higher stability cell performance as compared to the additives individually with the Gen2 electrolyte or to the Gen2 electrolyte alone.
An electrolyte composed of additives together in the Gen2 electrolyte improved the energy and power density as well as the longevity of coin cell batteries cycled with the earth-abundant cathodes against graphite anodes. While electrolyte engineering is improving battery performance, the interfacial mechanism for this process is not understood. Here we used cryogenic electron microscopy (cryo-EM) sample preparation with air-free transfer and cryogenic scanning transmission electron microscopy (STEM) with electron energy loss spectroscopy (EELS) mapping to identify the nanoscale interfacial composition and the manganese oxidation state in cross-section at

the surfaces of cycled cathode particles. This characterization allowed for the comparison of each individual additive with the Gen2 electrolyte to the additive combination with the Gen 2 electrolyte, each after 100 Li-ion charge and discharge cycles.
Analysis from the different electrolytes has found Ni enrichment and Mn depletion at the cathode particle surface in certain samples. The manganese oxidation state at the cathode surface has a broader range of values, reaching down to a Mn mixed valency of 2+ and 3+ in the Gen2 electrolyte without additives. Since the Mn2+ is known to readily dissolve from the particles during cycling, this indicates that the combined cathode and anode additives are stabilizing the cathode particle surfaces to prevent Mn loss and impedance rise. This study reveals the differences between individual additives and the role that each additive played in concert to decrease interfacial impedance and prevent manganese ion dissolution. Cryo-EM methods were essential to obtaining this site-specific information from the beam-sensitive cycled cathode surfaces, without disturbing the formed cathode electrolyte interface or reduction of the transition metals in the cathode structure. The combination of electrolyte engineering with site-specific high-resolution cryogenic STEM/EELS characterization is yielding earth-abundant cathodes that operate with good capacity retention and a better understanding of the mechanism of this performance improvement.

Nanoscale Analysis of Hydrogen Interaction and Material Degradation Mechanisms Using Cryogenic Transfer Atom Probe Tomography and Correlative Transmission Electron Microscopy Arun Devaraj; Pacific Northwest National Laboratory, United States

The mechanistic understanding of hydrogen's role in altering the functional and structural properties of materials, as well as its involvement in material degradation mechanisms, can be enhanced by leveraging atom probe tomography to map nanoscale hydrogen segregation to defects and interfaces. However, due to hydrogen's tendency to diffuse out of most materials even at room temperature, a streamlined procedure is necessary for charging materials with hydrogen isotopes and then transferring the samples under vacuum and cryogenic conditions to the atom probe tomography. Such information when paired with the structural analysis of materials achieved using transmission electron microscopy can be key for achieving spatially resolved mapping of hydrogen to defects and interfaces in materials.

This presentation will showcase the state-of-the-art capabilities at the Pacific Northwest National Laboratory for seamless transfer of material samples before and after hydrogen isotope charging. Transfers are performed between a plasma-focused ion beam (PFIB—Helios Hydra), an atom probe tomography system (APT—LEAP 6000XR), and a nitrogen-containing glovebox (N2-GB) at both room and cryogenic temperatures. Using this advanced capability, we quantitatively analyzed hydrogen uptake in a model FeCrNi alloy, both with and without deformation-induced defects, and distinguished between diffusible and trapped hydrogen in the microstructure. This unique capability is also being extended to analyze the hydrogen segregation in complex oxides and in platinum group element catalysts to pinpoint the tendency for hydrogen to segregate to defects and interfaces.

2:30 PM CH07.04.03
Flowing and Freezing—Correlative *Operando* Liquid and Cryogenic Microscopy of Nanoscale Liquid-Solid Interfaces Neil Mulcahy[1], Ramin Jannat[1], Lukas Worch[1], James Douglas[1], Baptiste Gault[1,2], Mary Ryan[1] and Michele Conroy[1]; [1]Imperial College London, United Kingdom; [2]MPI-SM Max-Planck-Institut for Sustainable Materials, Germany

Liquid-solid interfaces are essential components of a range of different biological, chemical, and physical systems and processes and play an essential role in the field of electrochemistry. These types of electrochemical interfaces are often highly complex, multifarious and involve low atomic weight and mobile elements such as hydrogen, lithium, and carbon. The dynamic and beam-sensitive nature of these interfaces makes them extremely difficult to quantitatively characterise in their state of interest using standardised techniques. The performance of many of these electrochemical systems is currently limited due to a lack of high-resolution characterisation techniques which are capable of providing nanoscale understandings of complex interactions that occur between light mobile electrolyte species and various electrode materials, where information pertaining to the morphology, chemistry, and phase of these interfaces at the nanoscale is lacking. This is particularly evident with respect to nanoscale processes occurring in various battery systems, such as dendrite growth and solid-electrolyte interface (SEI) formation and growth, where high-resolution compositional and functional understandings of these phenomena have remained ambiguous after decades worth of research.

Operando liquid-based microscopy techniques such as Liquid Cell Transmission Electron Microscopy (LCTEM) provide the biggest opportunity to directly observe dynamic electrochemical processes at high resolutions in real-time. LCTEM is capable of observing changes in structure, morphology, phase, and elemental distributions in liquid-based systems at the nanoscale, and this has been used to probe various electrochemical processes using specialised MEMs based chip designs that allow for in operando electrical biasing. While this setup does give unique nanoscale insights into these processes, key problems with respect to spatial resolution and beam-induced effects hinder the necessary sub-nanometre spatial resolution needed to resolve complex dynamic liquid-based electrochemical phenomena such as SEI growth and formation, particularly phenomena involving light elements. While various strategies have been employed to overcome these problems through state-of-the-art dose limitation techniques and alternative liquid cell setups involving 2D materials, the necessary resolutions have not been achieved under in operando conditions.

The work presented here seeks to provide an alternative approach where operando liquid microscopy is combined with high-resolution cryogenic microscopy in order to provide both dynamic and atomic scale understandings of nanoscale electrochemical phenomena. The emerging field of cryogenic microscopy for material science has been proven capable of capturing a solid-liquid interface in its state of interest through techniques such as cryogenic STEM and cryogenic atom probe tomography (APT). Cryo APT is capable of providing 3D compositional analysis of frozen nanoscale volumes with ppm chemical sensitivity. Cryo APT is inherently a static microscopy technique, only capable of providing a snapshot of a particular system when in actuality these nanoscale processes are completely dynamic. This makes dynamic liquid microscopy techniques and high-resolution cryogenic microscopy techniques extremely complimentary.

This work has successfully combined operando LCTEM with cryogenic APT through the use of a cryogenic FIB/SEM, vacuum cryo transfer module technology (VCTM), and an inert glovebox. The combination of these distinct microscopy techniques has allowed for dynamic sub-nanometre understandings of various phenomena within nanoscale electrochemical systems such as dendrite growth as well as SEI growth and formation. This presentation will discuss the workflow needed to realise this combination and the results produced thus far.

2:45 PM CH07.04.04

‘Cry(o)ing’ Out for Safer Batteries—The Application of Cryo-Microscopy to Study Early-Stage Dendritic Growth in Lithium-Ion Batteries Ramin Jannat, Shelly Michele Conroy, James Douglas, Neil Mulcahy, Lukas Worch, Guo Zhenyu, Magdalena Titirici, Ifan E. Stephens and Mary Ryan; Imperial College London, United Kingdom

Lithium-ion batteries (LIBs) are the leading battery technology today, boasting high power and energy densities (250 – 350 Wh kg-1 and 100 – 265 Wh L-1, respectively) and a growing range of applications, including grid-level energy storage systems. Despite this, LIBs are prone to dendrite formation when conditions are unfavourable, which hinders their performance, reduces their Coulombic efficiency and can lead to internal short circuits (ISCs) and thermal runaway (TR). Dendrites therefore pose a critical safety issue in LIBs. To date, however, the mechanism of the nucleation and early-stage growth of these structures is still not well understood, mainly due to limitations in current characterisation techniques. These limitations include inadequate resolving capabilities, such that studying nanoscale degradation processes is not possible, as well as challenges in imaging and quantifying light elements that are air- and/or beam-sensitive (Li, H, O, S and C). Improving our understanding of this relationship, particularly during early-stage growth, is necessary to develop more effective mitigating strategies against this particular degradation.

In this work, an in situ electrochemical cell is used to visualise dendrite formation in a full cell-equivalent configuration. We are able to directly vary electrochemical conditions (namely the state of charge (SoC) and C-rate) and correlate real-time electrochemistry measurements with the onset of dendritic growth. Once this growth is probed, the cell is disassembled and immediately plunge frozen using liquid nitrogen to 'fix' the system in place, which is necessary to study the interfacial properties and lithium distribution. The plating is characterised using atom probe tomography (APT) to provide three-dimensional compositional information with sub-nanometre resolution.

This work is the first of its kind to characterise graphite electrodes using a complete cryogenic workflow, providing crucial insights for researchers globally to tackle other challenging carbonaceous systems, particularly in the study of battery materials. This research will provide an improved understanding of the growth mechanism and possible mitigation measures for dendrites in LIBs, aiding the accelerated development of vehicle electrification and large-scale grid energy storage.

The Radiation Chemistry of Vitrified Water Ice Interfaces Studied by Electron Energy Loss Spectroscopy

Patricia Abellan[1], Eric Gautron[1] and Jay A. LaVerne[2]; [1]Institut des Matériaux Jean Rouxel, France; [2]University of Notre Dame, United States

While the radiolysis of liquid water by high-energy electrons has been extensively studied by conventional radiation chemistry methods, the radiolysis of water at interfaces and inside an electron microscope and the radiolysis of water ice are still poorly understood. Electron energy loss spectroscopy (EELS) can be performed inside the scanning transmission electron microscope (STEM), and thus, can allow for in situ analysis of radiation damage effects. In frozen hydrated aqueous specimens, cryo-EELS has already been used to study radiation damage.[1-3] Using new monochromated sources, with higher energy resolutions on the order of < 100 meV[4] and increased peak(signal)-to-background (S/B) ratio, new insights on the radiation damage of materials have been recently made possible. Recently, we have shown that by using monochromated EELS at the oxygen K-edge and at cryogenic temperatures on thin films of ice, all radiolysis products (radicals and molecules) of water ice can be resolved (except for H_2 and .H)[5]. We also discussed the effect of different microscope parameters on the radiolysis of water ice and proposed a new high dose reaction scheme. In order to apply this method to the study of any water ice interface, samples must be prepared without artefacts caused by water loss or by the freezing process. Methods to monitor the vitrification process are thus relevant. For instance, low frequency Raman spectrometry can reveal the crystalline structure of ice and can also be used in combination with FIB/SEM to probe the depth of vitreous ice in plunge-freezed vitrified samples.[6] Additionally, certain materials with very high water content, such as hydrogels, are extremely sensitive to the cryofixation process process and will directly show if unsuccessful. Here we discuss our latest results on the study of the radiolysis of water ice interfaces and on the challenge of discerning whether vitrification at water interfaces has been truly achieved.[7]

Enhancing Cryogenic Scanning Transmission Electron Microscopy Efficiency with Machine Learning Jacob Smith[1], Guannan Zhang[1] and Miaofang Chi[1,2]; [1]Oak Ridge National Laboratory, United States; [2]Duke University, United States

Cryogenic scanning transmission electron microscopy (STEM) is an important characterization technique to study quantum phenomena and electron beam sensitive materials. However, the cryogenic temperature regime is susceptible to spatial distortions that reduce the quality of atomic resolution data. These distortions are a hardware limitation caused by thermal instability and cryogen bubbling and result in non-linear errors that cannot be easily removed. A common solution is to increase the acquisition speed to reduce the visible distortions, though this strategy results in much noisier data unless many frames are acquired and properly aligned. Non-rigid registration provides an effective solution to this problem, albeit at considerable computational expense using conventional algorithms. Further complicating this is that many materials have a low electron beam tolerance even under cryogenic conditions, making sparse sensing an inherent problem in addition to any acquisition errors. To overcome these challenges without expensive hardware investments, it is possible to use algorithmically-driven data acquisition and reconstruction to perform error correction, reduce data redundancy, and increase signal strength. We have developed a series of algorithms to enhance multimodal cryogenic STEM data quality through computational techniques. These include developments in the field of 4D-STEM compressive sensing and non-rigid registration.

Investigating Multiferroic Phase Change Dynamics at Cryogenic Temperatures Using *In-Situ* Electron Counted Spectrum Imaging with Synchronized Holder Control Liam Spillane[1] and Michele Conroy[2]; [1]Gatan Inc., United States; [2]Imperial College London, United Kingdom

Improper ferroelectrics have strong potential for use in low power domain wall nano-electronic devices, as the formation and motion of conducting domain walls in such materials is governed by strain as opposed to their electric polarization [1,2]. Multimodal STEM spectrum imaging performed in the (scanning) transmission electron microscope (S)TEM is ideal for characterization of the ferroelectric domain dynamics in improper ferroelectrics, as the technique enables correlation of local chemistry and bonding information, with crystallographic and strain information determined from identical specimen regions at micro to (near) atomic scale.

MEMS based heating-biassing and cooling-biassing holders can be used to investigate phase change dynamics in these materials as a function of applied temperature and bias, though manual holder control becomes impractical if high stimuli resolution is required, due to the large number of temperature steps required for meaningful analysis in combination with the large number of individual biassing steps required at each temperature. In order to overcome this challenge, an automation strategy for holder control was recently developed to generalize external stimulus control within the DigitalMicrograph Python scripting framework. In our automation framework, the high-level communication Python library, ZMQ, is used to execute control commands from the embedded *in-situ* SI data acquisition routine. This generalized modular framework, enables synchronized control of any external device supporting Python and ZMQ.

To validate this framework, ferroic phase change dynamics in the improper ferroelectric: Co-Cl boracite were investigated as a function of temperature and simultaneous applied bias, using a MEMS based heating-biassing holder (Lightning, DENSSolutions). The automation strategy allowed complex holder control patterns to be executed at previously unachieved temperature and bias resolution.

Here we use this automation framework to investigate ferroic phase change behaviour in Fe-I boracite at cryogenic temperatures. *In-situ* spectrum imaging was performed with a 50-80 pA probe at 300 kV, using a counted mode EELS / energy filter system (GIF Continuum K3, Gatan) and flexible scan control system (Digiscan3). Domain wall dynamics were investigated as a function of applied bias at cryogenic temperatures using a MEMS based *in-situ* cryogenic cooling-biassing holder (Lightning-Arctic, DENSSolutions). Holder control and synchronization to data capture was performed using Python scripting in the DigitalMicrograph and DENSSolutions Impulse software packages. This scripting allowed multiple pass *in-situ* spectrum image (SI) data acquisition with all SI passes acquired at fixed holder stimuli conditions. Full voltage sweeps were applied at cryogenic temperatures series, or multiple voltage sweeps performed to investigate cycling effects. All data acquisition and holder control was fully automated. Data processing was performed using a combination of DigitalMicrograph (EELS, 4D STEM) and the Py4DSTEM (4D STEM) software packages.

Custom (non-raster) scanning features available in Gatan DigitalMicrograph 3.62 were used to investigate potential enhancements for atomic resolution imaging, electron energy-loss spectroscopy and ptychography performed on the Fe-I boracite system.

Widest Temperature Range Cooling, Heating and Electrical Biasing *In-Situ* TEM Sample Holder Calvin A. Parkin, Norman Salmon and Daan Hein Alsem; Hummingbird Scientific, United States

Cryogenic S/TEM sample holders have enabled the atomic resolution in-situ imaging of various quantum interfaces, topological insulators, and phase interactions in two-dimensional (2D) and one-dimensional (1D) materials. Quantum materials must be studied at cryogenic temperatures because many relevant properties in these quantum materials only manifest at specific low temperatures, necessitating low temperature ranges and precise control. Investigation of such quantum properties at the fundamental level has historically been challenging due to inadequate spatial and temporal resolution of characterization techniques as well as inadequate sample stability, while lack of biasing capability has limited the study of electrical responses in these materials systems.

Because battery materials are highly sensitive to electron beam damage at room temperature, cryogenic holders have also enabled imaging of battery interfaces and mapping of their complex chemical evolutions. With increasing demand for high temperature battery performance and battery material phase information across a wide range of temperatures from cryogenic to high temperature, temperature-controlled in-situ electrical biasing systems benefit from an expanded temperature range that meets microscope specifications for resolution and drift. The combination of cryogenic cooling and the chip-based experimental platform has enabled combined in-situ sample cooling, heating, and biasing experiments.

The core functionalities of an in-situ electrical biasing S/TEM holder that simultaneously allows electrical stimulus and high-resolution imaging of a sample in-situ across the full temperature range, from cryogenic up to high temperatures, are presented. The exceptionally stable holder experiences drift performance across the entire temperature range comparable to standard holders at room temperature.

Biasing was performed on a single nanowire system bridging the electrodes on a biasing chip at near-liquid nitrogen temperature (<-170°C) to prevent electron beam damage. While applying constant current at cold temperature the voltage dropped with the growth of a dendrite layer on the nanowire's surface. With the modular heating controller, software, and chips, such experiments are extended to >1000°C alongside electrical biasing of the sample. This enables studying the temperature dependence of chemical and microstructural evolution under electrical bias.

Between liquid nitrogen and room temperature, where on-chip resistance-calibrated temperature measurements become increasingly inaccurate, precise temperature control is enabled using a conventional resistance heater and miniature thermocouple at the sample in the TEM holder tip. The combination of temperature regimes allows batteries to be electrochemically cycled even beyond their full operational temperature range of of -40°C to 80°C and then returned to cryogenic temperature for imaging, without fear of electron beam damage or the need to change holders.

At intermediately cold temperatures, the two heating and temperature sensing methods can be combined for precisely controlled rapid heating experiments. This enables in-situ study of quantum nanomaterial synthesis, processing, and electrical response across a range of different temperatures in the low temperature regime.

The cryo-biasing TEM holder enables investigation of structure-property relationships in materials, specifically electronic properties, across the widest available temperature range, facilitating the development of the next generation of electronic, quantum, and energy storage materials devices.

CH07.05.02
Scanning Tunneling Microscopy of Defects in the CDW Compound $Zr_{0.95}Hf_{0.05}Te_3$ Ghilles Ainouche[1], Reshmi Sudheer[1], Susree Mohapatra[1], Harikrishnan S[2], Cedomir Petrovic[3], Abhilash Ravikumar[2] and Michael Boyer[1]; [1]Clark University, United States; [2]Amrita School of Engineering-Bangalore, India; [3]Brookhaven National Laboratory, United States

$ZrTe_3$ is a low-dimensional material that exhibits both one-dimensional and two-dimensional characteristics. Above the charge density wave (CDW) transition, bulk $ZrTe_3$ displays isotropic in-plane electronic conduction. However, below approximately 63 K, the material transitions into a unidirectional charge density wave (CDW) state, believed to be driven by Fermi surface nesting of two nearly parallel Fermi surface sheets originating from the long parallel Te-Te chains along the *a*-crystal axis.
In this study, we present scanning tunneling microscope (STM) measurements of Hf-doped $ZrTe_3$, both above and below the CDW transition temperature. Using density functional theory (DFT) calculations, we simulate STM images and identify the origin of defects observed in our measurements. Additionally, we compute the cross-correlation between the defects and the CDW maxima which shows a significant pinning of the CDW to defect locations particularly at temperatures above the CDW transition.

Efficient Metal Halide Perovskite Nanocrystals for Next-Generation Vivid Displays Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Metal halide perovskites (MHPs) have emerged as promising candidates for future display technologies, primarily due to their superior high color purity. This talk will delve into the unique advantages and strategies of utilizing MHPs for display technologies, focusing on innovative nanostructures and material design approaches in precisely tailored colloidal perovskite nanocrystals (PNCs) to maximize luminous efficiency of perovskite light-emitting diodes (PeLEDs). First, we will introduce comprehensive material strategies aimed at suppressing defect generation, leading to the enhancement of the luminescent efficiency of PNCs. More specially, we incorporated zero-dipole guanidinium cation into formamidinium lead bromide ($FAPbBr_3$) PNCs and utilized interlayer based on bromide-incorporated molecules. We also developed a modified bar-coating technique capable of producing large-area PeLEDs that match the efficiency of the PeLEDs with a small emission area. Additionally, we'll present an advanced core/shell PNC synthesis method, enabling to demonstration of simultaneously bright, efficient, and stable PeLEDs. Moreover, we will explore a novel hybrid tandem PeLEDs with an ideal optical structure that emits light more efficiently with a narrow bandwidth. Finally, we incorporated conjugated molecular multipods that reduce the dynamic disorder of perovskite, resulting in significantly improved luminescent efficiency of PeLEDs. These advancements highlight the potential of MHPs as promising materials for next-generation vivid displays.

11:00 AM *EL01.01.02

The Undesired Electrochemical Reaction Induced by the Nickel Oxide Transport Layer with Perovskite in Perovskite-Based Light-Emitting Diodes Tzung-Fang Guo[1,2], Do T. Hoai[1] and Hsin-Yu Lin[1]; [1]National Cheng Kung University, Taiwan; [2]Academia Sinica, Taiwan

The application of NiO_x hole transport layer induces an electrochemical reaction in the contact interface with organolead halide perovskite, causing the reduction of Pb(II) to the metallic Pb. The formation of metallic lead atoms, as characterized by the measurement of X-ray photoelectron spectroscopy, quenches the electroluminescence (EL) in perovskite-based light-emitting diodes (PeLEDs). However, during the electric bias of PeLEDs, the magnitude of photoluminescence (PL) increases by 7 times of the perovskite active layer, which is correlated with the reversed electrochemical reaction of metallic Pb in NiO_x/perovskite interface. This would be the origin for the observation of EL magnitude overshoot in the initial bias of PeLEDs. Introducing an additional buffer layer at the interface preventing the direct contact of NiO_x hole transport layer with the perovskite layer inhibits the interfacial electrochemical reaction. The PL magnitude of the perovskite is relatively stabilized during the electric bias and the device output performance is enhanced. Most importantly, the overshoot of EL magnitude is markedly suppressed in our studies. Our results elucidate the undesired electrochemical reaction induced by NiO_x hole transport layer at the contact interface with perovskite, being one of the key components to modulate device performance and cause EL overshoot of PeLEDs.

SESSION EL01.02: Perovskite Films and LEDs for Displays II

2:00 PM *EL01.02.01

Vapor and Solution Growth of High-Quality Halide Perovskite Light-Emitting Diodes Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites are showing high promise for next-generation light-emitting diode (LED) technologies, utilising multi-dimensional structures to achieve ever higher performance. Yes, stability remains a significant issue.

Here I will present recent results showing growth of perovskite LEDs by thermal evaporation and solution processing. Through controlled growth, 2D, 3D and 2D/3D junctions can be controllably made by vapor processing, with evidence for expitaxy, leading to high quality emitter layers and reasonable LED performance. On the other hand, by solution processing, islands can be formed which lead to high performances and outcoupling efficiencies in red and blue colours. I will show how we can track the performance of LEDs over time using a range of operando techniques, giving critical information into operational losses and instabilities, which can be in turn fed back into the processing. These results show promise for improving both performance and stability of different coloured perovskite LEDs.

2:30 PM EL01.02.02

Design of Multifunctional Ligand Structures for Improving the Efficiency and Stability of Low-Dimensional Red-Green-Blue (RGB) Perovskites Wallace C. Choy; The University of Hong Kong, China

Halide perovskites have raised wide interest these years for photovoltaics, light-emitting diodes, and other applications due to their excellent optical and electronic properties, low cost, solution processability, and diversity as a group of materials. By ligand designs, we will discuss the influences on the phase distribution, carrier transfer and confinement of low dimensional perovskites will be improved. Using blue quasi-2D perovskites LEDs (PeLEDs) as examples, we can enhance the hole injection for better balance carrier and improve the efficiency [1], we also modulate the n-phase distribution [2,3], optimize the carrier transfer and confinement [4] and suppress the ion migration [5] to improve PeLED performances. For perovskite nanocrystals (NCs), we will design the functional side-branches for good NC dispersion and high electrical conduction and then optimize the spacing between polydentate functional groups of polymer ligands to match the surface pattern of $CsPbBr_{1.8}Cl_{1.2}$ PeNCs, resulting in effective synergistic passivation effect and significant improvements in PeLED efficiency and stability [6-9]. We then further extend the ligand design to enhance the mechanical stability by establishing ligand-termination surface structure on perovskites with anchoring points and polymeric soft chains on perovskites beyond the corresponding functional group-only or polymer-only strategies in reducing the Young’s modulus to achieve high efficiency and mechanical stabile flexible PeLEDs [9]. Overall, the efficiency and stability of the red-green-blue (RGB) perovskite LEDs can be significantly improved by comprehensively designing the ligand structures.

Phase Purity in Low Dimensional Perovskites Juan-Pablo Correa-Baena; Georgia Institute of Technology, United States

Achieving phase purity in metal halide perovskites is crucial for their optoelectronic properties and enables more efficient and stable devices. While there is a lot of work on understanding and controlling of phase purity of 3D perovskites, there is less work on lower dimensional perovskite structures. In this work, I will discuss the current understanding of phase purity and phase transformations in 2D perovskites. I will also discuss general pathways to control phase purity and stability via surface modification both in the substrate and in the bulk. Our findings provide new insights into the role of surface energies on the growth of phase pure materials.

Mixing Organic Cations in 2D Perovskites—Tuning Photoluminescence and Phase Transition Temperatures
Perry Martin, Jolene N. Keller and Connor G. Bischak; The University of Utah, United States

Blending cations and anions in hybrid perovskites has emerged as a powerful strategy to tune optoelectronic properties. Although blending inorganic cations and halides is a standard practice to tune both the absorption and emission of these materials, blending organic cations in two-dimensional (2D) perovskites is rarely pursued. In this work, we use a homebuilt high-throughput robotic platform to fabricate and characterize 2D perovskite thin films with mixed organic cations. By blending alkylammonium cations of different lengths, we demonstrate that we can precisely and continuously tune the phase transition temperature of 2D perovskites. When blending more chemically complex cations, we show that these cations either phase separate or mix. We characterize the arrangement of organic cations using nanoscale infrared imaging with photoinduced force microscopy (PiFM) and demonstrate mixed organic cation systems that allow us to continuously tune the emission wavelength of 2D perovskites. Our aim is to establish organic cation mixing as a powerful way to tune both the optoelectronic and thermodynamic properties of 2D perovskites.

White Light Emission from Mixed Composition Low Dimensionality Halide Perovskites Ido Hadar; The Hebrew University of Jerusalem, Israel

Hybrid halide perovskites are a novel class of semiconductor materials with promising and versatile optoelectronic properties enabled by their chemically adjustable structures and dimensionality. The diversity in the metal ions, halide anions, and organic spacers enables a wide range of materials with highly tunable properties and variable dimensionalities. These materials are studied for various applications, such as photovoltaics, detectors, and light-emitting devices. The chemical and structural agility of halide perovskites, enabling the adjustment of the optical and electronic properties for a desired application, is significant. In our research, we seek to gain additional information regarding the correlation between structure and composition to optoelectronic properties in low-dimensionality halide perovskites.

Specifically, we study low-dimensionality hybrid halide perovskites that exhibit broad-spectrum, white-light emission at room temperature, associated with self-trapped excitons (STE). These compounds are ideal candidates for illumination applications. We study the correlation between structural and chemical motifs of low-dimensionality halide perovskites and their STE emission.

In this research, we have studied how exchanging the halide anions while maintaining the structure affects the STE properties. We have focused on a unique 1D perovskite structure based on edge-sharing dimers, exhibiting strong, broad emission with PLQY of approximately 40%. By changing the halide from I to Br and Cl, we observe an increase in the bandgap energy, as expected. However, the broad emission shows an anti-correlated behavior, resulting in red-shifted broad emission for the Cl sample, with a significantly larger stokes shift. We further study how mixing Br and Cl in a single structure affects the broad emission properties and how different synthetic approaches can be utilized to fabricate these compounds.

To gain additional information regarding the STE properties with different compositions we have studied the temperature-dependent photoluminescence of these compounds. We utilize combined spectrally and temporally resolved photoluminescence measurements, allowing us to study the transition from band-edge to STE emission upon excitation. We observed how this transition, along with additional properties of the STE emission, evolved with temperature and composition.

4:00 PM EL01.02.06

Carrier Ultrafast Electrical Property Dynamics in Low Dimensional Perovskite Semiconductors Jianbo Gao; Brock University, Canada

Low-dimensional semiconductors such as quantum dots and 2D layers can be solution-processed into thin-film electronic and optoelectronic devices. Due to their solution processing under low temperatures and non-vacuum conditions, they are vulnerable to defect states. As a result, they exhibit similar carrier transport properties to amorphous silicon, which is manifested by lower carrier mobility and shorter carrier drift lengths.

In this study, we utilize novel ultrafast photocurrent spectroscopy, with sub-20 picosecond time resolution, to capture the carrier transport dynamics prior to defect trapping. Traditional optical property characterization techniques, such as pump-probe transient absorption and time-resolved photoluminescence, are limited in their ability to understand carrier diffusion dynamics. Additionally, they present a significant gap between carrier dynamics and the performance of devices in operation.

We use ultrafast photocurrent spectroscopy to study the electrical property dynamics in low-dimensional materials, such as perovskite quantum dots and 2D layers. We address the most critical carrier drift and carrier-phonon scattering dynamics, which are highly dependent on the nanostructure of the low-dimensional perovskite and temperature.

4:15 PM EL01.02.07

Controlling Phase Purity of Co-Evaporated Lower Dimensional Ruddlesden-Popper Films Using Surface Functionalization Kunal Datta[1], Esteban Rojas-Gatjens[1], Ruipeng Li[2], Diana K. LaFollette[1], Carlo Andrea Riccardo Perini[1] and Juan-Pablo Correa-Baena[1]; [1]Georgia Institute of Technology, United States; [2]Brookhaven National Laboratory, United States

High quality Ruddlesden-Popper lower-dimensional perovskite-derived phases (nominally $R_2A_{n-1}Pb_nI_{3n+1}$ where R is an organic spacer cation and A is a monovalent small organic cation) are an attractive materials platform for optoelectronic devices such as LEDs, lasers, photodetectors and solar cells. Changing the number of conjoined lead halide octahedral sheets (represented by the n value) between organic spacer cations can tune the optical bandgap, quantum confinement and exciton binding. This furthermore impacts defect formation energy and ion migration rates, affecting device performance and stability. However, solution-based thin film processing methods typically yield heterogeneous quasi-2D films consisting of several n-value phases with different optical bandgaps, and present a very narrow processing window for the deposition of high quality quasi-2D films. This results from solubility differences among precursor salts, leading to heterogeneous crystallization of different n-value phases and the formation of phase gradients.

In this work, we demonstrate thermal co-evaporation deposition routes for the development of phenethylammonium (PEA)-based Ruddlesden-Popper quasi-2D structures. The method is solvent-free and compatible with industrial processes used in the fabrication of optoelectronic devices. Using synchrotron-based structural characterization, we show that the elimination of precursor-solvent interactions can yield higher phase-purity and eliminate phase gradients across the thickness of the film. However, the crystallization of minority secondary phase, as probed by ultrafast transient absorption spectroscopy, limits exciton lifetime due to charge-carrier quenching by lower-bandgap states. We use phosphonic acid surface functionalization to drive the growth of the Ruddlesden-Popper phase and suppresses secondary phase crystallization. Using X-ray photoelectron spectroscopy, we study the diffusion of phosphonic acid molecules and their role in the crystallization process. This templated-growth results in an increase of the exciton lifetime from 4 ps to 220 ps from the quasi-2D phase. Finally, using in-situ synchrotron-based structural characterization, we study the impact of phase-purity on thin film stability under high humidity conditions.

4:30 PM EL01.02.08

Thermally Evaporated MAPbI$_3$ Perovskite Multiple-Quantum Wells for Enhanced Optoelectronic Properties

Luke R. White[1,1,1], Felix Kosasih[1], Ke Ma[2], Jianhui Fu[1], Minjun Feng[1], Matthew Sherburne[2], Mark Asta[2], Tze Chien Sum[1], Subodh Mhaisalkar[1,1,3] and Annalisa Bruno[1,1,1]; [1]Nanyang Technological University, Singapore; [2]University of California, Berkeley, United States; [3]Sungkyunkwan University, Korea (the Republic of)

Metal halide perovskites have delivered rapid advances in emissive and absorbing functionalities in a short period of time, demonstrating enhanced properties such as increased carrier mobilities, and improved luminescent device performances.[1]

Two-dimensional confinement has demonstrated advantageous optoelectronic properties and facilitated fundamental studies in a variety of materials. Sequential stacking of a semiconducting material with a layer thickness below its Bohr diameter with another material of a different bandgap produces a meta-structure known as a multi-quantum well (MQW), providing advantageous optoelectronic properties such as bandgap tunability and increased exciton binding energy.[2,3] Quantum wells have previously shown wide and prosperous use in III-V semiconductor materials, both for photovoltaics and light emission.[4,5]

Thermal evaporation provides a method to produce highly uniform, large area depositions with a high degree of thickness accuracy.[6] This method has allowed fully inorganic perovskite MQWs to be produced, demonstrating the viability and optoelectronic advantages of the structure over bulk counterparts.[2,7,8,9,10,11]

Here we present our work on the first type-I co-evaporated hybrid organic-inorganic perovskite MQWs, demonstrating enhanced luminescent properties and increased hot carrier temperatures. Study of sequentially decreasing thicknesses of MAPbI$_3$ from bulk to ultrathin layers shows a persistent composition, with morphological analysis displaying continuous films at ultrathin thicknesses. Using bathocuproine (BCP) as the barrier material to produce a type-I bandgap alignment, single quantum wells (SQWs) exhibited a 50x increase in integrated PL intensity. Ultrafast spectroscopy was used to uncover the mechanisms behind this enhancement, finding a significant increase in radiative recombination. In addition, through Maxwell-Boltzmann distribution

fitting, this examination exposed a significant increase in hot carrier temperature as the $MAPbI_3$ well thickness is reduced, opening the possibility for further study and utilisation of hot carriers in thermally evaporated organic-inorganic perovskite MQWs.
A secondary material, lead phthalocyanine (PbPC), was used to generate a type-II band alignment with the $MAPbI_3$ so as to further study the charge dynamics between the well and barrier materials. Both type-I and type-II MQWs were integrated into lateral photodetector devices, with minimal increase from the type-I, and a significant increase from the type-II structures, when comparing both to $MAPbI_3$ only layers of the same thickness. This exhibits the advantage of using type-II aligned MQWs for absorbing devices, where the charges separate into the well and barrier individually, reducing recombination.

Engineering Perovskite Nanocrystals as Quantum Light Sources Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

LHP NCs are of broad interest as classical light sources (LED/LCD displays) and as quantum light sources (quantum sensing and imaging, quantum communication, optical quantum computing). The current development in LHP NC surface chemistry, using designer phospholipid capping ligands, allows for their increased stability down to single particle level [1]. The brightness of such a quantum emitter is ultimately described by Fermi's golden rule, where a radiative rate is proportional to its oscillator strength (intrinsic emitter property) and the local density of photonic states (photonic engineering, i.e., cavity). With perovskite NCs, we present a record-low sub-100 ps radiative decay time for $CsPb(Br/Cl)_3$, almost as short as the reported exciton coherence time, by the NC size increase to 30 nm [2]. The characteristic dependence of radiative rates on QD size, composition, and temperature suggests the formation of giant transition dipoles, as confirmed by effective-mass calculations for the case of the giant oscillator strength. Importantly, the fast radiative rate is achieved along with the single-photon emission despite the NC size being ten times larger than the exciton Bohr radius. When such bright and coherent QDs are assembled into superlattices, collective properties emerge, such as superradiant emission from the inter-NC coupling [3]. In the most recent work [4], the functionality of the second SL component can give rise to the enhancement of the LHP NCs properties or the emergence of new collective effects. We present the formation of multicomponent SLs made from the $CsPbBr_3$ NCs of two different sizes. The diversity of obtained SLs encompassed the binary ABO_6-, ABO_3-, and NaCl-type structures, all of which contained orientationally and positionally confined NCs. For the selected model system, the ABO_6-type SL, we observed efficient NC coupling and Förster-like energy transfer from strongly confined 5.3 nm $CsPbBr_3$ NCs to weakly confined 17.6 nm $CsPbBr_3$ NCs. Exciton spatiotemporal dynamics measurements reveal that binary SLs exhibit enhanced exciton diffusivity compared to one-component SLs across the entire temperature range (from 5 K to 298 K). Observed incoherent NC coupling and controllable excitonic transport within the solid NC SLs hold promise for potential applications in optoelectronic devices.

9:00 AM EL01.03.02
Amino-As-Based Synthesis of Near-Infrared Emitting InAs-Based Quantum Dots Dongxu Zhu, Luca De Trizio and Liberato Manna; Istituto Italiano di Tecnologia, Italy

Colloidal quantum dots (QDs) that absorb and emit in the infrared (IR) region have gained significant interest as cost-effective active materials for future consumer market optoelectronic applications. Among IR materials, InAs QDs have emerged as the most promising candidates due to their tunable bandgap, which can be adjusted from the visible to the IR range, and their compliance with the European “Restriction of Hazardous Substances” directives. Although the first reported colloidal synthesis dates back to the 1990s, the use of an expensive and pyrophoric As precursor, namely trimethylsilyl arsine, limited the development of such QDs. In recent years, the discovery of a cheap and promising alternative As precursor, tris(dimethylamino)arsine (amino-As), has opened up new synthesis avenues for InAs QDs. The main current challenge is to improve the optical performance of amino-As-based InAs QDs in order to achieve tunable photoluminescence (PL) with high quantum yields (QY).
In this presentation, we will illustrate our recent studies on InAs QDs synthesized with amino-As, including 1) the impact of using $ZnCl_2$ as an additive and the effect of surfactants on InAs QDs;[1] 2) the development of the InAs@ZnSe core@shell system, focusing on controlling the interlayer between InAs and ZnSe, as well as the growth of an additional buffer interlayer or in-situ formation of the interlayer to improve their optical performance; [1,2] and 3) the fabrication of optoelectronic device utilizing these InAs@ZnSe QDs as the active NIR layer, including light-emitting diodes (LEDs) and photodetectors. [3]

Surface Morphology Control of Strongly Confined $CsPbBr_3$ PQDs Matthew L. Atteberry and Yitong Dong; The University of Oklahoma, United States

Highly confined perovskite quantum dots (PQDs) have gained significant attention for their promising use in optoelectronic devices and as quantum light sources. Synthetically, there have been significant advances reported in literature regarding the regulation of PQD sizes and morphology. However, due to lack of chemical stability of PQDs in the strongly confined region (< 5 nm), simultaneous regulation of PQD sizes and surface morphology for strongly confined PQDs has been underexplored. Here we propose that by utilizing ligands that have a stronger affinity for binding along a specific crystal facet of the PQDs, will result in selective binding to that facet that during growth, thus stabilizing the facet and yielding a desired surface morphology for the synthesized PQDs. Dicationic quaternary ammonium ligands with the linking carbon chain length tuned to match that of inter Cs^+ distance of the (100) and (110) facets of the PQD result in particle morphologies exposing the (100) and (110) facet selectively. By introducing these dicationic quaternary ammonium ligands into a thermodynamic equilibrium controlled synthesis, $CsPbBr_3$ PQDs < 5 nm with controlled morphologies have been synthesized. Our work offers a route to studying facet dependent optical properties of PQDs in the strongly confined region.

9:30 AM EL01.03.04

Synthesis of Metal Doped Strongly Confined Halide Perovskite Nanocrystals Under Ambient Conditions Zachary VanOrman[1,2], Mateo C. Wuttig[1] and Sascha Feldmann[1,2]; [1]Harvard University, United States; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Halide perovskite (HP) semiconductor nanocrystals (NCs) hold great promise for optoelectronic applications due to their high photoluminescence (PL) quantum yields and energetic tunability via composition and size. Substitution of the divalent metal ion can improve the native properties of the HP NCs, where the radiative rate or NC stability can improve, or the metal dopant can introduce novel properties, such as ferromagnetism. Synthesis of strongly confined doped HP NCs has been difficult historically, as hot injection techniques commonly produce polydisperse, large HP NCs.

In contrast, our novel synthetic method, which builds upon new work from the Kovalenko group, allows for facile doping of various divalent metal ions (Ni, Zn, Mn), which can be performed at room temperature and in ambient conditions. Here, we synthesize a variety of $CsPbCl_3$ NC sizes, with variable concentrations of metal dopants. Using Mn as a case study, we find that we can vary the Mn composition from 0.1 - 0.5% in NCs ranging in size from ~4 - 12 nm. Further, we find that Mn incorporates into the NC lattice, resulting in a variety of interesting photophysical phenomena, which we quantify using ultrafast transient absorption.

9:45 AM EL01.03.05

Equilibrium Shapes and Faceting of Colloidal $CsPbBr_3$ Nanocrystals Andriy Stelmakh[1,2], Ihor Cherniukh[1,2], Kseniia Shcherbak[1,2], Andrij Baumketner[3] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Institute for Condensed Matter Physics, NAS of Ukraine, Ukraine

Recent developments in the synthesis of colloidal semiconductor nanocrystals (NCs), also known as quantum dots (QDs), have led to an excellent control over their size and shape, often with a (nearly) atomic precision.[1-3] This level of control turned out to be the key to their practical applications in technologies that require precise control over the properties of emitted light, such as its energy, color purity, polarization, directionality, etc.[4,5] In contrast to the great experimental achievements in the colloidal synthesis and characterization techniques, little remains known about the detailed atomistic structure of colloidal QDs, especially the structure of the nanocrystal-ligand interface, which is paramount for controlling their size and shape, optical properties and environmental stability. Focusing on $CsPbBr_3$ NCs as a representative of a recently discovered family of ionic lead halide perovskite QDs, we will present the first computational investigation of the equilibrium structures of realistically sized (≈4 nm) QDs using large-scale classical force-field molecular dynamics (MD) simulations in explicit solvent. The NCs are predicted to have an inherently CsBr-rich composition and equilibrium nearly cubic shape with the main facets of the $\{100\}_p$ type (with respect to the primitive unit cell), whereas the analogous $PbBr_2$-terminated nanocubes are found to be unstable and phase separating with the formation of $PbBr_2$-rich material. These results agree with previous experimental observations and the fact that nanocube is the most frequently encountered shape for $CsPbBr_3$ NCs reported in the literature.[6,7] Exploration of the entire phase diagram in terms of NC composition and size further allowed us to shed light on the influence of composition on the NC shape, revealing the presence and structures of the minor $\{111\}_p$ and $\{110\}_p$ facets that cause truncation and chamfering of the nanocubes at low and high contents of CsBr. The structures and relative occurrence of different crystallographic facets are rationalized using the concept of nonpolar and polar crystal surfaces. Finally, a preferential binding of organic ligands to the different crystallographic facets and its effect on the NC shape will be discussed. The generated ensembles of representative NC structures will serve as a basis for further investigations of structure-property relationships in these nanomaterials, in particular the influence of surface chemistry and structural defects on the optical properties of the QDs.

Hybrid Semiconductor Nanomaterials William Tisdale; Massachusetts Institute of Technology, United States

Hybrid organic-inorganic semiconductor nanomaterials – including colloidal quantum dots (QDs), 2D halide perovskites, and metal-organic chalcogenolates (MOCs) – are excitonic materials with applications ranging from solar cells to light-emitting devices to quantum computing and quantum cryptography. In these emerging materials, the combination of quantum and dielectric confinement, strong exciton-phonon coupling, and dimensionality reduction offer unprecedented opportunities for controlling light-matter-charge interactions through chemistry. In this talk, I will describe recent work from my lab on the synthesis of hybrid semiconductor nanomaterials and our evolving understanding of how structure and chemical functionalization influence excited state dynamics. Using a combination of ultrafast laser spectroscopy, time-resolved optical microscopy, and kinetic modeling, we will explore the impact of nonequilibrium population dynamics on excited state transport phenomena and the emergence of unique electronic and vibrational phenomena.

11:00 AM EL01.03.07

Controlled Synthesis of Asymmetric Lead Halide Perovskite Nanocrystals with Excellent Stability Mengyun Chen and Feng Gao; Linköping University, Sweden

Nanoplatelets (NPLs) share excellent luminescent properties with their symmetric quantum dots counterparts, and entail special characters benefiting from the shape, like the thickness-dependent bandgap and anisotropic/polarized luminescence. However, the mechanism under formation of asymmetric perovskite NPLs is unclear, and thus the modification for high-quality perovskite NPLs is still unsatisfying. Here, we unveil the intrinsic parameters for synthesizing asymmetric NPLs and report stable $CsPbI_3$ NPLs obtained by accelerating the crystallization process. By this kinetic control, we tune the rectangular NPLs into quasi-square NPLs, where enlarged width endows the NPLs with a lower surface-area-to-volume ratio (S/V ratio), leading to lower surficial energy and thus improved endurance against NPL fusion (cause for spectral shift or phase transformation). The accelerated crystallization is enabled by preparing a precursor with complete transformation of PbI_2 into intermediates (PbI_3^-), through an additional iodide supplier (*e.g.*, zinc iodide). The excellent color stability of our materials remains in the light-emitting diodes under various bias stress.

11:15 AM EL01.03.08

Role of Inter-Particle Connectivity In the Photo-Carrier Cooling Dynamics and Coherent Nonlinear Interactions in Perovksite Quantum Dot Solids David O. Tiede[1,2], Katherine A. Koch[1], Esteban Rojas-Gatjens[3], Carlos Romero-Perez[2], Burak K. Ucer[1], Mauricio Calvo[2], Juan Galisteo-Lopez[2], Hernan Miguez[2] and Ajay Ram S. Kandada[1]; [1]Wake Forest University, United States; [2]Instituto de Ciencia de Materiales de Sevilla, Spain; [3]Georgia Institute of Technology, United States

The surface chemistry and inter-connectivity of perovskite nanocrystal assemblies play a critical role in determining the electronic characteristics and interactions[1]. They manifest in the Coulomb screening of electron–hole correlations and the carrier thermalization dynamics, among other many-body processes. Here, we characterize the role of inter-particle coupling in ultrafast photo-excitation dynamics in a ligand-free formamidinium lead bromide quantum dot solids. We observe that the inter-particle connectivity has deterministic effects on the many-body interactions that are relevant for carrier thermalization. These include carrier-carrier interactions that result in Auger-reheating of the carriers, and lattice characteristics that subsequently affect the phonon-assisted cooling dynamics. Independently, we also measure and analyse the coherence dynamics of these material systems using two-dimensional spectroscopy. We report the presence of Fano-like interference between the discrete excitonic states and the carrier continuum. We identify the spectroscopic signatures of a coupled exciton-carrier excited state, which provides a quantitive estimate of strength of exciton-carrier interactions. Our results highlight the presence of coherent coupling between exciton and free carriers, particularly in the sub-100 femtosecond timescales, which drives ultrafast carrier cooling in these QD solids [2]. This spectroscopic study of ultrafast carrier dynamics in perovskite QD solids establishes inter-dot separation as a critical material design parameter for the optimization of photo-generated carrier temperature and excitonic properties, which fundamentally determines the luminescence characteristics and thus the opto-electronic quality of the material.

11:30 AM *EL01.03.09

Lattice Symmetry Governs Spin Dynamics in Supramolecular Assemblies Xuedan Ma[1,2]; [1]Argonne National Laboratory, United States; [2]Rice University, United States

Synthetic soft materials mimicking biological structures are promising for many applications in fields such as photovoltaics and photocatalysis. For these applications, a deep understanding of charge- and energy-transfer mechanisms is required to build more efficient devices. In this work, we investigate self-assembled 2D supramolecular structures using angle-resolved photoluminescence imaging techniques and decompose the optical transition dipoles in the supramolecular structures. Combining these optical studies with Monte Carlo simulations, we reveal the important role played by lattice symmetry in charge dissociation, transport, and recombination, as well as the exciton spin states.[1] These mechanistic findings have important implications for engineering soft materials towards efficient energy conversion and photocatalytic applications.

Circularly-Polarized Excitons and Spin-Orbital Coupling Ordering Effects in Chiral-Structured Organic-Inorganic Hybrid Perovskites Bin Hu; South China University of Technology, China

Chiral-structured semiconducting materials have shown emerging phenomena such as chirality-induced spin selection, namely CISS. Here, we utilize magnetic field effects of circularly polarized photoluminescence (MFE-CPL) to probe circularly-polarized excitons and spin-orbital coupling (SOC) ordering effects based on chiral-structured metal-halide hybrid perovskite films where the chiral-structured 1D S-MBAPbBr$_3$ dispersed in nonchiral-structured 3D MAPbBr$_3$ matrix. The chiral-structured perovskites can demonstrate right-handed (s^+) and left-handed (s^-) CPL upon applying right-handed and left-handed circularly polarized excitations. This observation indicates that right-handed/left-handed circularly polarized lights can selectively excite the respective handed chiral structures. Interestingly, applying the magnetic field of 0.9 T can clearly increase the circular polarization of CPL at room temperature. Here, these magnetic field effects provide three fold critical information. First, light-emitting excitons can indeed exhibit circularly polarized orbital momentum, leading to circularly polarized excitons in the chiral perovskite structures. Second, the chiral structures are essentially formed with helically-ordered SOC, presenting SOC ordering effects towards generating CPL. Third, applying a magnetic field enhances the SOC ordering effects, consequently increasing the circular polarization of CPL by decreasing the dephasing of circularly polarized excitons in chiral structures. This presentation will discuss circularly-polarized excitons formed through spin-orbital coupling ordering effects in chiral-structured perovskites.

Ag Intercalation in Layered $Cs_3Bi_2Br_9$ Perovskite for Broadband Light Emission with Bound Interlayer Excitons

Seokhyoung Kim; Michigan State University, United States

Cesium bismuth bromide (CBB) has garnered considerable attention as a vacancy-ordered layered perovskite with notable optoelectronic applications. However, its use as a light source has been limited due to weak photoluminescence (PL). Here, we demonstrate metal intercalation as a novel approach to engineer the room-temperature PL of CBB using experimental and computational methods. Ag, when introduced to CBB, occupies vacancy sites in the spacer region, forming octahedral coordination with surrounding Br anions. First-principles density functional theory calculations reveal that intercalated Ag represents the most energetically stable Ag species compared to other potential forms, such as Ag substituting Bi. The intercalated Ag forms a strong polaronic trap state close to the conduction band minimum and quickly captures photoexcited electrons with holes remaining in CBB layers, leading to the formation of a bound interlayer exciton, or BIE. The radiative recombination of this BIE exhibits bright room-temperature PL at 600 nm and a decay time of 38.6 ns, 35 times greater than that of free excitons, originating from the spatial separation of photocarriers by half a unit cell separation distance. The BIE as a new form of interlayer excitons is expected to inspire new research directions for vacancy-ordered perovskites.

2:30 PM EL01.04.03

Role of Hydrocarbon Chain Length and Head Shape in Design of Low-Dimensional Metal Chlorides with Efficient Emission

Haimanti Majumder, Dhritiman Banerjee, Aislinn Miranda, Emily J. Brand, Kulatheepan Thanabalasingam and Kyle M. McCall; The University of Texas at Dallas, United States

The recent surge in low-dimensional metal halides with efficient luminescence has delivered new compounds for applications including LED phosphors, luminescent solar concentrators, and scintillation radiation detectors. The vast array of potential counter-cations offers similarly wide potential for design of these compounds, but this diversity poses a challenge to predictability of the resulting crystal structure. Here, we explore a) the role of hydrocarbon chain length and b) the impact of cation shape through comparison amongst a family of 0D antimony chlorides and a family of 2D and 0D manganese chlorides, respectively. This presentation will provide an overview of long-chain cation-based structure types compatible with efficient light emission, contributing to development of design principles for this burgeoning class of materials.

To illustrate the role of chain length, we developed a series of compounds A_2SbCl_5 based on the characteristic $SbCl_5$ square pyramid. We report three novel hybrid compounds $[BDXA]_2SbCl_5$ where BDXA are three quaternary ammonium cations that structurally identical save for having a terminal 14-, 16-, and 18-carbon chain, enabling analysis of the impact of this chain length on the optical properties. The compounds were synthesized via crystallization in DMF with several drops of HCl. Single crystal X-ray diffraction reveals that all three compounds are isostructural, crystallizing in a monoclinic crystal system comprising isolated $[SbCl_5]^{2-}$ square pyramids spaced out by A-cations. Intriguingly, all compounds exhibit bending of the long chain in 50% of the A-site cations, and this bent portion of the chain contributes to crystallographic disorder at room temperature. All three compounds exhibit a strong bright orange triplet emission, *e.g.* $[BDTA]_2SbCl_5$ emits at 620nm for a low energy excitation at 360nm, and exhibits singlet emission near 470nm for high energy excitation at 310nm. These compounds have a large Stokes shift of ~1.5 eV and a photoluminescent quantum yield (PLQY) above 90%, making them promising candidates for applications in lighting and scintillation. This presentation will present a novel structure type based on these mixed bent and straight chains, and relate the impact of the chain length by tying subtle changes in the structural details to the optical features of these candidate phosphors.

To probe the role of cation shape in long-chain hybrid metal halides, we report the discovery of 4 members of a series of A_2MnCl_4 based on long-chain A-site cations with two chain heads – one with a terminal ammonium group (denoted C_n-MA) while the other chain ends in a trimethylammonium head (denoted C_n-TMA). This chain-head engineering dictates the dimensionality of the final crystal structure, as the ammonium-terminated $(C_{12}\text{-MA})_2MnCl_4$ and $(C_{18}\text{-MA})_2MnCl_4$ form a 2D Ruddlesden-Popper perovskite structure with a 1-layer thick slab of corner-shared octahedra, while trimethyl-terminated $(C_{14}\text{-TMA})_2MnCl_4$ and $(C_{18}\text{-TMA})_2MnCl_4$ crystallize in a novel 0D structure with isolated $MnCl_4$ tetrahedra that pack in layers with the larger TMA chain heads; these layers are separated by the nonpolar carbon chains. The driver behind these structures is the size of the chain head: the methyl-terminated head fits in the terminal voids of the 2D perovskite framework, while the larger trimethyl-terminated cation is too large to coexist near this framework, splitting the would-be octahedra into isolated $MnCl_4$ tetrahedra. The 2D perovskite structures emit the faint red luminescence characteristic of $MnCl_6$ octahedra, while the 0D $(C_{14}\text{-TMA})_2MnCl_4$ and $(C_{18}\text{-TMA})_2MnCl_4$ emit bright green luminescence characteristic of tetrahedral MnCl4 coordination. These green emitters offer near-unity PLQY due to isolation of the tetrahedra provided by the large trimethyl chain heads. This study illustrates the role of cation shape in directing the structure of these hybrid halides, with implications for development of novel halide emitters.

Engineering Collective Excitonic Interactions for Halide Perovskite Nanocrystal Heterostructures and Superlattices Yehonadav Bekenstein; Technion-Israel Institute of Technology, Israel

Collective superfluorescent emission was reported for halide perovskite nanocrystal superlattices. It was confirmed to be coherent, stronger, and faster than spontaneous emission, surpassing standard isolated nanocrystals. The emission is similar to the famous Dicke superradiance first reported in the 1950s. However, a deeper inspection of the various reports raises questions regarding the limits of such an effect. In particular, natural linewidth-broadening reflects intrinsic energetic state variations between nanocrystals and excitonic interactions, which will prevent such collective emissions. I will describe two different colloidal schemes that enable the experimental testing of these ideas namely colloidal nanocrystal superlattices and perovskite heterostructures.

In both examples, interactions between excitons dominate the resulting collective emission properties. Superlattices made of weakly confined nanocrystals showed a red-shifted collective emission burst with a faster emission rate, showcasing key characteristics of superfluorescence (bunched light). In contrast, the exact composition of superlattices made of much smaller, strongly confined nanocrystals showed a blue-shifted emission burst. Further emphasis on the role of confinement of the neighboring excitons was achieved via testing same-size nanocrystals but engineered quantum confinement by a modified dielectric environment (halide composition). We assign these contrasting modes of collective emission to dipole-dipole interactions between neighboring excitons in the superlattice. Careful engineering of the quantum confinement results in either head-head exciton orientation (H-aggregates) or head-tail interaction (J-aggregates). Further indication that quantum confinement changes the preferred alignment/ interaction of transition dipoles comes from the angular-dependent emission patterns.

In a second example, we explore excitons in colloidal nanoparticles with periodic heterostructures within the material. We have developed a colloidal synthesis for nanocrystals that periodically incorporates two distinctive structures: a perovskite corner-sharing octahedra of $PbBr_4$ and an edge-sharing $(PbBr_2)_2AMTP_2$ decahedra, creating the edge-perovskite heterostructure. Our new colloidal synthesis demonstrates size control over the resulting nanocrystal and indicates quantum confinement effects compared to the bulk material. A clear double peak in the emission spectrum indicates non-trivial excitonic behavior and potentially correlated emission.

By comparing the two examples, I will convey the importance of excitonic interaction in achieving correlated emission from perovskite nanocrystals.

Excitons in Single-Crystal Halide Perovskite Heterostructures Arundhati Deshmukh[1], Jamie Cleron[1], Yinan Chen[2], Santanu Saha[2], Marina Filip[2] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]University of Oxford, United Kingdom

The distinctive excitonic behavior of organic-inorganic 2D halide perovskites affords many useful properties, such as sharp band-edge emission with high color purity and broad self-trapped emission with high color rendition. We recently devised a method to interleave a different 2D sublattice between the sheets of a 2D halide perovskite. These single-crystalline halide perovskite heterostructures afford a highly tunable platform for manipulating photogenerated excitons. I will discuss the physical and electronic structures of halide perovskite heterostructures, with a focus on new properties that arise due to the perovskite-nonperovskite interface.

Directing Singlet and Triplet Energy Transfer Pathways in Halide Perovskite QD-Chromophore Assemblies Jishnu Chakkamalayath, Akshaya Chemmangat and Prashant Kamat; University of Notre Dame, United States

Semiconductor-multiple chromophore hybrids modulated through bandgap engineering also allow switching from down conversion to upconversion of the incident light. By carefully selecting the donor ($CsPbBr_3$ or $CsPbI_3$) we can either induce down conversion with singlet energy cascade in CsPbBr3-Rubrene-Perylene dye films, or upconversion with triplet-triplet annihilation in Perovskite-rubrene-perylene dye films. The primary step in these two examples is either singlet or triplet energy transfer between excited perovskite nanocrystal and the dye. Factors such as bandgap energy of the semiconductor, energy levels of acceptor and spectral overlap between donor emission and acceptor absorption play a major role in dictating the mechanism of energy transfer. The factors that control the energy transfer pathways will be discussed. Identifying optimum conditions of energy transfer pathways and ability to tune individual energy transfer steps can enable the design of multi chromophore assembly for designing light harvesting assembly or display devices.

Lattice Engineering via Transition Metal Ions for Boosting Photoluminescence Quantum Yields of Lead-Free Layered Double Perovskite Nanocrystals Maning Liu; Lund University, Sweden

Very recently, so-called vacancy-ordered layered double perovskites with formula $Cs_4M(II)M(III)_2X_{12}$ ($M(II) = Cu^{2+}$, Zn^{2+}) have been discovered and synthesized both in the form of single crystals and colloidal nanocrystals (NCs), demonstrating several intriguing characteristics such as direct bandgap nature, narrow bandgap (down to ~1.0 eV), low effective masses and superior structural stability. The crystal structure of layered double perovskites consists of one layer of $[M(II)X_6]^{4-}$ octahedra sandwiched by two layers of $[M(III)X_6]^{3-}$ octahedra, which forms an anisotropic conformation. To date, colloidal $Cs_4M(II)Sb_2Cl_{12}$ NCs have been primarily synthesized by tuning the M(II) site with divalent metal ions such as Cu^{2+}[1,2] and Zn^{2+},[3] exhibiting ultrafast photoelectrical response and size-tunable photocatalytic activity, respectively. Nevertheless, the relatively high toxicity of Sb element as well as the lack of observed PL at room temperature (RT) from this kind of $Cs_4M(II)Sb_2Cl_{12}$ NCs restrict their further application. Our recent work[1] has proposed a new system of layered double perovskites by replacing toxic Sb with non-toxic In at M(III) site, resulting in $Cs_4CuIn_2Cl_{12}$ NCs, which show an almost 2% PLQY at RT in the near UV range upon the moisture-assistance during the synthetic process. We attributed the PL enhancement to the radiative transition of so-called self-trapped excitons (STEs) preferably in the lattices of $[CuCl_6]^{4-}$ octahedra, which were fairly distorted upon the involvement of minor water molecules, i.e., Jahn-Teller distortion.

In the context of metal halides, double perovskites have recently emerged as promising STE emitters, due to their 0D electronic dimensionality accompanied by the formation of strong electron-phonon coupling, which is in turn a drawback for solar cells application. Tang et al., significantly broke the parity-forbidden transition (i.e., dark transition) of double perovskite $Cs_2AgInCl_6$ bulk crystals by alloying Na^+ and doping Bi^{3+} cations, resulting in a dramatic increase in the PLQY up to 86% mainly from the STE emission.[4] Similar observation of STE emission has been reported for double perovskite $Cs_2AgInCl_6$ in the form of NCs, exhibiting stable white STE emissions.[5] On the other hand, the investigation of self-trapping mechanisms in emerging vacancy-ordered layered double perovskite nanocrystals, i.e., $Cs_4M(II)M(III)_2X_{12}$, is still at the infancy stage, which urgently requires in-depth understanding for their full potential.

In this work, we conduct lattice engineering on the established layered double perovskite system of $Cs_4CuIn_2Cl_{12}$ (abbreviated as CCuI hereafter) NCs, by replacing Cu^{2+} with other transition metal ions on the $[M(II)Cl_6]^{4-}$ octahedra, including Co^{2+} and Zn^{2+} cations, to synthesize first-ever colloidal $Cs_4CoIn_2Cl_{12}$ (CCoI) and $Cs_4ZnIn_2Cl_{12}$ (CZnI) NCs. Our density functional theory (DFT) calculations demonstrate the STEs are more easily formed in the lattice of CZnI crystal structure while the reference CCuI tends to limit the formation of STEs, due to the difference in their lattice deformation energies. This theoretical prediction aligns well with the observed longest time-resolved PL (TRPL) lifetime for CZnI NCs and shortest one for CCuI NCs. Benefiting from the formation of more STEs that relax in a radiative way, a broad PL spectrum with a long tail towards 800 nm was recorded with a highest PLQY of 11.4% for CZnI NCs, which is almost two orders of magnitude higher than that (0.12%) of CCuI NCs. Our transient absorption results also confirm the dramatically extended excited state lifetime of 2.2 ns in the case of CZnI NCs when compared to the highly short one (~44 ps) of CCuI NCs.

Ion Diffusion and Charge Transport Across 2D/2D and 2D/3D Perovskite Heterostructures Song Jin[1], Kristel Forlano[1], Chris R. Roy[1], Zihua Zhu[2] and John Wright[1]; [1]University of Wisconsin-Madison, United States; [2]Pacific Northwest National Laboratory, United States

Heterostructures of two-dimensional (2D) materials have been shown to display unique charge transport properties across the junction region beneficial for many device architectures. 2D metal halide perovskites provide a versatile platform of tunable structures and band energies from which 2D heterostructures have been utilized for light-emitting diodes and 2D/3D halide perovskite heterostructures have been extensively utilized in solar cell devices. We have carefully controlled the identity of the individual single-crystal 2D perovskite phases to assemble well-defined vertical 2D/2D or 2D/3D perovskite heterostructures, a more robust method than traditional thin film fabrication. While anion diffusion in halide perovskites has been extensively studied, our results reveal that A-site and B-site cation diffusion also needs to be carefully considered. A-site diffusion, shown through 2D/3D heterostructures, appears to often occur regardless of LA spacer or A-site cation identity. In contrast, B-site cation diffusion across heterostructures appears to be much slower. Control of the heterojunctions is imperative to understanding charge transfer across the heterostructures. With stability boundaries established, we study how charge transfer occurs across a variety of perovskite heterostructure combinations, exploring potential type I and type II band gap alignments. Such fundamental understanding could help to guide the rational design of high-performance perovskite optoelectronic devices.

Origins of Linewidth Broadening in Highly-Confined $CsPbBr_3$ Nanorods Tara Sverko, Hua Zhu, Niamh Brown, Shelby Elder and Moungi G. Bawendi; Massachusetts Institute of Technology, United States

Colloidal semiconductor nanocrystals, or quantum dots (QDs), are an exciting playground for photophysics, exhibiting atom-like behaviour while retaining advantages of molecular crystal size tunability and solution-phase synthesis.[1] Recently, colloidal QDs have been explored as two-level systems for single photon sources.[2] In particular, weakly-confined lead halide perovskite nanocrystals (LHPs) exhibit superior properties to conventional II-VI and III-V materials with a facile synthesis and minimal engineering.[3] However, these particles have high biexciton quantum yields at low temperature and emit from multiple fine structure states, both of which are sources of noise affecting coherence.[4] These can be mitigated by moving to the highly confined regime, where there are heightened size and morphology effects.

Highly confined $CsPbBr_3$ nanorods are a particularly interesting system to study, as the transition dipole aligns with the long axis of the material, resulting in strongly polarized, directional emission from a single fine structure state.[5] However, these particles are more unstable than their large counterparts due to a high surface area to volume ratio. For this reason, LHP nanorods have not been studied to the same degree as nanocubes and nanoplatelets. Our group has synthesized, for the first time, highly confined, stable LHP nanorods that exhibit complete antibunching, but whose linewidths are extremely broad on the single particle level. In this work, we examine the relevant contributing factors to the spectral linewidth and find that high-lying (35 meV ± 6 meV) longitudinal optical phonons are the dominant mechanism of vibrational broadening in these materials. Taking into account a large fine structure (15 meV) and structural inhomogeneities, we can begin to understand the relevant photophysics of these materials, with the goal of eventually controlling exciton-phonon coupling and fine structure towards single photon emitter applications. Our results give insight into future synthetic handles to develop stable, narrow, and bright emitters.

High Performance of Blue-Emitting $CsPbBr_3$ Quantum Dots Synthesized at Room Temperature

Saurabh Singh and Fuqian Yang; , United States

The excellent light-emitting characteristics of all inorganic halide perovskite quantum dots (IHQD) over hybrid perovskite QDs in terms of various optoelectronic properties has channelized the focus area of wide-spread research to further enhancement of the quality of IHQDs. However, blue emitting IHQDs are still struggling to compete with green and red IHQDs and generally exhibit low efficiency in luminescence. In this work, we present a facile approach to synthesize blue-emitting CsPbBr3 QDs under ambient conditions via an antisolvent method. The prepared QDs under ultraviolet light of 365 nm emit light with the emission wavelength experiencing red shift from 464 to 471 nm over a period of 18 days. The photoluminescence quantum yield is ~55.7%. The XRD pattern of the prepared QDs reveals dominant peaks between 2 to 10 degrees for 2θ, significantly different from the results reported in literature. The approach used in this work can provide a unique approach to produce blue emitting perovskite QDs of high quality.

Suppressing Spectral Instability of Vacuum-Deposited Blue Perovskite Light Emitting Diodes via Phenanthroline-Containing Organic Passivation Agents

Jiyoung Kwon and Byungha Shin; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The current premium display market is dominated by organic light-emitting diode (OLED) technology. Based on vacuum deposition processes, OLEDs have successfully achieved large-scale production and are used in various displays such as mobile devices and TVs. Although electroluminescent quantum dot (EL-QD) LEDs were once considered the next generation of displays after OLEDs, they have faced significant commercialization challenges, particularly due to difficulties associated with solution-based processes. Metal halide perovskites, which can be synthesized using the same vacuum deposition methods as OLEDs, present a promising alternative for future displays. They offer excellent color purity due to their narrow full-width at half maximum (FWHM), enabling them to achieve a color gamut that satisfies the Rec.2020 color space standard. Additionally, they can cover the entire visible spectrum through halide composition adjustments. However, perovskites synthesized via vacuum deposition face efficiency challenges compared to those produced through solution-based methods, limiting their practical applications in display technologies. In this study, we aimed to address these efficiency challenges by synthesizing true blue perovskites with a peak emission at 460-475 nm through co-deposition of three inorganic materials: $PbBr_2$, CsCl, and CsBr. By adjusting the deposition rates, we achieved the optimal peak wavelength for pure blue emission. By applying hole transport layer and electron transport layer materials, we achieved pure-blue emission at 472 nm with an external quantum efficiency (EQE) of 3.13% and an FWHM of 17 nm. This represents the highest efficiency reported to date for vacuum-deposited pure blue perovskite LEDs, highlighting significant progress in this area. However, these perovskite LEDs exhibited spectral shift issues when applied bias exceeded 6.5V. To address this problem, we investigated the incorporation of an organic material containing phenanthroline groups into the perovskite structure through co-deposition. This approach maintained a peak emission at 472 nm and resulted in a device with an EQE of 2.16% and an FWHM of 17 nm. Although the EQE is slightly lower than the counterpart without the phenanthroline additives, the device exhibited much improved spectral stability. The phenanthroline groups are expected to form complexes with lead, effectively passivating the perovskite emitter. Maintaining such stability is crucial for the development of reliable and durable display technologies. These findings demonstrate substantial progress in the development of vacuum-deposited metal halide perovskites for high-efficiency, high-purity blue light-emitting applications in next-generation displays.

EL01.05.03

Synthesis of Chalcogenide Perovskite Nanoparticles by Hot Injection Method Yoshinori Kimoto, Takuya Kato, Issei Takenaka and Toru Inatome; Idemitsu Kosan Co., Ltd., Japan

Chalcogenide perovskites (IIA-IVB-VIA_3: IIA = Ca, Sr ,Ba; IVB = Zr, Hf; VIA = S, Se, Te) are predicted to have excellent optical properties, such as high absorption coefficients exceeding 10^5 cm^{-1} and sharp absorption edges. [1] They have a tunable bandgap from visible to near-infrared regions and are robust to heat, oxygen, and water. Furthermore, they don't contain toxic elements. These characteristics make them potential materials for optoelectronic devices that could solve problems of conventional lead halide perovskites.[2] They are expected to a light absorber for thin film solar cells and an efficient light emitter for luminescent devices. Notably, $SrHfS_3$ has been reported as a green luminescent material.[3] The key challenge in using these in optoelectronics devices is the high synthesis temperature for the film deposition, which limits substrate and electrode selection.[4]

One of solution for this problem is to synthesize nanoparticle (NP) of chalcogenide perovskites: instead of the high-temperature deposition process, their thin films can be obtained by coating pre-synthesized nanocrystals dispersed in organic solvents. Furthermore, the luminescent efficiency improves due to quantum confinement effect, and the emission peak wavelength can be controlled via the quantum size effect.

We have found the difficulties to synthesize chalcogenide perovskite NPs: the common raw materials for liquid phase synthesis (carboxylates, alkoxides, halides) can't be used due to the robustness of the oxides of IVB(ZrO_2, HfO_2) preventing sulfide formation, and the formation of IIA-VIIA (such as $BaCl_2$) having poor solubility in organic solvents. Therefore, it was clarified that the precursor materials excluding oxygen or halogens are needed.

We have developed a liquid-phase synthesis method for chalcogenide perovskite NPs. This "hot injection" method utilizes metal-dithiocarbamate (DTC) complexes as precursors and oleylamine as the reaction initiator and surface ligand. DTC complexes are stable up to around 400°C but decompose to sulfide at around 120°C with primary amines. [5] Utilizing this reactivity difference, $BaZrS_3$ nanoparticles were successfully synthesized by heating Ba- and Zr-DTC in hydrocarbon solvent with injecting oleylamine.

The XRD pattern of synthesized NPs matched the calculated data of distorted orthorhombic $BaZrS_3$. The crystallite size calculated from the FWHM of the main peak at 25.2° using Scherrer's formula was 11 nm. This is equivalent to the average particle size obtained from STEM images of the synthesized $BaZrS_3$ NPs, suggesting that each individual NP is a single crystal. However, they have a broad size distribution ranging from a few nm to 20 nm, and irregular shapes. Rietveld analysis of the XRD pattern suggested a sulfur deficiency, and an elemental analysis also confirmed a sulfur deficient composition compared to stoichiometric ratios. Absorption spectroscopy revealed that the synthesized $BaZrS_3$ NPs have a higher absorption coefficient within the visible range compared to commercially available InP quantum dots. This suggests that they exhibit greater light absorption with lesser quantities, thereby indicating its potential applicability as a color conversion material. On the other hand, fluorescence spectroscopy revealed a broad emission spectrum and poor PLQY. The PLQY could be enhanced by forming a core-shell structure or passivating surface defects via surface ligands. To narrow the luminescence peak, the emission via defect states must be suppressed, and the bandgap maintained constant by the controlling the particle size distribution. We are now focusing on optimizing reaction conditions and suppressing defect formation.

EL01.05.04

Development of a New Class of Perovskite Quantum Dots for Diverse Applications Takuya Kato[1], Yoshinori Kimoto[1], Issei Takenaka[1], Toru Inatome[1], Taro Uematsu[2], Kiyoshi Kanie[3], Toranosuke Takagi[4], Martin Vacha[4], Takahito Nishimura[4], Akira Yamada[4], Mitsuki Yamanishi[5], Takahiro Wada[5], Yu Kawano[5] and Takashi Minemoto[5]; [1]Idemitsu Kosan Co., Ltd., Japan; [2]Osaka University, Japan; [3]Tohoku University, Japan; [4]Tokyo Institute of Technology, Japan; [5]Ritsumeikan University, Japan

Chalcogenide perovskites have recently attracted much attention as a new class of optoelectronic materials[1]. Typical chalcogenide perovskites consist of the composition IIA-IVB-VIA_3, and the prototypical material is $BaZrS_3$. They are characterized by optoelectronic properties intermediate between oxide and halide perovskites and exhibit high stability due to the presence of divalent anions, similar to oxides. In particular, chalcogenide perovskite has a band gap that can respond to visible light, a high optical absorption coefficient, and high stability enough to withstand aqueous environments, making it a candidate for next-generation perovskite absorber material to replace halides in photovoltaics. The high synthesis temperature of chalcogenide perovskites (which typically requires temperatures well above 600°C) makes their application to the thin-film solar cells a challenging task. On the other hand, it has been reported that the band-edge absorption in $BaZrS_3$ is extraordinary strong[2], indicating that it can also exhibit excellent luminescent properties[3]. Against this background, we are developing chalcogenide perovskite nanocrystals with multiple objectives. One is to develop highly durable and luminescent quantum dots as materials for color conversion and emission layers in displays and lighting, and the other is to develop nanocrystals as precursors for low-temperature deposition of the absorber layer in thin-film solar cells. Colloidal nanoparticles of $BaZrS_3$ were synthesized using dithiocarbamate complexes as precursors, using our independently developed recipe (similar to that of Ref [4]). While the X-ray diffraction patterns of the synthesized nanoparticles were consistent with the crystal peaks of BaZrS3, they exhibited a wide particle size distribution, irregular shape, and poor orange emission properties with FWHM > 100 nm and PLQY < 10%. Major improvement of synthesis technique is needed as a luminescent material, since monodispersion and narrow emission peak are required in practical applications. On the other hand, the optical absorption of the dispersed solution for blue light was demonstrated to be several to ten times higher than that of commercially available InP quantum dots. Detailed analysis of XRD peaks and compositions indicates that the synthesized $BaZrS_3$ is sulfur deficient, a possible origin of the low luminescence properties. However, theoretical calculation predicted that sulfur vacancies do not create deep defects. Therefore surface defects may dominate the nonradiative recombination. We are currently working with universities to improve the performance. Osaka University and Tohoku University are working to improve luminescence performance by understanding the synthesis mechanism and improving synthesis techniques including core-shell formation. Single-particle spectroscopy by Prof. Vacha at Tokyo Institute of Technology has shown that $BaZrS_3$ exhibited a very narrow luminescence peak as a single quantum dot. We are also collaborating with groups at Tokyo Institute of Technology and Ritsumeikan University to develop chalcogenide perovskite thin-film solar cells using $BaZrS_3$ nanoparticles or their precursors and have so far achieved in depositing $BaZrS_3$ thin-film. Meanwhile, we are exploring potential collaborators for diverse applications, from light emitting components and devices to photovoltaics, sensors and catalysts, and medical applications.

Bright, Lead-Free, Colloidal Perovskite Nanoplatelets Enabled by Rare-Earth Metal Halides Sebastian Fernandez, Manchen Hu, William Michaels, Pournima Narayanan, Qi Zhou, Natalia Murrietta and Daniel Congreve;

Stanford University, United States

Metal halide perovskite semiconductors show strong potential for next-generation optoelectronic devices including solar cells, light-emitting diodes, and lasers. This semiconductor class is distinguished by its bandgap tunability, sharp color purity, and inexpensive solution processing. Previously, by engineering the metal halide perovskite's cation, metal, and halide composition as well as the thickness, colloidal perovskite nanoplatelets demonstrated tunable light absorption and emission – showcasing their promise for broad optoelectronic applications.[1] Additionally, two-dimensional organic-inorganic hybrid perovskite nanosheets with formula PEA_2PbX_4 (PEA = Phenethylammonium; X = Cl, Br, I) demonstrated tunable light emission and absorption across the visible spectrum.[2] While the use of lead or tin within colloidal perovskite nanoplatelets/nanosheets has been well studied, other metal cations could enable new non-toxic pathways for optoelectronic devices in the deep blue and violet regimes.

In this work, we introduce europium within metal halide perovskites to synthesize bright, lead-free, colloidal perovskite nanoplatelets. Specifically, we focus on n = 1 and n = 2 europium-based nanoplatelets governed by the formula $L_2[AEuX_3]_{n-1}EuX_4$, where L is an organic ligand, A is a cation, and X is a halide anion. The photoluminescence spectra of the europium-based perovskite nanoplatelets are centered in the deep blue to violet range (i.e., between 400 and 460 nm) – demonstrating a new route towards non-toxic high energy visible light emission. Additionally, by changing solvents, we unlock further tunable luminescence from the europium-based perovskite nanoplatelets. These results demonstrate the potential of europium-based colloidal perovskite nanoplatelets for deep blue and violet light-emitting optoelectronic devices and encourage further investigations on the rare-earth metal-based colloidal perovskite nanoplatelet material class broadly.

Trade-off Between Efficiency and Stability in Mn^{2+}-Doped Perovskite Light-Emitting Diodes Sebastian Fernandez[1], William Michaels[1], Manchen Hu[1], Pournima Narayanan[1], Natalia Murrietta[1], Arynn O. Gallegos[1], Ghada Ahmed[1], Junrui Lyu[1], Mahesh Gangishetty[2] and Daniel Congreve[1]; [1]Stanford University, United States; [2]Mississippi State University, United States

While light-emitting diodes (LEDs) made from metal halide perovskites have demonstrated external quantum efficiencies (EQEs) well over 20%, their device instability limits their commercial viability. In an effort to improve the optoelectronic properties of metal halide perovskites for light emission, many researchers have investigated introducing both alkaline-earth metal ions[1] (e.g., Ba and Sr) and transition metal ions[2] (e.g., Mn, Zn, Cd, and Ni) into the B-site of the perovskite's ABX_3 structure. Additionally, the factors that limit the device stability of perovskite LEDs remain under investigation.

In this work,[3] we dope Mn^{2+} ions into an organic-inorganic hybrid quasi-bulk 3D perovskite resulting into $(PEABr)_{0.2}Cs_{0.4}MA_{0.6}Pb_{0.7}Mn_{0.3}Br_3$ thin films with the addition of tris(4-fluorophenyl)phosphine oxide (TFPPO) dissolved in a chloroform antisolvent to achieve an EQE of 14.0% and a peak luminance of 128,000 cd/m^2. While the inclusion of TFPPO into the chloroform antisolvent dramatically increases the EQE of perovskite LEDs, the device stability is severely compromised. At an electrical current bias of 5 mA/cm^2, our perovskite LED fabricated with a pure chloroform antisolvent (2.97% EQE) decays to half of its maximum luminance in 37.0 minutes. Alternatively, our perovskite LED fabricated with TFPPO (14.0% EQE) decays to half of its maximum luminance in 2.54 min. In order to investigate this trade-off in EQE and stability, we study both photophysical and optoelectronic characteristics before and after PeLED electrical operation. By measuring repeated electrical scans and time-resolved photoluminescence spectra under identical degradation conditions for all Mn^{2+}-doped perovskite LEDs, we find that with higher TFPPO-treated concentrations, there is decreased robustness in operational luminance, maximum luminance, turn-on voltage, and average decay lifetime. These results simultaneously illustrate the potential of efficient Mn^{2+}-doped metal halide perovskites for light emission while also suggesting that further investigations are needed to mitigate stability degradation mechanisms induced by TFPPO treatment.

EL01.05.07

Yb-Doped Double Halide Perovskite $Cs_2AgBiCl_6$ for Lead-Free High-Efficiency Downconversion Pulkita Jain, Minh N. Tran, Iver J. Cleveland, Yukun Liu, Seda Sarp and Eray S. Aydil; New York University, United States

The mismatch between the solar spectrum and band gap in silicon solar cells limits the light to electrical energy conversion to 33.6%, the Shockley-Queisser (SQ) limit. One approach to surpassing this limit is shifting the solar spectrum entering the silicon solar cell to better match the silicon’s band gap by downconverting ultraviolet (UV) and blue photons to near-infrared (NIR) photons. In some materials, downconversion can create two NIR photons from each UV/blue photon, a phenomenon called quantum cutting. Quantum cutting can eliminate significant energy loss due to mismatch and raise the SQ limit to 41%, with prospects to translate this to record solar module efficiencies and improve solar module lifetime. Yb-doped halide perovskite $CsPbCl_{3-x}Br_x$ (x<1) has been shown to absorb nearly all light above the perovskite’s bandgap and downconvert it to NIR at 1.25 eV close to the silicon’s bandgap energy via quantum cutting with nearly 200% photoluminescence quantum yield (PLQY). However, lead is toxic, and thus, there is a need to find alternatives. We have been exploring bismuth and silver-based halide double perovskite $Cs_2AgBiCl_6$ to fulfill this need. Previous studies on $Cs_2AgBiCl_6$ arrived at conflicting conclusions regarding its bandgap and the origin of its characteristic visible orange emission. Here, we address these knowledge gaps and report on undoped and Yb-doped $Cs_2AgBiCl_6$ thin films synthesized through reactive thermal evaporation. Specifically, CsCl, $BiCl_3$, and AgCl precursor powders are co-evaporated onto glass substrates and subsequently annealed (200-250 °C) either in air or in a nitrogen-filled glovebox, resulting in 400 nm thick polycrystalline thin films. Films are doped by adding $YbCl_3$ to the co-evaporation. Our optical characterization analysis of the undoped films reveals an indirect bandgap of 2.77 eV and a direct transition at 2.9 eV. X-ray

diffraction (XRD) and Raman spectroscopy were used to verify the phase purity and structure of the perovskite. Like in previous work, we observed an orange emission at around 650 nm. We explore the origin of this emission using time-resolved photoluminescence and lifetime measurements coupled with a physically based kinetic mathematical model of exciton decay channels that considers various recombination processes, including radiative and nonradiative recombination on defects and self-trapped excitons. With only a few adjustable physically-based time constants, photoluminescence lifetime data could be fit with high fidelity. Our analysis suggests that the orange emission comprises both self-trapped exciton and radiative defect emissions with fractional contribution depending on the details of the material synthesis conditions. We also doped the $Cs_2AgBiCl_6$ perovskite with $YbCl_3$ to explore the possibility of quantum cutting. The perovskite host absorbs the ultraviolet energy and transfers it to Yb, which then relaxes and emits photons in the NIR region. Doping with Yb resulted in PLQY of 50%, the highest reported in the literature for this material. We investigated various post-deposition treatments, such as annealing in air versus in a nitrogen-filled environment, and concluded that annealing in air, in the presence of moisture, results in the formation of bismuth oxychloride (BiOCl), confirmed by XRD and Raman spectroscopy. While these results suggest energy transfer to Yb could be efficient in $Cs_2AgBiCl_6$, quantum cutting, and PLQY exceeding 100% remains to be achieved by fine-tuning the synthesis conditions.

EL01.05.08

Stable Perovskite Quantum Dots Using a ZnX_2-Trioctylphosphine-Oxide—Application for High-Performance Full-Color Light-Emitting Diode

Saeyoung Oh, Sangwook Park, Hyukmin Kwon and Jongwook Park; Kyung Hee University, Korea (the Republic of)

Perovskite is a very promising material that is being extensively studied at the bulk and nano-size scales because it has outstanding optical properties, including high quantum efficiency and narrow emission spectra. However, perovskite has stability issues related to heat, air, and light. To overcome these, highly stable perovskite quantum dots (PeQDs) are developed using excess Zn precursor and trioctylphosphine-oxide (TOPO). Some of smaller ions can enter the perovskite structure, such as rubidium or potassium, and can change their diffraction by changing the tolerance factor. In our ZnX_2 cases, the XRD peak pattern does not change indicating that Zn ions do not affect the perovskite structure. Our PeQDs were synthesized using excess zinc halide and TOPO, which needs a higher reaction temperature (230 °C) compared with conventional methods (180 °C) because the reaction solution should be transparent for homogeneous reaction. In particular, it is clarified that Zn and TOPO are combined and these complexes are attached to the surface of the PeQDs through ^{31}P NMR. They not only have high quantum efficiency and sharp full width at half maximum values (15–30 nm) but also have improved long-term stability at high temperature. Among the blue, green, red particularly green device has the longest lifetime and blue device has the shortest lifetime. It can be explained by that the fact that the current efficiency of the green device is more than three times higher than for the other colors, which means that the joules for heating the green device are lower and the morphology of the film is superior to other colors. In the case of the green device, the stabilities of the pristine PeQD device and TOPO-Zn treated PeQD devices were also compared. The pristine device showed a very short lifetime of 1.5 min at 1.0 mA cm^{-2}. As seen in the thermal stability test, the structure of PeQDs is very weak, and cannot maintain the electrical and thermal energy after fabrication. However, TOPO-Zn treated PeQDs can emit light for a longer time compared to the pristine PeQDs because of their structural stability. These results appear to have an impact on the device as the stability of materials is also improved. Additionally, XPS measurements are conducted for a detailed surface analysis of PeQDs, finding that the TOPO-Zn complex effectively decrease Pb-O bonding in the lattice. Perovskite full-color electroluminescence (EL) devices are fabricated using PeQDs and 9,9-bis[4-[(4-ethenylphenyl)methoxy]phenyl]-N2,N7-di-1-naphthalenyl-N2,N7-diphenyl-9H-fluorene-2,7-diamine (VB-FNPD) as a new cross-linkable hole transporting material. The VB-FNPD has a high-hole carrier mobility compared to the PVK as conventional hole-transporting layer. As a result of EL performance, they have high EQE (%) and current efficiency(Cd A^{-1}) of (7.12%, 9.93 Cd A^{-1}) for red, (6.06%, 32.5 Cd

A^{-1}) for green, and(0.56%, 0.88 Cd A^{-1}) for blue-emitting devices, respectively.

Tuning Luminescence Through Molecular Packing—Insights into Halogenated Emitters for Advanced Optoelectronics

Haydee Pacheco[1], Rianne De Leon[1], Diego Jiménez Rivera[2], Thomas Emge[1] and Deirdre O'Carroll[1]; [1]Rutgers, The State University of New Jersey, United States; [2]University of Puerto Rico at Mayagüez, Puerto Rico

We report on the photophysical properties of two polymorphs of 2,5-dioctyloxy-4-bromobenzaldehyde (Br8), focusing on their potential applications in organic light-emitting diodes (OLEDs). These materials can exhibit a combination of thermally activated delayed fluorescence (TADF) and phosphorescence, characteristic of halide-containing compounds. The fluorophores incorporate bromine atoms, whose high atomic number induces significant electron density enhancement in their vicinity, (the heavy atom effect), which can amplify the luminescence properties of organic molecules. Using a combination of experimental techniques, including UV-visible spectroscopy, photoluminescence (PL) spectroscopy, X-ray diffraction (XRD), PL quantum yield (QY), and PL lifetime measurements, we thoroughly characterized the structure and optical properties of both polymorphs. The Br8-J polymorph adopts a triclinic crystal structure, while Br8-H adopts a monoclinic crystal structure, as determined by XRD analysis. These distinct polymorphic forms exhibit different packing arrangements, with J-aggregates displaying a head-to-tail arrangement and H-aggregates a face-to-face arrangement, significantly impacting their optical properties through variations in intermolecular distance and offset. The chirality of the molecular packing in Br8 polymorphs further influences their photophysical properties. The PL spectra show a single emission peak at 420 nm for Br8-H (H-aggregates) and 467 nm for Br8-J (J-aggregates). The PL QY of Br8-H (<5%) is significantly lower than that of Br8-J, which has a PL QY of up to 38%. Additionally, the valence band and optical conduction band measurements indicate that the energy levels are well-suited for the fabrication of blue OLEDs. These findings offer valuable insights into the structure and optimization of halogenated emitters, showcasing their suitability for advanced optoelectronic applications, including efficient blue OLEDs.

Exciton-Phonon Interactions in Halide Perovskite Quantum Dots

Yoshihiko Kanemitsu, Kenichi Cho, Takumi Yamada, Ryota Sato, Masashi Saruyama and Toshiharu Teranishi; Kyoto University, Japan

Recently, lead halide perovskites ($APbX_3$, A = Cs, MA (CH_3NH_3), FA ($HC(NH_2)_2$), X = Cl, Br, I) have attracted much attention as a new class of semiconductor materials because of their defect-tolerance structures and outstanding optical and electronic properties [1,2]. In addition, colloidal halide perovskite nanocrystal quantum dots (QDs) show almost 100% photoluminescence (PL) quantum yields at room temperature. Because of their unique electronic band-edge structures, PL dynamics of halide perovskite QDs are governed by the formation and recombination of excitons, trions, and biexcitons [3,4]. Furthermore, for ionic semiconductors, electron-phonon interactions strongly affect the PL spectra and dynamics of halide perovskites [5]. For example, at room temperature, efficient anti-Stokes PL clearly appears [6], and the relaxation dynamics of hot carriers is manipulated by direct phonon excitation [7]. At low temperatures, individual QDs show very narrow PL linewidths, and single QD spectroscopy is a powerful tool to investigate the exciton-exciton and exciton–phonon interactions in perovskite QDs. Deep understanding of exciton-phonon interactions in QDs is desirable for design for light sources with high color purity, narrow linewidth, and long exciton coherence time. Here, we report exciton-related multipeak PL structures of single perovskite QDs at low temperatures and discuss their origins and electron-phonon interactions in QDs.

In this work, we prepared three types of colloidal perovskite QD samples, $CsPbBr_3$, $CsPbI_3$, and $FAPbBr_3$, and studied their PL spectra of single QDs at low temperatures. All QD samples show strong exciton PL, and several PL peaks originating a trion and a biexciton appear in the low energy side of the strong exciton peak. PL spectra of all the samples were very similar to each other. However, the PL linewidths of all inorganic $CsPbBr_3$ and $CsPbI_3$ QDs were narrower than those of organic-inorganic hybrid $FAPbBr_3$ QDs, suggesting the stronger exciton–phonon coupling because of large organic cations. In addition, LO-phonon side bands of an exciton, a trion, and a biexciton are observed. We clarified the QD size dependence of the Huang–Rhys factors, i.e., the strength of the exciton–phonon coupling, in three different perovskites. We found that in all samples, the Huang–Rhys factors increase with a decrease of the QD size, but the LO-phonon energies are independent of the QD size [8-11]. Moreover, PL spectra clearly show the positive binding energies of trions and biexcitons and the attractive exciton–exciton Coulomb interactions in perovskite QDs. We found that the size dependence of the binding energies follows a universal scaling curve regardless of chemical composition [11]. These findings of the size-dependent optical responses provide new insights into understanding of the photophysics of halide perovskite QDs and the design of QD-based light sources.

Part of this work was supported by JST-CREST (JPMJCR21B4) and NEDO-GI (JPNP21016).

Ultraviolet Light-Emitting Diodes Based on Two-Dimensional Metal Halide Perovskites Manchen Hu, Junrui Lyu, Natalia Murrietta, Sebastian Fernandez, William Michaels, Qi Zhou, Pournima Narayanan and Daniel Congreve; Stanford University, United States

Recent advances in perovskite light-emitting diodes (PeLEDs) position them as promising candidates for next-generation displays and lighting, covering the full visible spectrum and extending into the deep blue and violet regions. These materials offer a simpler fabrication process compared to conventional III-V semiconductors, avoiding the need for lattice-matching and enabling easy deposition of polycrystalline films without metal-organic chemical vapor deposition. However, achieving shorter emission wavelengths is challenging due to the larger bandgaps required, complicating electron-hole recombination dynamics necessary for efficient electroluminescence. This study addresses these challenges by fine-tuning the halide composition in two-dimensional perovskites, extending the bandgap to 3.1 eV, and achieving photoluminescent emission at 393 nm. Introducing an optimized dual electron transport layer architecture improves electron injection and hole confinement within the perovskite matrix, resulting in high-purity electroluminescent emission at 399 nm. This approach achieves a maximum external quantum efficiency of 0.16%, setting a new benchmark for PeLEDs in the ultraviolet wavelength range. These results underscore the potential of large bandgap perovskite materials for next-generation light-emitting applications.

Room-Temperature Amplified Spontaneous Emission in Lead-Free Cesium Germanium Iodide Perovskite

Andrea Olivati[1,2], Giulia Giovilli[3], Annamaria Petrozza[2] and Lorenzo Malavasi[3]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Università degli Studi di Pavia, Italy

Lead halide perovskites (LHP), due to the ease of synthesis and great optoelectronic properties, have received significant attention for various applications including emitters in LEDs and semiconductor lasers. Unfortunately, the toxicity of lead is a drawback for the commercialization of such devices, therefore, a lead-free perovskite is needed. One of the most promising approaches is to replace lead (Pb) cation with the less toxic tin (Sn). However, these materials' performances are still inferior to those of lead counterparts. In fact, amplified spontaneous emission (ASE), a fundamental prerequisite for lasing application, has often been observed at cryogenic temperatures. Therefore, is still of fundamental importance to find efficient and stable nontoxic alternatives to LHP. Another emerging element that belongs to the same group as Pb and Sn is germanium (Ge). However, an extensive understanding of the optical properties of this class of materials is still missing.

In this work, we present an in-depth investigation of the structure and the optical properties of $CsGeI_3$. We structurally characterized solution-processed $CsGeI_3$ powder using X-ray total scattering and computational methods. The photoluminescence of this sample at high excitation fluence (4 mJ/cm^2) and low temperature (200K) shows a sharp ASE peak in the NIR (815nm). Furthermore, we propose a one-step deposition method of $CsGeI_3$ perovskite thin film maintaining the same crystalline structure. This sample shows much better performances. At room temperature, the ASE peak appears at 748nm with a notably low threshold (75 μJ/cm^2), comparable to the well-studied and optimized LHPs. Our work represents the first report of ASE in a germanium-based perovskite, and the low threshold at room temperature makes this material a really interesting candidate for lasing application paving the way to a new class of lead-free perovskite gain material.

Distributed Feedback Lasers Based on Phase-Stabilized $CsPbI_3$ Thin Films

Naho Kurahashi[1,2], Manuel Runkel[1,2], Cedric Kreusel[1,2], Maximilian Schiffer[1,2], Timo Maschwitz[1,2], Timo Kraus[1,2], Kai O. Brinkmann[1,2], Ralf Heiderhoff[1,2], Maximilian Buchmüller[2,2], Sven O. Schumacher[2,2], Julius Brunner[3,4], Detlef Rogalla[5], Sercan Özen[6], Felix Lang[6], Yana Vaynzof[3,4], Patrick Görrn[2,2] and Thomas Riedl[1,2]; [1]Universität Wuppertal, Germany; [2]University of Wuppertal, Germany; [3]Technische Universität Dresden, Germany; [4]Leibniz-Institute for Solid State and Materials Research Dresden, Germany; [5]Ruhr-Universität Bochum, Germany; [6]University of Potsdam, Germany

All-inorganic cesium lead halide perovskites ($CsPbX_3$, X = I, Br, Cl) are gaining significant attention for their use in light-emitting diodes and lasers, owing to their enhanced thermal stability compared to organic-inorganic hybrid perovskites. While $CsPbBr_3$ has been extensively studied for stimulated emission and lasing[1], $CsPbI_3$ has not received the same level of attention despite its favorable optical properties, with a band gap of about 1.7 eV and emission in the red spectral region. The phase instability of $CsPbI_3$ causes it to assume a non-perovskite phase (yellow phase) at room temperature, which limits its practical application in devices.

In this presentation, we introduce the first distributed feedback (DFB) lasers utilizing $CsPbI_3$ thin films, featuring a resonator directly patterned into the perovskite. The additive polyvinylpyrrolidone (PVP) is employed to stabilize the $CsPbI_3$ thin film in the black phase at room temperature. Previously, we could show that various halide perovskites can be patterned by thermal nanoimprint [2,3]. Here, we use thermal nanoimprint to pattern second order DFB gratings directly into the perovskite active layer. The γ-$CsPbI_3$ phase stabilized by PVP remained stable during thermal nanoimprinting at temperatures up to 170°C. Our DFB lasers demonstrate a low lasing threshold of 45 μJ cm^{-2} at room temperature under picosecond pulse laser excitation, with tunable emission in the deep red spectral range from 714.1 nm to 723.4 nm[4]. Additionally, as a further laser application of our phase-stabilized $CsPbI_3$ thin films, vertical cavity surface emitting lasers (VCSELs) fabricated utilizing the versatility of thermal nanoimprinting in laser device fabrication and their laser characteristics will be presented.

We expect that our results will have significant implications for the development of future electrically driven perovskite lasers and light-emitting diodes (LEDs) that use $CsPbI_3$ as the active medium.

Energy Transfer in Mixed-Dimensional Perovskite Heterostructures Maya Chattoraj, Seryio Saris and William Tisdale; Massachusetts Institute of Technology, United States

Continued advancements in the synthesis and application of nanomaterials dictate the need for well-developed analysis frameworks that fully capture the fundamentals behind their interactions. Förster theory accurately describes the transfer of excitons between molecules. However, this framework has repeatedly failed to quantitatively predict energy transfer rates between semiconducting nanomaterials, particularly in heterostructure systems that combine nanomaterials of different composition and dimensionality. The shortcomings of Förster theory are exacerbated in the case of lead halide perovskites, offering an optimal platform for pushing past the limits of current energy transfer models. Here, we synthesize mixed-dimensional perovskite heterostructures and study energy transfer in these systems using time-resolved photoluminescence spectroscopy. We focus on heterostructures combining spheroidal $CsPbBr_3$ quantum dots and two- and three-dimensional hybrid organic-inorganic perovskite crystals, and aim to contribute to a deeper, quantitative understanding of energy transfer mechanisms in novel nanomaterials, which will inform the design of optoelectronic devices with nanomaterial interfaces.

EL01.05.15

Impact of the Interface Layer on the Performance of the $CsPbBr_3$ Perovskite-Based LED Devices Parvez Akhtar[1], Hsiao-Chun Hung[2], Henam Sylvia Devi[1], Yuh-Renn Wu[2] and Madhusudan Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]National Taiwan University, Taiwan

The all-inorganic perovskite material ($CsPbBr_3$) is a promising light-emitting material due to its high efficiency, solution processability, and cost-effectiveness. Among the various intrinsic issues in the perovskite thin film, such as low surface coverage, chemical instability, and ion migration, the interfacial layer also impacts the performance of optoelectronic devices. The well-established PEDOT:PSS hole injection layer (HIL)[1], despite its ease of solution processing, high conductivity, and transparency, poses significant challenges due to its highly acidic and hygroscopic nature. These characteristics can cause various instabilities in the perovskite thin film, such as the absorption of oxygen and moisture, leading to hydrolysis, oxidation, and the formation of hydrated complexes with the perovskite material, ultimately contributing to device failure. In this work, we have developed a non-acidic, inorganic, and high-green index vanadium pentaoxide (V_2O_5) as a HIL with low surface roughness and a deep work function compared to conventional HIL PEDOT:PSS[2]. Precursors cesium bromide (CsBr) and lead bromide ($PbBr_2$) (in DMSO) were heated under vigorous stirring and then combined with the blend of non-expensive PEG:PVP in DMSO and DMF in a 1:1 ratio to form an ink ($CsPbBr_3$:PEG:PVP (CPP)) [3]. X-ray diffraction (Rigaku, Cu-Kα 1.54Å) reveals an orthorhombic phase (PDF:96-153-3063) of CPP thin film and field emission scanning electron microscope (FESEM, JSM-7800F Prime, JEOL) image, demonstrating well-packed perovskite crystal grains (101 nm) with almost 100% surface coverage. An intense PL peak is observed at 520 nm with an FWHM of 16nm for CPP thin films (bandgap:2.38eV, CIE-1931 coordinates (0.081,0.762)), indicating a narrow, pure green emission. LED devices (PEDOT:PSS (control) vs. V_2O_5 (test)/CPP/TPBi/LiF/Al) were fabricated using a combination of spin coating and thermal evaporation at a pressure 2.3 x 10^{-6} Torr (Angstrom Engineering). Test devices show nearly identical maximum current efficiencies (4.23 vs. 4.19 cd/A) and luminous efficacies (2.99 vs. 2.32 lm/W) compared to a control device. The EL spectra of both control and test devices exhibit an identical peak wavelength (518.4 nm, FWHM:17 nm), closely matching the PL measurements. Additionally, the EL spectra show almost no variation in peak position with applied bias, indicating the color stability of the LED device under varying bias conditions. Time-resolved photoluminescence (TRPL, 377nm, FLSP92, Edinburgh Instruments) data reveals an increased radiative and decreased non-radiative component in the test sample compared to the control, suggesting a higher defect density at the PEDOT:PSS/$CsPbBr_3$ interface, likely due to trap generation from halide vacancies under moisture conditions induced by PEDOT:PSS. The control sample requires a drive current density three times higher than the test device's to achieve maximum brightness. Since most device failures and dark spot formations strongly depend on the drive current density. To further study the mechanism at the interface, we have developed a model based on a physical charge control, including defect-assisted tunneling for hole injection[4]. The model predicts a higher radiative recombination rate in the emissive layer, suggesting a passivation effect at the interface, possibly due to a greater concentration of dipoles radiatively connected to the ground state, leading to a Förster energy transfer mechanism. These findings indicate that solution-processed V_2O_5 provides better interfacial properties than PEDOT:PSS. In future studies, we will investigate how the interfacial layer impacts the operational stability of perovskite-based devices through lifetime measurements.

Stretchable Primary-Blue Color-Conversion Layer Enabled by *In Situ* Fabricated Perovskite Nanocrystals Embedded in an Organic Matrix Junsu Yeo, Eun-Ha Cho, Joo Yoon Woo, Joo Hyeong Han, Yong Min Park, Won Bin Im and Tae-Hee Han; Hanyang University, Korea (the Republic of)

While the use of red, green, and blue color-conversion layers (CCLs) with backlighting ultraviolet (UV) light-emitting diodes enhances display uniformity and streamlines the fabrication process in the display industry, research on blue CCLs is still insufficient, particularly in the primary-blue region. In order to accomplish the Rec.2020 color standard, primary-blue CCL is necessary to be further explored. This work reports a stretchable primary-blue CCL enabled by *in-situ* fabrication of perovskite nanocrystals (NCs). The films exhibit high-stretchability characteristics, emit primary-blue light (~460 nm), and maintain steady photoluminescence (PL) under UV irradiation. By introducing fluorinated arylammonium salts, controlled quantum confinement and dielectric confinement effects adjust the energy transfer among diverse perovskite phases. Perovskite NCs are embedded in an organic matrix composed of ammonium salts, which prevent degradation under mechanical stress. Additionally, we suggest a novel set of scientific guidance rules related to the crucial factors that influence the nucleation and crystallization kinetics of *in-situ* fabrication of perovskite NCs. Consequently, the stretchable blue CCL emits spectrally stable PL at primary-blue region (~460 nm) under high tensile strain (>200%) and prolonged UV irradiation.

EL01.05.17

***In Situ* Crystallized Nanocuboid Perovskite Light Emitters for High-luminance Light-emitting Devices** Jeong Wook Jang, Joo Yoon Woo, Cheong Beom Lee, Wan Dong Kim, Jong Ho Park, Dae Hwan Kim, Junsu Yeo, Min Gyo Kim, Sanghyun Nam, Su Hwan Lee, Young-Hoon Kim, Kyeounghak Kim and Tae-Hee Han; Hanyang University, Korea (the Republic of)

Metal halide perovskites (MHPs) have been regarded as highly promising light-emitting materials due to their excellent color purity, adjustable bandgap energy, and ability to be processed from solutions, making them suitable for cost-effective display technologies. However, solution-processed polycrystalline perovskite thin films possess numerous charged defects at the grain boundaries and surfaces. The charged defects create convenient pathways for ion migration, which hastens the deterioration of materials and devices during operation. In this work, we introduce a chemically designed novel in-situ fabrication strategy that forms highly luminous and stable nanocuboid-shaped perovskite crystals in polycrystalline thin films. The in-situ crystallization process is effectively controlled to achieve low defect density and nanosized cubic perovskite crystals by managing crystal growth termination during the formation of the perovskite thin film. The light-emitting diodes that use the *in-situ* fabricated perovskite nanocube thin films as an emitting layer exhibit high luminance (>100,000 cd/m^2), high luminous efficiencies at high luminance, and unparalleled operational stability compared with those of conventionally used MHP light emitter thin film.

Enhanced Electroluminescence and Operational Stability in Cu-Doped CsPbI$_3$-Based LEDs Shaona Bose, Baidyanath Roy, Satayender K. Sangwan, Sanjeev Kumar Srivastava and Samit K. Ray; Indian Institute of Technology Kharagpur, India

Perovskites have recently attained significant attention in the field of semiconductors due to their exceptional light absorbance and emission properties. The only challenge impeding the industrialization of perovskites is its ambient stability. Previously, we studied that doping transition metals like Cu can greatly enhance the structural stability of all-inorganic halide perovskites like CsPbI$_3$. In this study, we investigate whether the structurally more stable Cu-doped CsPbI$_3$ also exhibits improved electroluminescence (EL) properties. We observe a redshift in the peak photoluminescence wavelength on doping till a certain concentration, after which there is a blue shift. This trend is reflected in the EL of light emitting diodes (LEDs) fabricated using the doped perovskites. Notably, 3.7% Cu-doped CsPbI$_3$ shows highest EL counts attributed to the maximum lowering of LED threshold voltage to 2.5 V, along with more than double the enhancement in operational stability of the LED. Actually, the work function increases on doping, supported by Density Functional Theory calculations, leading to increased hole current density and hence more balanced carrier recombination as compared to that in undoped CsPbI$_3$-based LEDs. By constructing single carrier devices under the same fabrication conditions as for the perovskite LEDs, we find that the carrier trap density decreases on doping, which leads to greater charge injection, and hence, much higher EL in the Cu-doped CsPbI$_3$-based LEDs.

EL01.05.19

Influence of Cu Dopant Ions on the Ultrafast Carrier Dynamics and Photodetector Performance of 2D CdS NPLs Anusri Medda[1] and Amitava Patra[1,2]; [1]Indian Association for the Cultivation of Science, India; [2]Institute of Nano Science and Technology, India

Semiconductors from the II-VI groups, notably CdS, have garnered significant research interest due to their excellent optical properties, direct band gaps, and environmental stability.[1, 2] These attributes make them ideal for several optoelectronic applications.[3] In this study, we selected CdS nanoplatelets (NPLs) as the active layer in our fabricated photodetectors. The choice was driven by the unique extrinsic properties of 2D NPLs,[4] which make them highly suitable for photodetector applications.[5] Additionally, the optical bands of semiconductors can be fine-tuned by introducing dopant energy levels into their band gaps.[6] We incorporated copper ions into CdS NPLs to significantly enhance the efficiency of the resulting photodetectors. Our Cu-doped CdS NPLs display a cubic CdS phase and a rectangular shape, as revealed by X-ray diffraction study and transmission electron microscopy.

Elemental energy dispersive spectroscopy mapping shows ~7% Cu ion content in the doped NPLs.[7] Additionally, X-ray photoelectron spectroscopy confirms the presence of Cu 2p peaks in the doped CdS NPLs.[8] The absorption spectrum of Cu-doped CdS NPLs shows sharp absorption features at 437 and 430 nm, corresponding to the heavy hole and light hole excitonic transitions, consistent with 5.5 monolayers of CdS NPLs.[9] The spectrum broadens slightly in the lower energy sub-bandgap region due to the $ML_{CB}CT$ (sub-band-gap copper metal to conduction band charge transfer) excitonic transition from the Cu d-state to the CdS conduction band. Photoluminescence reveals a broad dopant emission at ~685 nm with a large Stokes shift of ~1 eV and a minor peak at ~441 nm due to band edge emission. The dopant emission results from electron recombination from the conduction band with holes in the Cu d-levels near the CdS valence band, with a PL decay time of ~1.45 μs. The longer decay time is attributed to the weak spatial overlap between the conduction band wave functions of CdS and localized Cu d-states. Transient absorption spectroscopy reveals reduced trapping of photogenerated electrons in shallow trap states and enhanced non-radiative trapping in deep trap states after incorporating dopant ions in CdS NPLs. This results in slower overall recovery kinetics, indicating greater charge carrier separation in Cu-doped CdS NPLs. Photodetectors based on Cu-doped CdS NPLs exhibit fast rise and decay times of ~120 ms and ~150 ms, respectively, with a photoresponsivity of 16.5 mA/W, indicating better stability. The maximum detectivity achieved is ~4.1×10^{13} Jones. The high responsivity and detectivity are attributed to the broad absorption tail and delocalization of charge carriers in mid-gap Cu d-states, reducing defect states and enhancing photodetection performance. These findings suggest that Cu-doped CdS NPLs could be an efficient active photodetector material.

Pumping Molecular Quantum Emitters with GaN-based LEDs for Optoelectronic Devices

Gunilla W. Harm, Peer Kasten, Uta Schlickum and Tobias Voss; Braunschweig University of Technology, Germany

Scaling light-emitting devices (LEDs) down below the micrometer range enables new strategies to develop devices for quantum technologies. By combining molecular quantum emitters with micro- or nano-LEDs, the possibilities in this field can be exploited even further, since isolated molecules are promising candidates for single photon sources due to their high photostability and low multiphoton contribution. Integrating single-photon sources into quantum technologies remains still a complex challenge, requiring an electronic system for triggering the on-demand emission. Here, we demonstrate the integration of molecular quantum emitters with GaN-based LEDs. For this application, phthalocyanine molecules stand out with high chemical and thermal stability, as well as the ability to adjust their optical properties through chemical functionalization. However, improving the emission efficiency in the crystalline phase is still challenging, since fluorescence quenching through excitonic coupling becomes more prominent. To address this issue, we study the emission characteristics of Zinc Phthalocyanine

(ZnPc) thin films, nanoscale molecular clusters and isolated molecular quantum emitters, grown by organic molecular beam epitaxy. In order to reduce the excitonic coupling between the ZnPc molecules, we embedded them into a co-evaporated matrix formed by the alkane tetratetracontane (TTC). Using this approach, we could separate the molecules from each other, which improves the emission intensity and enables an efficient use of the molecular quantum emitters in future devices. For the measurement of the photoluminescence, we used a commercial GaN-based LED in addition to a laser diode to demonstrate efficient excitation in the ultraviolet spectral range. Our results demonstrate optical pumping of the molecular photon emission with the LED, paving the way for controlled integration of molecular quantum emitters in optoelectronic devices.

EL01.05.21

Elastic Relaxation of Coherent InGaN/GaN Interfaces at the Microwire LED Sidewall Jongil Kim[1], Jinwook Yeo[2], Bumsu Park[3], Jeehun Jeong[1], Seunghwa Ryu[2] and Sang Ho Oh[1]; [1]Korea Institute of Energy Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Centre National de la Recherche Scientifique, France

Elastic relaxation of the misfit strain via traction-free surface results in a complex three-dimensional strain distribution and morphological modification at the boundary of epitaxial heterostructure. While this phenomenon has been extensively studied for various epitaxial heterostructures, the influence of the interface lattice coherency constraining the strain relaxation has received little attention. Here we show that the inter facial shear stresses arise towards the traction free sidewall while the two complementary strained InGaN and GaN layers in a submicron wire light emitting diode are relaxed to revert their bulk lattice parameters in the near-surface region. The alternating shear stresses with opposite signs achieve mechanical equilibrium by counterbalancing the change in the sign of the in-plane strain in each layer of the near-surface region. A unique nonmonotonic modulation of both normal and shear strain has been detected unambiguously in the experimental strain maps and further corroborated by finite element modeling. An analytical model was developed based on the Airy stress function, which incorporates the superposition of alternating in-plane prestress and the image stress to satisfy the boundary condition at traction-free sidewall. The strain distribution identified in this study is likely prevalent in various nanostructured epitaxial heterostructures with substantial free surface portions, underscoring its importance in accurately understanding surface strain distribution.

EL01.05.22

Direct X-Ray Detectors Based on an Organic Zinc Bromide Hybrid Oluwadara J. Olasupo[1], Thanh-Hai Le[2], Tunde B. Shonde[1], He Liu[1], Alexander Bouchard[1], Sara Bouchard[1], Thilina Gamaralalage[1], Abiodun M. Adewolu[1], Tarannuma F. Manny[1], Xinsong Lin[1], Yan-Yan Hu[1], Wanyi Nie[3] and Biwu Ma[1]; [1]Florida State University, United States; [2]Los Alamos National Laboratory, United States; [3]University at Buffalo, The State University of New York, United States

Direct X-ray detectors, which convert X-ray radiation to electrical charge and then digital images, are used in various areas, including medical diagnostics, security screening, and industrial inspection. The most commonly used materials for the fabrication of direct X-ray detectors are inorganic semiconductors, such as silicon and selenium, which often suffer from limitations in performance, versatility, and cost-effectiveness. Searching for new-generation materials for direct X-ray detectors has been continually pursued to address these issues, among which metal halide perovskites have recently received great attention for their efficient X-ray absorption, high carrier transport properties, as well as facile synthesis. However, the lead toxicity, environmental instability, and high dark current due to ion migration have limited the potential of perovskite-based direct X-ray detectors for real-life applications. Zero-dimensional (0D) organic metal halide hybrids (OMHHs), containing metal halide polyhedral anions fully isolated and surrounded by organic cations, exhibit significantly better stability and lower current drift as compared to conventional metal halide perovskites. In this talk, I will introduce our recent efforts in the development of direct X-ray detectors based on 0D OMHHs. More specifically, I will discuss the use of a semiconducting 0D OMHH, $(TPA\text{-}P)_2ZnBr_4$, for the fabrication of highly sensitive and stable direct X-ray detectors. With molecular sensitization, wherein metal halide species ($ZnBr_4^{2-}$) act as X-ray absorber and organic semiconducting components ($TPA\text{-}P^+$, 4-(4-(diphenylamino)phenyl)-1-propylpyridin-1-ium) as charge transporters, 0D $(TPA\text{-}P)_2ZnBr_4$-based X-ray detectors are found to exhibit an impressive sensitivity of 1,984 $\mu C\ Gy_{air}^{-1}cm^{-2}$ at 20 V reverse bias and a low detection limit of 0.88 $\mu Gy_{air}s^{-1}$. Electronic characterizations have revealed a low trap density of $3.84x10^9$ cm^{-3} and a high mobility lifetime product of $5.67x10^{-4}cm^2.V^{-1}$ at 20 V for solution-grown 0D $(TPA\text{-}P)_2ZnBr_4$ single crystals. The high resistivity of 5.05×10^{10} Ω.cm of 0D $(TPA\text{-}P)_2ZnBr_4$ plays a crucial role in realizing a very low and stable dark current of around 13.4 pA under 24 hours of operation. The combination of low-cost facile preparation, high detection sensitivity, low detection limit, and superior stability make semiconducting 0D OMHHs highly promising active materials for direct X-ray detectors.

EL01.05.23

Photon Thermalization and Condensation in a Quantum Well Open Microcavity Ross Schofield[1], Ming Fu[1], Himadri S. Dhar[1], Rick Mukherjee[1], Ian Farrer[2], Edmund Clark[2], Jon Heffernan[2], Florian Mintert[1], Robert Nyman[1] and Rupert F. Oulton[1]; [1]Imperial College London, United Kingdom; [2]The University of Sheffield, United Kingdom

The thermalization of light and its ground state condensation has been extensively explored in recent years [1], with the link between laser action and Bose Einstein condensation of a thermalized photon gas in an open microcavity [2, 3] opening new ways to understand laser system. In this talk we report thermalization and condensation of light in a semiconductor quantum well weakly coupled to an open microcavity system [4]. This system consists of half a vertical external cavity surface emitting laser, constructed on GaAs with an InGaAs quantum well emitting near 925 nm, with a piezo controlled external spherical dielectric mirror positioned to achieve low cavity mode orders with well-defined transverse modes. We present evidence of cavity photon thermalization and since we have used a single quantum well with minimized absorption, , to match the cavity loss, , we explore the influence of thermalization coefficient, . This level of control allows us to compare our data to recent theory on photon condensation in semiconductor systems [5]. In the condensation regime, we identify a region of ground state mode stability with good thermalization . Meanwhile regions of poor thermalization , and at high operation power, show multi-mode or higher order spatial mode lasing, which is consistent with the theory of dye-based condensates [6, 7]. We also assess the strength of photon-photon interactions and find a normalized interaction parameter, . Since this value increases with quantum well number, this system is promising for the possibility of observing rich interaction physics.

Seaweed-Derived Carbon Dots for Green Energy Applications Deirdre A. McAdams, Leah Hourigan, Karlijn Hertsig, Annie Regan, Eleanor Cripwell, Sivagami Prabu and Peter W. Dunne; Trinity College Dublin, The University of Dublin, Ireland

Colloidal carbon dots (**CDs**) are considered a new and green 0-dimensional nanomaterial and an environmentally friendly alternative to quantum dots. Their luminescence and unique photophysical behaviours allow for a wide range of uses across sensing, optics, bioimaging, and energy generation technologies. **CDs** possess many attractive properties, such as tuneable photoluminescence, low toxicity and good biocompatibility.[1,2] This research highlights the valorisation of seaweed as a biomass for the production of **CDs**, while practicing green synthetic methodologies *via* hydrothermal synthesis routes.

Seaweeds were chosen as the biomass precursor to **CDs** due to their abundance, high growth rates and greater production yields when compared to terrestrial crops. Furthermore, they possess high concentrations of polysaccharides (*ca*. 40% dried mass) which act as suitable precursors to **CDs**.[3] In this study, Kelp and Irish moss seaweeds, and their components: glucose, galactose, alginic acid and *K*-carrageenan were assessed for the generation of **CDs** under mild hydrothermal conditions.

Synthetic procedures to **CDs** were optimised by varying conditions of precursor concentration, temperature and time. The "as-prepared" dots were assessed by detailed structural and photophysical characterisation methods and were subject to multiple purification techniques including syringe filtration, organic extraction techniques, precipitation methods, dialysis and column chromatography to yield blue emissive **CDs**. Photophysical analysis by UV-vis and fluorescence emission spectroscopies were performed which investigated the suitability of **CDs** as sensitisers for solar cells. Structural characterisation by DLS, XRD, IR, Raman and TEM were also performed and were fundamental to understanding the potential for **CDs** in technological applications, such as for incorporation into photovoltaic devices. This research ultimately aims to assess the viability of Irish seaweeds as precursors to added value products of functional carbon based nanomaterials.

Nature-Inspired Halide Perovskite Breath Figures—Unleashing Enhanced Light-Matter Interaction Prakash Sarkar[1,2], Tamaghna Maitra[1,2], Mozzakar Hosain[1,2], N. K. Murugasenapathi[3,4], Manohar Chirumamilla[5,6], Tamilarasan Palanisamy[3,4] and K. D. M. Rao[1,2]; [1]Indian Association for the Cultivation of Science, India; [2]Technical Research Centre, Indian Association for the Cultivation of Science (IACS), India; [3]CSIR-Central Electrochemical Research Institute, India; [4]Academy of Scientific and Innovative Research (AcSIR), India; [5]Aalborg University, Denmark; [6]Hamburg University of Technology, Germany

Halide perovskites offer a transformative potential for optoelectronics through tailoring the light-matter interactions at the nanoscale. However, their susceptibility to environmental factors and limited compatibility with standard lithography techniques present significant challenges in precise nanopatterning. This work unveils a nature-inspired breath figures (BFs) approach to pattern halide perovskites and enhancing their optoelectronic performance. The fabrication of BFs based on BiI_3 allows for changes in nanopore size (ranging from 247 to 423 nm) and their distribution. Subsequently, these BiI_3 BFs are transformed into hybrid halide $MA_3Bi_2I_9$ BFs using a vapor-assisted technique while retaining the nanoporous topology of the BiI_3 structure. The resultant $MA_3Bi_2I_9$ BFs show significantly enhanced light absorption compared to conventional thin films, attributed to the increased extinction and lower refractive index. The optoelectronic performance of the $MA_3Bi_2I_9$ BFs is showcased by constructing a photodetector, which exhibits three orders of magnitude higher responsivity and detectivity, up to 1 A/W and 1.3×10^{12} Jones, respectively, outperforming the photodetectors based on solution-processed $A_3B_2I_9$

halide perovskite thin films. The BFs method provides flexibility in tuning nanoscale morphology, showcasing its potential in advancing lead-free optoelectronics and paving the way for next-generation optoelectronic devices.

Crosslinking-Assisted Indirect Photopatterning of Quantum Dots Hyeokjun Kim[1], Hyobin Ham[2], Chang Hyeok Lim[1], BongSoo Kim[2] and Moon Sung Kang[1]; [1]Sogang University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Micrometer-scale patterns of quantum dots (QDs) with exceptional fidelity are formed using crosslinking-assisted, photoresist-guided indirect (PIN) photopatterning without compromising their luminescence characteristics. The method employs a crosslinker which is activated at low temperatures below 130 °C. Thanks to the sufficiently low processing temperature, the luminous properties of QDs (including their photoluminescence and electroluminescence characteristics) are preserved and the QD films are crosslinked without affecting the underlying photoresist pre-patterns which serve as structural guides in during QD pattern formation. By using PIN photopatterning, we form high-fidelity RGB QD patterns with pixel densities exceeding 4000 pixels per inch. The compatibility of PIN photopatterning with the apparatus used in the display industry signifies its application potential.

Super Bright Yellow Emissive InP/ZnSe/ZnS Core Shell Quantum Dot's Self Assembled Flower Like Nanostructure Barnali Mahato, Palash K. Das and Asha Bhardwaj; Indian Institute of Science, India

For the past two decades, indium phosphide (InP) colloidal quantum dots (QDs) have drawn a lot of interest as a potential non-toxic substitute for cadmium-based QDs[1-3].However, in spite of several studies focused on improvement of optical and structural properties of InP based QDs which emits in blue/green regions, yellow emitting InP based QDs are not much explored due to lack of suitable precursor for growth of large size InP QDs and their core shell heterostructure engineering.Yellow emissive colloidal semiconductor QDs are essential optoelectronic components that can facilitate solid-state lighting as colour-converting material, yellow LED, visible light communications, phototherapy and optogenetics. Therefore, efforts must be focused on enhancing the optical, physical, and structural characteristics of InP-based QDs that emit in yellow region.Also the InP QD based self assembly and their superstructures are not at all investigated. Self assembly of nanoparticles into nanocluster/aggregation represents a class of hybrid nanostructure which posses novel functionalities due to coupling phenomena which leads to an improvement in the functionalities or a blend of several functionalities. Controlling the assembly of nanoparticles is crucial for many technological applications. It allows for the combination of intrinsic features and the exploitation of their complex interplay, resulting in collective properties. Hence it is emerging as a very important field of study to focus on.
In this study one pot colloidal synthesis of highly emitting, nearly monodispersed, non-toxic, highly stable colloidal InP/ZnSe/ZnS core shell QDs are reported. Further, as synthesized QDs and their self-assembled flower like highly crystalline 3D nanostructures are reported and investigated.Selection of suitable ligand and Limited Ligand Protection (LLP) growth [4-6] plays the key role for evolution of nanoflower morphology and hence eliminating the need of template for the self assembly.The synthesized large sized core shell QDs exhibit bright yellow emission (570 nm) with very high absolute photoluminescence Quantum Yield (PLQY) of 87 % which is the highest reported to date in yellow emitting InP based QDs [7-8]. The reason behind this high PLQY and self-assembled flower like

morphology has been investigated in detail. The heavy metal free highly emitting InP based QD's size and composition tunability and their ability of forming self assembled superstructures may be highly beneficial for development of new solution-processable building blocks for QD based superstructures with superior and well controlled physical, optical and chemical properties.

Influence of Core Localization on the Electron Dynamics of CdSe/CdS Dot-in-Rod Heterostructures Jonathan Cotrino Lemus[1], Lucas Bezerra de Almeida Melo[1], Diogo B. Almeida[1], Gui M. Kim[2], Yujin Kim[2], Dahin Kim[3], Wan Ki Bae[4], Doh Chang Lee[2] and Lazaro Padilha[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]University of Seoul, Korea (the Republic of); [4]Sungkyunkwan University, Korea (the Republic of)

Nanoscale semiconductor heterostructures are solid states platforms where a variety of potential physical phenomena converge. These endows them with unique optical and electron properties of interest for both fundamental and applied fields of science. Some examples are high photoluminescence quantum yield, QY, high nonlinear optical responses, and control over exciton dynamics, among other. All of these being controllable by the nanostructure size (due to quantum confinement effects), composition and shape. Among the large family of heterostructures, the CdSe/CdS dot-in-rods (DinRs), a CdS rod-shaped shell seeded by a CdSe quantum dot, have attracted great attention, given their mixed dimensionality (0D core and quase-1D shell). In DinRs the CdS shell highly enhances the absorption cross sections, through which charge carriers diffuse until they reach the core region, where emission occurs. This is an effect of the band alignment, which can be of type-I or quasi-type-II, depending on the relative core and shell diameters (according to the CdSe and CdS exciton Bohr radii). Even though some properties of DinRs are well-understood, a deeper understanding of the influence of core localization on the exciton dynamics is still missing. The main reason is that only in the last years it was possible to implement control over the core position on the synthesizes process . Here, we present a study of the effect of core localization on the intraband dynamics, electron-phonon interactions, and multi-exciton dynamics of DinRs with different band alignments, and core localization (core is put at the center, at the edge, and at positions in between). The results show that single-exciton, biexciton and negative trion decay dynamics are slowed down as the core is moved away from the center for all samples except for the case of weak confinement regime, where there is an inversion of the dependence, i. e. multi-exciton recombination is speeded up as the core is moved from the center. Indicating complex exciton dynamics in DinRs. Using a multi-dimensional coherent spectroscopy setup, we also investigate the influence of the core localization on the exciton-phonon interaction, and how this influences the homogeneous linewidth and the zero-phonon line in DinRs.

Whispering Gallery Mode Lasing from Micro-Neck Structure Fiber Filled with CdZnSe/CdS Quantum Dots

Palash K. Das, Barnali Mahato and Asha Bhardwaj; Indian Institute of Science, India

One common effect in semiconductor quantum dots (QDs) is high Auger recombination rate, which is harmful to many of its applications, including lasing. Here, the potential surface is smoothed to promote alloy formation at the core-shell interface, thereby reducing the auger recombination rate of CdZnSe /CdS QDs. In addition to reduced Auger recombination rate, the synthesized CdZnSe/CdS QDs exhibit o a large Stoke's shift eliminating the problem of reabsorption. In order to achieve plasmonic-assisted absorption enhancement and support overall emission enhancement, AgNPs are selected so that their absorption profile overlaps with CdZnSe /CdS QDs. Conversely, Whispering gallery mode (WGM) resonators provide remarkable optical amplification due to their high Q-factor and low optical losses. While the use of pulsed lasers facilitates lasing, optoelectronic device integration has proven to be more challenging. Despite being a good substitute, CW lasers are not practical because of their low instantaneous power density. Here, a micro-neck fiber structure made of Ag NP-PVA composite and the QDs has been used to realize effective WGM lasing with CW excitation using CdZnSe/CdS colloidal quantum dots. Quality factor as high as 2026 has been achieved. Decrease in quality factor and increase in lasing threshold, with decrease in the diameter of the microneck structure has also been observed.

Near Infrared Photoluminescence from Nonthermal Plasma Synthesized SiGe Quantum Dots Induced by Heterostructuring with Hybrid Perovskite

Yeonjoo Lee[1,2], Doyun Kim[3], Mircea Cotlet[4], Benjamin Derby[1], John Watt[1], Wanyi Nie[5], Eric Bowes[1], Uwe R. Kortshagen[2] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]University of Minnesota, United States; [3]North Carolina State University, United States; [4]Brookhaven National Laboratory, United States; [5]University at Buffalo, The State University of New York, United States

Colloidal and luminescent quantum dots (QDs) have advantages in the fabrication of optoelectronic devices because they can serve as inks allowing for the printing devices in the form of thin films. Among materials for the production of QDs, silicon (Si) QDs are attractive due to Si's earth abundance, low toxicity and size-tunable emissions in the visible to near infrared (NIR) spectral range. Alloying germanium (Ge) offers the expansion of emission range of Si QDs through bandgap engineering. The luminescence of Si QDs is limited to < 1000 nm due to the band gap of bulk Si (1.12 eV), which confines their application in the visible range. Ge has a narrower band gap (0.6 eV), and complete miscibility with Si. Therefore, Si and Ge alloy QDs (SiGe QDs) can emit in longer wavelengths compared to pure Si QDs. We demonstrated the synthesis of colloidal SiGe QDs using a nonthermal plasma method. The nonthermal plasma synthesized SiGe QDs were able to form a colloid with benzonitrile without any post-processing for surface functionalization due to their chlorine terminated surfaces. X-ray diffraction and energy-dispersive X-ray spectroscopy verified that the SiGe QDs are spherical and crystalline, and the Ge composition is ~16%. Although NIR PL (> 1000 nm) was expected, the photoluminescence (PL) of SiGe QDs was not detectable. Heterostructuring with hybrid perovskite ($CsPbBr_3$) was chosen to improve the PL of SiGe QDs; energy or charge transfer from perovskite to SiGe QDs was expected considering the band structure of the materials. Heterostructuring was conducted by spin-coating perovskite and SiGe QD thin films. The sandwich-like structure (perovskite-SiGe QDs-perovskite) was confirmed by cross-sectional transmission electron microscopy. The perovskite PL (at ~520 nm) quenching and the SiGe QD PL (at ~1040 nm) rise were observed in the heterostructure. The PL lifetime of perovskite was also significantly reduced by heterostructuring. Transient absorption spectroscopy (TAS) showed changes in photoinduced absorption in perovskite under the presence of SiGe QDs. The changes in both radiative and nonradiative processes indicate that excited perovskite provided energy or charge to SiGe QDs resulting in PL rise in NIR region.

EL01.05.31

Heavy Metal Free Quantum Dot Inks for Near to Mid-Wave Infrared Detection Shlok Joseph Paul[1], Letian Li[1], Se Young Park[2], Thomas Kwye[1] and Ayaskanta Sahu[1]; [1]New York University, United States; [2]Sogang University, Korea (the Republic of)

High fabrication costs resulting from the complex processes of high-temperature epitaxy and hybridization have traditionally restricted the use of infrared cameras to military and defense applications (1). However, in the past decade, researchers have been investigating low-cost alternatives using colloidal quantum dots (cQD) to facilitate the adoption of these devices in the commercial detector market. Historically, this field has relied on toxic heavy metal compounds like mercury (Hg) and lead (Pb), which are now facing stricter regulations in consumer electronics across different regions (2,3).

In our study, we introduce a novel approach, utilizing Silver Selenide (Ag_2Se), a material composed of RoHS-compliant elements that are readily available for commercial applications. Our innovation lies in the development of a near-infrared photoconductive (<1600 nm) cQD ink using a variety of different ligands, now common amongst the Pb and Hg inks but not previously documented for Ag_2Se. A framework to extend these dots into the mid-wave via an intraband transition will be presented (4,5). Additionally we explore recent developments in Silver Telluride (Ag_2Te) by extending our approach to this material as well (6).

Lastly, we will highlight some preliminary work on integrating mesoporous transport layers and infrared transparent metal contacts with these cQD detectors to enhance light absorption and improve detector performance.

EL01.05.32

Large-Scale Black Phosphorus Ink Films for Multiplex Mid-Infrared Optoelectronics Naoki Higashitarumizu[1,2,3] and Ali Javey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]JST, PRESTO, Japan

Black phosphorus (bP) based ink with a bulk bandgap of 0.33 eV (λ = 3.7 μm) has recently been shown to be

promising for large-area, high-performance mid-wave infrared (MWIR) optoelectronics. However, the development of multicolor bP inks expanding across the MWIR wavelength range has been challenging. Here we demonstrate a multicolor ink process based on bP with spectral emission tuned from 0.28 eV (λ = 4.4 μm) to 0.8 eV (λ = 1.5 μm). Specifically, through the reduction of bP particle size distribution (i.e., lateral dimension and thickness), the optical bandgap systematically blueshifts, reaching up to 0.8 eV. Conversely, alloying bP with arsenic ($bP_{1-x}As_x$) induces a redshift in the bandgap to 0.28 eV. The ink-processed films are passivated with an infrared-transparent epoxy for stable infrared emission in ambient air. Utilizing these multicolor bP-based inks as a MWIR phosphor, a gas sensing system is demonstrated that selectively detects gases, such as CO_2 and CH_4 whose absorption band varies around 4.3 and 3.3 μm, respectively. The presented ink formulation sets the stage for the advancement of multiplex MWIR optoelectronics, including spectrometers and spectral imaging using a low-cost material processing platform.

Achieving Near Unity Photoluminescence Quantum Yield and High Stretchability in TADF Polymers with Small Molecule Plasticizer Blending

Glingna Wang[1], Wei Liu[1,2], Cheng Zhang[1], Zhiming Zhang[1] and Sihong Wang[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

Stretchable light-emitting polymers serve as key components for skin-like displays and optical bio-stimulations. In the development, it is crucial to enhance both luminescence efficiency and mechanical stretchability. While "first-generation" organic emitters can only harness singlet excitons with a theoretical quantum yield of 25%, "third-generation" organic emitters can harness triplet excitons through thermally activated delayed fluorescence (TADF), achieving a theoretical near-unity photoluminescence quantum yield (PLQY). However, in polymer systems, it remains challenging to achieve near-unity PLQY, while stretchability is lacking in most of the reported TADF polymers. In this talk, we will present a method of blending small molecule plasticizers into TADF polymers to both enhance luminescence efficiency and increase stretchability. For the luminescence property, this method gives universal enhancement of PLQY of all tested TADF polymers by as high as 165%, thereby achieving near-unity photoluminescence quantum yield (PLQY) of 98.7%. For mechanical properties, stretchability up to 150% strain can be obtained. Demonstrated in organic light-emitting diodes (OLEDs), the TADF-plasticizer system underscores the potential to improve both the optical and mechanical properties of TADF-based stretchable devices, paving the way for highly efficient, bright, and mechanically robust stretchable optoelectronics.

EL01.05.34

Direct Photopatterning of Heavy-Metal-Free Colloidal Quantum Dot for Multispectral Infrared Photodetector

Se Young Park[1,2], Shlok Joseph Paul[2], Moon Sung Kang[1] and Ayaskanta Sahu[2]; [1]Sogang University, Korea (the Republic of); [2]New York University, United States

Colloidal quantum dots have been extensively explored in recent decades as alternatives to epitaxial semiconductors across various applications such as spectrometers, phototransistors, focal plane array imagers, lasers, light-emitting diodes, and photovoltaics. Their unique characteristics include size-adjustable optical properties and potential for low-cost, large-area fabrication. These attributes make quantum dots highly suitable for infrared applications, particularly in advancing high-resolution multispectral infrared imaging devices, which remain technologically demanding. In this study, we demonstrate a multispectral infrared photodetector through direct photopatterning of different types of quantum dot pixels. By UV-induced ligand crosslinking via selective

illumination through a photomask, multispectral quantum dot pixels can be constructed, enabling facile photodetection of near-infrared and short-wave infrared wavelengths. Additionally, to meet environmental standards, silver-chalcogenide quantum dots in the near-infrared and short-wave infrared ranges are introduced to fabricate a high-resolution multispectral photodetector.

EL01.05.35

Efficient InAs Nanorod Colloidal Quantum Dot Deep-SWIR Absorbers and Emitters Tariq Sheikh and Osman M. Bakr; King Abdullah University of Science and Technology, Saudi Arabia

InAs colloidal quantum dots (CQDs) have emerged as promising lead- and mercury-free semiconductors for shortwave infrared (SWIR) technology due to their appropriate bulk bandgap tunable via quantum confinement and favorable charge-carrier transport properties. However, their application has been constrained by the scarcity of suitable arsenic precursors and the challenging synthesis conditions, limiting their bandgaps to <1400 nm in the near-infrared range. Conventional InAs CQD synthesis relies on highly reactive, hazardous arsenic precursors, complicating their controlled production and study. To address these limitations, we developed a novel synthesis strategy using readily available and less reactive precursors. This approach enabled the controlled growth of monodisperse InAs nanorod CQDs with tunable bandgaps up to ~1800 nm, significantly extending their absorption capability into the SWIR region. Through surface engineering, we enhanced the photoluminescence quantum yield (PLQY) of these SWIR-active InAs nanorod CQDs to as high as 60%. This marks the first efficient SWIR light emission from InAs CQDs. Moreover. utilizing these surface engineered InAs nanorod CQDs we demonstrated highly efficient SWIR-active photodetectors. Our work represents a significant advancement, expanding the potential applications of InAs CQDs across a broad spectrum of SWIR technologies.

EL01.05.36

Ligand Length Effects on the Structural and Optical Properties of 2D Perovskites Martin Gomez-Dominguez[1], Carlo Andrea Riccardo Perini[1], Carlos Silva[1], Ajay Ram S. Kandada[2] and Juan-Pablo Correa-Baena[1,1]; [1]Georgia Institute of Technology, United States; [2]Wake Forest University, United States

Two-dimensional (2D) perovskites, organic-inorganic heterostructures with confined excitons are ideal for light-emitting applications due to their high oscillator strengths, tunable emission bandwidths, and low non-radiative recombination rates. The valence and conduction band edges, primarily governed by orbital hybridization in the metal halide cage, allow significant band structure tuning by changing the composition of halides and metals. However, introducing mixed halides can cause undesired phase segregation and substituting lead with tin leads to stability issues. An alternative method to tune the bandgap is by using cations of different lengths. Although the organic cation does not significantly affect the electronic band structure, varying the ligand lengths rearranges the crystal structure, inducing tilting in the metal halide octahedra and altering lattice dynamics. Despite being widely used to control the electronic properties of 2D perovskites, the effects of these modifications are not fully understood.

In this study, we explore changes in the interplanar distance in 2D perovskites by synthesizing 2D perovskites with three different chain length phenylalkylammonium cations, ranging from one carbon chain Phenylmethylammonium to three carbon Phenylpropylammonium. We track the subtle changes in the crystallographic structure using x-ray diffraction and grazing incident wide angle x-ray scattering (GIWAXS) and correlate it with the excited state dynamics using transient absorption spectroscopy. Furthermore, we investigate the polaronic effects of these structural modifications using resonant impulsive stimulated Raman spectroscopy (RISRS). By directly probing the phonon dynamics and crystallographic structure as the interplanar distances change, we gain insights into the interplay between changes in excitonic transitions caused by crystallographic distortions and modifications to the phonon environment induced by the longer ligands.

EL01.05.37

Type-(I+II) Colloidal Quantum Dots for Liquid- and Solid-State Semiconductor Lasers Donghyo Hahm[1], Valerio Pinchetti[1], Clément Livache[1], Namyoung Ahn[1], Jungchul Noh[1], Changjo Kim[1], Tung H. Dang[1], Xueyang Li[2], Jun Du[2], Kaifeng Wu[2] and Victor I. Klimov[1]; [1]Los Alamos National Laboratory, United States; [2]Chinese Academy of Sciences, China

Due to their tunable emission wavelengths, high emission quantum yields, and low optical gain thresholds, colloidal quantum dots (QDs) are attractive materials for applications in laser technologies. However, the development of technologically viable QD lasing devices has been hindered by nonradiative Auger recombination, leading to rapid optical gain relaxation on 10s-to-100s ps time scales. Short optical gain lifetimes pose an especially serious problem in the case of dilute optical-gain media such as QD solutions or QD/glass (polymer) composites. Fast optical gain decay also complicates the realization of lasing with continuous wave (*cw*) optical pumping or electrical injection.

To address the ‘Auger recombination challenge’, we develop type-(I+II) QDs using which we implement a novel gain mechanism which relies on stimulated emission from hybrid biexcitons composed of a direct and an indirect exciton. Due to the reduced number of recombination pathways, the hybrid biexciton exhibits slow trion-like relaxation dynamics. As a result, the type-(I+II) QDs exhibit extended optical gain lifetimes of several nanoseconds, due to which a critical QD concentration needed for lasing is reduced to levels accessible with QD solutions. When integrated into a Littrow optical cavity, 'static' (non-circulated) solutions of type-(I+II) QDs exhibit narrow-line (<0.4 meV) lasing, tunable from 634 nm (red) to 590 nm (orange-yellow), which covers the lasing windows of two popular laser dyes, Rhodamine B and Rhodamine 101.

Type-(I+II) QDs also provide a distinct advantage in the case of *cw* lasing. Single excitons generated in these QDs occupy the long-lived indirect state which simplifies reaching the optical gain threshold (the regime where all QDs in the sample contain single excitons) with *cw* pumping. This further helps maintain the QDs in the ‘pre-lasing’, optical-transparency state. The resulting effect is a considerable reduction of the lasing threshold compared to standard type-I QDs with all-direct biexcitons. Importantly, this does not lead to the reduction of the gain coefficient (which would have happened in type-II QDs with all-indirect biexcitons) as stimulation emission of the hybrid direct/indirect biexciton occurs preferentially *via* the direct transition. Indeed, solid-state films of type-(I+II) QDs integrated with a distributed feedback (DFB) cavity, readily exhibit narrow-line (<0.8 meV) *cw* lasing with a threshold of only 560 W cm^{-2}.

The reported studies point towards a considerable potential of the novel type-(I+II) QDs as optical gain media for technologically viable liquid- and solid-state QD lasers.

This work was supported by the Laboratory Directed Research and Development (LDRD) program at Los Alamos National Laboratory under project 20230352ER. V.P. and N.A. acknowledge support by a LANL Director’s Postdoctoral Fellowship.

EL01.05.38

Facile and Cost-Effective Synthesis of Bright Silicon Quantum Dots—PLQY~80% and EQE>10% Ken-ichi Saitow and Honoka Ueda; Hiroshima University, Japan

Silicon (Si) is the second most abundant element in the Earth’s crust and has been considered an environmentally benign material. Si has been widely used in electronic devices and solar cells, and it has dominated the semiconductor industry. However, the photoluminescence (PL) of the bulk material shows an invisible NIR wavelength (λ = 1100 nm). In addition, the photoluminescence quantum yield (PLQY) of bulk Si is typically ~0.01% owing to the indirect nature of its interband transition. In contrast, Si quantum dots (SiQDs) exhibit luminescence in the entire visible spectral region [1,2]. Furthermore, colloidal SiQDs offer PLQYs approaching 80% [3,4], and therefore they have enormous potential impact as environmentally benign and heavy-metal-free QDs (i.e., In, Cd, and Pb free) for displays, lighting, and biomedical imaging via solution processing. Indeed, SiQD LEDs have recently been fabricated from a natural substance, by upcycling discarded rice husks [5].

To synthesize colloidal SiQDs, thermal pyrolysis of a hydrogen silsesquioxane (HSQ) cage cluster [$(HSiO_{1.5})_{n=8}$] to prepare hydride SiQDs (H-SiQDs), with subsequent ligand exchange, is a facile and useful method [2]. In particular, replacing the hydrogen atoms in H-SiQDs with alkyl ligands resulted in PLQYs of 70% [6] and 80% [3] for slow-band emissions at orange–red wavelengths. In addition, replacing the hydrogen atoms in H-SiQDs with amine ligands was shown to produce fast-band PL at blue and green wavelengths [2,7,8]. However, the preparation of such high-quality SiQDs requires the use of a specific and highly expensive precursor for the HSQ cage cluster $(HSiO_{1.5})_{n=8}$.

Alternatively, the HSQ polymer $(RSiO_{1.5})_n$ (R = H, alkyl, alkoxide, etc.) is another candidate precursor that has three particular advantages: i) HSQ polymers can be easily synthesized by mixing water and silane compounds. ii) The polymers can be prepared via a one-pot synthesis in a yield greater than 95%. iii) The HSQ polymer synthesis method is inexpensive, with synthesis costs being 380 times lower [9] than the cost of the HSQ cage cluster $(HSiO_{1.5})_{n=8}$. However, the disadvantage of this approach is low SiQD brightness. Indeed, almost all the PLQYs reported for SiQDs prepared via this method are low (approximately 20%), and the reason for this is not yet understood [2,4].

Herein, red PL with a PLQY of 60–80% and LEDs with an external quantum efficiency (EQE) of >10% were obtained at 1/3600th of the cost of existing methods [4]. This was achieved by using $HSiCl_3$ and a low-polarity solvent to prepare the HSQ polymer, and by optimizing the LED hole-injection-layer thickness. Based on a total of 31 SiQD syntheses and 13 SiQD systems, each of these SiQD systems allowed us to quantitatively understand the relationships linking HSQ polymer structure, SiQD PLQY, and LED efficiency. Moreover, the simple and cost-effective protocols proposed here should prove invaluable for the synthesis and characterization of SiQDs in the future. These results are expected to lead to the development and use of SiQDs as efficient and cost-effective heavy-metal-free light sources for displays, lighting, and biomedical imaging.

Core/Shell Perovskite Nanocrystals for Photoelectronic Applications Weiwei Zheng and Hanjie Lin; Syracuse University, United States

Metal halide perovskite nanocrystals (NCs) with excellent photoelectrical properties are one of the most interesting materials capturing the interest of researchers over the past decade, and have broad applications in optoelectronics, such as light-emitting diodes (LEDs), photodetectors, and solar cells. To overcome the glaring limitation of instability and toxicity of lead-based metal halide perovskites, we have developed shell coating strategies, including non-epitaxial oxide shell encapsulation and epitaxial perovskite shell growth, for metal halide perovskite NCs. The resulting core/shell perovskite NCs present excellent environmental stability and tunable charge separation efficiency with promising application for solar energy conversion such as photocatalysis in aqueous solution.

EL01.05.40

Light-Driven C-H Activation and Carbon Dots Synthesis Mediated by 2D Transition Metal Dichalcogenides

Jingang Li; University of California, Berkeley, United States

Low-dimensional luminescent materials have emerged as crucial components for next-generation optoelectronic applications. In this work, we present a novel approach to synthesizing and patterning luminescent carbon dots (CDs) based on light-driven C-H activation mediated by 2D transition metal dichalcogenides (TMDCs). We successfully transform long-chain organic molecules, such as polyethylene, cetyltrimethylammonium chloride, and polymers, into luminescent CDs on monolayer TMDCs (e.g., WSe_2, WS_2, and MoS_2) under low-power continuous-wave laser irradiation. The synthesized CDs exhibit broadband photoluminescence with excitation-dependent emission characteristics. Through comprehensive material characterizations and density functional theory calculations, we elucidate the underlying mechanisms of this light-driven process, revealing the crucial role of TMDCs in facilitating C-H activation and lowering the energy barrier of C-C coupling for CDs synthesis.
Our technique enables the solid-state patterning of CDs with high spatial control, opening up possibilities for applications in data encryption and information technology. In addition to advancing the fundamental understanding of light-matter interactions in 2D materials, this work also provides a new strategy for creating functional luminescent nanostructures that could lead to innovations in display technologies and solid-state emitting devices.

Comprehensive Interior/Surface Defect Management Strategy for Halide Perovskite Nanocrystal Light-Emitting Diodes

Dae Hwan Kim, Jong Ho Park, Ji Su Ha and Tae-Hee Han; Hanyang University, Korea (the Republic of)

Perovskite nanocrystals (PeNCs) have emerged as highly promising materials for a wide range of optoelectronic applications due to their high color purity, tunable bandgap, and solution processability. However, labile nature and low stability, primarily caused by interior/surface defects of PeNCs, remain as a bottleneck for commercialization. To address these problems, we introduce two-steps strategy to efficiently passivate both internal and surface defects via compositional and surface ligand engineering. We carefully control tensile and compressive strains by incorporating A and B-site cations of varying radii to alleviate lattice strain, thereby reducing interior defects arising from size mismatches. Additionally, a simple and efficient surface ligand exchange method employing a short conjugated molecular ligand as a tridentate binding ligand effectively passivates surface defects in PeNCs. This comprehensive two-step defect passivation strategy results in a significant increase in the efficiency and stability of PeNCs light-emitting diodes (LEDs), demonstrating its potential for advancing the practical application of PeNCs in optoelectronic devices.

EL01.05.42

Structural Effects on Optical Properties—Insights from Correlative Optical and Electron Microscopies Minhal Hasham and A. Paul Alivisatos; The University of Chicago, United States

Synthetic control over quantum dot (QD) nucleation and growth generates highly crystalline particles with narrow size distributions while subsequent shelling passivates the QD surface.[1,2] Together, these techniques have yielded particles with near-unity photoluminescence quantum yield (PLQY), high photostability, and tailored surfaces.[3] These advances have directly contributed to the commercialization of QDs in display technologies. However, such optimizations target ensemble observables, hindering microscopic insight into the underlying structural factors that give rise to these superior properties. Here, single-particle techniques offer an avenue to build ensemble statistics from individual observations. Specifically, correlating between particle structure and photoluminescence at the single-dot level will provide a direct link between the anatomy of a QD and its resulting optical properties, thereby providing specific targets for synthetic optimization.[4]

Here, we combine single particle optical spectroscopy and scanning transmission electron microscopy (STEM) to reveal the link between QD structure and optical properties with high spatial and temporal resolution. Using fiduciary markers to reproducibly observe the same QDs in both optical and electron microscopes, we find that QDs with ON fractions >90% are observably defect-free and show regular, uninterrupted crystallinity at the atomic level. In addition, these particles are routinely well-passivated by shells and lack exposed core facets. On the other hand, QDs with ON fractions <80% exhibit characteristic structural defects such as under-passivated core facets, stacking faults, or irregular shell growth. Monitoring the dynamics of the exciton in these QDs, we find that the lifetime and linewidth of the excitonic emission is correlated with the QD structure. Specifically, defected particles show shorter exciton recombination lifetimes and broader linewidths, consistent with these defects serving as parasitic recombination sites. Finally, we identify a permanently non-emissive sub-ensemble of QDs which are only directly observed *via* electron microscopy but nonetheless contribute to photon absorption. Though we find that a subset of these "dark" particles suffer from exacerbated structural defects, a separate population intriguingly does not show clear structural anomalies yet remains non-emissive. Importantly, these results demonstrate that non-structural considerations such as the identity and extent of ligand coverage also play a decisive role during photon emission.

Our results offer a microscopic view of the ensemble and demonstrate that both the structure of the core and shell should be highly crystalline and free of defects and that this condition is necessary but insufficient to guarantee efficient photon emission. Now, we are exploring the effects of photoinduced structural dynamism, particularly at the particle surface.[5,6] Photoexcitation has been shown to induce anisotropic lattice displacement in QDs which can persist on timescales up to exciton recombination lifetimes. Using an electron microscope equipped with an optical fiber, we image QDs under laser irradiation. Our preliminary results suggest that some fraction of photoexcitations become trapped, leading to structural disorder which is captured in electron diffraction. Taken together, our technique provides for a direct method to correlate between the structure of an individual QD and its optical properties. Our methods offer an avenue to build ensemble statistics from single particle observations, thereby circumventing ensemble averaging techniques and offering microscopic insight into the structure-function relationships of emissive nanomaterials.

Novel Iodine Source Strategy for Red Mixed Halide Perovskite Quantum Dots and Enhanced LED Efficiency

Seungmin Baek, Hyeon Woo Jeong, Hyejin Na, Seon Joo Lee, Sung Ho Choi and Jaemin Lee; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Perovskite nanocrystals (PeNCs) are highly promising materials for next-generation display technologies due to their outstanding optical properties, including high photoluminescence quantum yields, narrow emission linewidths, and tunable emission wavelengths. However, persistent challenges such as surface defects and halide vacancies, particularly during the purification process after synthesis, hinder the efficiency and stability of PeNC-based devices. These defects often degrade device performance, making it difficult to achieve both high efficiency and long-term stability in optoelectronic applications.

A key advantage of PeNCs is their ability to modulate emission wavelengths by adjusting the halide composition, as halide anions can be easily exchanged within the perovskite lattice. This anion exchange not only enables precise wavelength tuning but also helps mitigate defects by replenishing missing or deficient anions on the surface or within the crystal structure.

To further exploit these advantages, we developed a novel anion exchange precursor based on a mixture of trimethylsilyl iodide (TMSI) and tri-n-octylphosphine (TOP). 31P NMR spectroscopy confirmed the formation of a phosphonium iodide complex containing silicon, and we proposed a reaction mechanism in which phosphonium ions are generated through the interaction of TMSI and TOP. This precursor was applied to green-emitting PeNCs, successfully inducing anion exchange to produce red-emitting PeNCs with a high quantum yield of 90%.

In addition, we conducted a comparative analysis using various anion exchange precursors to evaluate their effects on the PeNC surface, employing a range of analytical techniques. The red-emitting PeNCs synthesized with the TMSI-TOP precursor were integrated into electroluminescent (EL) devices, achieving an impressive external quantum efficiency (EQE) of 21.69% and demonstrating high operational stability, maintaining stable performance for approximately 16 hours at a luminance of 100 Cd/m^2.

This study highlights the potential of TMSI-TOP as a highly effective anion exchange precursor, providing a pathway to high-efficiency, stable PeNC-based devices by addressing critical issues related to defect passivation and halide management.

Progress of QD in Display Technology and the Emergence of Autonomous Material Development

Taekhoon Kim, Nayoun Won, Jooyeon Ahn and Tae-Gon Kim; Samsung Advanced Institute of Technology, Korea (the Republic of)

Colloidal quantum dots (QDs) are known as the most suitable candidates for luminescent materials due to their

unique optical properties, including high color purity and quantum efficiency, and easily adjustable bandgap. Among them, InP QD has a disadvantage of being prone to oxidation and defects on the surface due to its high covalent bonding characteristics, which makes it difficult to develop. Despite this, in the past, Samsung decided to apply indium phosphide (InP) QD, which has significantly less toxicity, to commercial products. After much effort, various display products ranging from QD monitors to QD-OLED TVs have been produced and sold based on InP QD, starting with the launch of the first QLED TV in 2015. I will introduce how these InP QDs can be developed into QDs with high quantum efficiencies approaching almost 100% and high process stability, and how they can be produced identically without changing the material's properties from the lab to mass production. Additionally, I will also, briefly introduce how we have been using the autonomous material development system at SAIT to accelerate material development over the past few years.

9:00 AM *EL01.06.02

Fuzzy Band Structure of Quantum Dots by Bloch State Expansion of Single-Electron Eigenstates Zeger Hens[1], Jordi Llusar[2] and Ivan Infante[2]; [1]Ghent University, Belgium; [2]BCMaterials, Spain

Fundamental and application-oriented QD research, in particular in view of light emission, has greatly benefited from the theoretical or computational analysis of QDs. Effective mass and theory, for example, describe quantized states starting from the bulk band structure, where well-established semiconductor characteristics, such as effective masses and band offsets, are considered known parameters. The resulting single-electron states are, by design, linear combinations of bulk Bloch states, and can be combined to describe excited states as interacting electron-hole pairs, in good agreement with experimental findings. Not unlike atomistic tight-binding or pseudopotential methods, however, effective-mass theory cannot be used to relax structure, analyze surface-related properties or predict band offsets within a heteronanostructure.

Opposite from solid-state physics methods, density-functional theory (DFT) provides molecular orbitals calculated from an atomistic model structure that includes, by default, the QD surface. Using DFT, stable QD structures can be identified through energy minimization, different surface terminations can be implemented, and single-electron states are not predesigned as consisting of bulk Bloch states. As a result, DFT has been successfully used to identify trap states, determine ligand binding energies, or calibrate molecular dynamics simulations, even if the method has limitations to describe the energetics and spin properties of excited states. However, incorporating the surface in the analysis often leads to highest occupied and lowest unoccupied orbitals that seem dominated by surface contributions, while the delocalized states derived from the bulk Bloch states can be difficult, if not impossible, to identify. Bridging this gap between DFT and solid-state physics methods would create an entirely new perspective for the computational study of QDs, with ramifications well beyond the particular case of semiconductor nanocrystals.

In this work, we show that projecting the single-electron eigenstates as provided by DFT on Bloch states provides a unique tool to classify orbitals as surface-induced or Bloch-state derived. After outlining the concepts, we show that through a so-called Bloch-state expansion (BSE), the QD eigenstates transform into a fuzzy band structure that overlaps with the semiconductor bulk bands calculated at the same level of theory. Using a wide range of QDs, we demonstrate that for states around the band-edges, BSE enables surface-localized and delocalized states to be distinguished, and the dominant symmetry of delocalized states to be identified. Next, we implement BSE to highlight the crucial role of surface reconstructions for eliminating mid-gap surface-induced states and obtain QDs featuring delocalized highest occupied and lowest unoccupied orbitals. Finally, we extend BSE to core/shell QDs, a step that creates the first pathway to predict band-offsets between two semiconductors within a heteronanostructure. These examples underscore that connecting DFT results with a solid-state physics approach through BSE, creates a powerful framework to assess the outcome of DFT calculations, and use the ab-initio character of DFT to predict QD properties that are otherwise taken as adjustable parameters.

9:30 AM EL01.06.03

Colloidal Chemistry in Molten Inorganic Salts—Direct Synthesis of III-V Quantum Dots *via* Dehalosilylation of $(Me_3Si)_3Pn$ (Pn=P, As) with Group III-Halides Zirui Zhou, Justin Ondry, Yi-Chun Liu, Haoqi Wu, Ahhyun Jeong, Tanya Chen, Aritrajit Gupta, Jun Hyuk Chang and Dmitri V. Talapin; The University of Chicago, United States

Gallium pnictides, such as GaAs and GaP, are among the most widely used materials for electronic, opto-electronic, and photonic applications. However, the solution colloidal synthesis of gallium pnictides is underdeveloped compared to many other colloidal semiconductors, including indium pnictides, II-VI, IV-VI, and lead halide perovskites. In this work, we demonstrate that Wells dehalosilylation reaction can be carried out in molten inorganic salt solvents to synthesize colloidal GaAs, GaP and $GaP_{1-x}As_x$ nanocrystals. We demonstrate that discrete colloidal nanocrystals with control over size and composition can be nucleated and grown in a molten salt. We provide evidence that reaction temperatures above 400 deg C are crucial for eliminating structural defects in GaAs nanocrystals. We also show that GaP can be solution processed into high refractive index coatings and patterned by direct lithography[1–5] with micron resolution. Finally, we demonstrate that the dehalosilylation reactions in molten salts can be generalized to synthesize indium pnictide (InP, InAs) and ternary ($In_{1-x}Ga_xAs$, $In_{1-x}Ga_xP$) quantum dots.

9:45 AM EL01.06.04

Ultrafast Optical Response and Photoinduced Modulation of Quantum Dot Superparticles Unraveled by Transient Absorption Microscopy Pietro Castronovo[1], Marco Reale[1], Cherie R. Kagan[2], Christopher B. Murray[2], Emanuele Marino[1], Alice Sciortino[1] and Fabrizio Messina[1]; [1]Università di Palermo, Italy; [2]University of Pennsylvania, United States

The assembly of nanosystems into larger superstructures (SPs) enables the emergence of new physico-chemical properties deriving from the cross-talk among individual constituents. Among the nanosystems eligible as building blocks for SPs, quantum dots (QDs) occupy a prominent place thanks to their well-established synthesis and intriguing size-tunable photophysics. Here we focus on quasi-monodisperse, 10 μm-sized spherical superparticles (SPs), assembled from CdSe/CdS core/shell QDs [1-2]. These SPs display excellent photophysical properties: beside the near-unity photoluminescence quantum yield, they strongly couple to the electromagnetic field via whispering gallery modes (WGMs), which allows them to behave as active laser microresonators.

To unravel the photoinduced response of individual photoexcited SPs, we employed a home-built Transient Absorption Microscopy (TAM) setup, combining the temporal resolution of ultrafast pump-probe spectroscopy with the spatial resolution of microscopy. Such an approach is crucial to disentangle the contributions of individual micrometer-sized superparticles from the ensemble, and allows to interrogate their optical response with femtosecond time resolution. Indeed, the fundamental photocycle, the charge carrier relaxation pathways, and the collective response of SPs to optical excitation have remained largely unexplored so far, despite a better understanding and control of these aspects may lead to novel applications in photonics and telecommunication technologies.

We show that the photoexcitation of our spherical QD superparticles leads to an impulsive change of WGM resonances due to the photoinduced variation of the refractive index of the microresonator, evolving on subpicosecond and picosecond time scales due to a combination of electronic and thermal effects. These results may pave the way to novel uses of these SPs as optically-responsive photonic microdevices, where WGM resonances can be modulated by an optical pulse. Interestingly, both the spectral shape of the pump/probe signal and position of the WGM modulations depend on the specific superparticle, highlighting the strong dependence of such effects to tiny changes in superparticle morphology. We also use pump/probe microscopy to provide evidence of excitation transfer between two neighbouring supeparticles on sub-picosecond time scales, suggesting the possibility of exploiting the cross-talk between coupled SPs in designing optical microdevices with more complex architectures.

Our results provide a wealth of information of the photoinduced dynamics of QD superstructures upon impulsive optical excitation, and pave the way to novel applications in photonics revealing their potential as ultrafast photonic microdevices. Besides, our experiments highlight the ability of femtosecond pump/probe microscopy to probe the optical absorption features of individual SPs, and their characteristic frequency spectrum as microresonators, which would be difficult by other available methods.

10:30 AM *EL01.06.05
Exploring the Shape-Dependent Optical Properties of Tetrahedral Semiconductor Nanocrystals Sohee Jeong; Sungkyunkwan University, Korea (the Republic of)

Over the last four decades, the size-dependent photophysical characteristics of quantum dots (QDs) have been extensively studied through the quantum confinement effect, typically described by the three-dimensional particle-in-a-box equation assuming a spherical shape with infinite potential barriers. While the shape effect in spatially confined charges and excitons has been extensively investigated for anisotropic semiconductor nanocrystals, QDs with specific shapes remain relatively underexplored. In this talk, we present a synthetic strategy to achieve tetrahedral semiconductor nanocrystals with high shape homogeneity. Notably, the sizing curve of tetrahedral semiconductor nanocrystals with well-defined facets reveals an unconventionally smaller band gap compared to spherical QDs of equivalent volume. We suggest that upon ligand passivation, the (111) in-gap state significantly hybridizes with the bulk conduction band minimum (CBM) and remains at CBM, resulting in a reduced band gap, especially when the bulk bandgap is small. This unique surface-originated quantum confinement effect positions tetrahedral InAs QDs at lower energies in the sizing curve. Conversely, tetrahedral InP QDs, with a relatively larger band gap, exhibit opposite trends in the sizing curve, which can be explained by the particle-in-a-box model based on previous understandings. Finally, we fabricate photodetectors utilizing these materials and demonstrate their enhanced performance in terms of specific detectivity and response time, showing the potential of tetrahedral nanocrystals in advanced optoelectronic applications.

11:00 AM EL01.06.06
Colloidal Quantum Shells for Optoelectronic Applications Mikhail Zamkov; Bowling Green State University, United States

We will discuss a novel class of low-dimensional semiconductors, called colloidal semiconductor quantum shells (QSs). These nanomaterials exhibit strong suppression of Auger recombination, which is critical for improving the stability and efficiency of nanocrystal optoelectronic devices. Our comparative analysis will focus on the distinctive benefits of QSs and will extend to their roles as optical gain media, X-ray scintillators, and light upconversion materials for both visible and infrared spectral domains. Furthermore, we will investigate the feasibility of fabricating QSs using non-toxic, readily available semiconductor materials, paving the way for their integration into "printable" electronics. We will demonstrate that quantum shells effectively mitigate two primary mechanisms of non-radiative decay in colloidal nanocrystals: surface recombination and Auger recombination, which makes them a promising nanocrystal morphology for applications utilizing intense optical or electrical excitations.

11:15 AM EL01.06.07

Interfacial Engineering Increases the Photoluminescence Efficiency and the Biexciton Auger Lifetime in InP/ZnSe QDs Luca Giordano[1], Pieter Schiettecatte[1], Dobromil Respekta[1], Yannick Coppel[2], Guillaume Bonifas[2], Hannes Van Avermaet[1], Qiang Zhao[3], Celine Nayral[2], Andre Van Tomme[3], Fabien Delpech[2] and Zeger Hens[1]; [1]Ghent University, Belgium; [2]Université de Toulouse, France; [3]KU Leuven, Belgium

Quantum dots (QDs) are zero-dimensional materials suitable for advanced optical applications. Especially Cd-based QDs have shown rousing results, but are difficult to implement in end-user applications due to restrictions on toxic elements, such as Cd. The most widely used, unrestricted alternative for light-emission applications are probably InP QDs. However, while light emitting devices using luminescent color conversion or direct electroluminescence by InP QDs show great promise, progress has been glacial for applications relying on stimulated emission. Lasers using Cd-based QDs as the gain material proliferated after research demonstrating that biexcitons – the excitation giving rise to net stimulated emission – in CdSe/CdS core/shell QDs with an alloyed interface exhibited a markedly increased lifetime related to slower Auger recombination. This result suggests that understanding and adjusting the interfacial composition in InP-based core/shell QDs is an important step for obtaining optical gain suitable for laser application from these materials.

In this study, we report on the relation between the Auger recombination rate in InP/ZnSe QDs and the composition of the InP/ZnSe interface, which we adjust through (1) oxidation of the InP core surface and (2) addition of $InCl_3$ during the ZnSe shell growth. The resulting 4 possible samples – the untreated reference, two single-treatment and one double treatment combinations – have similar sizes and morphologies, featuring an 3 nm in diameter InP core and a 1.8 nm thick shell. However, elemental analysis by Rutherford backscattering spectrometry and solid-state NMR spectroscopy, shows that treatment 1 leads to the formation of oxidized phosphorous at the interface, while treatment 2 results in the incorporation of In in the layers of ZnSe closest to the interface. Interestingly, both separate treatments increase the PLQY from 44% for the reference sample to 51 and 63%, while the double treatment results in an 83% PLQY. Moreover, while the transient absorption decay of the reference sample points towards a rapid loss of biexcitons with an ill-defined rate constant, sample with an oxidized or an In-enriched interface exhibit a well-defined biexciton lifetime of ~40 ps. Most promisingly, the combined sample shows an even slower Auger lifetime of ~64 ps. Building on this result, we analyzed a set of samples with this double interfacial treatment, and a gradually increasing ZnSe shell thickness. This led to a further lengthening of the Auger lifetime to ~108 ps. We conclude that such interfacial treatment provide a promising path for reducing the Auger lifetime of biexcitons in InP-based QDs, thereby opening the path towards lasers using these QDs as the optical gain material.

Colloidal Quantum Dots for Wearable Optoelectronics Xiwen Gong; University of Michigan, United States

I will first discuss innovative material design strategies for imparting mechanical deformability to colloidal quantum dots, focusing on precisely controlling their interactions with deformable polymer semiconductors. Next, I will discuss recent advancements in device engineering, focusing on the construction of fully stretchable optoelectronic devices utilizing these materials. Finally, I will discuss the promise and technical challenges within the quantum dots-based wearable optoelectronics in health care and soft electronics.

2:15 PM EL01.07.02

Improvement of Current Efficiency in Inverted Top-Emitting Quantum Dot Light-Emitting Diodes Using p-Doped Hole Transporting Layer Soobin Sim[1], Hyeonjun Lee[2], Hak June Lee[3], Wan Ki Bae[3], Doh Chang Lee[2] and Hyunkoo Lee[1]; [1]Sookmyung Women's University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Quantum-dot light-emitting diodes (QLEDs) have attracted considerable interest as next-generation displays due to low-cost processing using solution processes, high color purity by narrow full-width half maximum of quantum dots (QDs), and potential for high luminance and stability based on inorganic emitting materials (EML) [1]. In QLEDs, injecting holes from the hole transporting layer (HTL) into the QD EML is considered challenging due to the presence of a relatively high hole injection barrier at the HTL/QD interface. On the other hand, the electron from the electron transporting layer (ETL) is relatively easily inject to QD EML compared with the hole injection. This causes charge imbalance in the QD EML, resulting in low efficiency of QLEDs [2]. The p-dopant is widely used in the organic light-emitting diode for lowering hole injection barrier and enhancing hole charge carrier concentration. Although p-doping effect is used for improving device performance in the QLEDs, it has not been as extensively studied in QLEDs as in OLEDs.

In this study, we fabricated inverted top-emitting red QLEDs using indium-tin-oxide (ITO)/Ag/ITO as a reflective cathode, ZnMgO as an ETL, CdSe/CdZnSe/ZnSeS red QDs as an EML, TcTa as a HTL, 2-(7-dicyanomethylene-1,3,4,5,6,8,9,10-octafluoro-7H-pyrene-2-ylidene) malononitrile (NDP-9)-doped tris(4-carbazoyl 9-ylphenyl)amine (TcTa) as hole injction layer (HIL), and thin Ag as a top anode. NDP-9 is a representative p-type dopant owing to its strong electron affinity and hole generation property. We investigated effect of NDP-9-doped TcTa in the inverted top-emitting red QLEDs. By applying NDP-9-doped TcTa instead of molybdenum oxides typically used as the HIL in the inverted QLEDs, the current efficiency of the device dramatically increases approximately two times. In addition, we analyzed device characteristics depending on NDP-9 doping ratios. P-type doping can be an effective strategy for improving efficiency of QLEDs.

2:30 PM SPECIAL BREAK - EXHIBIT HALL SOCIAL AND SIP

3:30 PM *EL01.07.03
Doped Two-Dimensional Layered Magnets Daniel R. Gamelin; University of Washington, United States

Luminescent materials with strongly coupled optical and magnetic properties offer unique fundamental probes of electron correlations as well as new opportunities to manipulate and measure spin effects using light. This talk will describe development of a new family of luminescent materials based on doping two-dimensional layered magnets with optical impurities. In one example, we have demonstrated that doping the layered van der Waals ferromagnet CrI_3 with Yb^{3+} transforms this material's nondescript broadband emission into narrow line emission. The improved resolution allows detection of spin correlations, exchange fields, and spontaneous magnetic ordering via luminescence. Strong magnetic exchange coupling between the lattice and the impurity also strongly amplifies the effect of an external field felt by Yb^{3+}, again probed by luminescence. Broadening this family of materials has allowed detection of impurity-magnet exchange splittings and their dependence on temperature, external field, and hydrostatic pressure, and has allowed quantitative descriptions of exciton diffusion dynamics. Fundamental aspects of the electronic structures of these materials will be discussed in this context.

4:00 PM EL01.07.04
Spatially-Resolved Exciton Dynamics Under an Electric Field in Colloidal QD-LEDs Shreyas Srinivasan[1], Ruiqi Zhang[1,1], Taehyung Kim[2], Moungi G. Bawendi[1] and Vladimir Bulovic[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

Colloidal quantum dots (QDs) are solution-processable emitters with high quantum efficiencies and tunable emission wavelengths. They have emerged as promising materials for displays, solid-state lighting, and optical communication. The demand for QD-based display technologies has necessitated the development of environmentally-benign QD compositions with similar optical properties to high-performing, but toxic, heavy-metal-containing QDs. Using time-resolved confocal micro-photoluminescence mapping under an applied electric field and transmission electron microscopy (TEM), we observe direct evidence of inhomogeneity in exciton response to the electric field for InP/ZnSe/ZnS quantum dot light emitting diodes (QD-LEDs). By applying a negative bias across the diode while photo-exciting the QDs, the steady-state and time-resolved exciton dynamics are modulated, resulting in PL quenching and a decrease in average exciton lifetime. Under confocal micro-PL mapping, intensity hotspots imaged in the QD thin film are found to be less-reactive to the applied electric field, resulting in spatial inhomogeneity in PL quenching. Finally, cross-sectional TEM images of the QD-LED demonstrate distinct regions of inhomogeneous layer height in the spin-coated QD thin film. We hypothesize that thicker regions of the QD film screen the effective electric field experienced by the dots in that region, leading to limited field-induced modulation. Subsequently, we posit that under positive bias, the regions that are unreactive under negative bias do not contribute to charge injection and electroluminescence, leading to increased field exposure and aging in the surrounding QDs. This work provides a possible mechanism for the accelerated operational lifetime decays observed for InP/ZnSe/ZnS QD-LEDs.

4:15 PM EL01.07.05
Operation Degradation Influence on InP/ZnSe/ZnS and ZnTeSe/ZnSe/ZnS QD-LEDs Ruiqi Zhang[1], Shreyas Srinivasan[1], Taehyung Kim[2], Moungi G. Bawendi[1] and Vladimir Bulovic[1]; [1]Massachusetts Institute of Technology, United States; [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

Cadmium-free colloidal quantum dots have been previously reported as promising candidates in quantum dot light-emitting diodes (QD-LEDs) due to their tunable optical properties and quantum confinement effects. With the state-of-art external quantum efficiency of red, green and blue QD-LEDs, light out-coupling theoretical limits have been nearly achieved. However, comparing to the high T95 operational lifetime of red and green QD-LEDs counterparts, blue QD-LEDs perform a much lower operation lifetime. In this work, we probe the operation degradation mechanisms on both InP/ZnSe/ZnS (red) and ZnSe(Te)/ZnSe/ZnS (blue) QD-LEDs from a perspective of nanoscale device morphology and interlayer elemental tracing. A coarsening and thinning phenomenon is observed in both quantum dots and Mg-doped zinc oxide nanoparticle (ZnMgO NP) layers after LT50 aging. Meanwhile, an extra oxygen peak shows up in the InP/ZnSe QD layer after biasing the device. Additionally, our findings indicate that long-time high-dose electron beam irradiation contributes to the coarsening of the ZnMgO NP layer, and the presence of hydrogen significantly accelerates the coarsening process under electron beam exposure. This study reveals the morphological thinning and particle coarsening in the electron transport layer (ETL) and active layer after diode aging, establishing a framework for understanding QD-LED degradation mechanisms during operation.

4:30 PM EL01.07.06

Atomic Layer Deposition Strategies for Quantum Dot Displays—From Photolithographic Passivation Layers to Charge Transport Engineering Seong-Yong Cho; Hanyang University, Korea (the Republic of)

In this presentation, we will discuss research on applying Atomic Layer Deposition (ALD) techniques to quantum dot electroluminescent displays. Initially, we demonstrated the feasibility of fabricating light-emitting diodes (LEDs) using a solution process by applying ALD to Cs-based inorganic perovskite materials. Traditional perovskites, which involve ionic bonding and organic ligands, face processing challenges as subsequent functional layers must be deposited in a vacuum environment. To address this issue, we treated the perovskite surface with ALD oxides, discovering that the reaction between ALD precursors and the perovskite surface is a complex vapor-phase reaction with the surface ligands, rather than a simple deposition. We optimized this reaction pathway to minimize the precipitation of Pb metal, which can reduce emission efficiency.
We also applied ALD ZnO to the surface of quantum dot materials for a very limited number of cycles, significantly improving their resistance to solvents. This enabled us to apply traditional photolithography with photoresist coating to achieve high-resolution patterning of over 3,600 PPI, suitable for AR/VR/XR applications.
Furthermore, we extended the application of ALD beyond interlayers to charge transport layers by doping Al2O3 and MgO in ultrathin cycles, forming Al-doped ZnMgO alloy thin films. These were applied in QD-LED devices, resulting in high-efficiency, long-lifetime, and high-brightness QD electroluminescent devices. This ALD-based process suggests that such techniques can be utilized not only for the encapsulation or semiconductor processes of conventional display devices but also within the active layers of displays, offering diverse functionality for emissive materials.

4:45 PM EL01.07.07

Mitigating Edge Etching in Cation Exchange Synthesis of Two-Dimensional Lead Chalcogenide Colloidal Quantum Wells Ulas Yaprak, Eren Topcu and Yusuf Kelestemur; Middle East Technical University, Turkey

Two-dimensional colloidal quantum wells are emerging as an exciting class of semiconductor nanocrystals with promising applications in solar cells, owing to their thickness-dependent excitonic properties, including a strong absorption cross-section and suppressed Auger recombination. However, compared to their spherical counterparts, two-dimensional lead chalcogenide-based colloidal quantum wells have not been extensively studied. Among the various synthesis pathways, cation exchange is the most commonly employed approach for

synthesizing two-dimensional lead chalcogenide colloidal quantum wells. However, this method often encounters a significant etching problem along the edges of core colloidal quantum wells. To address this issue, we investigated the effect of sidewall protection using core/crown heterostructured cadmium chalcogenide-based colloidal quantum wells in cation exchange experiments. Our results revealed that in CdSe/CdS core/crown nanoplatelets, the etching process was unexpectedly accelerated compared to the bare CdSe core structure, significantly destroying the initial morphology of the core/crown nanoplatelets. In contrast, when using CdSe/CdTe core/crown nanoplatelets, the initial morphology was successfully maintained after the cation exchange. We attribute these results to the different strain states in core/crown heterostructured quantum wells covered with CdS and CdTe, underscoring the importance of strain in cation exchange experiments. This study highlights the critical role of strain in preserving the structural integrity of two-dimensional colloidal quantum wells during cation exchange and provides insights for improving synthesis methods for advanced nanocrystal applications.

This study was partially supported by the Scientific and Technological Research Council of Turkey (TUBITAK) under the grant no. 121C227.

Unlocking the Potential of Large-Area InP-Based Quantum Dot Light-Emitting Diodes Through Blade-Coating

Yiman Xu[1], Grant Dixon[2], Brandi Cossairt[2] and Elsa Reichmanis[1]; [1]Lehigh University, United States; [2]University of Washington, United States

Quantum dot (QD) light-emitting diodes (LEDs) are attractive candidates for next-generation displays due to their high efficiency, brightness, wide color gamut, and solution processability. Large-scale solution-processing of electroluminescent QLEDs poses significant challenges, particularly concerning the precise control of the active layer's thickness and uniformity. These obstacles directly impact charge transport, leading to current leakage and reduced overall efficiency. Blade-coating is a prevalent and scalable solution processing technique known for its speed and minimal waste. Additionally, it allows for continuous "roll-to-roll" processing, making it highly adaptable in various applications. Furthermore, it is necessary to find a more environmentally friendly alternative to the toxic cadmium-containing active layer composition. In this study, we focus on indium phosphide (InP)-based all-blade-coated QLEDs. The blade speeds significantly influence the thickness and morphology of active thin films. The blade-coated QD thin film reached 25 nm thickness and 5.1 nm root mean square height roughness at optimized speed, comparable to the spin-coated films. We further measured the photoluminescence quantum yield (PLQY) of the active thin film to guide improvements in the external quantum efficiency (EQE) of QLED devices. We aim to transfer existing knowledge to demonstrate the potential for the large-area blade-coating processing technique, emphasizing exploring the relationship between processing parameters, thin film structure, and device performance. This approach addresses current limitations and paves the way for more efficient, sustainable, and scalable QLED technologies.

Perylene Bisimide Red Emitters as Organic Downconverters for High-Luminance Hybrid-LED Applications
Paramveer Kumar[1], Lyudmyla Kanibolotska[1], Oleksandr Kanibolotskyy[1], Peter Skabara[1], Samir Mezouari[2] and John Whiteman[2]; [1]University of Glasgow, United Kingdom; [2]Plessey Semiconductors, United Kingdom

Virtual-reality (VR) and augmented-reality (AR) applications require miniature displays with high-luminance in red, green, and blue, to create a full-colour display that remains visible in daylight. The miniaturization of inorganic LEDs, specifically in the case of AlInGaP for red LEDs, where pixels are reduced to micron size and pitch, can result in surface defects caused by processing steps. These defects have a notable impact on the external quantum efficiency of micro-LED devices, leading to significant attenuation.

Down-converting organic semiconductor materials can utilise the high-power density of blue GaN-based LEDs to offer high lighting efficiency across the colour spectrum. This can provide a high-luminance RGB display from an array of blue LEDs, especially beneficial for micro-LED displays. Organic materials avoid the processing difficulties of phosphors and quantum dots, however, they are seldom explored in high-luminance applications because of their poor photostability.

We present the synthesis of a series of red perylene bisimide derivatives, a family of organic materials which are renowned for their strong fluorescence and high photostability. They are investigated for their solid-state properties, blended in polymer matrices, and are deposited on blue GaN-based LEDs to explore their photostability at high-power density. Many important factors are considered, such as ensuring strong blue absorption, colour-accurate emission, and good processability.

Ensuring that the colour conversion film is thinner than the size of the pixel is important for micro-LED displays in order to avoid optical cross-talk and light leakage. To achieve this, donor-acceptor dye compositions are explored, where a series of strongly blue-absorbing donor dyes are incorporated, which can facilitate non-radiative transfer to the acceptor dyes. This enables stronger absorption of blue light without the need to increase the concentration of dyes to a level that would lead to aggregation quenching, thereby preserving the efficiency of the device.

Highly Responsive Switchable Broadband Photodetector and Tunable Light-Emitter Enabled by AlGaN Based Nanowire on Silicon Substrate for Integrated Photonics Wei Chen, Haiding Sun, Huabin Yu, Yuanmin Luo and Yang Kang; University of Science and Technology of China, China

Low-dimensional semiconductor nanostructures, particularly in the form of nanowire configurations with large surface-to-volume-ratio, offer intriguing optoelectronic properties for the advancement of integrated photonic technologies. Here we report a bias-controlled, superior dual-functional broadband light detecting and emitting diode enabled by constructing the alluminum-gallium-nitride-based p-n nanowire on Si-platform. Strikingly, the diode exhibits a stable and high responsivity (R) of over 200 mA/W covering an extremely wide operation band under reverse bias conditions, ranging from deep ultraviolet (DUV: 254 nm) to near-infrared (NIR: 1000 nm) spectrum region. While at zero bias, it still possesses superior DUV light selectivity with a high off-rejection ratio of 106. When it comes to the operation of the light-emitting mode under forward bias, it can achieve large spectral changes from UV to red simply by coating colloid quantum dots on the nanowires. Based on the multifunctional features of the diodes, we further employed them in various optoelectronic systems, demonstrating outstanding applications in multicolor imaging, filterless color discrimination, and DUV/NIR visualization. Such highly responsive broadband photodetector with a tunable emitter enabled by III-V nanowire on silicon provides a new avenue towards the realization of integrated photonics and holds great promise for future applications in communication, sensing, imaging, and visualization.

EL01.08.04
Luminescence of Nb Oxide Nanoparticles and Its Application to Light Emitting Devices Shumpei Toyoshima, Akito Mizobata, Mahito Yamamoto, Yasushi Obora and Mitsuru Inada; Kansai University, Japan

In transition metal oxides, slight differences in structure, composition, and oxidation state can result in completely different physical properties due to the flexibility of the crystal structure and the diversity of the electronic structure. Therefore, in bulk materials, these different physical properties can appear mixed due to the presence of a large number of different impurities and different types of oxygen defects. However, in nanostructures, the number of atoms is limited, so unique properties can appear due to specific impurities, defects or oxidation states.

It has been difficult to synthesize nano-sized particles of transition metal oxides because of their susceptibility to oxidation and aggregation. Recently, we have successfully synthesized Nb oxide nanoparticles by DMF reduction method. The Nb oxide nanoparticles are 2-4 nm in diameter, passivated in DMF and extremely stable in solvents such as water, ethanol and DMF. The Nb oxide nanoparticles exhibited a broad, bluish-white photoluminescence in solution. The broad emission spectrum could be separated into several emissions. As the concentration of nanoparticles in solution was increased, the peak emission wavelength showed a red shift. This shift was due to Förster-type resonance energy transfer. The results indicate that the Nb oxide nanoparticles have several different emission wavelengths, blue, green and red color regions. Indeed, in EL devices with Nb oxide nanoparticles as the emitting layer, red and blue emission were observed depending on the charge transport (injection) materials sandwiching the Nb oxide nanoparticles. Although the origin of the luminescence of Nb oxide nanoparticles is not yet understood, these results indicate that transition metal oxide nanoparticles have potential applications as light-emitting devices.

EL01.08.05
Heat-Assisted Direct-Photolithography of Small Molecule Emitters SeungHwan Roh and Moon Sung Kang; Sogang University, Korea (the Republic of)

Patterning the emissive layer is a crucial step in fabricating full-color organic light-emitting diode (OLED) displays. Traditional manufacturing relies on thermal evaporation, but using fine metal masks limits achievable resolution that is required for emerging microdisplay technology. Alternatively, direct photolithography, where the layer to be patterned acts as a photoresist, offers a time- and cost-effective method for producing high-resolution displays. In this study, we introduce a direct photopatterning method for organic small molecules used in OLED emissive layers. To photopattern the layers, our method employs a photo-crosslinkable vinyl benzyl moiety directly anchored the host and guest organic small molecule emitters. By photoinitiating a free radical polymerization reaction between the vinyl benzyl moieties under mild annealing conditions (60°C), the emissive layer can be photopatterned using an i-line UV source (wavelength: 365 nm) without degrading its luminescent properties. Here, mild annealing was critical for achieving thorough crosslinking of the emissive layer, where no crosslinking occurred without it. Thus, we refer to this process as heat-assisted direct photopatterning (HADP). Using HADP, we successfully fabricated patterns of red, green, and blue OLED emitters with widths of a few microns achieving a minimum pattern width of 2 μm. We believe this method offers a promising alternative for producing microscale patterns with organic small molecules, which is in high demand for ultrahigh-resolution OLED-based microdisplay technology.

Ultrasmall HgTe Quantum Dots with Near Unity Photoluminescent Quantum Yields in the Near and

Up-to-date as of November 14, 2024

Shortwave Infrared Belle Coffey, Elise Skytte, Tasnim Ahmed, Eugenia S. Vasileiadou, Eric Lin, Ash Sueh Hua, Elijah Cook, Stephanie Tenney, Ellen Sletten and Justin R. Caram; University of California, Los Angeles, United States

The near and short-wave infrared spectral window (700-1000 and 1000-2000 nms respectively) enables remarkable penetrative imaging and sensing applications. However there are few highly emissive chromophores in this spectral window. Of the available optically active materials in the infrared, mercury chalcogenide nanocrystals are promising candidates for infrared optoelectronic applications due to their narrow bulk bandgaps, spectral tunability and solution processability. Here we demonstrate a low temperature synthesis of ultrasmall HgTe quantum dots with superlative optical properties in the near and shortwave infrared. The tunable cold-injection synthesis produces nanocrystals 1.7 to 2.3 nm diameter, with photoluminescence maxima ranging from 900-1180 nm and a full width half max of ~100 nm (~130 meV). The synthesized quantum dots display extraordinarily high photoluminescence quantum yields (PLQY) ranging from 80-95% based on both relative and absolute methods. The QDs have a short lifetime of 7 ns and retain their high quantum yields (~60%) in the solid state, allowing for first of their kind photoluminescence imaging and blinking studies of HgTe QDs. Future work will focus on expanding the spectral tunability of the synthesis further into the infrared and optimizing water solubility of the HgTe QDs for in-vivo imaging.

EL01.08.07

Manganese Doped Zinc Germanate (Mn:Zn2GeO4)—Exploring a Novel Synthesis and Its Potential Application in Bioimaging Dave A. Philips, S M Anyet U. Shohag, Bhupendra Srivastava, Ashwin James, Swati Mohan and Mohammad J. Uddin; The University of Texas at Rio Grande Valley, United States

Compared to traditional organic fluorescent dyes used in bioimaging, semi-conductor nanocrystals possess better photo-luminescent properties, such as a broad absorption, narrow and symmetric emission band, large Stokes shift, and weak self-absorption. However, many of these nanocrystals, like CdSe and CdTe, are toxic to biological systems and to the environment. Along with other limitations, such as solubility, luminescence, and cost, incorporating these nanocrystals has presented as a challenge to researchers. However, this novel synthesis of Mn:Zn2GeO4 overcomes many of these limitations and exhibits characteristics promising to the realm of bioimaging. By incorporating a hydrothermal method under pH- controlled conditions, this new nanocrystal shows promising results, such as a quantum yield of 52% under UV irradiation with persistent photoluminescence. Already shown to be non-toxic and environmentally benign for large-scale production, an in-situ addition of poly-acrylic acid allows this particle to be soluble in water as well. Due to being doped with a magnetic element (Mn), this particle may have potential in binary probing with both fluorescent and magnetic functions so that deeper labeled tissues may be examined with MRI. In this work, we had successfully synthesized a promising cost-effective particle with potential in bioimaging and performed exploratory analysis on the nanoparticle by characterizing it via X-Ray Diffraction as well as finding the morphology with a scanning electron microscope, as well as measuring excitation using photoluminescent spectroscopy.

EL01.08.08

The Synthesis of In(As,P)/InP Core/Shell Quantum Dots to Enhance Photoluminescence Efficiency in Infrared Optoelectronics Pepijn Verscheure; Ghent University, Belgium

Indium arsenide (InAs) quantum dots (QDs) have the potential to enable restriction of hazardous substances-compliant solution-processed infrared optoelectronic devices. However, their photoluminescence efficiency with centre of emission wavelength longer than 1000 nm remains very poor. It has been shown that ZnSe can improve PLQY significantly of InAs QDs, however due to the relatively high lattice mismatch it is very difficult to synthesize

InAs/ZnSe QDs. In this work, we present a novel synthesis approach for In(As,P)/InP core/shell QDs with tunable shell thickness, demonstrating versatility across a range of core sizes with absorbance feature between 1150 and 1500 nm. The InP shell thickness can be readily tuned between 1 to 5 monolayers of InP. The resulting In(As,P)/InP core/shell quantum dots exhibit well-defined tetrahedral structures with excellent crystallinity. Importantly, the core is only minimally strained by the shell, indicating a high degree of structural compatibility and promising stability for optoelectronic applications. A key advantage of this procedure is the effective reduction of lattice mismatch between the core and subsequent ZnSe shell growth, enhancing the structural integrity of the core/shell architecture. Leveraging the established surface termination techniques developed for InP QDs, the chemically distinct core/shell structure can be utilized with these methods to further enhance the optical properties of the QDs.

EL01.08.09

Synthesis of Bulk Nanocrystal In(As, P) Jing Bai; Ghent University, Belgium

Colloidal III-V group quantum dots (QDs) are widely studied as a promising optoelectronic material, which is not restricted by regulations on hazardous substances. However, synthesizing large-sized (>10 nm) QDs even bulk nanocrystals with high-quality remains challenging. Here, we successfully synthesized In(As,P) QDs with a first excitonic absorption up to approximately 1750 nm. By suppressing the secondary nucleation, we can grow In(As, P) QDs to bulk size of 20 nm. The synthetic procedures introduced here are expected to significantly advance the development of III-V nanocrystals opto-electronic technology based on non-restricted materials.

EL01.08.10

Understanding the Defect Chemistry of $CaAlSiN_3$ Inorganic Phosphor Host Material for Solid State Lighting Applications Maryia Shymanovich, Alexander Squires and David O. Scanlon; University of Birmingham, United Kingdom

Lightning is a major source of world energy consumption, and the development of more efficient lighting technologies is of high importance. Light emitting diodes (LEDs) have been shown to achieve high efficiency, durability, and stability compared to conventional lighting. One way to produce LEDs is to combine blue- or UV-LED chip with one or more inorganic phosphor(s) that absorbs high-energy light from chip and down-convert to longer-wavelength. Phosphor-converted light emitting diodes, pc-LEDs, have attracted significant attention since different combinations of phosphors allow to tune the overall quality of light. Therefore, the development of novel inorganic phosphors with the desired properties has become a necessity to improve the performance of pc-LED devices.

$CaAlSiN_3$ (CASN) is a member of nitride group (Ca_3N_2 – AlN – Si_3N_4) and when doped with Eu^{2+} ions, produces a red light under blue excitation and, thus, is used as an inorganic phosphor in highly-efficient warm-white pc-LEDs. Several studies have shown that doped-CASN serves as a promising inorganic red phosphor due to its high quantum output, good thermal and chemical stability, and low thermal quenching. One of the important structural features of CASN is that Al^{3+} and Si^{4+} ions are randomly distributed among identical tetrahedral sites. The Al/Si disorder can influence the electronic and optical propertiies of host material. However, the defect chemistry in this material is not well understood and requires further research.

The goal of this project is the investigation of cation disorder in CASN and the analysis of the defect chemistry in this material using a combination of computational methods (including Density Functional Theory, cluster expansion, Monte Carlo simulations, Madelung analysis). The results of our investigations of the intrinsic defects and their influence on electronic and optical properties of CASN crystal material will be presented.

Quantum Dot Waveguide—Novel Ultrafast Efficient Scintillator Serge R. Oktyabrsky[1], Tushar Mahajan[1], Allan Minns[1], Gyana Biswal[1], Michael Yakimov[1], Vadim Tokranov[1], Michael Hedges[2] and Pavel Murat[2]; [1]University at Albany, State University of New York, United States; [2]FermiLab, United States

Using nano-engineered InAs Quantum Dots (QDs) as high-efficiency luminescence centers enables the fabrication of a scintillating material with unique properties. In this work, we developed epitaxial heterostructures consisting of self-assembled epitaxial QDs sheets separated with GaAs featuring built-in photoelectron-collecting potential, and an integrated spectrum-tuned metamorphic InGaAs photodetector (PD). A thick (10-25 μm) GaAs layer with QDs acts as a stopping material for charged particles or x-ray photons and as a waveguide when layer-transferred onto a low-index substrate. The QD medium was designed to provide fast capture of electrons into QDs (few ps), high QD luminescence efficiency at room temperature (>50%), and strong red shift of photoluminescence (PL) from the GaAs absorption edge (>250 nm). Waveguiding optical losses due to interface scattering and self-absorption (~1cm^{-1}) were studied using the scanning photoluminescence technique and modeled with Monte-Carlo simulations. Scintillating signals were recorded by the integrated PD from 5.5 MeV alpha particles and 60-122 keV x-ray photons. The mean charge collected was in the range of 30÷50 photoelectrons per 1 keV of the deposited energy, or ~13-20% of the theoretically achievable light yield of 240 el./keV. The scintillation response shows an extremely fast 0.3-0.6 ns decay constant and about 40-70 ps time resolution for alpha particles, limited by the system noise. The combined light yield and decay time make the InAs/GaAs QD heterostructures the fastest high-yield scintillation material reported making it valuable for medical imaging, high-energy physics particle tracking, and nuclear security applications.

EL01.08.12

Efficiency Enhancement of Circularly Polarized Electroluminescence by Eliminating Chiral Inducers
Chenyuhe Yuan[1], Miyu Abe[1], Haoran Sun[1], Tomoyuki Ikai[2], Keitaro Eguchi[1] and Hideyuki Murata[1]; [1]Japan Advanced Institute of Science and Technology, Japan; [2]Nagoya University, Japan

Organic light-emitting diodes (OLEDs) capable of emitting circularly polarized light (CPL) have attracted considerable attention from researchers due to their potential applications, such as 3D display and optical information storage.[1] One of the effective approaches to realize CP-OLEDs is to construct chiral light-emitting layers by chiral induction, where chiral small molecules are doped as chiral inducers into achiral luminescent polymers. Due to the chiral transfer, strong circularly polarized luminescence of the polymer can be achieved. While this method can yield high asymmetry factor g, the presence of chiral inducers within the film can decrease the device performance of the CP-OLEDs.[2] To address this issue, it may be important to remove the chiral inducers from the emitting polymer after chiral induction is complete.

In this study, we doped the axially chiral small molecule BINOL into thin films of the achiral conjugated polymer F8BT. After the preparation of F8BT/BINOL films, only the CD signal of BINOL was detected and no signal of F8BT was observed. Upon annealing the films, the CD signal associated with BINOL disappeared and a clear CD signal from F8BT appeared, indicating the induction of chiroptical properties in F8BT.[3] NMR spectra of the samples before and after annealing confirmed the complete removal of BINOL by sublimation during annealing, resulting in the formation of pure F8BT films. By increasing the annealing temperature to 180 °C and the doping ratio of BINOL to 50 wt%, the CD signal intensity was enhanced and the $|g_{CD}|$ reached almost 0.1. Moreover, the annealed samples exhibited circularly polarized luminescence (CPL) with the maximum $|g_{PL}|$ reaching 0.1. The red shift of F8BT in absorption spectra and the fibrous morphology in AFM after annealing indicated that the chiroptical properties of F8BT were caused by intermolecular exciton coupling due to aggregation. The photoluminescence quantum yield (PLQY) of as-prepared F8BT/BINOL films was remarkably low (4.95% for F8BT/R-BINOL film and

8.35% for F8BT/S-BINOL film) but after annealing it increased to that of pure F8BT films (25.70% for F8BT/R-BINOL and 24.20% for F8BT/S-BINOL), suggesting that the removal of chiral inducers by high-temperature sublimation realized both high g factor and PLQY simultaneously.

We applied this thin film to the emitting layer of CP-OLEDs. TFB was used as the hole injection layer and the exciton blocking layer. The device after removing the chiral inducer achieved a maximum current efficiency (CE_{max}) of 1.46 cd/A and 1.45 cd/A for R-BINOL and S-BINOL samples. The g_{EL} of -5×10^{-3} and 7×10^{-3} for R-BINOL and S-BINOL sample were achieved without any optimization of the device structures.

This study demonstrates for the first time a way to realize CP-OLEDs by sublimable chiral inducers to avoid the negative impact of chiral inducers on the device performance.

Unique TADF Behavior Around Zero Gap Between Singlet and Triplet Excited States Youichi Tsuchiya, Keita Mizukoshi, Hyunje Jung and Chihaya Adachi; Kyushu University, Japan

In recent years, thermally activated delayed fluorescence (TADF) has garnered significant attention due to its straightforward application in creating high-efficiency organic light-emitting diodes (OLEDs). To develop high-performance TADF materials, researchers have focused on designing novel molecules with a small energy gap between the lowest excited singlet and triplet states (dE_{ST}). Detailed analysis indicates a substantial contribution from higher-lying excited states in spin-flipping processes. Most recently, a heptazine derivative that violated Hund's rule by exhibiting a negative dE_{ST} was reported, sparking considerable interest among photophysics researchers. In this study, we discovered an unusual thermal behavior in a donor-acceptor type TADF molecule, TMCz-BO, which shows nominal negative dE_{ST} but can be explained without a negative dE_{ST} through comprehensive kinetic analysis across various temperatures and solvents. Although activation energy has traditionally been considered temperature-independent, we emphasize that it should be viewed as a dynamic parameter influenced by environmental temperature, especially in cases of small energy gaps. Inadequate analysis could confuse and obscure a true understanding of the TADF mechanism. We intend to systematically organize the peculiar ST gap behavior around the zero gap and present an ideal molecular design.

EL01.08.14

***In Situ* Ultrafast Charge Carrier Dynamics of the Two-Dimensional Perovskites** Tuhin Ghosh and Jianbo Gao; Brock University, Canada

Skyrocketing the power conversion efficiency (PCE) of organic-inorganic metal halide perovskite (HOIP) beyond 25%, makes it a promising candidate for the low-cost next generation thin film based solar cell technology. However, long term environmental stability hinders its further development in their commercial application. Interestingly, Two-dimensional (2D) perovskite, originating from 3D perovskite structures, can be tuned by atomic scales, leading to electronic band structure tunability beyond 3D perovskites. In addition, they show much higher environmental stability as compared to their 3D counterpart. However, the carrier photogeneration and transport mechanisms remain unclear.

In comparison to that widely explored time-resolved optical spectroscopic techniques including pump–probe and fluorescence approaches to investigate carrier diffusion dynamics, we have used the novel ultrafast photocurrent spectroscopy to investigate the carrier drift dynamics.[i],[ii] In this project, we have investigated the 2D perovskites system including type 1 and type 2 perovskite (e.g., $(4Tm)_2SnI_4$, $(4Tm)_2PbI_4$, $(BTm)_2PbI_4$, BA_2PbI_4) and elucidated the nature of fundamental carrier photogeneration mechanism. Inaddition, to the proposed free carrier generation model, we demonstrated the importance of interlayer spacing in determining the exciton binding energy. Our work establishes the foundation for the 2D perovskite application in photovoltaics, photodetection, and LEDs.

Keywords: low dimensional, drift dynamics, charge trapping, exciton diffusion

Superradiance from Strongly Quantum-Confined Perovskite Quantum Dot Superlattices with Ligand-Tuned Electronic Coupling Lanyin Luo, Junhee Park and Chih-Wei Wang; Texas A&M University, United States

Cooperative emission of photons as superradiance from an ensemble of quantum dots arises from the coupled quantum dots that prepare a coherent emitting state, unlike in superfluorescence which emits coherent photons via synchronization of the incoherently excited quantum dots. Strongly confined metal halide perovskite quantum dots, with their sizes significantly smaller than the exciton Bohr diameter, are particularly suitable for generating superradiance due to the stronger delocalization of the exciton wavefunction among the quantum dots in their superlattices. The ability to control the interfacial ligand structure further allows us to systematically vary the inter-quantum dot electronic coupling, which can directly affect the coherent photon-emitting behavior. Here, we have examined the superradiance from 2D and 3D superlattices of $CsPbBr_3$ quantum dots in a strongly quantum-confined regime (4 nm quantum dot size vs 7 nm Bohr diameter) using surface ligands of varying lengths that tune the electronic coupling. While 2D superlattice $CsPbBr_3$ quantum dots do not exhibit superradiance, even with the ligand that reduce the facet-to-facet distance to 0.5 nm, 3D quantum dot superlattices exhibit well-defined superradiance emission when the original long ligand (oleylammonium bromide) is replaced with a ligand with shorter carbon chains at cryogenic temperatures (e.g., below 100-150 K). The superradiance from 4 nm CsPbBr3 quantum dot superlattices exhibits a much larger redshift (<150 meV) from the incoherent exciton emission, a narrower linewidth (3 meV), and stronger photon anti-bunching ($g^{(2)}$ of 1.6) compared to the weakly confined QD superlattices. These observations indicate a higher degree of exciton delocalization and electronic coupling of the state generating superradiance. The 4 nm $CsPbBr_3$ quantum dot superlattices also exhibit a preferred direction of linear polarization, indicating the anisotropic electronic coupling within the superlattice that may result from the lowered symmetry of the superlattice, especially when shorter ligands are used. These results demonstrate the potential of the superlattices of strongly confined perovskite quantum dots with controlled surface ligand structures as effective coherent multiphoton emitters.

Plasmon-Enhanced Fluorescence Test Strip for Rapid COVID-19 Detection Yingjie Hang, Weirui Tan, Anyang Wang and Nianqiang Wu; University of Massachusetts Amherst, United States

Infectious diseases, such as COVID-19, caused by the SARS-CoV-2 virus, have had a global impact in recent years. It is crucial to conduct rapid Covid-19 testing early on the onset of disease to effectively manage the spread of SARS-CoV-2 virus and to have medical intervention early. In this study, plasmon-enhanced fluorescence probes have been developed to detect SARS-CoV-2 antigen via lateral flow immunoassay. Surface plasmon resonance (SPR) is utilized to enhance the intensity of fluorescence dyes based on principles of excitation and emission enhancement. Then, a paper microfluidic strip has been engineered with integrated fluorescent probes to generate a point-of-care testing (POCT) tool. The performance of the integrated microfluidic strip has been used to test clinical samples and to compare its sensitivity and specificity with commercial rapid Covid-19 antigen test kits. This study highlights the potential of plasmon-enhanced fluorescence in managing infectious diseases.

EL01.08.17

Optical Coherence Time of CdSe Nanoplatelets Niamh Brown[1], Tara Sverko[1], Colette Sullivan[2], Lea Nienhaus[3], William Tisdale[1] and Moungi G. Bawendi[1]; [1]Massachusetts Institute of Technology, United States; [2]Florida State University, United States; [3]Rice University, United States

Optical quantum technologies are dependent on quantum emitters with near-perfect optical coherences, meaning highly efficient single-photon emission with long coherence times. CdSe Nanoplatelets (NPLs) present as a promising material for quantum emitters due to their high photoluminescence quantum yields, tunable emission energies, narrow size distribution and fast radiative lifetimes. Compared to their colloidal quantum dot analogues, NPLs feature order of magnitude faster radiative lifetimes at cryogenic temperatures, meaning much more efficient photon emission. However, to fully understand their potential as quantum emitters, understanding of their optical dephasing processes, and their coherence times, at cryogenic temperatures is necessary. Dephasing can occur due to a variety of processes including scattering with phonons, relaxation from multiple fine structure states, and interactions with charges resulting in spectral diffusion. To understand the dephasing mechanisms, single particle studies are necessary to avoid obfuscation that occurs with ensemble inhomogeneities. At the single particle level, conventional fluorescence techniques are limited due to low photon counts reducing the temporal resolution, and finite dispersing power of the spectrometer restricting the frequency resolution. To extend beyond these limits, we used photon correlation Fourier spectroscopy. Photon correlation Fourier spectroscopy allows for increased spectral and temporal resolution by combining the high temporal resolution of photon correlation spectroscopy and high frequency resolution of Fourier spectroscopy. Here, intensity correlations are measured at different interferometer positions, while dithering a mirror, to get a time dependent spectral correlation function. Here, we have used this unique technique on single particle CdSe NPLs, extract the spectral line shape, emitter dynamics, and lower bound for their optical decoherence time.

EL01.08.18

Near-Infrared-Light Emitting π-Conjugated Polymers Based on Boron-Fused Azobenzene Complexes with Multi-Functions Masayuki Gon and Kazuo Tanaka; Kyoto University, Japan

Heteroatoms have received a great deal of attention because of the potential to add unique characteristics of elements to carbon-based materials. Azobenzene, which includes a nitrogen–nitrogen double (N=N) bond in the structure, is a well-known scaffold showing photoisomerization. However, it is scarcely known that azobenzene has high electron affinity, and azobenzene is hardly used as a framework of π-conjugated polymer due to the photoisomerization. Therefore, electronic properties of azobenzene have not been clarified completely. Recently, it was reported that azobenzene exhibited luminescence with a boron–nitrogen (B–N) coordination which inhibited the photoisomerization and changed electronic conditions of azobenzene. This strategy suggests that azobenzene has a potential to be a new scaffold for π-conjugated polymers. Moreover, the excellent electron-accepting ability

is suitable for using an acceptor to construct donor–acceptor (D–A) π-conjugated system. Furthermore, the substituent on boron is perpendicularly protruded from the π-surface and effective in introducing functional units. In this research, we synthesized new boron-fused azobenzene (BAz) scaffolds by using azobenzene-based O,N,O-tridentate ligands as the acceptor and prepared D–A π-conjugated polymers showing near-infrared (NIR) emission composed of functional units on boron.

The monomer **BAzCF3**, where the trifluoromethyl group is introduced on boron of the BAz scaffold, was synthesized by the reaction of the brominated azobenzene-based O,N,O-tridentate ligand and potassium trifluoro(trifluoromethyl)borate (CF_3BF_3K). **BAzCF3** showed a strong electron-accepting ability with the low-lying lowest unoccupied molecular orbital (LUMO) energy level (−4.08 eV). **BAzCF3** was copolymerized by the Migita–Kosugi–Stille coupling reaction with bithiophene (BT) and cyclopentadithiophene (CDT) comonomers as donors to afford the D–A copolymers **P-BAzCF3-BT** (M_n = 23,800, M_w = 34,400, M_w/M_n = 1.5) and **P-BAzCF3-CDT** (M_n = 15,900, M_w = 36,900, M_w/M_n = 2.3), respectively. **P-BAzCF3-BT** and **P-BAzCF3-CDT** exhibited the highly efficient NIR emission in diluted toluene solution (λ_{abs} = 674 nm, λ_{PL} = 802 nm, Φ_{PL} = 11.7% for **P-BAzCF3-BT**, and λ_{abs} = 927 nm, λ_{PL} = 991 nm, Φ_{PL} = 2.0% for **P-BAzCF3-CDT**) and in film (λ_{abs} = 697 nm, λ_{PL} = 883 nm, Φ_{PL} = 3.8% for **P-BAzCF3-BT**, and λ_{abs} = 937 nm, λ_{PL} = 1026 nm, Φ_{PL} = 0.4% for **P-BAzCF3-CDT**). These polymers can be used in water by making water-dispersible nanoparticles with by the assistance of the amphiphilic polymer DSPE-MPEG(5000). As a result, we observed NIR emission in water without any aggregation (λ_{abs} = 641 nm, λ_{PL} = 891 nm, Φ_{PL} = 1.4%, brightness = 1022 $cm^{-1}M^{-1}$ for **P-BAzCF3-BT**, and λ_{abs} = 916 nm, λ_{PL} = 1036 nm, Φ_{PL} = 0.03%, brightness = 29 $cm^{-1}M^{-1}$ for **P-BAzCF3-CDT**). The performance is comparable to the other water-soluble π-conjugated polymers showing excellent emissions in the NIR-I (700 ~ 900 nm) and NIR-II region (1000 ~ 1700 nm).

We also prepared BAz-based π-conjugated polymers with azide moiety on the boron, enabling post-polymerization modification (PPM). The azide group reacts with alkyne group to form a triazole ring structure by copper-catalyzed alkyne–azide cycloaddition (CuAAC), which is widely known as click chemistry. The introduced functional units on boron by PPM were able to be released by chemical reactions triggered by boron. Indeed, we achieved the release of the functional units by UV irradiation by using radical generation from a photo-radical initiator. The system is available in water by making water-dispersible nanoparticles composed of the π-conjugated polymer and photo-radical initiator. Therefore, we concluded that the π-conjugated polymers based on BAz scaffolds are useful for the platform not only showing excellent NIR emission but also having releasable functional units based on the reactivity of boron.

Development of Zinc Chalcogenide Based Shell Layers for Colloidal Quantum Wells Cagatay Han Aldemir, Nehir Ergezer, Taha C. Korkmaz and Yusuf Kelestemur; Middle East Technical University, Turkey

Two-dimensional colloidal quantum wells have emerged as a promising class of materials for light-emitting devices due to their distinct excitonic properties, including narrow emission linewidths, suppressed Auger recombination, and directional emission. These properties are poised to enhance color quality, brightness, and efficiency in light-emitting devices. However, the commonly studied core/shell heterostructures employing cadmium sulfide shells, present limitations such as quasi type II electronic structures and incomplete electronic passivation for electrons. To address these challenges, we have developed a novel synthetic approach for the growth of zinc chalcogenide-based shell layers for colloidal quantum wells. Our initial investigations focused on the growth of ZnSe shell layers on CdSe colloidal quantum wells having a four-monolayer thickness. These newly synthesized core/shell quantum wells exhibit emission in the range of 620-630 nm with a remarkably narrow emission linewidth of approximately 20 nm. Furthermore, we synthesized core/shell quantum wells terminated with ZnS shell layers for improved surface passivation. These colloidal quantum wells, featuring a graded ZnSexS1-x shell layer, demonstrated a significantly enhanced photoluminescence quantum yield exceeding 85% by preserving their narrow emission linewidth. Finally, we assessed the performance of these newly synthesized colloidal quantum wells in light-emitting devices. Colloidal quantum wells with graded shell structures outperformed those with bare ZnSe shells, achieving an external quantum efficiency of 8.8%. Our findings highlight the potential of zinc chalcogenide shell layers to enhance the performance of colloidal quantum wells, paving the way for advanced light-emitting devices with superior efficiency and color quality.

This study was partially supported by the Scientific and Technological Research Council of Turkey (TUBITAK) under the grant no. 123E391 and partially supported by Research Fund of the Middle East Technical University under the project no. 11197.

Strategies for the Alignment of Electronic States in Quantum-Dot Tunnel-Injection Lasers and Their Influence on the Emission Dynamics

Michael Lorke[1,2], Igor Khanonkin[3], Johann Peter Reithmaier[4], Gadi Eisenstein[3] and Frank Jahnke[2]; [1]Universität Duisburg-Essen, Germany; [2]Universität Bremen, Germany; [3]Technion–Israel Institute of Technology, Israel; [4]Universitat Kassel, Germany

Tunnel injection (TI) lasers are an appealing concept for the next generation of semiconductor lasers, as they promise improved modulation rates and better temperature stability. Moreover, they eliminate a major detrimental effect of quantum dot (QDs) lasers, which is the gain nonlinearity caused by hot carriers.
In QD-TI lasers, the excited charge carriers are efficiently captured from the bulk states via an injector quantum well and then transferred into the QDs via a tunnel barrier.
The introduction of a tunnel barrier for controlling the coupling of QDs to an injector quantum well (QW) introduces significant design changes in comparison to conventional QD or QW lasers. As a result, nanoscale physics and quantum mechanical interaction processes take a more important role in the device properties.
The alignment of the electronic levels is crucial for the high efficiency of these processes and especially for the fast modulation dynamics of these lasers. In particular, the quantum mechanical nature of the tunneling process must be taken into account in the transition from two-dimensional quantum well states to zero-dimensional quantum dot states. This results in hybrid states, from which the scattering into the QD ground states takes place. We combine electronic state calculations of the tunnel-injection structures with many-body calculations of the scattering processes and insert this into a complete laser simulator. This allows us to study the influence of the level alignment and limitations due to inhomogeneous quantum-dot distributions. We find that the optimal alignment deviates from a simple picture in which the of the quantum-dot ground state energies are one LO-phonon energy below the injector quantum well ground state.

We present [1] a theoretical study of dynamical laser properties inclusing the transport within the device and show the impact of alignment between the injector quantum well and the QDs on the laser switch-on process and modulation properties. These are important for the use of these laser systems in novel telecommunication applications.

Dual-Microcavity Electroluminescent Devices for Ultra-High-Resolution Displays Jun Yong Kim[1], Sang Youn Lee[2], Kwan Hyun Cho[2] and Yun Seon Do[1]; [1]Kyungpook National University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Electroluminescent (EL) devices are being developed for next-generation displays. Among the various EL devices, organic light-emitting diodes (OLEDs), made from organic semiconductor materials, have advantages such as self-emission, flexible shape [1], and suitability for large-area processing [2]. To enhance OLED performance, microcavity structures have been extensively utilized. The strong resonance modes in these structures improve the color purity [3], light efficiency [3], and stability of OLEDs. However, traditional microcavity OLEDs (MOLEDs) face challenges in achieving ultra-high-resolution displays because the cavity lengths for red, green, and blue (RGB) wavelengths differ. Adjusting the cavity length in OLEDs requires additional patterning steps of the electron and hole transport layers. Additionally, MOLEDs without distributed Bragg reflectors (DBRs) have difficulty extending the color gamut in the International Commission on Illumination (CIE) 1931 color space owing to the broad emission spectrum of typical organic materials.

In this paper, we have introduced how to optically design a dual-microcavity structure by forming an external cavity layer on top of an OLED device. The dual-microcavity effect allows for the simultaneous creation of three peaks at each RGB wavelength, simplifying the patterning of RGB subpixels [4]. By controlling the external cavity length, the spectral characteristics of OLEDs can be manipulated independently of their electrical properties. Light amplification through the strong resonance modes of the dual-microcavity structures enables the OLEDs to achieve luminance values exceeding 50,000 cd/m^2. This outstanding luminance can be applied not only to commercial display applications but also to augmented reality applications and outdoor displays, which require high luminance. Additionally, dual-microcavity OLEDs (DMOLEDs) exhibit a narrower full width at half maximum value (FWHM<30 nm) compared to conventional MOLEDs, resulting in higher color purity. Therefore, we anticipate that the dual-microcavity effect will lead to advancements in various EL devices, offering high luminance and vivid color for ultra-high-resolution displays.

Quantitative Analysis of Stability and Degradation Mechanism of Low Work Function Electrodes in Ambient Moisture

Takuya Okada[1], Tsubasa Sasaki[1], Taku Oono[1], Hirohiko Fukagawa[2] and Takahisa Shimizu[1]; [1]NHK Science & Technology Research Laboratories, Japan; [2]Chiba University, Japan

Charge injection techniques that can control the electrical contact between metal electrodes and organic/inorganic layers have advanced to enhance electron transport across various semiconductors such as organic materials, perovskite, and quantum dots. Many semiconductors with unoccupied energy levels below 3.5 eV effectively utilize alkali metals with low work functions (WFs) as electrodes, facilitating electron transfer at electrode-semiconductor interfaces. However, these alkali metals are highly reactive to ambient oxygen and moisture, leading to semiconductor performance degradation. Consequently, researchers intensively have explored alternative electrodes that combine high chemical stability and low WFs [1-4]. Despite these efforts, understanding the exact mechanisms through which ambient oxygen and moisture degrade these electrodes remains contentious, highlighting the need for a further quantitative evaluation.

Herein, we developed an evaluation method to quantitatively assess the stability of low-WF electrodes in ambient moisture by shooting organic light-emitting diodes (OLEDs) and detecting changes in the luminescent area. By evaluating the OLEDs with phenanthroline derivatives [3] as a low-WF cathode, the luminescence area shrinkage depending on these electrode materials was clarified. Furthermore, the shrinkage velocity of the luminescent area depends not only on the relative humidity, previously reported [5], but also on the Phen derivatives membrane density calculated using molecular dynamics simulations. These results indicate that the degradation of the low-WF cathode is originated from the moisture diffusion into organic layers, driven by the density gradient of water molecules. Further details will be presented in the presentation.

RoHS Compliant, Efficient, Short Wave Infrared (SWIR) Quantum Dot Emitters

Avijit Saha and Vladimir Lesnyak; Technische Universität Dresden, Germany

Colloidal quantum dots (CQDs) that absorb and emit in the short-wave infrared (SWIR, 0.9–1.7 μm) region are critically important in optoelectronics (e.g., SWIR-based LEDs, lasers, photodetectors, telecommunication) and biological imaging. However, SWIR CQD LEDs often underperform due to the low photoluminescence quantum yield (PLQY) of the QDs. Furthermore, many efficient SWIR active QDs demonstrated in application[1] are based on heavy metals such as lead (Pb), cadmium (Cd), and mercury (Hg), which are highly toxic and subject to RoHS (Restriction of Hazardous Substances) regulatory restrictions for consumer electronics applications. This emphasizes the critical need for the development of more SWIR-efficient, environmentally friendly QDs to replace conventional Cd/Pb/Hg-based QDs in various applications.

In my presentation, I will explore the potential of I-III-VI-based nanocrystals, particularly Cu/Ag-In-Se, as **eco-friendly** alternatives to toxic heavy metal-based QDs[2]. Specifically, I will discuss the development of Cu-In-Zn-Se/ZnS (CIZSe-ZnS) core-shell QDs that emit in the SWIR range. I will detail our synthetic methodologies that enable precise modulation of composition and size tunability, facilitating targeted monitoring of PL emission over a wide range from **915 nm to 1230 nm**. To enhance the biocompatibility and chemical stability of the material, we passivated the QDs' surfaces with amorphous alumina (CIZSe/ZnS/Al_2O_3). This surface passivation not only ensures environmental and photostability but also enhances the PLQY. Notably, we achieved a **record PLQY of 53% at 1050 nm and 20% at 1230 nm, the highest** reported to date from heavy metal-free QDs. Unlike other indium-based multinary core-shell QDs (e.g., $CuInS_2$/ZnS), these nanocrystals exhibit a **narrow PL full width at half maximum (FWHM) of 102 meV** comparable to the Pb based QDs and platelets. Finally, I will demonstrate the application of these QDs as efficient SWIR-LEDs, underscoring their practical utility and potential for advancing optoelectronic technologies.

EL01.08.24

Enhanced Efficiency of NIR-OLEDs by Deuteration of Both Host and Guest Molecules Yuika Tamura[1], Hajime Nakanotani[1,2] and Chihaya Adachi[1,2]; [1]Kyushu University, Japan; [2]WPI I2-CNER, Kyushu Univ., Japan

The external quantum efficiency (EQE) of organic light-emitting diodes (OLEDs) in the visible area has reached its theoretical limit due to advancements in material development and device physics. Although OLEDs that emit near-infrared (NIR) light have the potential for valuable sensing applications in the future, they currently face the serious problem of low EQE, preventing practical use. This issue stems from the low photoluminescence quantum yield (PLQY) of NIR-emitting molecules resulting from a significant nonradiative decay rate following the energy gap law. Particularly, NIR-OLEDs emitting wavelengths over 900 nm are limited to only a few percent efficiency. Recently, a strategy involving the deuteration of C-H bonds in NIR emitters has been proposed to suppress nonradiative decay. Deuteration reduces the molecular vibrations of the emitting molecule, potentially suppressing nonradiative decay processes. However, there are only a few reports on the effect of deuteration on the NIR PL properties in host-guest codeposited films.

In this study, we investigated the impact of deuteration of both the host (mCP-d_{20}: 1,3-dicarbazole-benzene-d_{20}) and guest (BBT-TPA-d_{28}: 4,8-bis[4-(N,N-diphenylamino)phenyl]benzo[1,2-c:4,5-c']bis[1,2,5]thiadiazole-d_{28}) on the NIR PL and EL properties in the host-guest codeposited film. The 1wt%-BBT-TPA-d_{28}:mCP-d_{20} codeposited film exhibited a PLQY of 15 ± 2% with an emission peak wavelength at approximately 900 nm that is about three times higher than that of the film composed of the undeuterated molecule (~5%). Furthermore, the fluorescence lifetime of the codeposited film with 1wt% BBT-TPA-d_{28}:mCP-d_{20} is significantly longer (4.7 ns) compared to the undeuterated system (2.0 ns). This indicates suppression of nonradiative decay in the deuterated film.

We observed that the deuteration of only one of the host or guest molecules does not suppress the nonradiative decay process compared to the deuteration of both. This suggests that the host-guest interaction is important for suppressing the nonradiative decay process. Furthermore, NIR-OLEDs incorporating the deuterated codeposited film as an emissive layer demonstrated a maximum external EL quantum efficiency of 2.3 ± 0.2% with an EL peak wavelength of around 900 nm.

EL01.08.25

Efficient Formation of ALD-based Al-doped ZnMgO Alloys for Electron Transport Layer of Quantum Dot Light-Emitting Diodes Hyo Geun Lee[1,2], Yong Woo Kwon[2], Woon Ho Jung[2], Hyeonjun Lee[3], Min Seok Kim[1], Doh Chang Lee[3], Jaehoon Lim[2] and Seong-Yong Cho[1]; [1]Hanyang University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Colloidal quantum dots (QDs) are promising materials for next-generation self-emissive displays. The rapid development of colloidal quantum dot-based light-emitting diodes (QD-LEDs) is paving the way for QD-LEDs to become a core technology for future displays. Currently, ZnO is primarily used as the electron transport layer (ETL) material in QD-LEDs due to its high electron mobility and barrier-free electron transport properties. Therefore, it is essential to produce high-quality ZnO to maximize the performance of QD-LEDs. High-quality ZnO can be fabricated using the atomic layer deposition (ALD) process. ALD enables atomic-level processing through self-limiting reactions of each precursor via sequential adsorption. This method easily produces highly uniform and defect-free thin films and is suitable for display processes due to its capability to operate under vacuum conditions. However, high-quality ALD ZnO films experience charge imbalance due to their high mobility, which hinders optimal performance. To address this issue, a new approach considering charge transport and balance is needed.

While solution-processed alloyed ZnO nanoparticles, which are currently widely used, have improved QD-LED performance by suppressing excessive electron injection through alloying with various compositions, precise control of alloying remains a challenge due to differences in precursor reactivity, and introducing ternary and quaternary oxide components increases the complexity of synthesis conditions. However, to mitigate the high mobility of ALD ZnO, we employed an alternate deposition method (supercycle) by alternating Al_2O_3 and MgO layers between ZnO cycles to form Al-doped ZnMgO. This confirmed that simple composition control over a wide doping range is possible merely by adjusting the cycle ratio of Al_2O_3 and MgO. Al-doped ZnMgO with simultaneous addition of Al and Mg resulted in reduced hole mobility and increased conduction band without significantly decreasing conductivity. This effectively suppressed excessive electron injection without reducing electron injection efficiency, preventing QD negative charging at the ETL/QD junction and enhancing the photoluminescence quantum yield (PLQY). QD-LED devices using ALD Al-doped ZnMgO as the ETL achieved an external quantum efficiency (EQE) of 15.7%, compared to less than 6.5% for QD-LED devices using ALD ZnO, and increased the device lifetime by seven times. This study reports on ALD-based QD-LED devices that systematically introduce a series of doping elements into ALD ZnO and adjust the electrical properties and band gap of the ETL to overcome solubility limits of each element.

EL01.08.26

ZnMgO Nanoparticles via Ultrasonic-Assisted Synthesis for Electron Transport Layer in InP-Based QD-LEDs

Hyeonseung Ban[1], Yeongho Choi[2], Hyo Geun Lee[1], Woon Ho Jung[2], Jaehoon Lim[2] and Seong-Yong Cho[1]; [1]Hanyang University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Colloidal quantum dot-based quantum dot light-emitting diodes (QD-LEDs) have garnered attention as next-generation displays due to their high color purity, exceptional brightness, and simple solution-processing. Recently, the incorporation of Mg-doped ZnO nanoparticles (ZnMgO or ZMO) as the electron transport layer (ETL) in QD-LED structures has led to significant performance improvements by reducing excessive electron mobility compared to holes and suppressing surface defects. ZMO nanoparticles are synthesized through a solution process; however, traditional heating methods result in a very low Mg doping ratio compared to the amount of Mg precursor added. To increase the Mg doping ratio in ZMO, ultrasonic-assisted synthesis was introduced. When ultrasonic waves are applied to the ZMO precursor solution, cavitation bubbles are generated and collapse, momentarily producing high heat and pressure, thereby enhancing the low reactivity of the Mg precursor. Compared to heating-assisted synthesis, ZMO obtained via ultrasonic-assisted synthesis demonstrated relatively higher Mg content, as confirmed by X-ray photoelectron spectroscopy (XPS). Additionally, absorption and transmission electron microscope (TEM) measurements showed that the nanoparticles were relatively more uniform and smaller. When the ultrasonic synthesized ZMO and heating synthesized ZMO were applied as the ETL layer in green-emitting InP-based QD-LED devices, the smaller particle size and higher Mg content of the ultrasonic synthesized ZMO led to a more significant reduction in electron mobility compared to the heating synthesized ZMO. This resulted in maximum external quantum efficiencies (EQE) of 2.06% and 1.50%, respectively, with the ultrasonic synthesized ZMO achieving a 1.37-fold higher device performance.

To further exploit the benefits of ultrasonic-assisted synthesis in enhancing the reactivity of the Mg precursor, Mg precursor was added to pre-synthesized ZnO, followed by ultrasonic treatment, resulting in Mg-coated ZnO (ZnO/Mg). When ZnO/Mg was used as the ETL in environmentally friendly QD-LED devices with red and green-emitting InP-based quantum dots, the maximum EQE achieved were 11.35% and 2.51%, respectively, surpassing devices using both ZnO and ZMO. The brightness lifetime measurement of devices incorporating ZnO/Mg showed that it took approximately 43 hours to reach 50% brightness at 2,200 cd/m^2, demonstrating higher stability compared to devices using ZnO and ZMO (1.69-fold increase compared to ZnO). The enhanced stability of devices with ZnO/Mg is attributed to the formation of a stable ETL layer under electrical stress, which was confirmed by the sustained electrical stability of electron-only devices incorporating ZnO/Mg over time.

EL01.08.27

Dexter Energy Transfer from Quantum Dots to Closely-Bound Dye Molecules Mariam Kurashvili[1], Jordi Llusar[2], Tim Würthner[1], David Ederle[1], Ivan Infante[2,3], Jochen Feldmann[1] and Quinten A. Akkerman[1]; [1]Ludwig-Maximilians-Universität München, Germany; [2]BCMaterials, Spain; [3]Ikerbasque Basque Foundation for Science, Spain

Quantum dots (QDs) are semiconductor nanocrystals confined in all three dimensions, whose optical properties can be tuned by altering their size.[1,2] By combining QDs with dye molecules, we can make hybrid QD-dye systems that exhibit efficient energy transfer (ET) from QDs to dyes, important for sensing and lighting applications. ET usually proceeds through Förster resonance energy transfer (FRET), which requires significant spectral overlap between QD emission and dye absorbance, and large oscillator strengths of those transitions. This severely limits the choice of suitable dyes. Perovskite QDs do not require passivating inorganic shells for bright emission. Consequently, we can attach dye molecules directly to their surface, making ET mechanisms beyond FRET accessible. This work explores the design of a CsPbBr$_3$ QD-dye system with the aim of achieving efficient ET from CsPbBr$_3$ QDs to dyes with dimethyl iminium binding groups. The close binding of dyes to the CsPbBr$_3$ surface should facilitate spatial wavefunction overlap. We observe efficient ET from CsPbBr$_3$ to dyes with minimal spectral overlap. We show by steady-state and time-resolved photoluminescence experiments, that the ET proceeds via the Dexter exchange-type mechanism. This significantly improves the tuneability of such QD-dye systems, opening avenues for QD-molecule hybrids in a wide range of applications, such as lighting.[3]

Sculpting Light with Chiral Organic Crystals Hui Taou Kok[1], Chiao-Jung Su[1], Holly M. Johnson[1], Marta Rzeszutko[1], Prakruti Raghunarayan[2] and Barry P. Rand[1,1]; [1]Princeton University, United States; [2]The University of Texas at Austin, United States

The commercialization of organic light-emitting diodes is attributed to the versatility and energy-efficient fabrication of organic semiconductors (OSCs). Among all the organic options, chiral materials can selectively control circularly polarized light and dictate spin transport, unlocking innovations for OSCs in data storage, advanced sensors, and immersive 3D displays (*Adv. Photonics Res.* ***2021,*** *2 (4), 2000136*). As such, understanding the effects of molecular and solid-state chirality on the optical and electronic properties of chiral crystalline organic semiconductors is essential to fabricate state-of-the-art electronics.
In this study, thin films of 2,2-bis-(diphenylphosphino)-1,1-naphthalene (BINAP), an axially chiral molecule, are fabricated by thermally evaporating varying proportions of its R and S enantiomer. The as-fabricated thin films show similar luminescent behavior regardless of their R and S enantiomeric ratio. After thermal annealing into crystalline thin films, the intensity of luminescence increases significantly. Interestingly, a red-shifted emission was observed for the crystalline racemic mixture (1:1 ratio of R- and S-BINAP, or rac-BINAP) upon crystallization, whereas the crystalline R- and S-BINAP show blue-shifted emission. The different luminescent properties may be attributed to the different molecular arrangements of the crystals. While rac-BINAP exhibits platelet crystals up to the size of hundreds of microns with smooth molecular terraces, consistent with predictions based on their thermal properties (*J. Phys. Chem. C* ***2020****, 124 (49), 27213-27221*), R- and S-BINAP crystallize as spherulites with relatively rougher surfaces. Both platelet and spherulitic crystals can be fabricated on various substrates (e.g., glass, quartz, transparent conducting oxides, silicon, etc.) with high surface coverage. Systems with R- and S-BINAP deposited in other ratios exhibit platelet-like crystals with large-area coverage, with a higher tolerance to an excess of S-BINAP from 35% to 80%. Notably, similar crystallization was observed for both co-evaporated and discrete layered systems of S-BINAP R-BINAP layers, implying considerable molecular mobility upon annealing. Furthermore, these films showed similar fluorescence properties as the rac-BINAP crystalline thin films. The optical properties of the BINAP thin films and their solutions are further explored by circular dichroism (CD) and UV-Vis spectroscopy.

As a result, this work highlights the distinct crystallization behavior of chiral BINAPs and provides insights into controlling crystal morphology in chiral organic materials and their optical properties, which are important for their use in optoelectronic devices.

Light-Induced Fine-Tuning of Optical Cavities for Organic Optoelectronic Devices Shen Xing, Vasiliki Prifti, Hans Kleemann, Johannes Benduhn and Karl Leo; Technische Universität Dresden, Germany

Photonic processing techniques offer novel perspectives on material manipulation and device enhancement. Yet their potential remains largely untapped in organic materials due to complex material interactions. Here we report a transformative approach for the optimization of organic hole transport layers (HTLs) through light irradiation in ambient conditions. This innovative method maintains the conductivity of HTLs robustly while achieving a uniform reduction in thickness. Remarkably, the thickness reduction is controlled and is applicable to various organic materials. The practical application of this technique is validated in the successful fabrication of organic photodetectors and organic light-emitting diodes. Moreover, this strategy enables the precise structuring of organic HTLs with micrometer-scale resolution, opening new opportunities for the integration in organic electronic devices.

EL01.08.30

Surface Oxidation of Quantum Wires and Dots—Explaining Photoluminescent Blue Shift in Nanocrystalline Silicon Arturo Ramírez-Porras, Alexander Godínez and Luis M. Chacón; Universidad de Costa Rica, Costa Rica

Nanocrystalline structures were produced by electrochemical etching of boron-doped crystalline silicon in the presence of a strong acid. The resulting films, a few microns in depth, exhibited strong photoluminescence under blue or ultraviolet excitation in laboratory room conditions. Emission spectra were recorded using a spectrofluorometer with excitation wavelengths from 450 nm to 250 nm for both fresh and aged samples. The data showed broad photoluminescence (PL) peaks centered around 650 nm with distinct structural features. A blue shift in the PL peak maxima was observed with increasing excitation photon energy, more pronounced in aged samples compared to fresh ones. These results are interpreted using the Smart Quantum Confinement model, which considers contributions from silicon quantum wires (QWs) and quantum dots (QDs).

EL01.08.31

Engineering the Surface of PbS Quantum Dots—Insights from Solution NMR and Small-Angle Neutron Scattering

Eliza Price[1], Seryio Saris[1], Angelina Rogatch[2], Guilherme Bejar[1], Lilin He[3] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]Bryn Mawr College, United States; [3]Oak Ridge National Laboratory, United States

PbS quantum dots (QDs) possess tunable absorbance and emission in the near-infrared spectrum and are of interest for next-generation photovoltaic and photodetector devices. Like all QDs, PbS QDs are coated in organic ligands which enable solution processability, passivate defect sites, and guide self-assembly into ordered superlattices. A common method of synthesizing PbS QDs uses an excess of $PbCl_2$ to produce PbS-eCl QDs with record monodispersity and improved air stability. Although prior studies of PbS-eCl QDs suggest that they are coated by a $PbCl_2$ shell and passivated by oleic acid ligands, a recent study by Green, Wilson, and coworkers demonstrated that PbS-eCl QDs are actually passivated by oleylammonium-chloride.[1] Building upon this study, we refined a ligand exchange method for these QDs and found that the hallmark $PbCl_2$ shell of PbS-eCl QDs is highly sensitive to the presence of excess $PbCl_2$ during ligand exchange.

We detail our findings studying the surface of eCl-PbS QDs, including our ligand exchange methodology, characterization of the $PbCl_2$ shell, and evidence of defect passivation from photoluminescence quantum yield (PL QY) measurements. We observe that the native oleylammonium-chloride ligands of PbS-eCl QDs can be exchanged with an alkylamine-carboxylic acid pair. From 1D and 2D NMR experiments, we find that the new ligands bind in dynamic equilibrium with the surface and completely displace the native ligands. However, small-angle neutron scattering (SANS) measurements reveal that the $PbCl_2$ shell is absent from PbS-eCl if the excess $PbCl_2$ remaining from the synthesis is removed from solution prior to ligand exchange. Interestingly, we measure a PL QY > 50% for PbS-eCl synthesized both with and without the $PbCl_2$ shell a few weeks after synthesis, but further experiments are needed to assess the stability of the QDs. Our study indicates that despite their complex surface chemistry, eCl-PbS QDs can be engineered with precision through careful washing and ligand exchange methodologies.

Rational Molecular Design for Balanced Locally Excited and Charge Transfer Character to Achieve Dual Function of Two-Photon Absorption and TADF

Gomathi V. Mageswari, Yohei Chitose, Yoichi Tsuchiya and Chihaya Adachi; Kyushu University, Japan

The pursuit of molecular design of highly efficient thermally activated delayed fluorescence (TADF) emitters with two-photon absorption (2PA) character is hampered by the concurrent achievement of a small singlet-triplet energy gap (ΔE_{ST}) and a large oscillator strength (f). Here, by introducing a terephthalonitrile unit into a sterically crowded D-π-D structure, we designed TADF emitters with a 2PA phenomenon bearing hybrid electronic excitation character. This rational molecular design was achieved through a main π-conjugated donor-acceptor-donor (π-DAD) in line with locally excited features and an auxiliary N-donor-acceptor-donor (N-DAD) with charge transfer (CT) character, highly balancing the TADF phenomenon by a small ΔE_{ST} and maintaining high 2PA cross-section with a large f value. Moreover, the incorporation of naphthyl groups was found to manipulate the emission properties without surrendering the Φ_{PL} values. Through this approach, the emission modulation from yellow to orange-red was successfully realized by compromising the trade-off between a small ΔE_{ST} and a large f towards the goal of efficient OLEDs while retaining the TADF and 2PA character with rigid molecular framework. A near-unity Φ_{PL} value with a large radiative decay rate over an order of magnitude higher than the intersystem crossing (ISC) rate and a high horizontal orientation ratio ($\Theta_{//}$) of 0.95 were simultaneously obtained for the emitter of **TPCz2NP**. The organic light-emitting diode (OLED) fabricated with this material exhibits a record-high maximum external quantum efficiency (EQE) of 25.4% and EL peak at 573 nm with CIE coordinates of (0.50, 0.49). Notably, the **TPCzTPA** and **TPCz1NP**-based OLEDs displayed improved performance of a high EQE of 24.2% and 23.1% with EL peak at 564 nm and 550 nm, respectively, when compared with **2PhCzTPN** suggesting the merit of the design approach. Moreover, it is envisioned that the balanced RISC with high Φ_{PL} and radiative decay also render these compounds an ideal emitter for 2PA applications. Consequently, the elevated σ^2_{max} value of 143 GM at 850nm was realized for **TPCz2NP** which is highest among the reported TADF emitters with EQE_{max} values exceeding 25%. The successful integration of asymmetric electron-donating segments into the acceptor core underscores the full potential of this approach for advanced molecular systems with TADF and 2PA capabilities and would shed light on the futuristic realization of bio-applications. These findings offer a venue for designing high-performance TADF emitters with exceptional 2PA properties, expanding future OLEDs.

EL01.08.33

Photoluminescence from Undoped SnO_2 Thin Films by Chemical Vapor Deposition Poting Liu[1,2], Mohammed A. Nouh[3], Martin Koch[3], Vaidas Klimkevicius[4], Pilar Ferrer[5] and Vladimir Sivakov[1]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Friedrich-Schiller-University Jena, Germany; [3]Philipps-Universität Marburg, Germany; [4]Vilnius University, Lithuania; [5]Diamond Light Source, United Kingdom

Tin dioxide (SnO_2), as a direct band gap semiconductor with the reported bandgap value of 3.6 eV, has been widely applied in various applications, such as optoelectronics, photocatalysis, gas sensing and energy conversion devices (for example perovskite solar cells) [1]. Due to the high electron mobility, SnO_2 thin film manufactured by deposition methods is usually used as electron transport layer in optoelectronics, making it a curial role in these devices. Therefore, the understanding of fundamental properties of SnO_2 thin film is important to further promote its functions. In our previous studies, we have reported the possibility to conduct nanoscale engineering to deposit unique Sn-based nanostructures by using nanostructured/planar silicon surfaces [2-3]. Here, we report a strong photoluminescence effect was observed by a metal organic chemical vapor deposition (MOCVD) process. Under ultraviolet radiation in the wavelength range between 250-325 nm, the deposited SnO_2 thin film exhibited a broad orange photoluminescence near 600 nm or blue plotoluminescenc near 400 nm by different excitation source. Extensive surface and bulk characterization techniques such as electron microscopy, XRD, and synchrotron radiation based XPS and NEXAFS techniques were applied to study the atomic and electronic structure features of the deposited SnO_2 thin film. Furthermore, low-temperature photoluminescence and grazing-incidence small-angle scattering techniques were applied to understanding the origins of the observed photoluminescence. This study revealed deep fundamental understanding about the relationship between the structural features of SnO_2 thin film and its optoelectronic properties, providing theoretical basis for the further applications of SnO_2 in various devices.

Heteroepitaxial Growth of Ag(In,Ga)S2-AgGaS2 Colloidal Quantum Dots Seongbin Im; Sungkyunkwan University, Korea (the Republic of)

Colloidal Ag(In,Ga)S2 nanocrystals (AIGS NCs) with the band gap tunability by their size and composition have garnered surging interest. High absorption cross-section and narrow emission linewidth of AIGS NCs make them ideally suited to address the challenges of Cd-free NCs in wide-ranging photonic applications. Here, we report the heteroepitaxy for AIGS-AgGaS2 (AIGS-AGS) core-shell NCs bearing near-unity PL QYs in almost full visible. The heteroepitaxy between AIGS and AGS results in the Type I heterojunction that effectively confines charge carriers within the emissive core without optically active interfacial defects. AIGS-AGS NCs show remarkably higher extinction coefficient and narrower spectral linewidth compared to state-of-the-art heavy metal-free NCs, prompting their immediate use in practicable applications.

EL01.08.35

Enhanced Optical Properties of Green-Emitting InP Quantum Dots with Novel Mn-Doped Shells Akihito Okamoto, Shintaro Toda, Takumi Tsujihata, Takaki Kamada, Maowei Huang, Hirotake Kajii, Satoshi Seino and Tetsusei Kurashiki; Osaka University, Japan

Introduction:
Quantum dots (QDs) have made advances in display technology with tunable emission wavelengths, sharp spectra, and high quantum yield (QY). InP QDs are attracting attention as an environmentally friendly alternative to cadmium-based QDs due to the need to comply with environmental regulations. However, InP QDs currently underperform them in terms of QY and full-width at half-maximum (FWHM).[1] This performance gap is primarily attributed to two factors. First, the broad size distributions of InP QDs lead to wider emission spectra.[2, 3] Second, the relatively narrow bandgap of the ZnSe intermediate shell of InP/ZnSe/ZnS QDs, which is the current common structure for InP QDs, results in insufficient electron confinement, especially in the green emission range.[4]
Therefore, this study introduces InP/Zn(Mn)Se/Zn(Mn)S as novel shell materials that aim to enhance electron confinement by widening the bandgap and reducing the core-shell interfacial defects by improving lattice match.

Experimental Methods:
InP cores were synthesized by a reaction between indium and phosphorus precursors at 300 °C under an argon-purged environment. Then, epitaxial growth of InP/Zn(Mn)Se shells on the InP cores was conducted, and Zn(Mn)S shells were grown on that sequentially. We prepared samples with different adding ratios of Mn to Zn, ***X*** and compared their optical properties, which are ultraviolet-visible absorption (UV-Vis), photoluminescence (PL), and time-resolved PL. In addition, material analysis data was collected by X-ray diffraction (XRD), transmission electron microscopy (TEM), and energy-dispersive X-ray spectroscopy (EDX).

Results and Discussion:
TEM analysis confirmed spherical InP/Zn(Mn)Se/Zn(Mn)S QDs with an average diameter of 6.6 nm. PL measurements revealed that QYs of the InP/Zn(Mn)Se/Zn(Mn)S QDs were significantly improved compared to the

Mn non-doped ones. When ***X*** = 0.10, the QY reaches around 85% in the green-emission region, with the longest fluorescence lifetime in this study. These PL enhancements originate from the lattice matching and the bandgap engineering between InP-core and Zn(Mn)Se-shell. The data of EDX and XRD indicate Mn-doping into the ZnSe and ZnS lattices and that lattice constants of shells have become closer to that of InP-core with an increase of the ***X***. Furthermore, an increase of Mn proportion expected to widen the bandgap of Zn(Mn)Se shell to a value between 2.7 eV (for ZnSe) and 3.4 eV (for sphalerite-type MnSe). These effects result in the reduction of interfacial defect, enhancement of electron confinement, and improvement of radiative recombination rate. However, above ***X*** = 0.10, QYs decreased slightly (70% in ***X*** = 0.15 and 60% in ***X*** = 0.20). These results are likely due to Mn clustering or changes in the crystal structure of MnSe/MnS.

Conclusion and Outlook:
Zn(Mn) Se and Zn(Mn) S shells significantly improve the optical properties of green-emitting InP QDs. Future work includes extending to red and blue emission, studying long-term stability, and scaling up synthesis. This work bridges the gap between eco-friendly and high-performance QDs, paving the way for sustainable, advanced applications.

Understanding Trap States in InP and GaP Quantum Dots Through Density Functional Theory Ezra A. Alexander[1], Matthias Kick[1,2] and Troy Van Voorhis[1]; [1]Massachusetts Institute of Technology, United States; [2]Fritz-Haber Institute, Germany

The implementation of non-toxic, highly tunable III-V quantum dots (QDs) for emission is held back by low PLQY arising from trap states. Here, we apply density functional theory (DFT) to study trap states in a diverse set of realistic core-only InP and GaP QDs. Orbital localization allows us to deconvolute dense manifolds of trap states at the band edges to facilitate detailed study of surface defects. We show that three-coordinate species are the primary origin of trap states in III-V QDs and identify geometric and charge features which modulate and suppress the depth of traps. We observe different surface reconstruction in InP and GaP, where the more labile InP reconstructs to passivate three-coordinate indium at the cost of distortion elsewhere. This distortion gives rise in turn to trap states arising from four-coordinate cations and anions, denoted here as structural trap states. We delve deeper into the nature of these structural trap states here, investigating the prevalence of different types and providing intuitive arguments for their origin.

Passivation and Optical Emission Modification of Gallium Nitride Surface Quantum Wells Benjamin J. Sekely[1,1], Haotian Xue[1], Christopher T. Kuhs[2], Henry O. Everitt[2,3], Jonathan J. Wierer[1] and John F. Muth[1]; [1]North Carolina State University, United States; [2]U.S. Army Research Laboratory, United States; [3]Rice University, United States

Semiconductors are highly sensitive to surface adsorbents and the bonding of molecules to the surface. Often, surface cleaning and passivation practices are based on empirical evidence or studies conducted in high vacuum environments. An alternative is to use surface quantum wells (SQWs) consisting of a thin layer of lower bandgap material sandwiched by a vacuum or air interface on one side and a higher bandgap material on the other. These structures have been shown previously to have strong emission and to be sensitive to changes in surface recombination velocity that surface passivation treatments can alter. [1,2] Here, we systematically study the luminescence from GaN SQWs as a probe to investigate the interaction of acids and bases with a GaN surface. This is of special interest since III-Nitride devices, such as sensors, can depend on strain-induced spontaneous polarization, which can be strongly influenced by surface charge.

The MOCVD-grown samples studied are similar to GaN capping layers sometimes used on high-electron-mobility transistors (HEMTs). The thin Ga-face terminated GaN SQWs vary in thickness between 2 and 2.8 nm and were formed on $Al_{0.2}Ga_{0.8}N$ barriers to create the air or vacuum/GaN/AlGaN/GaN structure. The luminescence experiments were interpreted using self-consistent Schrödinger-Poisson equations to calculate the polarization and band structure of the GaN SQWs.

Using photoluminescence (PL) and cathodoluminescence (CL) spectroscopy, we show that the electronegativity of the passivating agent plays a substantial role in the emission efficiency and wavelength of emitted light. Passivating with more electronegative species like chlorine from hydrochloric acid (HCl) shifts the SQW emission to the blue, while using less electronegative species like sulfur from ammonium sulfide results in a redshift. Additionally, if the sulfide passivation is performed after an HCl passivation, the amount of blueshift can be reduced. This results from the added bonding molecule that passivates the surface defects and changes the charge balance and amount of spontaneous polarization that tilts the SQW energy band.

The changes in the magnitude of the SQW energy band tilt that result in the blue or redshift depend on the electronegativity of the passivating species relative to nitrogen and the number of bonded molecules. For example, when treated with HCl, a large ~8 meV blueshift is seen compared to an untreated sample due to interactions with chlorine anions, which have a greater electronegativity than nitrogen. When treated with ammonium sulfide, a redshift of ~5 meV is observed due to the sulfur anions, which are relatively electropositive compared to nitrogen. If treated with ammonium sulfide after HCl treatment, a smaller blueshift of ~2 meV is observed. We also observe corresponding changes in the intensity of the SQW peak. These changes are attributed to changes in surface recombination velocity and passivation of defects, as well as changes in recombination lifetime associated with the relative positions of the electron and hole wavefunctions as the SQW energy band is tilted.

Thermally Activated Delayed Fluorescence in Optical Cavities Inseong Cho[1], William Kendrick[2], Alexandra Stuart[1], Pria Ramkissoon[2], Kenneth Ghiggino[2], Wallace Wong[2] and Girish Lakhwani[1]; [1]The University of Sydney, Australia; [2]The University of Melbourne, Australia

Thermally activated delayed fluorescence (TADF) has gained great attention in light-emitting applications due to its potential to achieve 100% efficiency by recycling dark triplet excitons back into bright singlet excitons using ambient thermal energy. In recent years, multi-resonant TADF (MR-TADF) emitters have emerged as great candidates for next-generation organic light-emitting diodes (OLEDs) and lasing due to the high quantum yield and narrow emission bandwidth. However, MR-TADF emitters face molecular aggregation issues due to their planar structure, limiting their use in a host matrix at low doping concentrations. In particular, aggregate formation can lead to thermalisation and the formation of excimers that feature a large Stokes shift and broader emission. Here, we show that excimer emission can be appreciably suppressed by placing a thin film of MR-TADF emitters embedded in a host PMMA matrix within an optical cavity. Strong light-matter interactions in these microcavities result in Rabi splitting larger than 200 meV, placing lowest singlet excited state, i.e., lower polariton states close to the triplet state. Under the strong coupling regime, excimer emission is significantly reduced due to the strong emission from the lower polariton states. The rate constant of reverse intersystem crossing to the lower polariton states increases up to 33% in optical cavities, resulting from a lower activation energy barrier. This work highlights that strong light-matter interactions can mitigate excimer emission of highly aggregating emitter molecules post-synthetically, paving the way towards efficient light-emitting devices even at high doping concentrations.

EL01.08.40

Quantum Dots Dielectric Shelling Optimization Exploiting a Design of Experiment Approach Sergio Fiorito[1], Matteo Silvestri[2], Matilde Cirignano[1], Mauro Garbarino[1,3], Andrea Marini[2] and Francesco Di Stasio[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi dell'Aquila, Italy; [3]Università degli studi di Genova, Italy

Colloidal Quantum Dots (QDs) are a mature technology, currently exploited in consumer electronics products such as displays [1]. Some of the QDs light-emission properties are exploitable at the nanoscale too, via their integration in advanced photonic devices. Usually, to accomplish this integration, photonic components are added through microfabrication on the same substrate where QDs are deposited. A novel approach would be to combine photonic components directly on the QD surface, thus obtaining single particles presenting efficient and tunable photoluminescence together with a controlled emission. However, the difference in size between photonics components (> 100 nm) and QDs (< 20 nm) strongly hinders this approach. Dielectric shells such as SiO_2 or TiO_2 are promising candidates to increase the size of QDs to make their incorporation possible into larger structures with no or low impact on their emission properties. Other than increasing the particles' size, these shells can also be exploited as a support for their combination with photonic components through nano fabrication, or as a template for building multi-layer and multi-materials structures [2]. Recently, our group exploited the growth of a SiO_2 shell on CdSe/CdS QDs to create ordered arrays of single photon emitters inside a poly(methyl methacrylate) pattern [3]. In most cases, however, the final particles size obtained through literature available procedures (either Reverse Microemulsion or Stöber) is modest. These procedures suffer from low reproducibility and tunability mainly because they were developed and optimized exploiting an OVAT (one-variable-at-a-time) approach [4]. Here we report a systematic optimization study on SiO_2 shell growth on CdSe/CdS QDs, exploiting a full factorial "design of experiments" (DoE) [5]. Our approach allowed us to increase the SiO_2 shell thickness obtained with a single Reverse Microemulsion reaction from 15.5 nm to 22.75 nm, with a 47% improvement. The addition of a further Reverse Microemulsion step and of a Stöber process, made viable by the increased stability of the particles obtained through the optimized procedure, allowed to consistently grow a thicker SiO_2 shell, increasing the total diameter of QDs up to 95 nm. Finally, the influence of a SiO_2 shell having

different structures (glass, SiO_2 and quartz) or the presence of multi-materials shells on the emission of a QD was investigated through a dedicated modelling. Our results showed that the presence of a large enough shell with high refractive index or the presence of multiple layers of different materials can enhance the emission of the quantum dots through photon outcoupling.

One-Step Microwave-Irradiation Assisted Synthesis of Pure and Doped Zinc Sulfide Quantum Dots for Photocatalytic Applications

Angelie M. Núñez Colón and Sonia Bailon Ruiz; University of Puerto Rico, Puerto Rico

The uncontrolled release of antibiotics into natural water bodies by pharmaceutical industries is increasingly recognized as a significant threat to human and environmental health. Antibiotic pollution has emerged as a global issue due to its adverse effects on ecosystems and the potential risks it poses to organism well-being. The toxicity and resistance capacity of these pharmaceutical contaminants to conventional water treatment methods make it necessary to investigate degradation techniques that are environmentally conscious. In recent years, semiconductor materials, such as zinc sulfide nanoparticles, have gained significant attention due to their potential role in the photodegradation of pollutants such as antibiotics or dyes from textile companies due to their distinctive optical and electronic characteristics. Semiconductor materials like zinc sulfide have attracted significant attention for their potential in effectively addressing this issue.

These nanomaterials are typically synthesized in various methods, including hydrothermal, reflux system, and co-precipitation techniques. Based on these considerations, the present research was focused on the one-step synthesis of pure and doped zinc sulfide nanostructures using a microwave-assisted technique in an aqueous solution. It is known that the optical characteristics and subsequent its photocatalytic properties of QDs can be affected by several parameters such as type of coating (*3-Mercaptopropionic* acid and *Thioglycolic acid)*, synthesis temperature (120 °C, 140 °C, 160 °C, and 180 °C), reaction time (15 and 30 minutes) and the presence of dopant agent (Fe II). Based on the mentioned before, the primary objectives were to (I) evaluate the synthesis of zinc sulfide nanoparticles in the presence of different thiols, temperatures, reaction times, and concentrations of dopant agents, (II) characterize their optical properties, morphology, size and surface of QDs using ultraviolet visible light spectroscopy (UV-vis), photoluminescence spectroscopy (PL), High Resolution Transmission Electron Microscopy (HR-TEM) and Infrared Spectroscopy (FT-IR). Our findings from UV-vis results show an absorbance peak ranging from 320 nm to 323 nm. Photoluminescence spectroscopy revealed robust emission peaks with varying intensities ranging from 440 nm to 470 nm, indicating the influence of reaction time, temperature, and dopant concentration in the optical properties of the nanoparticles. Our findings indicate that the presence of dopants into the ZnS crystalline structure decreases the recombination processes, making them a potential candidate for use in the photodegradation of emerging organic compounds.

Development of Near-Infrared Emissive and Stimuli-Responsive π-Conjugated Materials Using Hypervalent Antimony Compounds Kazuya Tanimura, Masayuki Gon and Kazuo Tanaka; Kyoto University, Japan

Recently, main-group elements have been introduced into π-conjugated scaffolds for functionalization. However, heavy main-group elements have not been studied much because of their difficult handling and high toxicity. Our group previously reported hypervalent compounds combined with heavy main-group elements and π-conjugated scaffolds to explore the use of the heavy elements. In our previous work on the hypervalent tin (Tanaka, K. *et al. Chem. Eur. J.* **2021**, *27*, 7561), the heavy main-group element has unique electronic contributions to π-conjugated scaffolds, like a narrower energy gap between HOMO and LUMO because of the three-center four-electron (3c-4e) bond. In addition, the hypervalent tin compounds were able to interact with Lewis bases such as DMSO by using the Lewis acidic hypervalent tin, and the coordination changed the absorption and emission colors. In other words, we have succeeded in reflecting the changes in the elements as the variations in the electronic state of the π-conjugated scaffolds. Therefore, further development of heavy main-group elements in hypervalent states is expected to find novel functionalities derived from the properties of the elements.

This research focuses on “Antimony (Sb)” in group 15, fifth period. Antimony has different oxidation numbers (+3 and +5), and various hypervalent antimony compounds have been reported. We newly synthesized hypervalent antimony compounds **Sb** and **Sb5** with varying numbers of oxidation. Sb showed pseudo-trigonal bipyramidal geometry from their crystal structures, while **Sb5** showed octahedral geometry. The absorption spectra of **Sb** and **Sb5** implied significant differences in electronic states. According to density functional theory (DFT) calculation, these differences were caused by the electronic contribution of the hypervalent state. Furthermore, owing to the octahedral geometry, we revealed that **Sb5** was able to avoid the aggregation-caused quenching (ACQ). **P-Sb5**, polymerized **Sb5** with a bithiophene comonomer, showed high luminescence from the deep-red to the near-infrared region both in solution and film.

Next, focusing on the different optical properties of each oxidation number of the antimony, we tried to change their oxidation state by mechanochemical oxidation. In general, mechanochromism requires the crystallization of compounds, which makes it challenging to develop in materials. In addition, it is difficult to predict changes before and after mechanical stimulation, and new strategies are needed to design more designable mechanically stimuli-responsive materials. Therefore, we focused on mechanochemical reactions that do not require crystallization. Mechanochemical reactions can predict the optical properties of reactants and products, which can lead to high designability. Since trivalent antimony is easily oxidized to pentavalent antimony, we observed the change of the optical properties in response to mechanical stimuli by oxidation reaction in the solid state. As a result, we achieved different directions of the color changes with hypsochromic and bathochromic shifts based on the exact mechanism of the oxidation of the antimony. Furthermore, we were able to predict the color changes by quantum chemical calculation of the reactant and the product.

In summary, we synthesized novel hypervalent antimony compounds and developed unique materials derived from the properties of the hypervalent state of the heavy main-group elements. In the first topic, we succeeded in synthesizing near-infrared luminescent materials owing to the geometry of the elements. In the second topic, we have developed mechanically stimuli-responsive materials by utilizing the reactivity of the hypervalent antimony to change color in response to mechanical stimuli. The unique utilization of heavy main-group elements in hypervalent states, combined with π-conjugated scaffolds, demonstrates the potential to create a wide range of novel materials that have not been previously observed.

Towards an Atomistic Picture of Quantum Dots—Simulating Absorption Spectra and Exciton-Phonon Coupling

Alexandra Alexiu and Troy Van Voorhis; Massachusetts Institute of Technology, United States

Understanding the electronic structure of quantum dots (QDs) on an atomistic scale has the potential to drastically improve the performance of nanomaterial devices. Previous density functional theory (DFT) results draw a clear connection between undercoordinated chalcogenide atoms and the existence of deep trap states in II-VI QDs, for example. [1] However, most computational works only consider equilibrium structures at 0 K, which impedes direct comparison with experiment. Even routine measurements such as UV-Vis absorption spectra are not accurately predicted by simple DFT methodologies [2, 3]. Our work seeks to bridge the gap between theory and experiment, to facilitate a better atomistic understanding of QDs.

The Nuclear Ensemble Approach (NEA) [4] is the conventional method for simulating spectra that account for thermal and ensemble averaging. We show that NEA is effective in reproducing experimental results, but is prohibitively expensive for QDs that are beyond the ultrasmall regime.

To address this issue, our group proposes the less resource-intensive Harmonic Approximation (HA) approach, inspired by the independent mode displaced harmonic oscillator model. We assume the electronic potential energy surfaces of QDs to be harmonic, with excited states having the same curvature as the ground state. Absorption spectra for a series of II-VI QDs computed with the equilibrium HA accurately capture homogeneous broadening, at a fraction of the cost of the NEA method. To further include inhomogeneous broadening, we also developed the averaged HA. This technique requires limited sampling from an ab-initio molecular dynamics trajectory and accounts for the thermal expansion of QDs, as well as for some anharmonicity. This method yields highly accurate absorption spectra, at less than 50% of the cost of NEA.

With these results in mind, we hypothesize that the harmonic approximation works sufficiently well for modelling broadening effects in II-VI QD linear spectra. A leading cause of spectral broadening, exciton-phonon coupling, is subsequently investigated using the Huang-Rhys (HR) factor metric. Our findings suggest that low-frequency modes and LO phonons have the strongest coupling to electronic excitations, particularly with surface-localized trap states. Additionally, the degree of surface passivation drastically affects the average HR factor, with higher ligand coverage decreasing the exciton-phonon coupling. This leads to narrower absorption lines and steeper Urbach slopes, suggesting that phonons play a significant role in explaining passivation behavior.

The Harmonic Approximation DFT-based toolbox thus allows users to disentangle homogeneous and inhomogeneous broadening effects in QD absorption spectra across a wide range of temperatures. It also provides qualitative insights into the strength of exciton-phonon coupling and the slope of Urbach spectral tails. These methods could facilitate the more robust computational testing of passivation strategies and their effects on absorption and emission spectra, before experimentally validating them.

EL01.08.45

Dark Current Suppression and Enhancement of Photoconductivity Using Annealing and Sn-Ion Implantation in β-Ga_2O_3 Based UV Photodetector Kishor Upadhyaya[1], Fatimah Alreshidi[1], Hadeel Alamoudi[1], Duarte Esteves[2], Marco Peres[2], Katharina Lorenz[2] and Iman S. Roqan[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Técnico Lisboa, Portugal

β-Ga_2O_3-based self-powered solar-blind deep ultraviolet (DUV) photodetectors (PDs) are well known for their suitability for various optoelectronic applications. While Sn doping has been previously used to modify the electrical properties of β-Ga_2O_3, the impact of Sn implantation and subsequent annealing on PD performance remains unexplored. This study investigates the effects of Sn implantation and annealing on Ga_2O_3-based DUV PDs, aiming to optimize their sensitivity, response time, and self-powered operation. In this work, we report a systematic investigation of the effect of Sn ion implantation under different conditions such as energy, charge, and dosage, as well as post-annealing of the pulsed laser deposition grown β-Ga_2O_3 films on their electrical, structural, and optical properties. We also study the correlation between implantation and annealing with the performance of DUV PD devices. X-ray diffraction (XRD) studies reveal that the orientation of the films along the (-201) plane largely remains unaffected due to implantation, although there is a slight improvement in crystal quality post-annealing. Raman studies indicate the formation of vacancies in octahedral Ga_2O_3 chains due to substituting Sn ions at Ga sites, which could play a crucial role in enhancing the optical and electrical properties. XRD and Raman studies on all films confirm good damage recovery due to annealing after implantation. High-resolution transmission electron microscopy (HR-TEM) along with secondary ion mass spectroscopy (SIMS) reveal that the implantation depth is approximately 160 nm from the surface and the implanted region consists of smaller crystallites, while RBS studies are consistent with XRD and Raman, confirming the damage recovery post-annealing. UV-Vis spectroscopy shows a reduction in the bandgap as the implantation dosage increases due to the introduction of donor states below the conduction band. PD devices based on as-grown β-Ga_2O_3 exhibit significant dark current attributed to persistent photoconductivity (PPC), whereas the PDs based on annealed and Sn-implanted β-Ga_2O_3 films exhibit almost no dark current. Implanted Ga_2O_3 PDs demonstrate a remarkable reduction in dark current by 10^7 times and an improvement in the photo-to-dark current ratio by 10^5 times compared to as-grown PDs, along with an improvement in the rise and fall time. The effect of double charge on the ions, implantation energy, and dosage on device performance is studied to understand the underlying mechanism of dark current suppression. We discuss the mechanism of persistent photoconductivity suppression and its connection to surface oxygen vacancies, as well as the effect of annealing using X-ray photoelectron spectroscopy (XPS). This is the first report on a study of significantly enhanced self-powered solar-blind DUV PD devices fabricated via Sn^+ ion implantation (post-annealed) β-Ga_2O_3.

EL01.08.46

Two-Dimensional Layered Perovskites are Quasi 3D Semiconductors Jianbo Gao and Tuhin Ghosh; Brock University, Canada

Two-dimensional layered perovskites (2DLPs) have emerged as one of the most prominent candidates for next-generation optoelectronic applications due to their structural stability and tunable spacer design. However, the fundamental mechanism of carrier photogeneration remains unknown. Similar to other materials such as semiconductor quantum wells and transition-metal dichalcogenides (TMDCs), the primary mechanism is the formation of strongly bound excitons, as characterized by optical spectroscopies.

In this study, we observe free carrier generation in various spacer cation-based 2DLP structures, using both Pb and Sn, through ultrafast photocurrent spectroscopy with sub-25 picosecond time resolution. These 2DLPs exhibit carrier mobilities exceeding 3 cm2/Vs, exciton binding energies lower than those at room temperature, nearly

100% photogeneration quantum yield, and larger exciton Bohr radii. All these critical performance metrics are consistent with a dimensionality parameter greater than 2, suggesting these materials behave more like quasi-3D structures rather than exhibiting strong quantum confinement, as seen in typical 2D materials.

Our findings establish that 2DLPs with low-dielectric-constant spacer environments are quasi-3D materials. This work lays the foundation for the application of 2DLPs in a variety of optoelectronic devices, including solar cells, LEDs, photodetectors, and x-ray detectors.

EL01.08.47
Improved Stability of Quantum Dot Light-Emitting Diode with Alternatingly Doped Structure of Hole Transport Layer Dong Hyun Kim[1], Jeong Ha Hwang[2], Jaehoon Lim[2] and Donggu Lee[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Quantum dot light-emitting diodes (QLEDs) have garnered attention as next-generation light-emitting diodes (LEDs) due to their tunable spectra, wide color gamut, high color purity, cost-effective processing, and excellent optoelectronic properties. While extensive research has improved the performance of InP-based QLEDs, their stability needs further enhancement to compete with organic LEDs. InP quantum dots face challenges such as imprecise synthesis and weak electron stress, leading to lower exciton stability compared to Cd-based QDs. Therefore, improving the chemical and device engineering of InP QDs is essential for enhancing the stability of QLEDs.
Using a thick hole transport layer is an effective method for enhancing the lifetime and stability of QLEDs. However, increasing HTL thickness also increases resistance. Furthermore, the underlayer washing out during solution processing complicates the use of the thick HTL. Typically, doped charge transport layers using transition metal oxides such as MoO_3, WO_3 or organic molecules with high electron affinity are employed to increase the conductivity of the organic charge transport layers. Additionally, delta doping has been investigated as a method to precisely control the doping profile by inserting thin dopant layers at the nanometer scale in organic LEDs.
In this study, we propose a delta-doping structure with high conductivity and thick, solution-processed HTL to enhance the lifetime of QLEDs. The structure consists of alternating stacked layers of N4,N4'-di(naphthalen-1-yl)-N4,N4'-bis(4-vinylphenyl)biphenyl-4,4'-diamine (VNPB) and phosphomolybdic acid (PMA). We investigated the conductivity enhancement mechanism in alternatingly doped structure and examined the effect of HTL thickness on QLED performance and operational lifetime. This research represents a significant advancement in the commercialization of QLEDs, with substantial implications for new technologies and applications.

SESSION EL01.09: Photophysics of Perovskites and Quantum Dots

8:30 AM *EL01.09.01
Optical Probes of Emergent Low-Dimensional Semiconductors Laura Herz; University of Oxford, United Kingdom

Low-dimensional semiconductors have emerged as attractive materials for light-emitting diodes and solar cells, with lead halide perovskites emerging as particularly high-performing materials. The search for less toxic ingredients has led to the emergence of a plethora of new bismuth-based semiconductors, including bismuth halides and chalcogenides. Rapidly improving power conversion efficiencies have been realised for such materials, triggering new research efforts to explore and eliminate current limitations to performance. We examine thin films of $AgBiS_2$ nanocrystals as a function of Ag and Bi cation-ordering,[1] which is modified via thermal-annealing. Local Ag-rich and Bi-rich domains formed during hot-injection synthesis are transformed to induce homogeneous disorder (random Ag-Bi distribution). Such cation-disorder engineering results in a sixfold increase in the charge-carrier mobility, reaching 2.7 $cm^2 V^{-1} s^{-1}$ in $AgBiS_2$ nanocrystal thin films. We reveal an ultrafast charge-carrier self-trapping process that reduces charge-carrier mobilities on an ultrafast timescale, similar to previous observations for other bismuth-based semiconductors.[2-4] We show that homogeneous cation disorder reduces such charge-carrier localization, most likely because cation-disorder engineering flattens the disordered electronic landscape, removing tail states that would otherwise exacerbate Anderson localization of small polaronic states.[1]

We further discuss the charge-carrier photoconductivity dynamics in layered, 2D perovskites that have been found to improve the stability of metal halide perovskite thin films and devices.[5] We show that the 2D perovskite PEA_2PbI_4exhibits an excellent long-range mobility of 8.0 $cm^2 (V s)^{-1}$, ten times greater than the long-range mobility determined for a comparable 3D material $FA_{0.9}Cs_{0.1}PbI_3$. These values shows that the polycrystalline 2D thin films already have single-crystal-like qualities. We further demonstrate that PEA_2PbI_4 and BA_2PbI_4 exhibit unexpectedly high densities of sustained populations of free charge carriers, surpassing the Saha equation predictions even at low temperature.[6]These findings provide new insights into the temperature-dependent interplay of exciton and free-carrier populations in 2D MHPs. Furthermore, such sustained free charge-carrier population and high mobilities demonstrate the potential of these semiconductors for applications such as solar cells, transistors, and electrically driven light sources. In addition, we examine the transfer of excitations in the direction vertical to the 2D planes, examining anisotropy of transport in these materials.

9:00 AM *EL01.09.02
Perovskite Quantum Emitters Tze Chien Sum; Nanyang Technological University, Singapore

Halide perovskites are forerunners for next-generation photovoltaics and light-emitting devices. Their remarkable rise is driven by exceptional properties such as large absorption cross-sections, defect tolerance, significant spin-orbit coupling, long balanced charge diffusion lengths, slow hot carrier cooling, ion migration, and radiation tolerance. Consequently, their applications have rapidly expanded beyond traditional optoelectronics into areas such as spintronics, radiation detectors, memristors, bioimaging, and quantum light sources. Of late, low-dimensional halide perovskites have demonstrated great promise as single photon sources and as bunched multiphoton sources. In this talk, I will focus on our recent efforts on the basic photophysics studies and engineering of perovskite quantum emitters [1-4].

Spin-Exchange Carrier Multiplication in Manganese-Doped Inverted CdSe/HgSe Quantum Dots Jungchul Noh, Clément Livache, Donghyo Hahm, Valerio Pinchetti, Ho Jin, Changjo Kim and Victor I. Klimov; Los Alamos National Laboratory, United States

Carrier multiplication (CM) is a process whereby a single absorbed photon generates multiple excitons. In a standard scenario, CM occurs due to a Coulombic collision of an energetic, *hot* carrier that promotes a near-valence-band electron to the conduction band. A competing energy-relaxation pathway is fast phonon-assisted cooling, which is the major factor limiting CM yields. Here, we show that this limitation can be overcome by employing not direct but *spin-exchange (SE) Coulomb interactions* in Mn-doped core/shell CdSe/HgSe/ZnS quantum dots (QDs). We aim to enhance the SE-CM process by exploiting a high exchange coupling in the Mn-HgSe system where the resulting excitons are generated in the QDs. Furthermore, we 'invert' a core/shell structure by placing a lower bandgap material in the shell region to make both an electron and a hole electrically accessible. In the developed QD structure, SE-CM occurs via two steps: (1) SE-energy transfer from a 'hot' exciton generated in the CdSe core to an interfacial Mn ion, followed by (2) energy- and spin-conserving relaxation of the excited Mn ion to create two excitons (bright and dark) in the HgSe shell. Due to extremely short SE time scales, both SE steps occur without considerable interference from phonon emission, leading to high SE-CM efficiencies. Transient absorption (TA) measurements with spectrally tunable pump pulses indicate a sharp onset of SE-CM near the energy of the Mn spin-flip transition (E_{Mn} = 2.1 eV). The measured quantum efficiency (QE) of photon-to-exciton conversion exhibits a step-like growth and reaches 164%. Importantly, due to an 'inverted' architecture, SE-CM also leads to a considerable enhancement of a photocurrent in close-packed QD films. The QEs obtained from photocurrent measurements are in excellent agreement with those inferred from the TA studies. Our findings provide a considerable potential of SE-CM in advanced photoconversion systems.

Two-Photon Quantum Interference in Colloidal Lead-Halide Perovskite Quantum Dots Hendrik Utzat[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Chemically prepared colloidal semiconductor quantum dots have long been proposed as scalable and color-tunable single emitters in quantum optics, but they have typically suffered from prohibitively incoherent emission. Recent work has demonstrated the remarkable properties of individual lead-halide perovskite quantum dots (PQDs), which show remarkably coherent optical emission at low temperatures [1]. I highlight the latest developments of perovskite quantum emitters, including our first demonstration of two-photon (Hong-Ou-Mandel) interference of sequentially emitted single photons. We achieve visibilities of up to 0.55, above the limit for genuine quantum interference, even without cavity acceleration of the emission, indicating that entangled-photon generation is indeed possible with perovskites.[2] Our results highlight the potential of perovskite quantum dots as versatile, colloidal sources of coherent, indistinguishable single photons, that can further be engineered to emit circularly-polarized light with high efficiency and degree of polarization to open new avenues in chiral quantum optics.

Synthesis and Single Particle Spectroscopic Measurements of Strongly Confined Perovskite Quantum Dots

Yitong Dong, Chenjia Mi, Gavin C. Gee and Matthew L. Atteberry; The University of Oklahoma, United States

Colloidal lead halide perovskite quantum dots (QDs) have attracted much attention owing to their facile synthesis and high photoluminescence (PL) quantum yields. To understand their exotic optical properties, synthetic control over the size and shape of perovskite QDs is necessary. However, perovskite QDs grow very fast due to their low crystal formation energy, making their kinetic growth control difficult. Using $CsPbBr_3$ as an example, traditional hot-injection synthesis often produces large (> 7 nm) QDs with inadequate size uniformity. Instead of kinetically controlled growth, a thermodynamic equilibrium-controlled method was developed to produce strongly confined perovskite QDs with narrow QD size distributions from 3.5 nm to 7 nm. During this synthesis, QD growth is mediated by metastable nanoclusters with sizes around 2.4 nm. These nanoclusters can grow into strongly confined QDs if sufficient Cs-precursors are present. Otherwise, nanoclusters will self-assemble and fuse into nanoplatelets. By controlling the precursor ratio and concentrations, strongly confined perovskite QDs can be synthesized at the gram scale and are thermodynamically stable in solution at elevated temperatures for hours. The high structural stability enabled their surface morphology control and impurity doping synthetic control.

Despite the improved synthetic control of perovskite QDs, accurately determining their optical properties requires single-particle spectroscopic studies. Efforts on spectroscopic measurements of individual perovskite QDs were mainly focused on large, weakly-confined nanocrystals. The poor photostability of small (< 7 nm) $CsPbBr_3$ QDs makes their single-particle studies extremely challenging. In particular, they exhibit severe PL blinking and photodarkening since strong quantum confinement makes them more sensitive to surface defects. We found that the repulsive intermolecular interaction in QDs covered by conventional entropic ligands with bulky carbon chains will reduce the surface ligand coverage when QDs are isolated and solidified for single QD studies. We present that phenethylammonium (PEA) ligands with low steric effect and attractive inter-ligand interaction promote near-epitaxial surface passivation of single $CsPbBr_3$ QDs. Our QDs are nearly non-blinking and exhibit non-observable spectral shifting. Moreover, these QDs remain non-blinking after 12 hours of continuous measurements with no photodarkening. Size-dependent exciton properties of perovskite QDs are hence accurately determined using single-particle spectroscopies.

11:15 AM EL01.09.06

Optically-Pumped Lasing from Lead-Free Layered Halide Perovskites

Wenhao Shao[1], Jeong Hui Kim[1], Sangyeon Cho[2,3], Alexandra Boltasseva[1], Vladimir M. Shalaev[1] and Letian Dou[1]; [1]Purdue University, United States; [2]Massachusetts General Hospital, United States; [3]Harvard Medical School, United States

Layered metal-halide perovskites, or two-dimensional perovskites have excellent optical and electronic properties easily tunable via changing their composition. Morphological control of their nanocrystals enabled cavity-confined light amplification. In the first section of the talk, I will discuss the optically-pumped lasing performances in lead and tin-based layered perovskites from a photophysical perspective. In lead-based candidates, the lasing threshold is often constrained by the strong exciton-phonon interaction or Auger re-combination. Enhanced lasing performances have been pursued in quasi-2D systems (1). Lead-free tin-iodide-based candidates may exhibit lasing performances surpassing those of their lead counterparts, as has been shown in recent studies (2). However, their cryogenic lasing thresholds are still in the 100s μJ/cm^2 regime with substantial sample-to-sample variation and infamous stability. These limitations arise from the lack of compositional and morphological control.

The second section will discuss our recent crystal design and engineering toward scalable wet synthesis of 2D and quasi-2D layered perovskite nanowires. This "molecular templating method" suppresses crystal growth along all crystallographic directions except for a designable primary axis. Their exceptionally well-defined Fabry-Pérot cavities facilitated efficient low-loss waveguiding (below 3 dB/mm) and low-threshold light amplification (below 20 μJ/cm^2) in 2D tin-iodide nanowires at 80K (3). Subsequently, our recent progress will be discussed achieving room-temperature lasing and ambient-stable plasmonic lasing in quasi-2D tin-iodide perovskites.

2:00 PM *EL01.10.02
Hierarchically Structured Porphyrin Nanoparticle Photosensitizers Hongyou Fan; Sandia National Laboratories, United States

Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanoparticles for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, we report the synthesis of such nanoparticles through a surfactant-assisted interfacial self-assembly process using optically active porphyrin as a functional building block. The self-assembly process relies on specific interactions such as π–π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanooctahedra, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for potential synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange (MO) pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

3:00 PM EL01.10.03
Bright Near-Infrared Emission from Luminescent Defects in Semiconducting Single-Walled Carbon Nanotubes Simon Settele, Finn Sebastian, Nicolas F. Zorn and Jana Zaumseil; Universität Heidelberg, Germany

The controlled functionalization of chirality-sorted semiconducting single-walled carbon nanotubes (SWCNTs) with luminescent sp^3 or oxygen defects increases their photoluminescence quantum yield in the near-infrared (1000 – 1500 nm) and enables their application in optoelectronic devices (Adv. Opt. Mater. 2023, 11, 2300236), as single photon emitters at room temperature (Nat. Commun. 2021, 12, 2119), optical biosensors (Nat. Commun. 2024, 15, 706) or as fluorescent probes for in-vivo imaging in the second-biological window (NIR-II). However, obtaining luminescent defects with high brightness can be challenging with the current functionalization methods due to a small window of reaction conditions and the need for special chemicals (e.g., harmful diazonium salts). Here we report a novel method for introducing luminescent oxygen defects that only uses benign and inexpensive reactants. Sorted (6,5) SWCNTs in aqueous dispersion that are functionalized this way show bright defect emission at 1105 nm with a six times higher absolute photoluminescence quantum yield than the pristine nanotubes, reaching 3%. This functionalization can be performed within a wide range of reaction parameters and even with unsorted nanotube raw material at high concentrations, thus giving access to large amounts of brightly luminescent SWCNTs. The functionalization of biocompatible and ultra-short SWCNTs with these oxygen defects enables sufficiently bright emission for easy single-particle tracking in biological tissue.

3:15 PM EL01.10.04
Unraveling Exciton-Lattice Dynamics on the Emission from Excitons to Multiexcitons in Metal-halide Perovskite Quantum Dots Patanjali Kambhampati[1], Oleg Prezhdo[2] and Maksym V. Kovalenko[3]; [1]McGill University, Canada; [2]University of Southern California, United States; [3]ETH Zürich, Switzerland

Metal-halide perovskites have been under intense investigation for their promise in a variety of energy conversion applications that arise from their unique exciton-lattice interactions. Quamtum dots of these perovskites further enable exciton-lattice interactions and exploiting quantum size effects. These materials are attractive for light emission due to their high quantum yields, fast radiative recombination, and defect tolerance. They show efficient single photon emission with long coherence times, and a puzzling giant oscillator strength effect at low temperature. Like II-VI quantum dots, they show promise for optical gain and lasing. All these processes arise from the excitonics of the system and the way in which the excitonic system couples to the lattice bath.

Here, we apply time-resolved photoluminescence (t-PL) spectroscopy with 3 ps resolution to probe the excitonics if light emission in CsPbBr3 metal-halide perovskite quantum dots spanning weakly to strongly confined. This unprecedented time resolution enables, improving our prior work with 100 ps resolution, us to make first observations of key processes from low temperature superradiance, to multiexciton formation dynamics, to non-equilibrium exciton-phonon interactions, to strong exciton-lattice coupling that breaks the near universal Condon approximation. These ultrafast t-PL measurements reveal the richness of the system-bath interactions in metal-halide perovskite quantum dots. These measurements provide a first glimpse into light emission from high quality model system perovskite QD.
Key results are highlighted below:

The striking result is that the radiative rate constant of the single exciton increases at low temperatures with an exponential functional form, suggesting quantum coherent effects with dephasing at high temperatures. The opposing directions of the radiative and non-radiative decay rate constants enable enhanced brightening of PL from excitons to biexcitons due to quantum effects, promoting a faster approach to the quantum theoretical limits of light emission. *Ab initio* quantum dynamics simulations reproduce the experimental observations of radiation controlled by quantum spatial coherence enhanced at low temperatures.

The presence of higher fine structure states, let alone non-equilibrium processes within the fine structure, and multiexcitonic fine structure remains poorly understood due to a lack of experimental probes. The simple and immediate observation from temperature dependence is a previously unobserved fine structure to the multiexcitons. The bandwidth trajectories reveal the presence of a previously unobserved fine structure in excitons as well as multi-excitons. The bandwidth trajectories reveal a complex history, from multiexciton recombination to exciton thermalization to Auger heating to lattice thermalization.

Comparing the same size of QD reveals that perovskite QD have a large radiative rate constant for emission from X than CdSe QD due to a larger oscillator strength. The multiexciton (MX) regime reveals that perovskite QD emit brightly and with more focused bandwidth than equivalent sized CdSe QD enabling more spectrally pure brightness. The MX kinetics reveals that perovskite QD maintain efficient radiative decay, effectively competing with Auger recombination. These experiments reveal that strongly confined QD of perovskites can be efficient multiexcitonic emitters, such as in high brightness light emitting diodes, especially in the blue.

3:30 PM EL01.10.05

Hybrid Interfacial Layer for Enhancing Hole Injection in Quantum Dot Light Emitting Diodes Jeong Ha Hwang[1], Dong Hyun Kim[2], Donggu Lee[2] and Jaehoon Lim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of)

Colloidal quantum dots (QDs) have been applied in the display industry due to their outstanding optical properties, including tunable spectra, narrow full-width at half-maximum (FWHM), and compatibility with solution processing. To achieve high performance, QD light-emitting diodes (QD-LEDs), electroluminescent devices utilizing QDs, require efficient hole injection by engineering charge transport layers. This is essential for balanced charge injection, suppressing unwanted non-radiative recombination such as Auger recombination, and mitigating the hole transport layer (HTL) degradation caused by inefficient hole injection. It is typically reported that hole injection from the highest occupied molecular orbital (HOMO) of the HTL into the QD is inefficient. Therefore, techniques such as designing a stepwise injection structure using an HTL with a deep HOMO or fabricating the HTL structure with materials having high hole mobility have primarily focused on controlling injection at the HTL-QD interface. However, it is difficult to conclude that the injection characteristics at the HTL-QD interface solely determine inefficient hole injection.
Herein, we suggest increasing the hole injection efficiency by inducing p-type doping of the HTL through interface engineering between the hole injection layer (HIL) and HTL. To achieve p-type doping of the HTL, we prepared a solution-processed hybrid functional thin film (PVK:PMA) by mixing the organic molecular material poly(9-vinylcarbazole) (PVK) with the inorganic material phosphomolybdic acid (PMA). Through X-ray photoelectron spectroscopy and ultraviolet-visible spectroscopy analyses, we confirmed that a charge transfer complex (CTC) was induced by mixing PVK and PMA. Furthermore, the positive charges generated in the CTC can be easily separated into free charges by the electric field, and the separated positive charges can be injected into the HTL matrix without overcoming the hole injection barrier. However, since the negative charges separated from the CTC can recombine within the HIL, it is necessary to suppress the recombination of the negative charges. Therefore, by introducing transition metal oxide between HIL and PVK:PMA layer, the recombination caused by the negative charges from the CTC, is effectively suppressed due to the deep conduction band energy levels of transition metal oxide. Moreover, using ultraviolet photoelectron spectroscopy has shown that the high ionization energy of PVK:PMA contributes to alleviating the hole injection barrier at the transition metal oxide-HTL interface. These

results provide clear evidence for the increase in hole injection characteristics in QD-LEDs incorporating the PVK:PMA hybrid functional thin film. The HIL with the PVK:PMA hybrid functional thin film showed significant performance improvements compared to conventional HIL structures, with power efficiency increasing by 2 times and lifetime extending by 6 times. This approach highlights that efficient hole injection in QD-LEDs is determined by the number of holes present in the HTL, and it suggests that this approach could enable the realization of stable QD-LEDs suitable for applications requiring high efficiency and enhanced stability.

Supramolecular Metal Halide Complexes for High-Temperature Nonlinear Optical Switches Qian Wang[1], Jianbo Jin[2], Zhongxuan Wang[3], Shenqiang Ren[3], Qingyu Ye[1], Yixuan Dou[1], Sunhao Liu[1], Amanda Morris[1], Carla Slebodnick[1] and Lina Quan[1,1]; [1]Virginia Tech, United States; [2]University of California, Berkeley, United States; [3]University of Maryland, United States

Nonlinear optical (NLO) switching materials, which exhibit reversible intensity modulation in response to thermal stimuli, have found extensive applications across diverse fields including sensing, photoelectronics, and photonic applications. While significant progress has been made in solid-state NLO switching materials, these materials typically showcase their highest NLO performance near room temperature. However, this performance drastically deteriorates upon heating, primarily due to the phase transition undergone by the materials from noncentrosymmetric to centrosymmetric phase.
In this presentation, I will introduce a new class of supramolecular metal halide materials that exhibit switchable NLO when subjected to near-infrared (NIR) photoexcitation and/or thermal stimuli. The crystal structure in response to external stimuli is attributed to the presence of a weakly coordinated bridging water molecule facilitated by hydrogen bonding/chelation interactions between the metal halide and crown-ether supramolecules. We observed an exceptionally high second-harmonic generation (SHG) signal under continuous photoexcitation, even at temperatures exceeding 110 °C. Additionally, the bridging water molecules within the complex can be released and recaptured in a fully reversible manner, all without requiring excessive energy input. This feature allows for precise control of SHG signal activation and deactivation through structural transformations, resulting in a high-contrast off/on ratio, reaching values in the million-fold range.

4:00 PM EL01.10.07

Overcoming the Absorption Bottleneck for Solid-State Infrared-to-Visible Upconversion Pournima Narayanan[1], Manchen Hu[1], Arynn O. Gallegos[1], Linda Pucurimay[1], Qi Zhou[1], Emma Belliveau[1], Ghada Ahmed[1], Sebastian Fernandez[1], William Michaels[1], Natalia Murrietta[1], Vongaishe Mutatu[1], Demeng Feng[2], Rabeeya Hamid[2], Kyra M. Yap[1], Tracy H. Schloemer[1], Thomas Jaramillo[1], Mikhail Kats[2] and Daniel Congreve[1]; [1]Stanford University, United States; [2]University of Wisconsin–Madison, United States

Upconversion (UC) of near-infrared photons into visible photons can revolutionize state-of-the-art technologies in photovoltaics, night vision, anti-counterfeiting, photodetectors, and beyond. However, current solid-state triplet-triplet annihilation UC devices that rely on PbS quantum dots and organic semiconductor annihilators suffer from low absorption, low energy transfer rates, and highly parasitic back transfer processes which lead to low external quantum efficiencies (EQE). Here, we propose a device architecture which mitigates FRET-based back transfer to improve the EQE. We demonstrate the use of 5-tetracene carboxylic acid (TCA) as a ligand and blocker layer to drastically improve EQEs. Finally, the mechanism of improvement is deconvolved through spectroscopic studies of the system.

Deterministic Lattice Distortion in Mn-Doped Hybrid Layered Perovskite Microcrystals Grown by Chemical

Vapor Deposition Pushpender Yadav; Michigan State University, United States

Two-dimensional (2D) layered organic-inorganic hybrid perovskite (OIHP) semiconductors have gained significant interest in optoelectronics due to their high exciton binding energy and enhanced photoluminescence (PL) quantum yield. Perovskites doped with external impurities have opened up new avenues for modulating the structural and optical properties and exploring novel phenomena by inducing energy transfer from the free excitons to the dopants. Extensive studies on Mn2+ incorporation as a dopant have revealed intriguing optical and magnetic properties, making them attractive for next-generation applications in light-emitting diodes (LEDs), low-threshold lasers, solar cells, and spintronics. Despite significant investigations in optical properties in Mn-doped quantum dots and nanocrystals, the growth of such system beyond the nanoscale is scarce, leaving the precise influence of doping on crystal structure elusive. In this work, we present the synthesis of single-crystalline microcrystals of Mn-doped butylammonium lead bromide (BA2PbBr4) via chemical vapor deposition. For the first time, we observe significant lattice distortions upon Mn doping, resulting in orthorhombic-to-monoclinic phase transition. The distortion angle, observed in optical images of nanoplatelets (NPLs), is corroborated by high-angle annular dark-field (HAADF) transmission electron microscopy (TEM) images. Powder X-ray diffraction (PXRD) patterns suggest a layered crystal structure with an interlayer spacing reduced from 27Å to 25Å after doping. While the exact origin of such phase transition is unclear, I will discuss several plausible mechanisms. Electron spin resonance (EPR) spectroscopy revealed hyperfine coupling peaks and broad PL centered at 600 nm exhibiting decay lifetime of 0.3 milliseconds, confirming the dilute incorporation of Mn2+ into the host lattice. These findings offer significant insights into the structural modifications induced by doping, highlighting the possibility of tailoring material's optical and physical properties through lattice deformation.

Structural Transformations and Kinetic Properties of Supercooled-Liquid Phase-Change Materials Riccardo Mazzarello; Sapienza Università di Roma, Italy

Phase-change materials (PCMs) are employed in storage and neuromorphic computing devices, which exploit their ability to undergo fast and reversible transitions between crystalline and amorphous phases at moderately high temperature. At ambient temperature, both phases are very stable. Thus, the crystallization kinetics of PCMs depends very strongly on temperature. This property has been ascribed to the high fragility index of their supercooled liquid phase and, for some PCMs, to a strong-fragile crossover, probably associated to a structural liquid-liquid transition. In this work, we employ molecular dynamics simulations based on neural network potentials to investigate the structural and kinetic properties of selected PCMs, including GeTe and Sb-rich PCMs. We study the evolution of short- and medium-range structural order in the liquid phase as a function of temperature. In parallel, we calculate the viscosity and the α-relaxation time in the same temperature range. For a reliable extrapolation of the results to lower temperatures, we also evaluate the configurational entropy by computing the distribution of the local minima of the potential energy landscape. This quantity provides information on the possible occurrence of a fragile-to-strong kinetic crossover as well. Finally, we use the Adam-Gibbs equation to estimate the fragility index.

11:00 AM EL02.01.02

Finite-Element Modeling of Hopping Transport and Percolation in Reset Phase Change Memory Cells Md Samzid Bin Hafiz[1], Md Tashfiq Bin Kashem[2], Raihan Sayeed Khan[3], ABM Hasan Talukder[3], Faruk Dirisaglik[4], Helena Silva[1] and Ali Gokirmak[1]; [1]University of Connecticut, United States; [2]Ahsanullah University of Science and Technology, Bangladesh; [3]Intel Corporation, United States; [4]Eskisehir Osmangazi University, Turkey

Phase change memory (PCM) is an emerging high-speed non-volatile electronic memory technology that has been scaled down to sub-10 nm regime. Typical PCM cells are composed of a small volume of a phase change material, such as $Ge_2Sb_2Te_5$ (GST), and two electrical contacts The phase change materials in the active areas of PCM cells are electrothermally switched between highly-conductive crystalline phase and the highly-resistive amorphous phase using short (~1-1000 ns) voltage pulses. In our experiments on GST line-cells with width x length x thickness of ~ 100 nm x ~ 500 nm x ~ 20 nm, performed in the 80 K – 250 K temperature range, we observe (i) linear current-voltage (I-V) characteristics when the cells are in their low-resistance (crystalline) state, (ii) I-V characteristics with a hyperbolic sine behavior in the low-field regime (< 20 MV/m) and (iii) I-V characteristics with a stronger exponential response in the high-field (> 20 MV/m) regime, in their high-resistance (amorphous) state[1-3]. We are able to accelerate and stop resistance drift by stressing the devices with high-field for a few minutes. Hence, the characteristics obtained after the high-field stress are stable. Hyperbolic sine behavior is expected for thermionic emission over an energy barrier modulated by an external field and possibly hopping transport as a result. We have constructed a 2D hopping transport model using our experimental results that allows us to extract the hopping distances, hopping angles and activation energies related to the rate-limiting processes as a function of temperature.

In this study, we use a finite-element multi-physics platform (COMSOL) to study the impact of random variations in activation energy within GST to capture the naturally occurring random distributions inside the amorphous material. The exponential nature of the thermionic emission process leads to filaments (percolation paths) that carry significant portion of the current and are prone to threshold switching and local thermal runaway that initiates the set process. The fluctuations in the activation energy give rise to read noise in the high-resistance state, which hampers the multi-bit-per-cell implementations for PCM. Details of the model, the finite element results and the consequences of local variations will be presented.

Atomistic Simulations of the Crystallization Kinetics of $Ge_2Sb_2Te_5$ and GeTe in Confined Geometries Omar Abou El Kheir, Debdipto Acharya, Davide Campi and Marco Bernasconi; University of Milano-Bicocca, Italy

Phase change alloys are among the most promising materials for the realization of artificial neurons and synapses for neuromorphic computing. In these applications, one exploits the different resistive levels that can be realized by full or partial crystallization of the amorphous phase upon application of current pulses. In a recent work [1], it was proposed that a superlattice (SL) geometry made of alternating layers of the phase change material Sb_2Te_3 and more thermally stable confining layers of $TiTe_2$ woud exhibit superior properties for neuromorphic computing. However, Sb_2Te_3 suffers from insufficient data retention due to its low crystallization temperature T_x . Substituting Sb_2Te_3 with a phase change compound with a higher T_x, such as GeTe or $Ge_2Sb_2Te_5$ (GST), seems an interesting option in this respect. Nanoconfinement might, however, alters the crystallization kinetics with respect to the bulk. In this contribution, we will discuss the results of molecular dynamics simulations of the crystallization process of $Ge_2Sb_2Te_5$ and GeTe [2] nanoconfined in geometries mimicking GST/$TiTe_2$ or GeTe/$TiTe_2$ superlattices. To this aim, we performed large scale simulations with machine learning interatomic potentials [3,4]. The simulations reveal that nanoconfinement induces a mild reduction in the crystal growth velocities which would not hinder the application of GST/$TiTe_2$ or GeTe/$TiTe_2$ heterostructures in neuromorphic devices with superior data retention.

11:30 AM *EL02.01.04
Density Functional Simulations of Ag Migration in a Conductive Bridging Random Access Memory Cell Jaakko Akola[1,2], Konstantinos Konstantinou[3] and Robert O. Jones[4]; [1]Norwegian University of Science and Technology, Norway; [2]Tampere University, Finland; [3]University of Turku, Finland; [4]Forschungszentrum Jülich GmbH, Germany

We have performed density functional/molecular dynamics (DF/MD) simulations to investigate the drift of Ag atoms in an amorphous GeS2 solid-state electrolyte between Ag and Pt electrodes in the presence of a finite electric field. The model structure of 1019 atoms represents a conductive bridging random access memory (CBRAM) device. Simulations under an external electrostatic potential show Ag migration and the formation of percolating single-atom Ag wires through the solid-state electrolyte. The electronic structure analysis of selected snapshots shows that dissolved Ag atoms become markedly cationic, which changes when Ag clusters form at the Pt electrode. Sulfur becomes more anionic during the migration as a result of Ag-S bonding, and the effect is most pronounced near the active (Ag) electrode. The formation of conductive filaments requires a percolating network of Ag clusters to grow from the Pt interface, and the weakest links of this network appear at the Ag electrode. We also presents result for our latest electronic structure analyses of the prototypical phase-change material Ge2Sb2Te5. Hybrid DF simulations have enabled us to pinpoint electron/hole localization effects with local geometrical motifs both in the amorphous and re-crystallized phases.

SESSION EL02.02: Material Development—Synthesis and Characterization I

Advances in Phase Change Materials for Flexible Embedded Electronics Sabrina Calvi[1], Sara De Simone[2], Simone Prili[1,2], Massimo Longo[1,2], Raffaella Calarco[2] and Fabrizio Arciprete[1,2]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Nowadays smart systems, mainly for biomedical, automotive and aerospace fields, are strongly driving the request for innovative technologies to ensure in loco fast and safe data processing along with power and cost efficiency. Nevertheless, the stability, the mechanical flexibility, the huge computational and storage requirements of these applications are beyond the capability of current embedded devices. Phase-change materials (PCMs) are known as a solution to overcome the Von Neumann architecture, as active materials in a computational memory device that can in loco store data and carry out calculations at once, with a unique prospect of high performance and power efficiency. In line with the circular economy model, PCM-based devices can be fabricated with low cost technologies directly on flexible and large-area recyclable substrates. However, currently the potential of PCM materials in flexible devices is far from being fully exploited and their behavior on flexible substrates is still not clear.
Recently, our research group identified a suitable PCM alloy, with excellent thermal stability and mechanical toughness. The proposed work was intended to lay the groundwork for the development of low-cost and large-area compatible processes for high performance flexible PCM-based memories. Primarily, we evaluated the compatibility of these alloys with large-area scalability and their processability on flexible substrates. The electronic properties and the compliance of the performance to the target requirements were assessed with specific figures of merit, such as the resistance contrast between the amorphous and crystalline phases and the mechanical stability through bending tests. Additionally, the structural changes induced by annealing the alloys were examined to gain insights into the onset of crystallization and to highlight some differences during crystallization between film deposited on flexible substrates and standard SiOx, used as a reference for a rigid substrate. The integration of PCMs alloys as active material in flexible memories is discussed and the prospects of PCMs for flexible edge electronics will be presented. Overall, the research work done demonstrated that the PCM features and performances are well in line with the current industrial targets for flexible edge electronics.

2:00 PM EL02.02.02

The Complete Scenario of the Thermal Crystallization of Ge-Rich GST Alloys Eloise Rahier[1], Minh-Anh Luong[1], Sijia Ran[1], Sabyasachi Saha[1], Nicolas Ratel-Ramond[2] and Alain Claverie[1]; [1]Centre National de la Recherche Scientifique, France; [2]Institut National des Sciences Appliquées, France

Germanium enrichment of GeSbTe (Ge-rich GST or GGST) alloys appears to be a promising way of increasing their crystallization temperature and thus enabling their integration as PCMs in embedded systems. However, the crystallization stages of these highly non-stoichiometric alloys - a key phenomenon in their programming, but also in their degradation within memory cells - remain incomplete to date.

While numerous experiments show that crystallization of amorphous GGST layers ultimately leads to the formation of a two-phase material in which pure Ge and GST-225 crystalline phases coexist, the order of appearance of these two phases and the details of this crystallization are still debated. Moreover, the observation that Ge crystallizes at temperatures of around 310-330°C, well below the homogeneous crystallization temperature of bulk pure Ge (380-400°C), merits explanation.

To answer these questions, we carried out a campaign of XRD measurements at the synchrotron during 5 isothermal anneals (in situ) of GGST samples at low temperature (310 - 340°C). These isothermal anneals enable the mechanisms involved to be studied in detail over a wide time interval (several hours), and their energetic and kinetic characteristics to be decoupled, which is impossible when measurements are carried out during ramping-up. These results were complemented by analyses of samples annealed ex-situ at higher temperatures (up to 500°C). The characteristic parameters of the different phases present, such as grain sizes and weight fractions, were then extracted from the Rietveld analysis of the spectra obtained during annealing.

However, the many cubic GST phases that can be formed have extremely close lattice parameters, making them indistinguishable by XRD. For this reason, we complemented these analyses with structural and chemical analyses of in situ and ex-situ annealed samples using advanced transmission electron microscopy techniques such as STEM-HAADF and STEM-EELS. All these analyses were performed on extremely thin (< 25 nm) fresh lamella obtained by means of a new advanced approach using Focused Ion Beam (FIB) to avoid too much overlapping of the grains and mistakenly assigning them “exotic” phases.

We were thus able to formally identify the successive phases through which these alloys crystallize and identify the mechanisms underlying their formation.

At low temperatures (< 350°C), the homogeneous amorphous material undergoes phase separation, during which small regions of varying Ge content are formed (STEM-HAADF). After ripening, orthorhombic GeTe embryos (SG *Pnma*) are formed, triggering heterogeneous crystallization of the cubic Ge phase. The growth of this phase is totally dominated by nucleation (5 nm grains), and its kinetics limited by the production, via phase separation, of regions of ad hoc size and stoichiometry. In parallel, the *Pnma* GeTe phase transits to its cubic GeTe phase. At this point, the microstructure ceases to evolve over time. Sb is still dispersed and contained in an amorphous residue with a composition close to that of Sb-Te. Higher annealing temperatures (> 400°C) are required to force Sb to take part in crystallization. We show that it then gradually inserts itself into existing cubic GeTe grains to form increasingly Sb-rich GST phases (with $0.1<Sb/Te<0.4$) and to form new grains of hexagonal Sb-rich phases (Sb_2, Sb_2Te_3, GST-147 etc...).

This study shows that the crystallization kinetics of GGST are limited by the phase separation between Ge-rich and Sb-rich regions. This crystallization does not generate exotic phases but grains of listed Sb-poor cubic phases and of Sb-rich hexagonal phases. The GST-225 phase is not formed directly (as often claimed without demonstration) but gradually, via the insertion of Sb into the cubic GeTe lattice. All these phases are prone to be found in the pristine and active areas of PCM devices based on GGST.

2:15 PM EL02.02.03

Effects of Underlayer Engineering on Crystallization Kinetics of Ge-Rich GeSbTe Phase-Change Memory Alloys Ngoc Anh Nguyen, Jean-Baptiste Dory, Magali Tessaire, Van-Hoan Le, Frederic Fillot, Francois Aussenac, Mathieu Bernard, Guillaume Bourgeois, Antoine Salvi, Sylvain Gout, Francois Andrieu and Gabriele Navarro; CEA-

Leti, France

Phase change memory (PCM) is recognized as one of the most advanced and promising non-volatile memory technologies due to its high scalability, endurance, and retention time [1]. Among phase-change materials, Ge-rich GeSbTe (GGST) chalcogenide alloys are particularly noteworthy for their superior thermal stability compared to congruent compositions, a key attribute to address the strict reliability specifications of embedded automotive applications [2].

There is a growing interest in understanding the effects on crystallization kinetics of GGST in presence of various interfacial systems. Encapsulation layers can function as oxidation barriers or promote heterogeneous nucleation of Ge through interfacial chemical reactions [3]. Underlayers (UL) composed of Ge-deficient alloys serve as pathways for Ge atomic diffusion from GGST via grain boundaries, providing a crucial engineering tool to modulate the crystallization kinetics of GGST layers [4]. However, the impact of ULs with varying starting crystallization states and stoichiometries on GGST has not yet been comprehensively studied.

In this work, we investigate the effects of GST-based and Ge-based ULs, prepared under different thermal conditions, on the crystallization process of GGST bulk phase-change layers. The evolution of the UL/PCM interface under different temperature profiles reveals the atomic Ge absorption kinetics of the bottom layers, resulting in a delay in the stack crystallization temperature. This phenomenon is distinctly observed through film resistivity measurements using four-point probes coupled with a hot plate. The Ge concentration mismatch after diffusion influences the crystallographic arrangement of Sb-Te and Ge grains within the bulk material, as evidenced by a combination of physicochemical characterization techniques, including Raman spectroscopy, X-ray diffraction (XRD), and transmission electron microscopy with energy-dispersive X-ray spectroscopy (TEM/EDX) analyses.

In conclusion, our analysis of GGST systems interfaced with various ULs highlights the important effect of UL structure and stoichiometry on the phases' segregation and crystallization kinetics in Ge-rich GeSbTe alloys. We believe that these results can provide important insights into possible engineering pathways for delaying and controlling segregation phenomena in Ge-rich GeSbTe systems.

2:30 PM *EL02.02.04

Crystallization Behavior of Ge-Rich Ge-Sb-Te Thin Films for Embedded Memory Applications—Insights from Synchrotron X-Ray Scattering Olivier Thomas[1,2], Thomas Fernandes[1,3], Michaël Texier[1,2], Thomas W. Cornelius[1,2], Solene Dassonneville[1,2], Simon Jeannot[3], Yannick Le Friec[3], Philippe Boivin[3], Roberto Simola[3], Gabriele Navarro[4], Philipp Hans[1,5], Cristian Mocuta[6], Madeleine Han[7], Martin Rosenthal[7] and Celine Mariette[7]; [1]Aix-Marseille Université, France; [2]CNRS, France; [3]STMicroelectronics, France; [4]Commissariat à l'énergie atomique et aux énergies alternatives, France; [5]SESAME, Jordan; [6]Synchrotron SOLEIL, France; [7]European Synchrotron Radiation Facility, France

Phase-Change Memory is a very promising non-volatile memory that is being considered by several companies for

a wide range of applications (storage-class memory, in-memory computing, neuromorphic computing, eNVM for microcontrollers ...). At STMicroelectronics a new Ge-rich Ge-Sb-Te alloy (GGST) has been developed with a crystallization temperature above 350°C [1] for addressing the specific needs of the automotive market where high operating temperatures are needed. Although this new alloy meets the requirements of the industry (robustness, stability at elevated temperatures, endurance...) an in-depth understanding of the materials physics of the memory cell at the nanoscale is needed for technology evolution as well as future downscaling. Among important issues it is important to underline that GGST composition does not correspond to a single crystal phase, which implies that crystallization is accompanied by phase separation (Ge followed by $Ge_2Sb_2Te_5$) as observed experimentally [2]. This has important consequences regarding elemental segregation during the operation of memory cells.
The high X-ray photon flux provided by synchrotron facilities allow investigating *in situ* ultra thin (50 nm and below) GGST thin films during crystallization either using X-ray diffraction (XRD) or X-ray fluorescence (XRF). *In situ* XRD experiments [2-4] performed at DiffAbs beamline (SOLEIL) provide detailed information about phase change kinetics, stress and texture evolution as a function of film thickness or nature of underlayer. XRF microscopy [5] allows monitoring elemental segregation during the phase transformation (ID16B beamline at ESRF) and its dependance on doping. Finally, laser induced crystallization as well as time-resolved pump probe dynamics of Ge and GST have been investigated at ID09 beamline (ESRF). These latter experiments help bridging the huge time gap between furnace annealing experiment and memory cells operation (more than 10 orders of magnitude). These X-ray scattering results bear important consequences for the understanding of the crystallization process in memory cells and demonstrate the usefulness of synchrotron radiation for investigating these complex materials.

Acknowledgments:
The authors gratefully acknowledge the ESRF and SOLEIL synchrotrons for allocating beam time. This research is supported by IPCEI/Nano 2022 and Nano 2025 programs.

Nanoscale Characterization of Ge-Rich GeSbTe in Thin Films, Memory Cells and Heterostructures Antonio Massimiliano Mio; Consiglio Nazionale delle Ricerche, Italy

Phase-Change Materials (PCMs), mainly represented by (GeTe) -(Sb_2Te_3) (GST) alloys, are used for high-density data storage in optical media and for solid-state non-volatile memories. Among all, Ge-rich GeSbTe alloys has been proposed to increase the crystallization temperature and therefore to improve data retention in high-temperature applications of non-volatile PCM memories. However, Ge-rich GeSbTe alloys tend to decompose, producing Ge segregation and compositional changes, as a consequence of elemental diffusion.
In PCM devices, the failure mechanism is strongly related with mass transport occurring during programming. Due to this elemental transport both phase separation and segregations can occur and indeed these issues has been reported both in heater-based architectures, like vertical mushroom cells, and in self-heating planar architectures, like line cells.

While the details of such mass transport strictly depend on the architecture and the programming conditions, some general trends can be recognized. To this aim, the local structural and chemical analysis of memory cells after forming and cycling could provide an insight into the degradation mechanism.
In this work, Ge-rich PCMs have been investigated at the nanoscale, by means of conventional Transmission Electron Microscopy (TEM), High Angular Annular Dark Field (HAADF) Scanning/TEM (S/TEM) and correlated Energy X-ray Dispersive Spectroscopy (EDXS) and Electron Energy Loss Spectroscopy (EELS). The behavior of several Ge-rich GST systems is discussed, starting from Ge-rich thin films to memory cells and heterostructures.
Ge-rich GST thin films with high Ge amount (>40%) are characterized by a high crystallization temperature (270 °C). By EELS mapping and electron diffraction, we studied the phase separation as function of the as grown alloy composition.
Single Cell Vehicle (SCV) mushroom Ge-rich GST cells, with a TiN heater in the range of 50-100nm, have been prepared in fresh reset, cycled reset and stuck reset states. The present study shows with high spatial resolution how the forming process modifies the initial elemental distribution and how it evolves upon cycling.
Finally, with a focus on S/TEM and EELS analyses, we present our last results on PCM heterostructures upon annealing. Chalcogenide heterostructures, fabricated by a combination of PCM and Confinement Materials (CMs), offer indeed the opportunity of tuning different physical properties, possibly combining features ascribed to the constituent single thin films. For multilayers containing Ge-rich GST we have observed a minimized Ge segregation, while increasing the crystallization temperature with respect to GST225.

Laser-Induced Crystallization of Ge-rich GST Thin Films—Insights from *In Situ* Synchrotron X-Ray Diffraction and Electron Microscopy Thomas Fernandes[1,2], Michaël Texier[2], Philipp Hans[3], Solene Dassonneville[2], Simon Jeannot[1], Celine Mariette[4], Yannick Le Friec[1], Roberto Simola[1] and Olivier Thomas[2]; [1]STMicroelectronics, France; [2]Aix-Marseille Université, France; [3]SESAME, Jordan; [4]European Synchrotron Radiation Facility, France

Phase Change Materials (PCM) are very promising candidates for future non-volatile memory applications [1]. The contrast between two phases (amorphous and crystalline) and the differences in their physical properties (resistivity, optical reflectivity ...) allows modifying and reading the state of the memory. The most studied PCM is $Ge_2Sb_2Te_5$ (GST), with a crystallization temperature within the 150-170°C range. This temperature is too low for data retention in automotive applications but Ge-rich GST (GGST) with a crystallization temperature of 350°C has been developed [2] and is fully suitable for this purpose. While *in situ* furnace-annealing of GGST have been recently performed at low heating rates (few °C/min) evidencing a sequential crystallization of the Ge and $Ge_2Sb_2Te_5$ phases [3], real memories are switched at the ns timescale. In the aim of performing time-resolved investigations of the phase transformations in GGST and reproducing the crystallization dynamics of operating devices, laser irradiation experiments were performed *in situ*. The X-ray Diffraction (XRD) experiments have been performed on ID09 beamline at ESRF (France). Samples were irradiated *in situ* thanks to a laser with an 800nm wavelength and a pulse duration of 100ps which matches the minimal pulse length of the X-ray beam. Laser pulses had fluences going from 14 to 219 mJ/cm^2 and a focused pink (14.5 keV, $\Delta E/E \sim 1.5$ %, size ~ 25 µm (V) x 49 µm (H)) X-ray beam was used for probing the sample response at an incident angle of 1° with high enough flux (~10^8 photons/100ps pulse). The laser is connected to the synchrotron bunch clock which allows laser and x-ray pulses to be emitted synchronously. The laser had an angle of incidence of 15°. A charge coupled device (CCD) detector was used with a total active area of 170x170mm^2. A piezoelectric stage allowed positioning the X-ray beam at the maximum of the laser intensity. The investigated samples were 50nm thick GGST thin films with the following structure: Si(001) substrate// 30nm SiO_2 // 15nm SiN// 50nm GGST// 15nm SiN. GGST layers are deposited by physical vapor deposition SiN capping is deposited by chemical vapor deposition). From the 2D diffraction patterns Ge and GST crystallization have been evidenced. The diffraction peaks are fitted with a Gaussian function after background subtraction. The evolution of integrated intensity, integral breadth and peak position for Ge 111 and GST 200 as a function of laser fluence and number of laser pulses will be presented and discussed. These results demonstrate the ability to control the crystallization of GGST with laser irradiation and open the way to future time-resolved experiments of the reversible phase change mechanisms. Time resolved experiments have been also performed on partially crystallized samples at a fluence of 34mJ/cm^2. The time evolution of the Ge 111 peak position has been monitored and shows a 300 ps rise time followed by a slow 20ns relaxation**.** *Post mortem* scanning electron microscopy observations of the samples allows different regimes of the laser-sample interaction to be distinguished depending on the laser fluence and number of pulses.

***In Situ* Thermal Imaging of Threshold Switching Devices** Etienne Puyoo[1], David Albertini[1], Nicolas Baboux[1], Sanjoy Nandi[2], Sujan Das[2] and Rob Elliman[2]; [1]Institut des Nanotechnologies de Lyon, France; [2]The Australian National University, Australia

Negative Differential Resistor (NDR) devices based on Metal Oxide Metal (MOM) junctions are good candidates for the development of high-density memory selectors, and are also being considered as a building block for the development of neuromorphic hardware architectures [1, 2]. We will demonstrate through two case studies that the development of in situ Scanning Thermal Microscopy (SThM) experiments is well suited to the characterization of threshold switching devices whose operating principle relies essentially on electro-thermal effects. The first case study will focus on the observation and analysis of current line redistribution in niobium oxide devices [3]. The second case study will focus on devices based on vanadium oxide V_3O_5, which exhibits an insulator to metal transition (IMT) around 420K [4]. Analysis of SThM images taken at different operating points enables us to observe the initiation of NDR behavior at a temperature well below the transition temperature of the V_3O_5 material. This result confirms a theory according to which the initiation of NDR behavior is essentially attributed to the temperature dependence of the conductivity of the insulating phase of V_3O_5, and not directly to the IMT. In addition to confirming existing theories, SThM cartographies enable us to develop multiphysics finite element models, and open the way to thermal management of the studied structures for a global control of device operation.

Electrical and Structural Properties of Partial-RESET States in Ge-Rich GeSbTe PCM Cells Adrien Delpoux[1], Sijia Ran[2], Alain Claverie[2], Daniel Benoit[3], Simon Jeannot[3] and Jérémie Grisolia[1]; [1]Institut National des Sciences Appliquées, France; [2]Centre d'Élaboration des Matériaux et d'Etudes Structurales, France; [3]STMicroelectronics, France

Phase change memories (PCMs) are a promising candidate for the next generation of electronic devices (e.g. neuromorphic and in-memory computing, artificial intelligence, ...). Nowadays, the $Ge_2Sb_2Te_5$ (GST-225) alloy is one of the most common material for PCM, notably explained by its properties: high resistive contrast, fast switching speed, cycling performance...
Nevertheless, the low crystallization temperature of GST-225 (around 150°C) makes it not suitable for embedded and automotive applications. Thus, recent work has proposed the Ge-rich GST alloy (GGST) as a good candidate to address high-temperature applications. Indeed, the crystallization temperature of such alloys increases with the Ge content enabling to reach crystallization temperatures above 300°C.
During thermal annealing, GGST alloys undergo chemical phase separation and form grains of different phases during crystallization, such as GST and Ge [1]. In PCM cells, the GGST material experiences high-temperature heating when applying write pulses which significantly change the microstructure and chemical composition within a dome in the active region. This results in unique electrical properties even for the basic logic states, which show better resistance stability than offered by the conventional GST-225 cells [2]. Beyond binary data storage, GGST cells are also attracting attention for applications in multilevel storage. Given the complex phase change mechanism in GGST-based PCMs, it is essential to develop appropriate programming methods to access intermediate resistance states (IRS) in such cells and understand the origin of their electrical properties.
This work combines electrical & physical characterizations to compare cells programmed to IRS using different methods. For this, we make use of "pRESET" pulses (partial RESET pulse) of low amplitudes which amorphize only a fraction of the dome. First, we compare the effect of using different pulse sequences to access IRS: RESET-SET-pRESET or direct SET-pRESET. We study the accuracy and reliability of these methods to target a specific resistance value possibly stable over cycling. (S)TEM techniques have been used to analyse the microstructure and composition of these cells. It is shown that the programming method has an impact on the shape of the amorphous dome. Finally, we complement these findings by showing results obtained by impedance spectroscopy which, beyond the single resistance of the cells, provides valuable quantitative information regarding their capacitance.

Van der Waals Epitaxy and Characterization of Quasi Two-Dimensional Ge-Sb-Te Materials and Heterostructures

Stefano Cecchi[1,2]; [1]University of Milano-Bicocca, Italy; [2]Paul-Drude-Instit für Festkörperelektronik, Germany

The advent of two-dimensional materials redefined the horizons of materials science in the last decade, promising disrupting advances in many technological fields. Among the available synthesis techniques, van der Waals (vdW) epitaxy [1] ensures high quality, purity and scalability, all crucial for the integration with microelectronic technology. Chalcogenide phase change materials have been identified as promising candidates for the development of storage class memories, [2] as well as brain-inspired computing. [3] Beyond the well-known phase change functionality used in non-volatile memories, the Ge-Sb-Te family possesses a unique variety of functional properties. As an example, the binary compound GeTe is the father of a new class of materials, namely ferroelectric Rashba semiconductors, in which ferroelectricity is used to control the spin texture at room temperature. [4] A key element for the exploitation of this rich playground is the high crystal quality and interface control achieved for the material deposited by molecular beam epitaxy (MBE).
In this presentation, I will first give an overview on the fabrication by MBE of Ge-Sb-Te layered materials and heterostructures on Sb-passivated Si(111) substrates. [5–7] Next, I will discuss results on the vdW epitaxy and characterization of GeTe-rich $(GeTe)_m(Sb_2Te_3)_n$ (GST) films, which recently provided breakthrough evidence of their composition-dependent ferroelectric behavior. [8] Finally, I will present the investigation of the electronic and vibrational properties of epitaxial GST films. The analysis, based on X-ray photoemission spectroscopy and THz spectroscopy, respectively, is supported by density functional theory calculations.

Phase-Change Heterostructures and Nanocomposites for Low-Power Computing Asir Intisar Khan[1,2], Xiangjin Wu[2], Heungdong Kwon[2], Kenneth Goodson[2], H.S. Philip Wong[2] and Eric Pop[2]; [1]University of California, Berkeley, United States; [2]Stanford University, United States

Today's nanoelectronics systems are reaching the limits of energy and latency for numerous data-intensive applications. Among the existing non-volatile memory technologies, phase-change memory (PCM) holds promise for high-density storage [1]. However, this technology must achieve low-power and stable operation at nanoscale dimensions to be useful in heterogeneously integrated logic and memory. This talk will delve into our recent efforts on the atomic-scale interface and electro-thermal engineering of new phase-change materials for low-power and brain-inspired computing.

Using a combination of phase-change heterostructures and nanocomposites, we have demonstrated sub-1 picojoule switching energy and sub-1 V switching voltage in nanoscale PCM devices [2,3], which are promising for on-chip logic and memory integration. These devices also show low resistance drift, good endurance, fast switching (40 ns), and a large on-off ratio (>100) [1, 2]. The energy-efficient switching is enabled by strong heat confinement within the superlattice material interfaces [3,4]. The heat confinement is further amplified in low-thermal conductivity flexible polyimide substrates, a new paradigm in low-power memory for flexible electronics [5]. We also demonstrate that the material and thermal properties of the heterostructures are controlled by the interface density, which ultimately plays a crucial role in regulating the device performance [6,7]. Additionally, phase-change nanocomposites facilitate the fast-switching speed and gradual bi-directional conductance change in PCM devices, favorable for low-power spiking neural networks [8,9]. These results demonstrate the promise of novel heterostructures and their interface-driven transport modulation for low-power and high-density neuro-inspired memory.

$TiTe_2$/PCM Heterostructures—Epitaxial Growth, Interface Formation and Stability Christian Petrucci[1], Simone Prili[1,2], Antonio Massimiliano Mio[2], Flavia Righi Riva[1], Sabrina Calvi[1], Sara De Simone[2], Valentina Mussi[2], Adriano Diaz Fattorini[1], Massimo Longo[2,3], Raffaella Calarco[2] and Fabrizio Arciprete[1,2]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]University of Rome Tor Vergata, Italy

Device non-idealities, particularly resistance drift, electromigration, and high reset current, significantly limit the widespread of Phase Change Materials (PCM) -based memory cells. In this context, PCM-based heterostructures (PCHs) have shown the potential to overcome these limitations, where the key role of the interfaces between alternating layers has been lately highlighted [1]. Very recently, PCH composed of PCMs and two-dimensional (2D) chalcogenides as confinement materials (CMs) were realized, addressing several drawbacks of standard phase change memories. Notably, intercalating Sb_2Te_3 with $TiTe_2$ has shown promising results, producing PCM cells with reduced drift and reset current [2]. However, the stability of such structures is still debated, especially regarding the intermixing and the persistence of the $TiTe_2$ layers after cycling [3].

In this work, we aim at studying the stability of the interfaces in heterostructures based on $TiTe_2$ and Sb_2Te_3 or Ge-Sb-Te (GST). In this regard, we have investigated the epitaxial growth of the single layers, in order to produce highly ordered PCH. Samples grown by Molecular Beam Epitaxy (MBE) were analyzed by *in situ* X-ray Photoemission

Spectroscopy (XPS) to characterize their electronic properties, to assess the film composition and to evaluate intermixing. The crystal structure of as-grown, as well as annealed, epitaxial layers was evaluated by X-ray Diffraction (XRD), Raman spectroscopy and High-Resolution Scanning Transmission Electron Microscopy (HR-STEM).The epitaxy of $TiTe_2$, Sb_2Te_3 and GST was obtained on Mica after a fine tuning of the relevant parameters such as: growth temperature, flux ratios and deposition rate.

The formation of the interface between $TiTe_2$ and Sb_2Te_3 was evaluated by *in situ* XPS for increasing thicknesses of $TiTe_2$ deposited on Sb_2Te_3. The analysis of the Sb, Te, and Ti core levels and their evolution with $TiTe_2$ coverage suggests the formation of a sharp interface without significant intermixing at the growth temperature. This result is supported by HR-STEM and Raman spectroscopy. Highly ordered epitaxial $TiTe_2/Sb_2Te_3$ and $TiTe_2$/GST multilayers where then grown and characterized by XRD, Raman spectroscopy and HR-STEM. The structure and the local chemical composition of as grown and annealed PCHs were investigated by correlated Energy X-ray Dispersive Spectroscopy and Electron Energy Loss Spectroscopy. The stability of the interfaces and $TiTe_2$ layers upon thermal treatment at temperatures up to 400 °C will be discussed.

Comprehensive Development and Analysis of Sputter-Grown Superlattice Films Simone Prili[1,2,3], Vara P. Jonnalagadda[2], Valeria Bragaglia[2], Jesse Luchtenveld[2,4], Fabrizio Arciprete[1,3], Abu Sebastian[2] and Syed G. Sarwat[2]; [1]Università degli Studi di Roma Tor Vergata, Italy; [2]IBM Research-Zurich, Switzerland; [3]National Research Council, Italy; [4]University of Groningen, Netherlands

Phase change materials (PCMs) hold great promise for next-generation neuromorphic hardware. Although standard Ge-Sb-Te (GST) alloys face challenges with high reset currents and resistance drift, limiting scalability and precision, chalcogenide superlattices (CSLs) offer a compelling solution. Particularly GST/Sb_2Te_3 combinations offer a solution by reducing reset currents through enhanced control over van der Waals (vdW) gaps and interfaces [1]. Unlike $GeTe/Sb_2Te_3$ CSLs, which suffer from intermixing, GST/Sb_2Te_3 maintains better interface control [2], essential for reset current reduction.

Our research provides a systematic study of the optimal sputter growth conditions for highly oriented GST/Sb_2Te_3 CSLs on SiO_2 and carbon substrates, offering an overview of the deposition window exploring various growth parameters. Substrates were pre-cleaned with acetone and isopropanol, followed by Ar+ inverse sputtering etching. The deposition involved a two-step process [3]: room temperature deposition of a Sb_2Te_3 seed layer, followed by annealing and high T deposition of the rest of the film. X-ray diffraction (XRD) and spectroscopic ellipsometry were used to analyze structural properties and energy bandgaps, respectively.

High-temperature deposition of Sb_2Te_3 can cause Te desorption, impacting CSL quality. By fine-tuning deposition parameters, we mitigated these effects on Sb_2Te_3 and also grew ordered cubic GST films with different stacking. We developed a diagram of optimal growth conditions for both materials, facilitating the fabrication of CSLs with various periodicities. XRD confirmed satellite peaks, indicative of periodicity, consistent across different substrates. Resistivity measurements revealed strong anisotropy, with significant in-plane/cross-plane differences.

The impact of the Sb_2Te_3 seed layer was explored, with high-temperature deposited seed introduced for stress mitigation at the crystallization interface. Ellipsometry showed that the energy bandgap remained consistent across different periodicities. Finally, TEM analysis provided insights into the local structure of low periodicity superlattices.

Telluride-Based Multilayered Heterostructures for Thermally Stable Phase Change Materials Massimo Longo[1,2], Marco Bertelli[1], Gianfranco Sfuncia[1], Sara De Simone[1], Adriano Diaz Fattorini[3], Sabrina Calvi[3], Valentina Mussi[1], Fabrizio Arciprete[1,3], Antonio Massimiliano Mio[1] and Raffaella Calarco[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]University of Rome Tor Vergata, Italy; [3]Università degli Studi di Roma Tor Vergata, Italy

Chalcogenide phase change memory (PCM) alloys are extensively used in non-volatile electronic memory devices due to their ability to alternate between two distinct solid-state structural phases, crystalline and amorphous, triggered by electrical stimuli.

While the standard $Ge_2Sb_2Te_5$ (GST-225) alloy is prevalent in phase change memory technology, its application in the automotive sector is hindered by its low thermal stability, with a crystallization onset temperature of approximately 140 °C. Conversely, automotive memory systems require data retention at temperatures up to 155°C for $2x10^3$ cycles. Compounds with a higher Ge content in the GST-x25 ($x > 0.22$) composition have already been shown to demonstrate enhanced thermal stability over GST-225, however, the challenge of Ge segregation, especially when the Ge content surpasses 40%, limits their adoption [1,2].

In this study, combining different chalcogenide films of the system Ge/Sb_2Te_3/GST-225/Ge-rich Ge-Sb-Te, multilayered heterostructures will be shown to exhibit adjustable physical properties compared to their individual film components, thanks to the pairing of thermally stable layers (such as Ge-rich $Ge_{5.5}Sb_2Te_5$ and Ge) with films that have rapid switching capabilities (such as Sb_2Te_3). The heterostructures were deposited onto Si(100) substrates using radio frequency sputtering and then heated to 400 °C. Both the pristine and heat-treated samples underwent analysis through X-ray fluorescence, X-ray diffraction, scanning transmission electron microscopy, electron energy loss spectroscopy, and Raman spectroscopy. The studied multilayers not only exhibited higher temperatures for the onset of crystallization compared to the conventional GST-225 alloy but also showed little to no segregation of Ge. Such heterostructures turned out to be promising in view of their integration into automotive PCM applications.

11:00 AM EL02.03.06

Heteroepitaxy of Sb_2Se_3 on GaAs(001) via Molecular Beam Epitaxy Kelly Xiao[1], Anna-Katharina Preidl[1], Pooja Reddy[1], Jarod Meyer[1], Alec Skipper[2], Leland Nordin[3,3] and Kunal Mukherjee[1]; [1]Stanford University, United States; [2]University of California, Santa Barbara, United States; [3]University of Central Florida, United States

The quasi-1D antimony selenide (Sb_2Se_3) material is an emerging candidate for phase change programmable photonics. Beyond large refractive index contrast, Sb_2Se_3’s amorphous-crystalline phase transition is rare in that it maintains near-zero extinction coefficients in the near and mid-infrared spectral ranges [1]. To leverage the pronounced anisotropy of the crystalline form, on-chip Sb_2Se_3 phase change material technology would benefit from investigation of film interactions with functional single crystal substrates. The lengthy chained structure imparts birefringence, axial crystal growth morphology, as well as undesired polymer-like crystallization and quenching behavior [2]. Here, we aim to realize structurally oriented Sb_2Se_3 thin films towards tuning these qualities.

Bottom-up synthesis control of layered Sb_2Se_3 has motivated the use of ultra-high vacuum growth techniques. Without controlled surface preparation and slower growth rates, Sb_2Se_3 has a propensity to form sharded and prismatic polycrystalline structures [3]. In this work, we demonstrate a synthesis route towards textured-epitaxial and amorphous Sb_2Se_3 films (< 232 nm) directly on GaAs(001) substrates via molecular beam epitaxy (MBE).

X-ray diffraction indicates that for growth temperatures of 230 – 265 °C, Sb_2Se_3 is prone to mixed-orientation nucleation and growth out-of-plane, although it remains oriented along the covalent axis in-plane. We hypothesize this behavior is due to an abundance of low energy van der Waals terminations in the system. More importantly, we identify a narrow epitaxial growth window at a lower range of 180 – 200 °C. Transmission electron microscopy shows an unusual growth progression in this regime, where initially disordered growth transitions into (010)-oriented Sb_2Se_3 with increasing film thickness. Atomic force microscopy reveals the nm-level smoothness and signature ribbon-like surface morphology in these films.

Furthermore, we demonstrate that MBE-synthesized films can span the structural spectrum from epitaxial to amorphous character. Below 150 °C, MBE conditions can produce glassy Sb_2Se_3 films, opening opportunities for solid phase epitaxy studies. We will present initial results on laser-irradiated amorphous Sb_2Se_3. With room for further tuning of film-substrate interaction and stoichiometry, these initial synthesis results offer a preliminary model system grown on a conventional III-V substrate, representing new ways to probe and integrate the photonic functionality of thin film Sb_2Se_3.

11:15 AM EL02.03.07
Structure, Thermodynamics and Relaxations in Amorphous Phase-Change Materials Shuai Wei; Aarhus University, Denmark

The amorphous phases of phase-change materials (PCMs) exhibit important properties relevant for non-volatile memory, photonic, and neuromorphic computing devices. However, due to their disordered structures and poor glass forming ability, the amorphous phases are not well characterized, and a better understanding of structure-property relations is an urgency for the relevance of applications.

Here we demonstrate structure, thermodynamics, and relaxation behaviors of amorphous PCMs over 14 orders magnitude in timescale and a thousand degree of temperature. In amorphous solid, we show how thermal annealing and pressure may induce and diminish local distortions of defective octahedral structures (Peierls-like distortion), which drastically alter materials properties (e.g. stability, crystallization, compressibility, electronic density of states). Above the glass transition temperature, materials enter a metastable supercooled liquid state, where thermodynamic anomalies are associated with dynamic crossovers and switching behaviors. At higher temperature above the melting point, the density fluctuations of liquid state exhibit ultrafast structural relaxations.

We demonstrate directly observation of atomic-scale relaxations using femtosecond X-ray photon correlation spectroscopy by harnessing the coherent X-rays of XFEL. The fast atomistic dynamics is underlying the low viscosity and high fragility behaviour of PCM liquids. We will also briefly discuss the Boson peak in low-temperature heat capacity and development of new PCM alloys. A better understanding of amorphous PCMs may lead to the tailoring of materials properties for novel applications in photonic, and neuromorphic computing devices.

Migration Phenomena in Ge-Rich GeSbTe Alloys for Embedded Memory Applications Stefania M. Privitera; Consiglio Nazionale delle Ricerche, Italy

Phase change memory is based on the peculiar properties of the phase change materials adopted as active media, that strongly depend on the material composition. Among the others, $Ge_2Sb_2Te_5$ has been often considered the alloy of choice because of its fast switching properties, high resistance contrast and stability. However, the low crystallization temperature (around 150°C) prevents the use of $Ge_2Sb_2Te_5$ for high temperature applications, such as embedded or automotive. Recently, Ge enrichment of GeSbTe alloys has been proposed as a valid approach to increase the crystallization temperature and therefore to address high temperature applications of non-volatile phase change memories. In normal operation, the PCM cell is subject to high current density to raise the local temperature above the melting point. This produces repetition of electrical and thermal stress during the device lifetime, causing the motion of the different atoms and leading to compositional variations over time and/or across the device, which may have impact on performance and reliability. Such a process may be enhanced in Ge rich GeSbTe since these alloys commonly suffer of segregation of pure Ge, with the formation of less Ge-rich compositions that may adversely affect the device cyclability and endurance. With the aim to find some possible routes to limit the Ge segregation we investigated several Ge enriched GeSbTe alloys. The temperature dependence of the electrical properties of the amorphous alloys and the formation of the crystalline phases have been studied in thin films by in situ electrical measurements and ex-situ structural analysis. The segregation and decomposition processes have been also discussed on the basis of density functional theory calculations, identifying the compositions which are expected to be less prone to decompose with Ge segregation. The most promising composition has been adopted to manufacture single cell memory devices, with a device structure enhancing the thermal and electrical stress and therefore suitable to study the atomic migration. The characterization of the devices confirms the expected material performance. After a forming process, the devices operate between two distinct logic states (SET and RESET) with one order of magnitude of resistance contrast, and can be reversible switched for up to 10^6 cycles. Despite the Ge enrichment, the drift coefficient in the SET state resembles that of $Ge_2Sb_2Te_5$. After cycling, the atomic distribution in the device has been investigated by scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS), indicating that a compositional reconfiguration of the material in the active region occurs.

d- and f-Electron Type Chalcogenides Realizing Unique Resistive Change Behavior Shogo Hatayama[1], Yuta Saito[2,1,2], Shunsuke Mori[2], Yi Shuang[2], Paul Fons[3] and Yuji Sutou[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Tohoku University, Japan; [3]Keio University, Japan

The unique electrical properties of chalcogenides make them functional in semiconductor devices. Chalcogenides, which exhibit reversible phase transitions between amorphous and crystalline phases, are known as phase change materials (PCMs). These PCMs are utilized as recording layers in non-volatile memory and for synaptic functions in neuromorphic computing. Most PCMs are developed from combinations of chalcogen and p-block elements (groups 14-16). The valence electrons in p-orbitals are considered crucial for material design, while d- and f-orbital electrons are traditionally regarded less significant. Although there is potential within the 3-12 group elements, material design has primarily focused on the p-block. To overcome this limitation, the authors propose d- and f-electron type chalcogenides, which exhibit superior or unique properties compared to conventional p-electron chalcogenides.

Typically, PCMs exhibit phase transitions between high-resistance amorphous states and low-resistance crystalline states. The large resistive contrast upon phase transition enables the non-volatile recording function of PCMs. Ge-Sb-Te (GST) is the most developed PCM, offering high resistance contrast and fast phase change speed, leading to reliable operation. However, the high energy required for amorphization in GST needs improvement. Increasing the resistivity of the crystalline phase is an effective strategy to reduce amorphization energy, but achieving a substantial increase in resistivity in p-electron PCMs is challenging.

$Cr_2Ge_2Te_6$ (CrGT) has been developed as a d-electron-type PCM and demonstrates an inverse resistance change with high-resistive crystalline and low-resistive amorphous phases. Due to the high resistivity of the crystalline phase, the amorphization energy of CrGT-based memory devices is significantly lower, approximately 1/300th of that for GST-based devices [1]. The authors have revealed the unique phase change mechanism of CrGT [2,3] and demonstrated the superior device properties of CrGT-based devices [4,5]. Furthermore, recent studies highlight the potential of f-electron-type chalcogenide, such as SmTe [6]. SmTe films exhibit over four orders of magnitude in resistive contrast between as-deposited and annealed states. Despite the large resistive contrast, no structural transition like the amorphous-to-crystalline transition occurs. This isomorphic transition is driven by the valence state change of Sm, suggesting a new principle for non-volatile recording.

The exploration of d- and f-electron-type chalcogenides opens new avenues in the designing new chalcogenides. By leveraging the high resistivity of the crystalline phase in d-electron chalcogenides, such as CrGT, it is possible to significantly reduce the energy required for phase transitions. Additionally, the discovery of isomorphic transitions in f-electron chalcogenides like SmTe, driven by valence state changes, introduces novel mechanisms for data storage. These findings pave the way for high-performance non-volatile recording applications, advancing the field of semiconductor technology.

Two-Step Thin Film Growth of Quasi-One-Dimensional Penta-Telluride $ZrTe_5$ Realized by an Amorphous-to-Crystalline Transition Yi Shuang[1], Yuta Saito[1], Shogo Hatayama[2], Paul Fons[3], Daisuke Ando[1] and Yuji Sutou[1]; [1]Tohoku University, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Keio University, Japan

Quasi-one-dimensional (quasi-1D) van der Waals (vdWs) materials, such as black phosphorus (BP) and transition metal chalcogenides ($MX_{3\sim5}$, M=transition metal, X=S, Se, and Te), have emerged as a forefront in materials science due to their unique electric, optical, and mechanical properties rooted in their distinctive 1D chain structures, distinct from their two-dimensional counterparts. Among these, $ZrTe_5$ has attracted attention due to its exceptional electrical properties as both a Dirac and Weyl semimetal, coupled with its potential for novel quantum phenomena and robust thermoelectric performance. However, the large-scale fabrication of $ZrTe_5$ thin films has remained a challenge, hindering its integration into practical semiconductor devices. In this study, we propose a novel approach to address this challenge by employing radio frequency (RF) magnetron sputtering, a well-established physical vapor deposition (PVD) technique, for the large-area growth of $ZrTe_5$ thin films.[1] Through meticulous investigation combining structural, electrical, and optical characterization techniques, we unveil a comprehensive understanding of the amorphous-to-crystalline phase transition in $ZrTe_5$ thin films. Our findings reveal a dramatic four-order-of-magnitude decrease in resistivity upon crystallization, accompanied by a significant change in optical properties and band structure. Detailed structural analysis using X-ray diffraction (XRD) and Raman spectroscopy elucidated the phase transition of the amorphous $ZrTe_5$ phase into a single orthorhombic crystalline structure. Furthermore, high-resolution hard X-ray photoelectron spectroscopy (HAXPES) has been applied for insight into the evolution of the electronic states and bonding configurations during the phase transition. We observed the phase transition from an amorphous phase characterized by Zr-Zr and Te-Te homopolar bonds to a crystalline phase dominated by Zr-Te bonds, indicating the formation of quasi-1D trigonal prismatic chains. The electrical properties, probed through Hall measurements, revealed a remarkable increase in carrier density and mobility upon crystallization, resulting in a substantial drop in resistivity. These changes are attributed to modifications in the local bonding environment and band structure, as evidenced by a valence band structure analysis and determination of the optical bandgap. The observed nearly one-order-of-magnitude change in bandgap between the amorphous and crystalline phases underscores the potential of $ZrTe_5$ for applications such as optical switching.[1]

Our study not only contributes to the fundamental understanding of phase transition in quasi-1D materials but also presents a scalable fabrication method for large-area $ZrTe_5$ thin films, paving the way for their integration into advanced electronic and optical devices. These insights offer new avenues for exploring the diverse functionalities of quasi-1D materials and harnessing their unique properties for next-generation applications in materials science and beyond.

Physical and Electrical Characterization of Zinc Telluride Thin Films Deposited by Atomic Layer Deposition

Habeeb Mousa[1], Saidjafarzoda Ilhom[1], Guy Wicker[2], Oleg Maksimov[3], Katherine Hansen[3], Harish B. Bhandari[3] and Helena Silva[1]; [1]University of Connecticut, United States; [2]Ovshinsky Innovation, United States; [3]Radiation Monitoring Devices, United States

Zinc telluride has shown promising properties to replace complex quaternary chalcogenide alloys, such as GeAsSeTe, for Ovonic Threshold Switching (OTS) selector devices in GeSbTe based phase-change memory (PCM) arrays [1,2]. We have recently shown that thin films of ZnTe deposited by Atomic Layer Deposition on platinum also exhibit non-volatile memory behavior when electrically probed with tungsten tips, opening paths for OTS+PCM integration with a single material [3]. In this work we present and discuss XRD characterization, and temperature-dependent electrical resistivity and Hall carrier mobility measurements of ZnTe thin films deposited by Atomic Layer Deposition on different substrates. ZnTe layers deposited on GaAs and sapphire are polycrystalline while those on SiO_2 are amorphous. The resistance of a 600 nm as-deposited ZnTe film on sapphire was ~ $3x10^5$ Ω.cm at room temperature and decreased gradually with heating to ~ 50 Ω.cm at 550 K. Hall mobility measurements only yielded a consistent behavior of the Hall coefficient versus magnetic field between 490 K and 556 K. In this temperature range, the mobility increased from ~ 75 cm^2/V.s at 490 K to ~ 197 cm^2/V.s at 556 K. The room temperature resistivity after cooling was ~ 10 Ω.cm.

Materials Design of Phase Change Memory for Analog In-Memory Computing Applications Huai-Yu, Michelle Cheng[1,2], Zhi-Lun Liu[1,2], Alexander Grun[1,2], Amlan Majumdar[3,2], Matthew BrightSky[3,2] and Hsiang-Lan Lung[1,2]; [1]Macronix International Co., United States; [2]IBM/Macronix PCRAM Joint Project, United States; [3]IBM T.J. Watson Research Center, United States

The increasing size and complexity of AI models present a significant challenge to traditional Von-Neumann computing architectures, which require frequent data transfers between memory and compute elements. This creates a bottleneck known as the "memory wall" [1]. To overcome this challenge, innovative approaches such as in-memory computing (IMC) are being explored, where computations are performed directly within the memory. IMC has the potential to offer dramatic improvements in speed and energy efficiency. Analog AI accelerators can leverage IMC to eliminate resource-intensive data shuffling, resulting in enhanced computational efficiency. One promising technology for enabling this new compute paradigm is phase-change memory (PCM) [2]. However, PCM exhibits inherent imperfections that can introduce errors and reduce the accuracy of Deep Neural Network (DNN) computations. A major issue is the intrinsic structural relaxation in amorphous phase, causing resistance drift. Moreover, drift and its variability are dependent on conductance levels, posing significant challenges to maintaining compute precision.

In this talk, we will provide an overview of the material properties and device performance required for analog AI applications. We will show the evaluation of SiSbTe-based phase-change memory (PCM) devices, focusing on two crucial metrics for IMC applications: resistance drift and data retention. The absolute value of resistance drift and its dependence on resistance levels are both critical factors. However, PCM materials with low resistance drift coefficient (n) often exhibit poor data retention, presenting a trade-off between drift and retention when selecting optimized materials.

We will then present the results where we simulate PCM as analog weight elements for matrix-vector multiplication operations in BERT deep neural networks (DNNs) using the SQuAD dataset, employing the IBM Analog Hardware Acceleration Kit (AIHWKit) [3, 4]. Different drift vs. conductance profiles is designed to understand the importance of state-independent drift characteristic. The fabricated SiSbTe PCM devices maintain BERT accuracy for over 7 days at 65°C and demonstrate successful data retention at 85°C for 48 hours, showcasing a well-balanced performance between the two metrics.

Resistive Switching and Oscillator Functionality in NbO_2 Thin Films Nitin Kumar[1], Karsten Beckmann[2,3], Nathaniel Cady[3] and Sambandamurthy Ganapathy[1]; [1]University at Buffalo, The State University of New York, United States; [2]NYcreats, United States; [3]University at Albany, State University of New York, United States

NbO_2 exhibits an electric field driven insulator-to-metal transition at room temperature, making it a promising candidate for scalable elements in next-generation computing applications such as artificial neurons, oscillators, selector devices, and memory elements. These applications leverage the resistive switching properties of NbO_2 that can be altered based on device size. The effect of scaling on resistive switching parameters for device sizes ranging from 30 nm × 30 nm × 25 nm to 170 nm × 170 nm × 25 nm is investigated. Larger devices are found to exhibit only one or potentially no regions of negative differential resistance (NDR). As the device size is reduced, the on-off ratio increases, and the smaller devices manifest dual NDR regions. Ultra-low frequency noise measurements are carried out to understand the role of electrical domains in various applications of NbO_2 and noise levels were orders of magnitude higher in smaller devices. Oscillators (with tunable frequencies up to 5 MHz) based on resistive switching are built, and the dependence of resistive switching parameters on oscillator frequency across different sizes, applied voltages, and external parameters such as resistance and capacitance are studied. The transport measurements are supported by NSF award 1726303.

Resistive Switching Behaviour and Spiking Time Dependent Plasticity of PLD Grown VO_2/TiO_2 Thin Films Supplemented by Discrete Wavelength of Light

Chhotrai Soren, Rajesh K. Jha and Ankur Goswami; Indian Institute of Technology Delhi, India

Electronic computing is undergoing a paradigm shift with the advent of neuromorphic architecture from the archetype von Neuman architecture. In neuromorphic architecture [1], data processing occurs within the storage memory, eradicating the data latency period. The overall data processing speed reduces acutely, further decreasing energy costs. A memristor is a highly scalable fundamental circuit component that switches across multiple stable states [2] at a very low energy cost, deeming it suitable for neuromorphic application. Transition metal oxides (TMOs) are suitable materials for the fabrication of these memristive components [3] showcasing resistive switching due to physiochemical mechanisms based on ion migration, electrolyte gated, phase change, ferroelectric, spintronic, photonic migration, electronic migration, and metal-insulator transition. Owing to the abundance of materials showing MIT for vested interest of neuromorphic application VO_2 shows MIT at near room temperature [4]. VO_2 undergoes a transition from the low-temperature monoclinic (M1) phase to the tetragonal (R) phase at a temperature above 68 $^{\circ}$C, along with the occurrence of several unstable phases during the transition. The transition temperature of VO_2 can also be tuned to a higher or lower value under the effect of tensile or compressive strain in the lattice under the influence of an electric field, magnetic field, and the illumination of a specific wavelength of light [5]. VO_2/TiO_2 memristor fabricated using pulsed laser deposition, when illuminated with a laser source of 405 nm, 532 nm, 633 nm, and 980 nm, shows changes in memristive properties like R_{OFF}/R_{ON} ratio and switching power. In order to concretize the functioning of the memristor as an artificial synapse, spiking time-dependent plasticity (STDP) analysis [6] is performed under different illumination conditions to boot.

Phase Change Materials and Resistive RAM for Oscillatory Neural Network Implementation

Simanta Lahkar and Aida Todri-Sanial; Technische Universiteit Eindhoven, Netherlands

Current computing paradigm based on von Neumann architecture faces several critical challenges mainly due to the separation of memory from processing, which causes large power consumption. This challenge is becoming even more critical with the increasing demand for AI workloads that require memory-intensive calculations. Neuromorphic computing provides an alternative approach where processing and memory are merged, similar to biological neural networks. This work investigates the unique properties of advanced materials, like phase change materials (PCMs) and resistive RAM for computational devices to implement a neuromorphic computing paradigm based on coupled oscillatory neural networks.

Certain transition metal oxides (TMOs), such as VO_2, exhibit an insulator-to-metal transition (IMT) - when subjected to external stimuli, it undergoes a phase change until the entire material converts to its highly conductive metallic state - forming an interesting category of PCMs. We found that, for VO_2, the external stimuli causing IMT can directly be linked to the temperature inside the material using a physical model giving high experimental accuracy in predicting its behaviour. Furthermore, lowering the temperature can trigger the converse

metal-to-insulator transition (MIT) until the entire material reverts to its initial insulator phase upon sufficient reduction of its temperature. This offers an interesting adjustable resistive change that can be triggered using bias voltage due to Joule heating mechanism. A two-terminal VO_2 device exhibits a negative differential resistance (NDR) region that can be exploited to create self-sustaining oscillations. An external resistance and capacitance are used to design such a VO_2-based relaxation oscillator.
The coupling elements between oscillators play an important role in the dynamics of the neural network. At first, we investigate coupling VO_2 oscillators with discrete components, such as resistance and capacitance, to achieve in-phase and anti-phase relations. Next, we explore the impact of coupling resistance by utilizing a non-volatile memristor, such as bilayer HfO_2 devices. This marks the first-ever investigation of combining phase change VO_2 devices with resistive RAM HfO_2 devices to implement in-memory computing based on a coupled oscillatory neural network paradigm. This project has received funding from the EU's Horizon program under Projects No. 101092096, PHASTRAC.

4:30 PM EL02.05.05

Complex Optimization Problem Solving with Low Variability Neuromorphic VO2-Based Oscillators Olivier Maher, Valeria Bragaglia, Folkert Horst, Bert Jan Offrein and Siegfried Karg; IBM Research-Zurich, Switzerland

Recent advancements in phase-transition materials are paving the way for novel integrations in brain-inspired computing architectures.[1], [2] The pursuit of efficient, low-power neural processing systems mimicking biological brains' fundamental operations is driving the exploration of novel 'neuromorphic' materials and devices.[3], [4] Among the most promising candidates, vanadium dioxide (VO_2) stands out due to its unique properties. VO_2's polycrystalline morphology, compatible with CMOS technology, enables it to switch between resistive states when electrically activated at low power through Joule heating, triggered when the internal temperature reaches 68 °C. [5] Self-sustained oscillations in VO_2 devices provide means to design interconnected electronic oscillators with tremendous potential for neural network architectures, AI applications, and optimization tasks. [1], [3], [6], [7] Oscillation-based computing is highly effective for solving complex optimization problems (COPs), which typically require extensive computing resources, long processing times, along with even larger energy consumption figures. [8], [9] Our in-house fabricated VO_2 devices have been used to design complete oscillating neural networks (ONNs), which we leverage to compute COP solutions within just a few oscillation cycles (< 25) and reduced power consumption. [6], [10] Specifically, the networks have been successfully applied to solve Graph Coloring problems and have embodied Ising machine solvers to compute Max-cut and Maximum-3Satisfiability (Max-3SAT) problems by implementing a novelly improved frequency-harmonic injection locking technique (SHIL). [6], [11] Additionally, we have experimentally demonstrated how the phase-transition characteristics in VO_2 crossbar devices can be integrated with commercially available electronic components to create a biologically realistic FitzHugh-Nagumo oscillator. This oscillator generates complex waveforms similar to those in neurons, providing superior performance for computational tasks such as pattern retrieval and offering new possibilities for addressing and modeling complex time-dependent dynamic computing problems. [12]
To achieve these results, we developed an optimized fabrication process at IBM Research Europe – Zurich, which allows precise control over the formation of granular nanostructures and the switching behavior of individual grains. [10] The devices were characterized using Raman spectroscopy, Atomic Force Microscopy (AFM), X-Ray Reflectivity (XRR), and current-voltage (I-V) and resistance-temperature (R-T) measurements. These capabilities enable the production of devices tailored for specific applications, which can be easily co-integrated with CMOS peripheral circuitry.
Our VO_2-based oscillators excel in local data processing, thereby avoiding the von Neumann bottleneck arising from energy-intensive data transfer between memory units and processors. [2], [4] VO_2-based oscillator networks present compelling and scalable computing units for hardware accelerators, thanks to their high-performance switching properties and compatibility with Silicon.

This project has received funding from the EU's Horizon 2020 program under project No 101092096 (PHASTRAC).

4:45 PM EL02.05.06

Understanding the Selector-Only Memory (SOM) Mechanism of Te-Based Ovonic Threshold Switch Siwon Park, Su-Bong Lee, Young-Min Kim and Jong-Souk Yeo; Yonsei University, Korea (the Republic of)

In recent years, Artificial Intelligence (AI) has exponentially evolved, increasing the importance of efficient data processing in computing architecture. Addressing high-density and low-cost requirements, Storage-Class Memory (SCM) has emerged as a promising candidate for utilizing crossbar architecture while meeting the requirements of low latency and power consumption. In general, emerging phase-change or resistive-switching memories are used with selector devices as 1-selector 1-resistor (1S1R) to suppress unavoidable leakage current from half-selected cells. Ovonic Threshold Switch (OTS) selectors are one of the notable candidates for integration with memory in crossbar arrays, offering advantages such as high on/off ratio, endurance, and thermal stability, but an improved method is needed for overcoming scaling limitations and fabrication complexity.

Selector-Only Memory (SOM) was recently introduced to mitigate the scaling issues by utilizing a single selector cell with a programmable threshold voltage (V_{th}) similar to NAND Flash operations, thereby eliminating the need for multiple stacking. SOM device shows the effect of polarity-induced V_{th} shift in which, depending on the polarity of the input program pulse (whether positive or negative), V_{th} can be programmed to high (if negative) or low (if positive) states. To ensure reliable program and read operations, Read Window Margin (RWM) or the difference between high and low V_{th} states, needs to be sufficiently large.

This work aims to investigate one of the hypotheses, field-driven atomic segregation from preceding research, especially in Te-based OTS materials exhibiting SOM characteristics. The presence or absence of SOM characteristics based on pulse modulation is confirmed to indirectly verify whether a certain amount of time is required for atomic segregation. Additionally, analysis using Atomic Force Microscopy (AFM) reveals that the conductivity changes of confined switching region on the film depend on the applied voltage polarity, which is mainly observed on films with SOM characteristics. These results enhance our understanding and help validate the field-driven atomic segregation hypothesis for SOM characteristics.

EL02.06.01

Investigation of Thermal Disturbance in Vertically Stacked Phase-Change Memory Using Multiphysics Simulation by Coupling Phase-Field and Electrothermal Models Yechan Kim[1], Namwook Hur[2], Hyesoo Kim[1], Joonki Suh[2], Hongsik Jeong[2] and Yongwoo Kwon[1]; [1]Hongik University, Korea (the Republic of); [2]Ulsan National

Institute of Science and Technology, Korea (the Republic of)

Phase-change memory (PCM) is currently regarded as the most commercially viable technology among emerging non-volatile memory options due to its high density, long endurance, and large resistance window. Historically, thermal disturbance (TD) has been a limiting factor in increasing the density of a memory array because sufficient spacing between cells is required. The TD refers to unwanted data change caused by recrystallization occurring in neighboring unselected reset state cells due to excessive heat generated during reset operation of the selected cell. Device simulation of a cell array is important since it is practically impossible to directly measure the internal temperature distribution during PCM operation.

In this work, we use our multiphysics model to explore ways to mitigate TD in a vertically stacked PCM device. By coupling electrothermal and phase-field models in commercial finite-element software, COMSOL Multiphysics, we can simulate not only the temperature distribution in the cell array but also the partial crystallization in a reset cell, and finally obtain the resulting resistance change. The variation of the critical dimensions and their influences on the TD will be investigated. It will be also shown that a modification of the device structure, heater recess, can reduce the heat transfer to neighboring cells while lowering the reset energy.

State-Dependent Phase-Transition Kinetics in Phase-Change Materials Nur Qalishah Adanan[1], Simon Wredh[1], Joel Yang[1] and Robert E. Simpson[2]; [1]Singapore University of Technology and Design, Singapore; [2]University of Birmingham, United Kingdom

Analogue photonics states are important for optical computing, beam steering and displays. Phase change materials (PCMs) are promising materials for analogue photonics as they can be tuned to multiple optical levels by controlling the transition between their amorphous and crystalline phases. To design PCM-based optical switches with efficient and accurate multi-level control, the state dependent phase-transition kinetics must be understood. In this work, we show that the degree of disorder in the 'amorphous state' can be controlled by thermally activated crystallisation and melting processes, and in turn that these processes depend on the degree of disorder already present in the material. Firstly, we show using a thermo-optical phase-change model that $Ge_2Sb_2Te_5$ can be switched into states with different degrees of disorder by partial melting the nanocrystalline microstructure. Subsequent rapid quenching freezes-in the partially molten phase into a solid, with optical properties that depend on the energy applied during melting. The theory is supported by experiment results showing how 16 different reflectance levels can be amorphized into $Ge_2Sb_2Te_5$ using nanosecond-order heat pulses.

Secondly, we show how the level of disorder (amorphousness) in Sb_2Te_3 can be controlled using pulsed laser heating and that the recrystallisation temperature strongly depends on the local atomic configurations in the amorphous structure. Counterintuitively, high energy heat pulses tends to produce amorphous materials with higher activation energy yet shorter minimum crystallisation times. This catalyst-like effect is important because it provides a way we can switch PCM devices at higher rates. Our results for this work set the scene for energy efficient and high speed PCM-enabled analogue photonics.

Analysis of Threshold Voltage Drift Under Electrical Stress Accumulation in Ovonic Threshold Switching Chalcogenide Films Siwon Park, Young-Min Kim, Su-Bong Lee, Sangyeop Kim and Jong-Souk Yeo; Yonsei University, Korea (the Republic of)

A 3D crossbar array has received attention due to its simplified two-terminal structure, making it suitable for use in embedded conventional and emerging memories for brain-inspired computing applications. Emerging memories are generally used with selector devices as 1-selector 1-resistor (1S1R) to suppress leakage current from half-selected cells. Chalcogenide-based Ovonic Threshold Switching (OTS) selector is one of the candidates to address this leakage current issue, ensuring high selectivity, high endurance, and other requirements. For reliable operation, the threshold voltage (Vth) of OTS devices should be stable. However, Vth tends to fluctuate with repeated on/off switching cycles but can recover over some relaxation time. The cause of Vth drift under electrical stress accumulation remains unclear, due to the difficulty that confines the switching region inside the amorphous chalcogenide OTS thin films. Here, Atomic Force Microscopy (AFM) provides a powerful method to directly characterize the switching behavior induced in the local region. Thanks to the unique advantages of AFM, changes in the conductivity of OTS thin film can be characterized along with Vth drift. Furthermore, the slice and scan analysis with a diamond-coated tip allows 3D tomography of the nanoscale region after degradation (without recovery).
In this research, variations in conductivity within the local region of Te-based chalcogenide OTS films are investigated throughout the expected lifetime of OTS material, from the pristine state to the permanent degradation resulting in a fixed at the low-resistance state (LRS) by using Conductive AFM. A gradual drift in Vth, along with the increase of conductive region within the local switching region is generally observed after repeated on/off switching cycles. Given sufficient relaxation time, these highly conductive regions tend to diminish but can remain permanently degraded once a certain level of Vth drift is reached. The results can help us to understand why Vth drifts gradually under electrical stress accumulation by directly observing the physical changes in OTS thin films.

Challenges in the Implementation of Artificial Intelligence Hardware Based on Phase Change Devices Guy M. Cohen, Amlan Majumdar, Cheng-Wei Cheng, Asit Ray, Daniel Piatek, Lynne Gignac, Christian Lavoie, Takashi Ando, Nanbo Gong and Matthew BrightSky; IBM T.J. Watson Research Center, United States

Cross-point arrays built with phase change tunable resistors were suggested for a computationally efficient implementation of artificial neural networks (ANN) [1,2]. By storing the ANN weights as the conductance in the array elements and using Ohm's law and Kirchhoff’s current law the multiply-accumulate operation (MAC) can be realized using an analog computation. To maximize computational accuracy while maintaining low energy consumption, the phase change cells in the array need to have a low reset current, low resistance drift, and low read/write noise. In this paper we will discuss recent advances in textured heterostructure superlattice PCM devices and textured homostructure PCM devices which shown to exhibit low resent current and low resistance drift, and therefore may be used in ANN hardware [3-7]. We will also review limitation to the cross-point array size imposed by noise, and methods to improve the computation accuracy in the presence of noise.

9:00 AM EL02.07.02
Layer-By-Layer Phase Change in an In_2Se_3-Based Neuromorphic Device Nicholas D. Ignacio[1], Saban Hus[2] and Deji Akinwande[1]; [1]The University of Texas at Austin, United States; [2]Oak Ridge National Laboratory, United States

Indium selenide (In_2Se_3) undergoes multiple phase changes between crystalline phases including the layered ferroelectric (alpha), paraelectric (beta) and non-layered (gamma) phase through multiple stimuli including strain, thermal excitations, and electrial excitations. Thus, In_2Se_3 is a promising candidate for a new class of phase change memory (PCM) utilizing structural changes between two or more crystalline phases rather than relying on transitions between amorphous and crystalline phases seen in conventional phase change memories. Suitable for storage class memory or neuromorphic computing applications, PCM utilizing changes between crystalline phases are expected to have faster and lower energy write operations compared to conventional PCM due to the lower entropy of the crystalline-crystalline phase change as well as addressing issues of resistance drift stemming by removing use of the amorphous phase. In this work, we present a multi-level phase change memory (PCM) based on In_2Se_3, demonstrating device resistance spanning six orders of magnitude. Local transport measurements using scanning tunneling microscopy (STM) reveal that the resistance of vertical devices changes exponentially with the number of switching steps. These findings suggest a layer-by-layer phase change within the material's structure, rather than the conventional radial expansion of low and high resistance phases seen in typical PCM devices. In contrast to planar PCM structures, which exhibit a three-orders of magnitude resistance change, the vertical structure facilitates tunneling-like transport through the active material, resulting in the observed six-orders of magnitude resistance variation. We find van-der-Waals gaps to be the limiting mechanism for this phenomenon. The structural changes between crystalline alpha-In_2Se_3 and crystalline beta-In_2Se_3 phases of In_2Se_3 provide a low-entropy switching mechanism in conjunction with multi-level switching can allow for high density data storage and neuromorphic applications.

9:15 AM EL02.07.03
A New Paradigm for Ultra-Low Current Phase-Change Memory via a Phase-Changeable Nano-Filament See-On Park[1], Seokman Hong[1], Su-Jin Sung[1], Seokho Seo[1], Hakcheon Jeong[1], Taehoon Park[1], Jeehwan Kim[2,2] and Shinhyun Choi[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Phase-change memory (PCM), which switches its electrical resistance via thermal-induced phase transition, is one of the most mature non-volatile memory technologies. Following the development of $Ge_2Sb_2Te_5$ (GST)-based PCM with non-volatile memory, low latency, and high integration density, PCM has been considered a candidate for enabling emerging computing systems such as compute-in-memory, compute-express-link, and neuromorphic computing. In addition, intrinsic vector-matrix multiplication in PCM crossbar array without the need for external processors makes PCM desirable hardware for artificial intelligence. However, PCM requires a large reset current to melt phase-change materials, significantly reducing energy-efficiency [1].

Several studies have been conducted to address this issue, including scaling device dimensions with confined electrodes [2], utilizing super-lattice-like phase-change materials [3], and using carbon nanotube electrodes [4]. Although these approaches have experimentally demonstrated reduced reset current, some limitations still exist. For example, scaling device dimensions by using ArF-immersion or extreme ultraviolet (EUV) lithography technologies reduce the reset current as the device area decreases. However, reducing device dimensions usually increases fabrication complexity and cost, while the degree of reset current reduction is limited (~100 µA for device diameter of 10 nm). Super-lattice-like phase-change materials have shown lower reset current density compared to GST-based PCM, but the amount of current reduction is small (<5×). Using carbon nanotube electrodes for PCM enables ultra-low reset current under 10 µA, but uniform integration of carbon nanotubes for large-scale fabrication requires further development.

In this study, we propose a new paradigm to reduce the reset current in PCM without increasing fabrication complexity and cost by forming a phase-changeable $SiTe_x$ nano-filament via an electro-forming method [5]. Thanks to the self-confined filament structure with a diameter of approximately 5 nm, the nano-filament PCM (NFPCM) achieves an ultra-low reset current (~60 µA) regardless of device size. Compared to a GST-based PCM with a 40 nm electrode, the NFPCM with the same device size achieved an approximately 15 times lower reset current, demonstrating its effectiveness in reducing the reset current regardless of device size. In addition to the reset current, the device exhibited favorable memory characteristics, including a large on/off ratio, low variations, and multi-level memory properties. Furthermore, it was confirmed that the reset current can be further reduced (~10 µA) by controlling the stoichiometry of the filament. These findings represent a significant advancement towards novel non-volatile memory technologies applicable in neuromorphic computing systems, edge processors, in-memory computing systems, and traditional memory applications.

Low-Power Phase Change Memory Based on Nanotube Device Architecture Arvind Singh[1], Suresh Durai[2], Srinivasan Raj[3] and Anbarasu Manivannan[1]; [1]Indian Institute of Technology Madras, India; [2]Indian Institute of Technology Trichy, India; [3]SSN Engineering College, India

The reduction of RESET current (I_{RESET}) to achieve low-power phase change memory (PCM) has been a long-standing problem in the PCM community [1]. The structural engineering is one of the techniques to reduce the I_{RESET} by effectively confining the heat to the surroundings. In addition, the interfacial region (with different material properties as compared to the bulk) between the active material and surrounding materials play a greater role in better heat confinement. In this context, the conventional cylindrical mushroom-type PCM device architecture can be modified where the additional tubular oxide is embedded in the active material (Ge2Sb2Te5, GST), which runs from the top electrode till heater to give rise to the novel PCM nanotube structure. The performance of the proposed nanotube PCM device is investigated by using 3D TCAD simulations where the heat confinement is found to be high for two major reasons; One is the programmable volume lies very close to inner and outer oxide (SiO_2), and the other is that GST sees twice the amount of interfacial thermal resistance with inner and outer SiO2 ($TBR_{GST/SiO2}$–5e-4 cm^2.K/W) as compared to the conventional cylindrical mushroom-type PCM devices [2]. Here, the nanotube PCM device shows a significant reduction in I_{RESET} showing 57% for 113 nm^2 (GST/heater contact area) and 72% for 295 nm^2 as compared to the I_{RESET} of a conventional mushroom-type device of the same contact area. In addition, the RESET energy (E_{RESET}) of nanotube PCM device shows a three orders reduction in magnitude (with the contact area ranging from 113 to 295 nm^2) as compared to E_{RESET} of conventional-type devices. Hence, the results suggest that the nanotube PCM devices could be a potential alternative to achieve ultra-low RESET energy required for embedded memory.

9:45 AM EL02.07.05
Electronic Transport in Sub-100 nm Reset Phase Change Memory Line-Cells Hanyu Jiang[1], ABM Hasan Talukder[2], Md Tashfiq Bin Kashem[3], Md Samzid Bin Hafiz[1], Raihan Sayeed Khan[2], Faruk Dirisaglik[4], Ali Gokirmak[1] and Helena Silva[1]; [1]University of Connecticut, United States; [2]Intel Corporation, United States; [3]Ahsanullah University of Science and Technology, Bangladesh; [4]Eskisehir Osmangazi University, Turkey

Electronic transport in amorphous chalcogenides, such as amorphous Ge2Sb2Te5 (GST), has significant importance for scaling and multi-bit-per-cell implementations of phase change memory (PCM) cells. When the PCM cells are reset, a small volume of a phase change material, such as GST, thermally switches from its crystalline phase (low-resistance state) to its amorphous phase (high-resistance state). The resistance in the high-resistance state spontaneously increases in time, following a power-law trend, known as resistance drift. The cells also show a significant fluctuation in their read-current in the high-resistance state. Both resistance drift and electronic transport in the high-resistance state are poorly understood and are a topic of active research. A substantial effort has been put into understanding the amorphous phase change materials to understand the contribution of the defects in the bulk material.
In our experimental studies, we reset GST line cells with width x length x thickness of ~ 100 nm x ~ 500 nm x ~ 20 nm, in the 80 K – 350 K temperature range and performed slow high-voltage sweeps. The current-voltage (I-V) characteristics of these cells show an initial hysteresis behavior, with a clear hyperbolic sine I-V response in the low-field regime (<20 MV/m) and a much stronger exponential response in the high-field regime (>20 MV/m). Our experiments on cells wider than 100 nm show that the hysteresis behavior disappears in 1-2 sweeps and the resistance drift stops in the 80 K – 250 K range. The cells in the 60 nm – 100 nm regime tend to amorphized shorter segments (~ 100 nm) and can be stabilized with voltage stresses at room temperature (300 K).
In our studies, we construct a low-field and high-field transport model that explains transport in the amorphous phase and a charge-relaxation-based model that describes the acceleration and stoppage of resistance drift [1-3]. In this study, we analyze the cells stabilized at room temperature and show the same low-field and high-field characteristics at lower voltages to extend the research and prove the validity of our models.

Mastering the Interplay Between Active Material and Device Operation in Ge-GST ePCM Andrea Redaelli; STMicroelectronics, Italy

Phase Change Memory (PCM) is today one of the BEOL memories considered for embedded applications below 28nm node. Understanding the interplay between active material behavior and device operation is of critical importance to mastering the technology. In this work the effect of the electrical pulse on the material is studied along the programming curve, and the relationship between applied programming pulse, final phase and final composition is clarified. It has been shown that the states not only differ for microscopic phase distribution (crystal and amorphous) but also in chemical composition moving from a set state richer in antimony to a reset state more germanium rich. This feature of Ge-GST based ePCM has been highlighted as a key factor for cell functionality, guarantying a sufficiently low Set resistance despite the high Ge content in the as-deposited film. The compositional change in Set and Reset also can guarantee the reliability needed for the demanding mission profiles of embedded applications.

11:00 AM EL02.07.07
Stopping Resistance Drift in Reset $Ge_2Sb_2Te_5$ Phase Change Memory Cells—Field-Induced Charge Relaxation and Electronic Transport Helena Silva[1], Md Tashfiq Bin Kashem[1], Raihan Sayeed Khan[1], ABM Hasan Talukder[1], Md Samzid Bin Hafiz[1], Faruk Dirisaglik[1,2] and Ali Gokirmak[1]; [1]University of Connecticut, United States; [2]Eskisehir Osmangazi University, Turkey

Multi-bit-per-cell implementations of phase change memory (PCM) require multiple stable and distinct resistance levels. However, the spontaneous increase of resistance of reset PCM cell (drift) and read noise lead to mixing of the intermediate resistance levels [1]. We performed temperature (80 K – 350 K) and electric-field (0 ~ 40 MV/m) dependent experiments on $Ge_2Sb_2Te_5$ PCM line-cells with 20 nm thickness, 60 nm ~ 150 nm width and ~ 500 nm length [2] reset using 100 – 500 ns voltage pulses with and without photoexcitation. The current-voltage (I-V) characteristics of the cells show a clear low-field response with high sensitivity to photoexcitation for T< 250 K and a distinct high-field response that significantly accelerates resistance drift and shows no sensitivity to photo-excitation. High-field stresses (> 20 MV/m) substantially accelerate resistance drift and bring it to a stop, and significantly reduce read noise. Since the changes can be induced at very low temperatures (80 K) and low current levels (pA) but at high electric fields, we attribute the changes in the observed cell characteristics to electronic processes [3,4] rather than thermally induced structural relaxation [1,5].
We have constructed a low-field 2D hopping and a high-field transport model that fits the data and explains the observed characteristics. Resistance drift appears to be a result of the charge-exchanges between the crystalline (c-) GST (or TiN contacts) and amorphous (a-) GST at the junctions. The charge-exchanges are expected to take place starting immediately after reset until the steady state condition is achieved. The net charge in the a-GST region determines the electrostatic potential of the barrier between the two c-GST contacts. The time-to-escape

for the trapped charges increases over time with the increasing barrier height, which manifests itself as resistance drift following a power-law trend. When a sufficiently high electric-field is applied, the trapped (and the photo-generated) holes are removed from the a-GST region, accelerating resistance drift (and making the device insensitive to photo-excitation) [6]. The band-offset between the a-GST / c-GST (or metal) interfaces suggests that conduction in a-GST is through electrons injected at the tunnel junctions at the a-GST / c-GST (or metal) interfaces.
Results support an electronic origin of resistance drift caused by a potential profile formed by negative charging of the amorphous region with the escape of the holes and n-type conduction in reset PCM cells. The amorphized length, and the band-offsets between the a-GST, c-GST and metal contacts play a significant role in drift. Resistance drift can be mitigated with materials, device and waveform engineering.

11:15 AM EL02.07.08
Crystallization of the Amorphous Dome in Ge-Rich GeSbTe-Based Phase Change Memory Cells Sijia Ran[1], Minh-Anh Luong[1], Eloïse Rahier[1,2], Elisa Petroni[2], Daniel Benoit[2], Jérémie Grisolia[3] and Alain Claverie[1]; [1]Centre d’Élaboration des Matériaux et d’Etudes Structurales, France; [2]STMicroelectronics, France; [3]Institut National des Sciences Appliquées, France

Ge-rich GeSbTe (GGST) alloys have been developed by the industry to fulfill the high-temperature data retention requirements for embedded applications[1]. Due to the off-stoichiometry nature of the as-deposited amorphous GGST, it undergoes chemical phase separation during thermal annealing and forms multiple crystalline phases at different crystallization stages[2].

In phase change memory (PCM) cells, the GGST alloy is confined within a nanometer-scale volume. An amorphous dome is created by melt-quench and is in contact with grains of different crystalline phases. Crystallization of this dome can occur either by applying electrical pulses or under thermal stress. Since crystallization is involved during both cell programming and data retention, it is important to understand the crystallization behavior of GGST material in the real PCM device environment.

In this work, a variety of (scanning) transmission electron microscopy ((S)TEM) techniques have been used to study the microstructural and chemical evolution of the amorphous dome in GGST cells during crystallization. The studied devices are 1R analytical cells with the wall architecture. Electrical tests were first performed to prepare the cells to different resistance states. Extremely thin (< 30 nm) TEM lamellas were prepared using the focused-ion beam (FIB) technique. Multiple (S)TEM-based techniques were applied to study the GGST material: dark-field (DF) and high-resolution (HR) imaging for crystallographic analyses and high-angle annular dark-field (HAADF) imaging and electron-energy loss spectroscopy (EELS) for chemical mapping.

In the RESET state, the GGST cell contains an amorphous dome of a few tens of nanometers. The amorphous region is chemically homogenous, showing a Ge-rich composition. The dome is surrounded by a specific polycrystalline environment, including two crystalline "walls" where Ge grains have accumulated and a "ceiling" made of cubic Sb-poor GST grains.

We first show the crystallization of the dome during thermal annealing by combining *in-situ* TEM heating and *ex-situ* analyses. Progressive crystallization of the dome is observed during annealing from 250 to 330 °C. The growth of the GST crystals from the upper crystalline-to-amorphous interface is found to be the mechanism dominating the overall crystallization. During thermal recrystallization, chemical phase separation occurs inside the dome: Sb segregates and forms pure Sb_2 grains, while the remaining amorphous material becomes more enriched in Ge. Such Ge-rich amorphous compositions slow down the crystallization process, ensuring high RESET retention performances.

We then show the crystallization of the amorphous dome by electrical programming through *ex-situ* TEM analyses. By applying a proper partial-SET pulse, GGST cells show an intermediate resistance state, resulting from partial crystallization of the dome. The growth of GST grains from the upper crystalline periphery is again found to be an important process when crystallizing the dome by applying electrical pulses.

This study provides direct experimental observations of the crystallization behavior in GGST cells. The results apply to devices directly used for applications and offer important information for understanding the microscopic origin enabling the functionality and the high thermal stability of GGST-based PCM.

Energy-Efficient Phase-Change Memory Disc-Type Cells Leveraging Ultrathin Phase-Change Films Timothy M. Philicelli[1], Syed G. Sarwat[2], Jesse Luchtenveld[2,3], Vara P. Jonnalagadda[2], Kevin W. Brew[1], Bart J. Kooi[3], Vijay Narayanan[4], Nicole Saulnier[1] and Abu Sebastian[2]; [1]IBM Research-Albany, United States; [2]IBM Research-Zurich, Switzerland; [3]University of Groningen, Netherlands; [4]IBM T.J. Watson Research Center, United States

While phase change memory (PCM) is one of the most mature resistive memory technologies, innovations are still needed to reduce the relatively high programming current. At a structural level, PCM cell designs attempt to reduce this write energy by either minimizing the contact area of one electrode (e.g., mushroom cell) or by minimizing the phase-change material volume (e.g., bridge/line cell), but it has been challenging to continue to scale these techniques while maintaining manufacturability. Here, we introduce a PCM disc-type cell that accomplishes both volume minimization using an ultra-thin phase-change material and contact area minimization using the heater of a mushroom cell. Using finite-element method simulation and experimental validation, we show that this disc-type PCM cell offers superior programming performance, conductance tunability, and improved retention characteristics. This novel PCM device architecture provides a platform to further engineer electrical characteristics and leverage the unique properties of ultrathin phase-change material films, making it a promising candidate for emerging applications such as analog in-memory computing.

Free-Space Photonic Synaptic Modulators Based on Tamm Plasmon for Adaptive Multispectral Image Processing

Joo Hwan Ko, Dong Hyun Seo, Se Yeon Kim, Yubin Lee and Young Min Song; Gwangju Institute of Science and Technology, Korea (the Republic of)

The rapid advancement of computing technologies has underscored the increasing need for systems capable of efficiently processing and improving large datasets of visual information. Traditional electronic computing architectures, while robust, are facing growing challenges related to speed, power consumption, and adaptability in image processing tasks. In response, neuromorphic computing, inspired by the brain's complex neuronal and synaptic functions, has gained attention as a promising solution. Optical technologies, in particular, have garnered significant interest for their ability to deliver superior speed and parallelism, making them well-suited for modern image processing. Optical computing, especially through photonic integrated circuits (PICs), combines high-bandwidth optical communication with localized processing, significantly improving speed and energy efficiency [1]. Additionally, diffractive deep neural networks (D^2NN), a form of free-space optical computing, enable efficient processing of complex tasks by guiding light through diffractive layers, leveraging the advantages of speed, parallelism, and energy efficiency in optical systems [2].
Reconfigurable photonic structures are also gaining recognition for their role in adaptive image filtering within free-space optical systems. However, despite these advancements, challenges such as denoising, spectral filtering, and contrast enhancement in multispectral data still require further development. Addressing these challenges is essential for improving the management of complex visual information.
In this work, we propose the use of active Tamm plasmon resonators to create a highly adaptable and efficient photonic structure for multispectral image processing. We have developed a reconfigurable device with fine control over resonant wavelengths by adjusting the impedance matching condition of the Tamm plasmon resonator, allowing it to target specific spectral components with high quality factor (Q-factor). To achieve adaptive control with a gradual on/off function, we integrate poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) into the resonator. Depending on its doping state, PEDOT:PSS exhibits either metallic or dielectric properties, enabling high absorptance or reflectance at wavelengths longer than its plasma frequency. The coexistence of doped and undoped domains within PEDOT:PSS is crucial for achieving long-term memorizing functions, which are necessary for precise neuromorphic computations across multiple memory stages [3].
To ensure stable synaptic weights, we combine the large modulation depth of the Tamm plasmon, which theoretically reaches 99%, with the non-volatile characteristics of PEDOT:PSS, enabling the creation of multiple synaptic states without saturation. This results in stable synaptic weights with 256 distinct levels, achieved through continuous electrical pulse inputs. Additionally, the high Q-factor of the Tamm plasmon allows for effective multispectral filtering, enhancing target signals while minimizing noise interference in dynamic

environments, leading to more scalable and efficient technologies for complex image processing tasks.

The Photoinduced Response of Antimony from Femtoseconds to Minutes Sebastian Walfort[1], Nils Holle[1], Julia Vehndel[1], Daniel Yimam[2], Niklas Vollmar[1], Bart J. Kooi[3] and Martin Salinga[1]; [1]University of Münster, Germany; [2]Oak Ridge National Laboratory, United States; [3]University of Groningen, Netherlands

Antimony is an interesting candidate for photonic memory applications due to a number of desirable properties. These include a large optical contrast over a wide wavelength range between crystalline and amorphous solid states. In addition, switching between the states is possible on nanosecond timescales by applying short heating pulses. The amorphous (glass) state is then attained by melting and rapid quenching through a supercooled liquid regime, whereas recrystallisation requires only a more moderate temperature increase. While initial and final states in such a switching cycle are easily characterized, little is known about the optical properties on the path to forming a glass. Here we resolve the entire switching cycle of antimony with femtosecond resolution in stroboscopic optical pump-probe measurements and combine the experimental results with ab-initio molecular dynamics simulations. The glass formation process of antimony is revealed to be a complex multi-step process in which the intermediate transient states exhibit distinct optical properties with even larger contrasts than those observed between crystal and glass. Our findings indicate that the dissolution and formation of a structural distortion motif common to PCMs plays a significant role in the property contrast between distorted crystals and undistorted liquids. Moreover, it is the origin of the large optical response observed in both the ultrafast regime and during the transition from the metallic supercooled liquid to the semiconducting glass. The quantitative understanding that is provided forms the basis for its exploitation in high bandwidth photonic applications.

8:45 AM EL02.08.03
Development of Optical Phase Change Materials for Non-Volatile Photonics Kotaro Makino[1], Yuto Miyatake[2], Shogo Hatayama[1], Mitsuru Takenaka[2] and Junji Tominaga[1]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]The University of Tokyo, Japan

Optical applications based on phase change materials (PCMs), that exhibit a significant change in optical properties upon an amorphous-crystalline structural phase transition, have attracted a lot of attention. For PCM-based nonvolatile optical applications, development of new optical PCM other than conventional $Ge_2Sb_2Te_5$ (GST) is highly desired. Indeed, the new class of optical PMCs such as Sb_2S_3, Sb_2Se_3 and $Ge_2Sb_2Te_3Se_2$ were reported to be suitable for a low-loss optical switch and a plasmonic devices because these materials have wider band gap [1-3], namely smaller extinction coefficient than GST.
Here, we report on the simulation-based characterization and design of optical PCMs. We performed first principles calculations to find out new optical PCMs by using Vienna Ab initio Simulation Package (VASP). It was found that the partly substitutions of S atoms for Te atoms can enlarge the band depending on the composition and the position of the substitution sites. Based on the simulation results, a new composition $Ge_2Sb_2Te_3S_2$ (GSTS)

was found to possess wider band gap than GST and expected to be used for a low-loss optical switch. We carried out the experimental evaluation of the optical properties of the thin film of GSTS by spectroscopic ellipsometry. We also report on the performance of the GSTS optical switches and propose a low-insertion-loss and non-volatile optical switches working near-infrared and mid-infrared wavelength ranges [4-5]. Part of this presentation is on the result obtained from the commissioned research (JPJ012368C03701) by National Institute of Information and Communications Technology (NICT), JAPAN and JSPS KAKENHI Grant Number JP24K00949.

Optimizing Thermal Dynamics and Multilevel Control in Silicon Doped Microheaters for Optical Phase Change Memory Francis Vasquez-Aza[1], Liam Power[1], Hongyi Sun[2,2], Chuanyu Lian[2,2], Yi-Siou Huang[2,2], Steven A. Vitale[3], Ichiro Takeuchi[2,2], Juejun Hu[3], Nathan Youngblood[4], Carlos A. Rios Ocampo[2,2] and Georges Pavlidis[1]; [1]University of Connecticut, United States; [2]University of Maryland, United States; [3]Massachusetts Institute of Technology, United States; [4]University of Pittsburgh, United States

Nonvolatile memory (NVM) offers advantages for high performance computing such as improved energy efficiency and fast switching speeds. One approach is to use Phase Change Materials (PCM) with photonic integrated circuits. Both optical and electric approaches have been studied to switch the PCM from a high resistance state (amorphous) to a low resistance state (crystalline). Optical switching enables accurate multilevel control but is limited in scalability. In contrast, electrical switching offers effortless CMOS integration but faces reliability challenges to achieve reversible control. Recent studies using microheaters, for indirect switching, have demonstrated an inherent tradeoff between scalability and multilevel control. To address this hypothesis, two heater designs have been evaluated, metal and silicon doped microheaters. While metal heaters can efficiently offer a larger heating area, they require a thicker oxide spacing between the heater and substrate to avoid optical interference. Understanding the heat dissipation in silicon doped is thus vital for the optimization to accurately control the PCM. Addressing challenges such as high PCM melting temperatures, and rapid quenching rates required for re-amorphization is critical for achieving precise multilevel control. Various heater designs are investigated to address these issues. First, a bowtie design reveals challenges with multi-level accuracy as it relies on the stochastic nucleation process for intermediate state modulation. In contrast, a five bridge (equally spaced with same width) design controls the PCM's state through precise spatial temperature control at each island hotspot. However, since each hotspot simultaneously reaches a similar temperature, the control of intermediate multilevel states is limited. This study experimentally assesses an alternative multi-bridge design that varies each bridge width (non-homogeneous hotspots) and results in an overall triangle-like temperature distribution to achieve continuous multilevel control.

Previous efforts have characterized the steady state temperature distribution of microheaters using thermoreflectance techniques and numerical models. Under normal operating conditions, however, the microheaters are biased with sub microsecond pulse widths to achieve higher power densities that can reach the crystallization temperature of the PCM. Advanced thermal characterization techniques with both high spatial (< 1 μm) and temporal resolution (< 0.5 μs) are thus needed to quantify the impact of the microheater design on its transient thermal dynamic behavior. Specifically, the dependence of the electrical pulse width on the peak temperature, energy consumption, and the quenching rate has not been experimentally verified. This work leverages high throughput CCD based Transient Thermoreflectance Imaging with high speed pulsed IV to assess

the design parameters on the thermal response of multi-bridge microheaters.
First, the microheater’s transient thermal rise/decay was analyzed to extract the thermal time constants and obtain quenching rates of ≈ 0.8 K/ns. Under steady state conditions, temperature scales linearly with power. Based on the magnitude of the thermal time constants (≈ 0.48 μs), however, the maximum temperature was achieved in the non-linear regime where the tradeoff between maximum power density and transient heat accumulation must be assessed. This study reveals the maximum power density and temperature was achieved by reducing the pulse width down to 0.2 μs. As the energy consumption is inversely proportional to the electrical pulse width, the minimum energy was also achieved at 0.2 μs. Overall, short pulses enable effective management of higher temperatures, smaller quenching rates, and lower energy consumption per cycle of crystallization and amorphization processes.

9:15 AM EL02.08.05
Reconfigurable Nanophotonic Devices Using Spin-State Modulation Elena Pinilla-Cienfuegos[1], Lucas Mascaró-Burguera[1], Laura Mercadé[1], Ramon Torres-Cavanillas[2], Jorge Parra[1], Pablo Sanchis[1], Teresa Mengual[1], Ana Diaz-Rubio[1] and Javier Hernandez-Rueda[3]; [1]Universitat Politècnica de València, Spain; [2]Universitat de València, Spain; [3]Universidad Complutense de Madrid, Spain

The development of reconfigurable nanophotonic devices fundamentally relies on phase-change materials (PCMs) due to their ability to undergo significant alterations in optical properties when subjected to thermal or electrical stimuli. This work introduces a novel PCM nanomaterial that exhibits spin-crossover (SCO) behavior, demonstrating both reconfigurability and optical bistability at room temperature. This unique characteristic stems from the material's capability to transition between two distinct spin states when exposed to external triggers such as temperature, pressure, light, or voltage. Moreover, these transitions are accompanied by variations in structural (volume), magnetic, optical, electrical properties, and color. Utilizing these distinctive optical properties and the ability to modulate spin states at the nanoscale, we investigate the creation of adaptable platforms for modulating, steering, and controlling light within reconfigurable metasurfaces. Furthermore, SCO materials show immense promise for developing non-volatile, low-power nanophotonic switches operating in the infrared (IR) regime. This breakthrough enables dynamic, on-demand control of optical signals in real-time, facilitating a wide range of applications, from ultrafast data processing to adaptive optical systems.

9:30 AM *EL02.08.06
Nanophotonic Phase Change Material Devices for Tunable High-Purity Color Filters Ranjan Singh[1,2]; [1]University of Notre Dame, United States; [2]Nanyang Technological University, Singapore

Active thin-film coating-based reflective color displays have versatile applications including image sensors, camouflage devices, spatial light modulators, and intelligent windows. However, generating high-purity colors using such coatings has posed a challenge. Here, we will discuss high-purity color generation using an ultralow-loss phase change material (Sb2S3)-based tunable aperiodic distributed Bragg reflector (A-DBR). By adjusting the periodicity of the adjacent layers of A-DBRs, we realize a narrow photonic bandgap with high reflectivity to generate high-purity orange and yellow colors. Moreover, we experimentally demonstrate multistate tunable colors through external optical and thermal stimuli. Unlike conventional nano thin-film coatings, our proposed approach offers an irradiance-free, narrowband, and highly reflective color band, achieving high color purity through the supression of reflections in off-color bands.

Addressing Challenges in Programming Endurance and Speed for Nonvolatile Photonic Memory Nathan Youngblood; University of Pittsburgh, United States

Nonvolatile memory is an important component in photonic computing, yet suffers from challenges related to programming speed, efficiency, and endurance. In this talk, I will present our recent materials- and device-level work to address these challenges and improve the practicality and scalability of integrated memory for photonic computing applications.

11:00 AM EL02.08.08

Harnessing Structural Transitions in SnTe-GeTe (SGT) Alloys for Photonics Tri Nguyen, Pooja Reddy and Kunal Mukherjee; Stanford University, United States

The chalcogenide semiconductor alloy system of SnTe-GeTe (SGT) offers a combination of properties that could be attractive for applications in phase change materials, thermoelectrics, and infrared optoelectronics [1,2]. Since SnTe is always Sn-deficient and GeTe is always Ge-deficient, both semiconductors are degenerately p-typed doped above 10^{20} cm^{-3} [3,4]. Such a high concentration of holes leads to high free carrier reflection in the mid-infrared wavelengths, making them promising candidates for plasmonic mid-infrared materials [5]. SnTe crystalizes in a rocksalt crystal structure at 300K and undergoes a cubic to a distorted cubic (rhombohedral) structural transition at cryogenic temperatures ($T_c < 90K$). GeTe, with a rhombohedral structure at room temperature, undergoes a structural transition to cubic through distortion along the [111] direction at $T_c > 700K$. Because of this distortion, the rhombohedral and cubic phases are predicted to have a large difference in bandgap and reflectivity [6]. Synthesizing high-quality SGT thin films would open routes to engineer the cubic-rhombohedral ferroelectric transitions closer to room temperature, making SGT more practical for moderate-temperature thermoelectrics and infrared optoelectronics. Since the dielectric constants of materials depend on the crystal structure, the presence of a temperature-controlled structural transition in SGT offers an avenue to modulate optical properties. We aim to harness these unique properties towards integrated tunable epitaxial mirrors with applications in imaging and sensing.

We leverage the complete solid solution of SnTe-GeTe at high temperatures to synthesize SGT films. We deposit first a seed layer of SnTe and then a GeTe film on a Ge(001) substrate via sputtering. We intermix layers using rapid thermal annealing (RTA) at 500°C for 1 minute. To prevent materials evaporation at elevated temperatures, we use a ~40 nm SiO_2 capping layer. X-ray diffraction (XRD) measurements show that GeTe and SnTe are completely intermixed after RTA, and films are (001) out-of-plane single oriented. The SGT alloy composition is varied by changing the thickness ratio of SnTe and GeTe.

We show the composition-dependent structure of $Sn_{1-x}Ge_xTe$ thin films at room temperature is in good agreement with the bulk phase diagram. On the Sn-rich side, $Sn_{1-x}Ge_xTe$ adopts the rocksalt cubic structure. At higher Ge content ($x>0.35$), SGT transitions to the rhombohedral structure. As the Ge composition of SGT films increases, we see a trend in maximum reflectance which suggests that alloy composition affects the dielectric constants. We plan to also discuss further insights into the impact of the ferroelectric distortions on the dielectric constants of our SGT films. Overall, our work lays the foundation for harnessing the cubic-rhombohedral structural transition in SGT thin films for active mid-infrared optoelectronic devices.

Gallium Sulfide as Phase-Change Material for Photonic Applications Yael Gutierrez[1,2], Stefano Dicorato[2], Josef Resl[3], Kurt Hingerl[3], Christoph Cobet[3] and Maria Losurdo[2]; [1]Universidad de Cantabria, Spain; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Johannes Kepler Universität Linz, Austria

Interest in phase-change materials (PCMs) is growing steadily because of their major role in the development of reconfigurable photonic devices. Nevertheless, conventional PCMs such as GST exhibit large optical losses in either or both states. Therefore, there is a need for alternative low-loss PCMs both in the visible and near-IR wavelengths. In light of this, other chalcogenides phase change materials, such as Sb_2S_3 or Sb_2Se_3, with band gaps at optical frequencies have been proposed as low-loss PCMs to be integrated in reconfigurable optical devices. Similarly, to Sb chalcogenides, layered monochalcogenides from group III (III= In, Ga) can display band gaps at optical frequencies. In these materials, it is known that as the chalcogen element decreases in atomic number (i.e. Te → Se → S), the bandgap of the material tends to increase (e.g. band gap energies of GaTe, GaSe and GaS are 1.7, 2.1 and 2.5eV respectively) as well as their air stability.
In this contribution, we show the reversible amorphous to crystalline transition in phase change material GaS. We will present the result of the optimized deposition process of amorphous GaS stablishing some basic properties of the material such as Raman spectra, refractive index and absorption edge. We will additionally show the thermally activated amorphous-to-crystalline phase transformation of GaS demonstrating a refractive index contrast Δn ranging from 0.2 to 0.5 while maintaining negligible losses at telecommunication wavelengths. Finally, we will present the amorphization of the crystallized GaS using picosencond laser pulses identifying the energy density boundaries to achieve total amorphization with minimal ablation effects.

Advanced Silicon Photonics Designs for Lower Power, Ultrafast Switching with Integrated Phase Change Materials Sharon M. Weiss; Vanderbilt University, United States

The silicon photonics market continues to expand rapidly over a wide range of application areas including those related to optical computing. Innovations in silicon photonics design toward smaller footprint devices with lower power operation can also be applied to hybrid material platforms that take advantage of complementary material properties. In particular, hybrid integration of optical phase change materials with silicon photonics holds the potential to enable even faster and lower power switching on a platform that is compatible with CMOS electronics and can be fabricated at scale. In this presentation, we demonstrate how subwavelength-engineered photonic crystals can be employed to dramatically improve performance metrics of on-chip silicon photonic devices incorporating optical phase change materials, including vanadium dioxide. Prospects for foundry fabrication of such devices will also be discussed.

Reconfigurable Metasurface Optics Enabling Space Image Sensing Hyun Jung Kim[1,2]; [1]NASA Langley Research Center, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Reconfigurable optical metasurfaces are rapidly emerging as a major frontier in photonics research, development, and applications. They promise compact, lightweight, and energy-efficient reconfigurable optical systems with unprecedented performance and functions that can be dynamically defined on-demand. Space applications represent an emerging area in which these characteristics are highly prized. Among the potential candidates for reconfigurable optics, chalcogenide-based phase change materials (PCMs) offer great promise due to their non-volatile and analogue switching characteristics. The ability to dynamically tune optical functions through selective modulation of electromagnetic waves is crucial to the advancement of a variety of sensing applications, from imaging spectrometers to light detection and ranging (LiDAR).
This presentation introduces a reconfigurable metasurface optic project led by a research team at NASA Langley Research Center since 2018. It covers advances in PCM-based metafilters, performance data on reliability enhancements, image sensing system architectures, and mission concepts enabled through these advances.

The talk especially highlights two Materials International Space Station Experiment (MISSE) missions, MISSE-14 (completed in 2022) and MISSE-21 (launch scheduled in 2025). PCM samples are flown on the exterior of the International Space Station (ISS) to expose materials to the extreme conditions of the low Earth orbit (LEO) environment. Through the MISSE-14 exposure campaign entitled “Tunable mid-wave infrared (MWIR) filters based on exotic PCMs”, the team gained experience with LEO exposure of PCMs The results showed the space survivability of candidate PCMs on the ISS (https://spaceborne-pcms.github.io/). The PCM-based metafilters to be exposed and tested for the MISSE-21 mission are based on the experimental and theoretical results of the MISSE-14 data. The metafilter will be an essential piece of the NASA Artemis mission by providing accurate scientific images of the Space Launch System through an enhanced imaging spectrometer. Other NASA applications of the filter technology include the CLICK (CubeSat Laser Infrared CrosslinK), LCOT (Low-Cost Optical Terminal), and FSOS (Free-Space Optical Subsystem) projects.

2:00 PM EL02.09.02

Exploration of VO_2 Thin Films with Oxygen Deficiency Manish Kumar, Sunita Rani and Hyun H. Lee; Pohang University of Science and Technology, Korea (the Republic of)

VO_2 has captured the attention of researchers due to its thermochromic properties and rapid semiconductor-to-metal transition. The semiconductor-to-metal shift occurs within the monoclinic M1 phase around 343K, coupled with a transformation from monoclinic to rutile crystal structure. The transparency of the monoclinic phase to near-infrared (NIR) radiation stands in contrast to the NIR opaqueness of the rutile phase. Maintaining precise stoichiometry in VO_2 is crucial, as even slight adjustments in oxygen levels can lead to the stabilization of different VO_2 polymorphs. Additionally, fine-tuning the stoichiometry offers a means of controlling the characteristics of VO_2. With this motivation, we have prepared stoichiometric and oxygen deficient VO_2 thin films on differently oriented sapphire substrates by radio frequency (RF) sputtering technique. The stoichiometric VO_2 thin films depicted characteristic semiconductor to metal transition around 343K. We noticed a complete suppression of semiconductor to metal transition in oxygen deficient VO_2 thin films and a metallic behavior was seen throughout the studied temperature range i.e. 273K to 373K. Oxygen deficiency led to significant modifications in the structural, electronic and optical properties of VO_2 thin films.

2:15 PM EL02.09.03

Phase Transition-Enabled VO2 with Tailored Morphology for Advanced UV Photodetection Aman Singhal, Shobha Shukla and Sumit Saxena; Indian Institute of Technology Bombay, India

Vanadium dioxide (VO2) is a phase change material that exhibits a unique insulator-to-metal transition, making it an attractive candidate for various photonic applications, including ultraviolet (UV) photodetectors. This study presents the synthesis of VO2 using a hydrothermal method to achieve precise control over the morphology of the material, thereby enhancing its photonic properties and applicability in UV photodetection.

Nanophotonics has revolutionized the understanding of light–matter interactions, allowing for the manipulation of light at the nanoscale through the design of nanostructured materials. This advancement has enabled significant progress in applications such as datacom, quantum optics, displays, bio-sensing, and wavefront shaping. In particular, dielectric metasurfaces have facilitated the development of flat optical devices, offering potential alternatives to traditional bulk optics. However, the static nature of these devices poses challenges in dynamically varying their physical properties, which is a critical need across most nanophotonic applications. Addressing this challenge, phase-change materials (PCMs) like VO2 provide a promising solution through their ability to undergo rapid and reversible changes in their structural and optical properties upon external stimulation.

In this work, VO2 was synthesized via the hydrothermal method, enabling fine control over its nanostructure and morphology. This method involves the use of aqueous solutions at elevated temperatures and pressures, resulting in VO2 with well-defined crystalline structures. The resultant VO2 nanostructures exhibit significant modulation in electrical and optical properties when exposed to UV radiation, attributed to the material's insulator-to-metal transition. This transition facilitates a substantial change in the refractive index ($\Delta n \geq 1$), allowing dynamic tuning of the material's optical characteristics, a sought-after feature in nanoscale photonic devices.

The integration of VO2 into UV photodetectors demonstrated exceptional performance, characterized by high responsivity, rapid response times, and stable operation under varying UV intensities. The device's photocurrent exhibited a pronounced increase under UV illumination, underscoring the efficacy of VO2 in modulating conductivity through its phase change properties. Furthermore, the controlled morphology of VO2 achieved via the hydrothermal method enhanced the efficiency and sensitivity of the UV photodetector, making it a viable candidate for applications in environmental monitoring, optical communications, and biomedical sensing.

This study highlights the potential of VO2 as a tunable and reconfigurable material for next-generation photonic devices. The ability to dynamically control its optical properties without moving parts represents a significant advancement in the field of nanophotonics. By leveraging the unique characteristics of VO2, this research contributes to the development of innovative UV photodetectors and other photonic systems that require precise and dynamic manipulation of light at the nanoscale.

2:30 PM *EL02.09.04

Zero-Static-Power Reconfigurable Photonics Using Phase Change Metacoatings Behrad Gholipour, Avik Mandal, Joshua Perkins, Mahirah Zaini, Abbas Sheikh Ansari and Yihao Cui; University of Alberta, Canada

Training and running large artificial intelligence (AI) and machine learning (ML) models as well as emerging large language models (LLM’s) and the push towards online learning, inference and, more broadly, artificial general intelligence (AGI) require staggering amounts of energy to train in years to come.

This is in large part due to current hardware architectures' reliance on volatile transitions (for signal routing, switching and processing) such as carrier modulation and thermo-optic effects in silicon and its derivatives, transparent conducting oxides, as well as ferroelectrics. This creates an intense need for active thermal load management as volatile transitions require power to be maintained to the device at all times. This is a major obstacle to scaling up to increasingly dense chips and racks in hyperscale AI-centric data centres that would need ever more spacious rack layouts or energy-intensive cooling solutions to deal with the generated heat resulting from the volatile nature of all transitions used on the chip level. Going forward, zero-static power architectures are needed on the fundamental processing and memory component layers to enable scalable and environmentally sustainable systems.

The most scalable non-volatile transition available to us in nature is the phase transition commonly observed in chalcogenide semiconductors that relies on the reversible atomic rearrangement of an alloy using thermal, electrical, or optical stimuli between a reflective high conductivity crystalline and a transparent highly resistive amorphous phase. To this end, here we show that using phase change metacoatings, subwavelength thickness layers of chalcogenide phase change alloys nanostructured through bottom-up growth techniques can enable control of static optical properties as well as volatile and non-volatile transitions, with a view to photonic integrated circuits that will be the workhorse of emerging hyperscale AI-centric data centers. Notably, in these architectures, the mitigation of high insertion losses when introducing many of these alloys to the vicinity of waveguide platforms due to their inherent absorption across this band has resulted in devices with larger than necessary lateral footprints and/or poor modulation contrasts and an incessant search for low-loss/high switching contrast alloys.

Chalcogenide phase-change materials (PCMs) are high refractive index dielectrics across the visible/telecom band. We show that by making use of this high refractive index, mach-zender modulators (MZM's) with built-in memory functionality and zero static power consumption, capable of 2π phase shifts, can be realized with active lateral footprints down to 10 μm. Furthermore, the patterning of these alloys on the subwavelength scale has demonstrated high-quality factor optically resonant devices under the umbrella of metamaterials and metasurfaces. In this realm, subwavelength nanostructuring can also offer non-resonant dispersion engineering of a given dielectric/plasmonic material. We show that non-resonant, lithography-free, subwavelength patterning, which enables dispersion engineering of chalcogenide glasses, paves the way to the realization of alloys with tunable static optoelectronic properties. We then go on to show that volatile and non-volatile optical transitions can be tuned and engineered in PCMs without the need for stoichiometric changes to chemical composition through glancing angle deposition and interlayer nanostructuring, enabling ultra-compact phase/intensity modulators with tunable insertion losses.

Rapid Prototyping of 2D Transistors via Gel and Skin Dmitry Kireev; University of Massachusetts Amherst, United States

Characterization of 2D materials directly on their growth substrates is crucial for advancing their applications in bioelectronics and flexible electronics as well as fundamentally understanding the as-grown material properties. Traditional methods often require transferring these materials to different substrates, a process that can introduce defects, alter their properties, and limit their practical use. Characterizing 2D materials without transferring them preserves their intrinsic qualities and provides a more accurate understanding of their behavior in real-world conditions. This approach is particularly important for developing wearable technologies, such as graphene tattoos, where the materials must maintain their integrity and performance when integrated with flexible and soft substrates like human skin.
Here, we present a unique system to study 2D material properties in a mechanically soft, flexible, and realistic environment suitable for future wearable applications. The system comprises commercially available medical-grade gel electrodes, with the embedded Ag/AgCl acting as the reference electrode similar to those used in electrolytic field-effect transistors. The hydrogel serves as the electrolyte, with the 2D material, such as graphene, simply placed on top of the gel. These gel electrolytes are extremely robust under mechanical strain, flexible, exhibit insignificant gate leakage currents, and maintain high stability across a broad temperature range (-50C to +110C). The gels are reusable, with samples stored in ambient conditions for over three years without degradation.
Moreover, we show that utilizing human skin as an amplifier for transistor signals is feasible. By using the hypodermis as an electrolyte, we demonstrate that graphene transistor tattoos biased through the body exhibit remarkable charge carrier mobility up to 6500 cm2/V/s. Before testing on the skin, we validated our approach with low-cost, commercially available Ag/AgCl gel pads, which proved to be reliable test beds for transistor characterization. Using these gels, we introduced a novel approach for rapidly probing electronic properties. Similar to graphene, we demonstrated impressive performance with PtSe2-based transistors and MoS2-based transistors characterized via skin.

11:00 AM EL03.01.02
Graphene Multiplexed Sensor for Point-of-Need Viral Wastewater-Based Epidemiology Michael Geiwitz[1],

Owen R. Page[1], Tio Marello[1], Marina Nichols[1], Narendra Kumar[2,1], Stephen Hummel[3,1], Vsevolod Belosovich[1], Qiong Ma[1], Tim van Opijnen[4,1], Bruce Batten[2], Michelle Meyer[1] and Kenneth S. Burch[1]; [1]Boston College, United States; [2]GRIP Molecular, Inc, United States; [3]United States Military Academy, United States; [4]Boston Children's Hospital, United States

Wastewater-based epidemiology (WBE) can help mitigate the spread of respiratory infections through the early detection of viruses, pathogens, and other biomarkers in human waste. The need for sample collection, shipping, and testing facilities drives up the cost of WBE and hinders its use for rapid detection and isolation in environments with small populations and in low-resource settings. Given the ubiquitousness and regular outbreaks of respiratory syncytial virus, SARS-CoV-2, and various influenza strains, there is a rising need for a low-cost and easy-to-use biosensing platform to detect these viruses locally before outbreaks can occur and monitor their progression. To this end, we have developed an easy-to-use, cost-effective, multiplexed platform able to detect viral loads in wastewater with several orders of magnitude lower limit of detection than mass spectrometry. This is enabled by wafer scale production and aptamers pre-attached with linker molecules, producing forty-four chips at once. Each chip can simultaneously detect four target analytes using twenty transistors segregated into four sets of five for each analyte to allow for immediate statistical analysis. We show our platform's ability to rapidly detect three virus proteins (SARS-CoV-2, RSV, and Influenza A) and a population normalization molecule (caffeine) in wastewater. Going forward, turning these devices into hand-held systems would enable waste-water epidemiology in low-resource settings and be instrumental for rapid, local outbreak prevention.

Advancing Neurodegenerative Disease Diagnosis—Remote Gate Electrolyte-Gated Graphene Field Effect Transistors

Abdul Wadood Tadbier, Gabriele Kaminski Schierle and Stephan Hofmann; University of Cambridge, United Kingdom

Neurodegeneration signifies a persistent decline in neuronal function, characterised by irreversible damage, with Alzheimer's Disease (AD) and Parkinson's Disease (PD) being the most prevalent. The absence of a non-invasive, cost-effective, and user-friendly diagnostic method impedes early detection efforts, delaying progress in treatment development. We explore the use of graphene as a bio-interfacing material in this field, focusing on graphene-based multi-electrode arrays [1] and graphene field-effect transistors [2]. While the use of graphene offers high sensitivity and high transconductance, selectivity, reproducibility and stability in bio-interfacing environments remain significant obstacles. We report a remote gate electrolyte-gated graphene field-effect transistors (EGFETs) design that isolates the sensing electrolyte from the operational electrolyte. This design enables the utilisation of a single EGFET with multiple remote gates, reducing the need for multiple fabrications of EGFET and enhancing overall system reproducibility. We achieved reduced hysteresis and enhanced stability by optimising the fabrication process, including graphene transfer, substrate selection, contact resistance minimisation, bottom gate dielectric enhancement, and EGFET operation modifications. We applied such EGFET design to Alpha-synuclein (aSyn) detection. The aggregation of this protein has been well-established, notably leading to the formation of Lewy bodies, a hallmark associated with neuronal death in PD. We employed nanobodies, smaller fragments of whole antibodies, bringing the target protein closer to the surface of the sensor and enabling detection in high ionic media such as saliva which is demonstrated as a viable sampling location of aSyn and a promising alternative to cerebrospinal fluid, which requires highly invasive measurement. Our results showed an enhancement for the graphene-based biosensors which would offer a potential solution for neurodegenerative disease diagnosis.

Cervicare—Advancing Point-of-Care Diagnostics for Cervical Cancer Reema Rawat[1], Sonam Singh[1], Rahul Walia[1], Souradeep Roy[1], Tapas Goswami[1], Sourav Sain[2], Susanta S. Roy[2], Piyush Kuchhal[1], Ashish Mathur[1] and James McLaughlin[1]; [1]UPES, India; [2]Shivnadar University, India

Cervical cancer, predominantly caused by High-Risk Human Papillomavirus (HR-HPV) type 16, remains a formidable global health challenge due to its high mortality rates. Despite medical advancements, traditional cervical cancer detection methods suffer from inefficiencies and cost limitations. To address this critical need, our study focuses on the development of an innovative electroanalytical genosensor.
Our novel genosensor is based on $Ti_3C_2T_x$/DNA hybrid screen-printed paper electrode strips, specifically designed for the detection of HPV-16, a primary risk factor for cervical cancer. Leveraging the unique properties of Mxene nanostructures, we enhance sensor performance. Comprehensive characterization techniques, including X-Ray Diffraction (XRD), Field Emission Scanning Electron Microscopy (FESEM), Fourier Transform Infrared Spectroscopy (FTIR), and UV-Visible Spectroscopy (UV-Vis), provide insights into crystal structure, surface morphology, functional groups, and optical properties.
The genosensor demonstrates highly sensitive detection capabilities. Evaluated using Cyclic Voltammetry (CV) analysis, it exhibits a an impressively low Limit-of-Detection (LoD) of 2.4 fM for HPV-16 DNA. Integration with cutting-edge technology results in the creation of the Cervicare device-a portable, user-friendly solution with an LoD of 0.02 pM. This device holds promise for point-of-care diagnostics, especially in remote areas.
Cervicare represents a significant leap forward in cervical cancer screening. By providing a rapid, accurate, and affordable diagnostic solution, it holds the potential for earlier detection and improved disease management. Its practicality and suitability for resource-constrained settings make it a powerful tool in enhancing healthcare accessibility.

11:45 AM EL03.01.05

Additive Manufacturing of Laser-Induced Graphene with Piezoelectric Polymer for Wearable Ultrasound Transducers Shirin Movaghgharnezhad, Ehsan Ansari, Dulcce Valenzuela, Clayton Baker, Ahmed Bashatah, Pilgyu Kang and Parag Chitnis; George Mason University, United States

Ultrasound technology has emerged as a versatile and indispensable tool with applications in various specialized fields, such as non-invasive diagnostic imaging, therapeutic approaches for targeted treatments, and non-destructive testing of material structures. Ultrasound imaging relies on transmitting ultrasound pulses into the medium and detecting reflected echoes from different tissue interfaces. This process requires an ultrasound transducer (UST) that efficiently converts electrical energy into mechanical (acoustic pressure) energy and vice versa, using piezoelectric materials. Traditional USTs are designed for hand-held use and made of rigid piezoelectric ceramics, which are not suitable for wearable applications and long-term monitoring. To address the need for a new class of wearable and flexible USTs, we propose a novel approach by integrating piezopolymers with graphene, which offers exceptional mechanical strength, flexibility, and electrical conductivity. We present an innovative approach for developing disposable UST patches using laser-induced photothermal patterning of graphene electrodes on flexible polyimide substrates and additive manufacturing through 3D printing with Polyvinylidene fluoride-trifluoroethylene (PVDF-TrFE) ink. By utilizing a far-infrared laser, localized photothermal irradiation causes a temperature increase within the laser's focused area. This rise in temperature breaks the covalent bonds between carbon atoms in the polyimide precursor, resulting in the formation of porous structures as the gaseous molecules in the polyimide evaporate. Subsequently, a composite piezoelectric material is created by integrating PVDF-TrFE with 3D porous graphene. To complete the fabrication process, the transducer is subjected to a poling process. This poling process facilitates the piezoelectric domains' alignment within the

PVDF-TrFE composite, enhancing its overall piezoelectric properties. The fabrication was completed by gold sputter-coating and deposition of a 1µm thick parylene film for passivation. The piezoelectric coefficient (D33), electromechanical coupling coefficient (k), and signal-to-noise ratio (SNR) of the UST were characterized by applying compressional force, using LCR, and pulse-echo measurements, respectively.
Deposition and infiltration of PVDF into graphene pores increased surface area interaction and produced thin and durable wearable UST patches with enhanced piezoelectric performance and high imaging resolution (D33=99 pm/V, k=0.29, and SNR=109.45). To demonstrate the versatility of our approach, we fabricated graphene-based USTs of different geometries and configurations, which included a single circular element 3.5 mm in diameter, an M-shaped UST 7-mm across, a dual-element doppler transducer, and a 32-element array with 400-µm pitch. The PVDF deposition could be tuned to achieve a center frequency ranging from 5 MHz for the doppler transducer to 21 MHz for a single-element device. The patterning of graphene-based electrodes produced the desired sensor configuration with uniform PVDF deposition across the entire device. This illustrates the suitability of our novel technique for applications requiring special ultrasound geometries. The method is also amenable to producing transducer arrays for B-mode imaging. The production cost of our UST is estimated to be under $5 per unit, making them a low-cost solution for flexible USTs.

SESSION EL03.02: 2D Materials-Based Devices I

Session Chairs: Cinzia Casiraghi, Camilla Coletti, Carlo Grazianetti and Dmitry Kireev

Advancing System-Level Miniaturization with Graphene on Cubic Silicon Carbide Francesca Iacopi; University of Technology Sydney, Australia

Advances in the epitaxial graphene growth on silicon carbide wafers have led to exciting developments, including the achievement of ballistic conduction and semiconducting properties on the same platform, which may greatly benefit future SiC technologies [1, 2]. In parallel, the harnessing of graphene’s properties on silicon wafers, despite inherent challenges, could deliver a broad range of miniaturized and fast reconfigurable functionalities to complement CMOS technologies in a system with the smallest form-factor.
Over the last decade, we have pioneered an epitaxial graphene on silicon carbide on silicon technology able to fill this gap and, in addition, able to unlock unique functionalities for MEMS/NEMS, nano-optics and metasurfaces thanks to the specific combination of graphene with silicon carbide [3, 4, 5]. This platform allows to fabricate any complex graphene flat or 3D nanopattern in a site – selective fashion, ie without etching the graphene, at the wafer -scale and with sufficient adhesion for subsequent integration [3, 6]. We will review the fundamental hallmarks of this technology and some of its most promising applications. First, we show that the sheet resistance of epitaxial graphene on 3C-SiC on silicon is comparable to that of epitaxial graphene on SiC wafers, despite substantially smaller grains. We indicate that the control of the graphene interfaces, particularly when integrated, can be a more important factor than achieving large grain sizes [6]. Also, we show that well- engineered defects in graphene are preferable to defect -free graphene for most electrochemical applications. We will share exciting examples of application of this technology in areas as diverse as integrated energy storage [7], reconfigurable metasurfaces for MIR sensing and detection [8], and electrodes for electro-encephalography [9, 10] for brain-computer interfaces [11].

Pursuing Epitaxially Grown Single Crystalline Transition Metal Dichalcogenides in Industrial Reactors Inside a Silicon CMOS Fab

Henry Medina Silva[1], Benjamin Groven[1], Pawan Kumar[1], Iryna Kandybka[1], Yevhenii Rybalchenko[1], Joris Verdin[1], Apostolia Manasi[2], Sergej Pasko[2], Sreetama Banerjee[1], Ankit Nalin Mehta[1], Souvik Ghosh[1], Quentin Smets[1], Daire Cott[1], Tom Schram[1], Stefanie Sergeant[1], Steven Brems[1], Pierre Morin[1], Jan Mischke[2], Alexander Henning[2], Salim El Kazzi[2], Cesar Javier Lockhart de la Rosa[1], Inge Asselberghs[1] and Gouri Sankar Kar[1]; [1]imec, Belgium; [2]Aixtron, Germany

Significant progress has been made in the lab, where transistors of monolayer and single crystalline Transition Metal Dichalcogenides (TMDCs) have demonstrated performance that surpasses Silicon under channel thicknesses below 1nm [1]. As per technology roadmaps at A2 logic nodes, transistors' body thickness should be approaching these limits. This has propelled TMDCs as potential materials for integration into future logic nodes in the Armstrong era. Furthermore, TMDCs have also shown great potential for in-memory computing applications that, compared to the current Von Newman architectures, can lead to the more efficient energy consumption required due to the significant increase in computing capacity for artificial intelligence (AI) applications in the coming future [2-3]. Various approaches are being explored to achieve single crystalline TMDCs. Currently, epitaxial growth on sapphire and subsequent transfers have shown the most promising results for synthetic monolayer TMDCs in terms of electrical performance. Notably, significant progress has been achieved in producing single crystalline material on large areas. However, the integration of this approach into a Silicon Fab poses several challenges, including the introduction of sapphire and the use of compatible chemistries to meet contamination and safety requirements.

Therefore, this work focuses on 2 parts: (1) We use metalorganic chemical deposition (MOCVD) based on metal hexacarbonyl with hydrogen disulfide as a method that can be implemented in industrial reactors (200mm and 300mm) using pocket wafers. By carefully tuning the process conditions. We can achieve epitaxial growth of single crystalline monolayer molybdenum disulfide on sapphire[4-5]. (2) We demonstrate the integration of epitaxially grown MoS2 on sapphire into a 300mm CMOS flow [6-7]. We also show the growth of MoS2 and WS2 on 300mm sapphire, showing the scalability potential, paving the way for this method to be integrated into a 300mm silicon fab.

Finally, we share our perspective on the challenges that need attention for synthesizing monolayer TMDCs at 300mm scale on sapphire and integrating them as channel materials into advanced logic nodes.

This work was done in the imec IIAP core CMOS programs and received funding from the European Union's Graphene Flagship grant agreement No 952792, 2D-EPL.

Residue-Free 2D-Transfer Technology for High-Performance Field-Effect Transistors Chandan Biswas[1,2]; [1]The University of Texas at Austin, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Three-dimensional (3D) silicon technology suffers from degradation of FET performances beyond sub-3-nm technology node. One-atom thick (~0.7 nm) two-dimensional (2D) transition metal dichalcogenides (TMDs) offer an ideal FET platform and have been investigated intensively during the last decade to achieve high-performance FETs. Nevertheless, practical applications of TMD-based FETs are limited due to wafer-scale integration incapability and fabrication-provoked residues.

Such atomically thin fragile TMD materials further require transfer to a desired gate dielectric substrate by facilitating mechanical supporting holder. Traditionally, polymethyl methacrylate (PMMA) is used as a supporting holder for device transfer. PMMA leaves notorious insulating residues on TMD surface which often generates mechanical damage to the TMD during transfer. Over the last two decades, the removal of PMMA residues has been a major obstacle in the semiconductor community, although its origin remains arguable. Nevertheless, residues and mechanical damages are inevitably introduced during transfer under ambient conditions. Moreover, such residues adhered at the interface, especially between metal-semiconductor contact, often degrade FET performances.

Here, we show a residue-free transfer of CVD-grown TMD samples using polypropylene carbonate (PPC) as a supporting holder which leaves negligible residue coverage of ~0.08% on the TMD surface compared to traditional PMMA (~35%). PPC was previously used as a stamping holder in the typical dry-transfer process. However, the stamping technique is suitable for the monolayer flake size of as small as 30-40 µm. A larger TMD flake size transferred by the conventional stamping technique introduces wrinkling, mechanical damage, and transfer inhomogeneity. A conventional stamping technique cannot be implemented for CVD-grown large samples for integrated circuits. A wafer-scale, residue-free wet-transfer process is deemed necessary for electronics integration.

Here we introduce a residue-free wet-transfer approach in which PPC-enabled transfer can address supporting holder contamination and flake wrinkling in the large-area homogeneous transfer of CVD-TMDs. FET device fabricated by PPC method with CVD-grown monolayer MoS_2 reveals Ohmic contact resistance of R_C ~78 Ω-µm close to the quantum limit due to the absence of interfacial residues between MoS_2 and semimetal Bi. An ultrahigh current on/off ratio of ~10^{11} at 15 K was also achieved using the h-BN substrate. Our device exhibits state-of-the-art FET performances among all other previously reported literature values.

High-Performance Graphene/PVA Spray-Coated Electrode for Wearable Triboelectric Nanogenerators

Hongyang Dang[1,2], Antonio A. Leonardi[1,2], Benji Fenech-Salerno[3], Sihui Liu[3] and Felice Torrisi[1,2,3]; [1]Università degli Studi di Catania, Italy; [2]CNR-IMM, Italy; [3]Imperial College London, United Kingdom

Wearable mechanical energy-generating and harvesting devices have emerged in the past decade as potential power sources. [1, 2] As a new energy harvesting strategy, textile-based triboelectric nanogenerators (TENGs) have received enormous attention due to their high flexibility, low cost, and lightweight. [3, 4] TENG works on the combined principle of triboelectrification and electrostatic induction, which can convert low-frequent mechanical energy to electrical energy with high conversion efficiency. Two-dimensional (2D) materials are attractive for fabricating textile-based and lightweight wearable TENG devices. [5, 6] As a monolayer of atomic carbon of crystal, graphene offers remarkable electrical properties due to its linear dispersed band structure near the Dirac point.[7] Moreover, graphene has a high Young's modulus of 1 TPa and an inherent tensile strength of 130 GPa. [8, 9] Such high stiffness and robustness make graphene a good candidate for fabricating wearable e-devices. [10, 11] Graphene is commonly deposited on wearable substrates with various methods, serving as the electrode and triboelectric materials in TENGs. [12, 13] Emphasizing the need for careful consideration during fabrication, we stress the importance of ensuring strong adhesion and uniformity of the graphene layer on wearable TENGs. In our work, we proposed a cost-effective, large-scalable, and simple spray-coating technique to deposit graphene flakes on commercial cotton textiles, enabling the fabrication of 2x2 cm^2-sized wearable electrodes. The ultrasonication-assisted liquid phase exfoliation (LPE) is employed for the synthesis of graphene inks thanks to its high compatibility and scalability. Low-boiling-point 2-propanol (IPA) and biocompatible PVP were introduced as solvents and stabilizers for the graphene, respectively. The polyvinyl alcohol (PVA) solution was simply sprayed on the cotton textiles before spraying graphene ink. This process facilitates the establishment of hydrogen bonds between the chemical chains of PVA and PVP. It was demonstrated that a graphene/PVA composite layer on the textiles exhibits significant electrical conductivity and stability compared to a pure graphene layer, especially under conditions involving multiple bendings at different angles. As the electrode and the triboelectric part in a wearable TENG, this electrode effectively harvested mechanical energy from various human motions and powered daily tiny electronics.

2D Heterostructure Enabled Interspecies-Chimera Machine Vision with Polarimetry Tao Guo and Yimin Wu;

Up-to-date as of November 14, 2024

University of Waterloo, Canada

Cutting-edge humanoid machine vision merely mimics human systems and lacks polarimetric functionalities that convey the information of navigation and authentic images. Interspecies-chimera vision reserving multiple hosts' capacities will lead to advanced machine vision. However, implementing the visual functions of multiple species (human and non-human) in one optoelectronic device is still elusive. Here, we develop an optically-controlled polarimetry memtransistor based on a van der Waals heterostructure (ReS2/GeSe2). The device provides polarization sensitivity, nonvolatility, and positive/negative photoconductance simultaneously. The polarimetric measurement can identify celestial polarizations for real-time navigation like a honeybee. Meanwhile, cognitive tasks can be completed like a human by sensing, memory, and synaptic functions. Particularly, the anti-glare recognition with polarimetry saves an order of magnitude energy compared to the traditional humanoid counterpart. This technique promotes the concept of interspecies-chimera visual systems that will leverage the advances of autonomous vehicles, medical diagnoses, intelligent robotics, etc.

3:30 PM *EL03.02.06
2D TMD Growth and Fabrication for Large-Area Electronics Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Large-area electronics like displays and sensors rely on Thin Film Transistors (TFTs) for their backplane circuitry. Amorphous silicon (a-Si), polysilicon (poly-Si), and IGZO are common backplane TFT semiconductors, but they lack the ideal combination of high carrier mobility, on/off ratio, and stability. To address this and enable flexible devices, Transition Metal Dichalcogenide (TMD) semiconductors, particularly MoS_2, are emerging as promising alternatives. This talk will explore the synthesis and fabrication process of MoS_2-based backplane TFTs designed to advance large-area displays and tactile sensors. Our approach utilizes a modified metal-organic chemical vapor deposition (MOCVD) process to synthesize high-quality MoS_2, followed by conventional photolithography and etching for TFT array fabrication. The inherent mechanical flexibility of MoS_2 offers the potential for diverse wearable devices, including OLEDs, micro-LED displays, and tactile sensors, which are challenging to achieve with traditional materials.

4:00 PM EL03.02.07
Intercalation in 2D Materials and *In Situ* Studies Zhiyuan Zeng; City University of Hong Kong, Hong Kong

We developed a lithium ion battery intercalation & exfoliation method with detailed experimental procedures for the mass production of 11 two dimensional TMDs and inorganic nanosheets, such as MoS_2, WS_2, TiS_2, TaS_2, ZrS_2, graphene, h-BN, $NbSe_2$, WSe_2, Sb_2Se_3 and Bi_2Te_3, among them 3 TMDs achieved mono- or double layer yield > 90%. This method involves the electrochemical intercalation of lithium ions into layered inorganic materials and a mild sonication process. The Li insertion can be monitored and finely controlled in the battery testing system, so that the galvanostatic discharge process is stopped at a proper Li content to avoid decomposition of the intercalated compounds. For lithium intercalation mechanism, the state-of-the-art In-Situ Liquid Phase TEM is an ideal technique for identifying the phase changes during intercalation process. With self-designed electrochemical liquid cell utilized, we can directly vapture the dynamic electrochemical lithiation and delithiation of electrode in a commercial $LiPF_6$/EC/DEC electrolyte, such as LiF nanocrystal formation, lithium metal dendritic growth, electrolyte decomposition, and solid-electrolyte interface (SEI) formation. In addition, we use in-situ XRD technique to assess the collective information of crystallinity and structure changes of TMDs during lithium intercalation, followed by in-situ Raman technique to probe vibrational modes of TMDs during lithium intercalation with shift in energy indicating phase changes. Then, we will elucidate the lithium intercalation behavior difference, influence factors, phase transition paths and phase structure stability during lithium intercalation in different TMDs. Also, we exfoliate a series of lithium intercalated TMDs with different lithium intercalation amount, and investigate the effects of the exfoliation process on phase, electrical conductivity, chemical state, and morphology of these exfoliated nanosheets by comparing only lithium intercalated TMDs and exfoliated TMDs nanosheets. Our target is to uncover the underlying mechanism during lithium intercalation and exfoliation process from thermodynamics and kinetic point of view, and finally optimize the intercalation and exfoliation parameters for high quality TMD nanosheets preparation.

Enhanced Subthreshold Slope in Black Phosphorus-Tin Diselenide Heterostructure Tunneling Field-Effect Transistors SeungHyun Oh, Hyeonseo Lee and Kyuhyun Kim; Kangwon National University, Korea (the Republic of)

Heterostructures composed of ultrathin two-dimensional (2D) van der Waals (vdW) materials are gaining significant attention due to their potential applications in photonic devices, logic devices, and other advanced technologies. The absence of dangling bonds in 2D vdW materials eliminates the conventional lattice mismatch issue when they are integrated into heterostructure forms. This study compares the electrical performance of a tunneling field-effect transistor (TFET) incorporating a black phosphorus (BP) and tin diselenide ($SnSe_2$) heterostructure with that of a conventional BP-FET.

The I_{ds}-V_{ds} curve of the BP-$SnSe_2$ device exhibits negative differential resistance (NDR) characteristics, demonstrating band-to-band tunneling (BTBT) operation as a TFET. This is facilitated by global bottom gate biasing, which enhances band alignment potential, promotes high carrier concentration in the $SnSe_2$ sheet, and allows for exclusive adjustment of the BP channel, simplifying device fabrication and operation. At room temperature, the BP-$SnSe_2$ TFET shows an improved subthreshold slope (SS) of approximately 6 V/dec compared to 13 V/dec for the BP FET. This reduction in SS is attributed to the minimization of charge injection caused by the Boltzmann tail in the TFET operation. Note that the SS values are higher than standard silicon devices due to the relatively thick gate dielectric (approximately 300 nm SiO_2) used in this study; further improvement in SS is expected by reducing the gate dielectric thickness.

Additionally, temperature-dependent SS analysis indicates that the BP-$SnSe_2$ TFET exhibits lower SS values compared to the BP FET, with a more gradual decrease in SS upon cooling. This is also attributed to different charge transport mechanisms in the subthreshold regime between the devices. Furthermore, in low-temperature regions, SS saturation is observed, caused by band tail states.

These results contribute to the development of TFET applications using 2D vdW material-based heterostructures and provide important insights for creating more reliable and efficient TFETs.

4:30 PM EL03.02.09

2D Homogeneous Integration for Advanced Electronics Yong Jyun Wang and Ying Hao Chu; National Tsing Hua University, Taiwan

With the trend of scaling down, two-dimensional (2D) materials are the most feasible candidate materials with excellent performance at the nanoscale. Among all the 2D semiconductors, the air-stable Bi_2O_2Se (BOSe) has some prominent advantages that make it particularly favorable in this field. The ultrahigh electron mobility (>20000 $cm^2/V*s$ at room temperature) and the native high-k Bi_2O_5Se layer make this material system more promising for exploiting advanced electronics. However, complementary metal-oxide-semiconductor (CMOS) integration is a crucial criterion for applying to practical usages. To achieve this goal, the homogeneous integration of BOSe is presented in this work, showcasing the p-type feature via a suitable doping process. The selection of suitable dopants allows one to create the hole carriers. At the same time, the area-selective doping at low temperatures meets the thermal budget (~600 K) in the front-end-of-line process. In view of these existing advantages, we present an epitaxial 2D homojunction for photoelectronics with an on/off ratio (~10^5) for ultrahigh photodetectivity (~10^{14}) and a CMOS-like device with compatible electron/hole mobility based on the doped BOSe/BOSe homojunction. Compared with the heterojunction, the homogeneous integration prevents the lattice mismatch and interfacial defects, leading to a better performance. With these efforts, this material system is expected to be more competitive in the next-generational electronics.

Scalable 2D Molybdenum Disulfide-Based Field Effect Transistor Sensor for Emerging Contaminants Detection Md Mohidul Alam Sabuj, Mariam Naseer and Mengqiang Zhao; New Jersey Institute of Technology, United States

Two-dimensional (2D) materials such as Graphene and Transition Metal Dichalcogenides (TMDs, e.g., MoS_2) are promising candidates for sensor applications due to their large surface-to-volume ratio, nanometer thickness, and significant response to external environmental changes. However, sensors based on these 2D materials always require proper chemical functionalization with a probe molecule or receptor to achieve the selective recognition of target molecules and ions, which involves a complex and difficult process. Here, we developed a hexagonal boron nitride (hBN)-assisted functionalization process for the fabrication of highly scalable, back-gated 2D materials-based field-effect transistor (FET) nanosensors through a single chemistry. The basic idea is to use an hBN layer as an intermediate layer and a pyrene-based molecule as the linker to facilitate the bonding with different types of probe molecules. Given the multiple choice of pyrene-based molecular chemistry, we successfully fabricated arrays of 2D MoS_2-based FET sensors for the sensitive and selective detection of different emerging contaminants, such as organic (e.g., per- and poly-fluoroalkyl substances, PFAS) and inorganic (e.g., Pb^{2+}) contaminants of concerns. The results show that low limit-of-detection values of 0.001 ppb and 0.07 ppb have been achieved for the detection of PFAS and Pb^{2+} ions, respectively, which also exhibit promising selectivities. The approach could be easily applied to any other 2D materials, therefore providing a universal pathway towards nanosensor fabrication.

Ultra-thin Semiconductor Films for Flexible Electronics and Bioelectronics Cunjiang Yu; University of Illinois at Urbana-Champaign, United States

Electronics that can seamlessly integrate with human body could have significant impact in medical diagnostic and therapeutics. However, seamless integration is a grand challenge because of the distinct nature between electronics and human body. Conventional electronics are rigid and planar, made out of rigid materials. Human body are soft, deformable and curvilinear, comprised of biological materials, organs and tissues. This talk will introduce our strategies to address the challenge through ultra-thin semiconductor film electronics based soft electronics technologies, such as flexible, stretchable electronics and most recently rubbery electronics. By taking the advantage of the enable mechanics of ultra-thin, open-mesh structures, conventionally non-stretchable electronic materials could become mechanically stretchable. Special mechanical structures or architectures accommodate or eliminate mechanical strain in the non-stretchable materials while stretched. Stretchable electronics in this fashion allow integration with skin, organ and tissues. On the other hand, rubbery electronics is constructed all based on elastic rubber electronic materials of semiconductors, conductors and dielectrics, which possesses tissue-like softness and mechanical stretchability to allow seamless integration with soft deformable tissues and organs.

SESSION EL03.03: Large-Scale Routes for 2D Materials

Large-Area Single-Crystal Graphene—Grown by CVD on Ni(111) and Its Macroscale Tensile Loading Mechanics Rodney S. Ruoff[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

We convert as-received polycrystalline Nickel (Ni) foils to Ni(111) foils and grow epitaxial large area single crystal graphene on these Ni(111) foils. This graphene on the Ni(111) has unique (remarkable) features that will be described (manuscript in preparation).
Large-area single crystal graphene is adhered to polymer films that are ~100-nm thick. *Macroscale* ‘dogbone’ specimens are floated on a water surface in a homebuilt “float on water” tensile loading system. Tensile loading of these specimens including as a function of crystallographic orientation (e.g., zig zag, armchair, and “in between” zz and ac) is used to obtain the Young’s modulus and fracture strength. The stiffness and particularly the strength values suggest the eventual widespread use of CVD-grown single crystal, large area, graphene in cars, trains, planes, and many, many, other applications calling for exceptionally high macroscale specific strength. We appreciate support by the Institute for Basic Science (IBS-R019-D1).

8:30 AM *EL03.03.02

Novel Synthetic Approaches for High-Mobility Graphene—From Decoupled Graphene on Cu/Sapphire to Artificial Intelligence Assisted Growth Camilla Coletti; Istituto Italiano di Tecnologia, Italy

The scalable synthesis of graphene over flat and rigid templates – displaying quality comparable to that of mechanically exfoliated crystals – has become a central topic in the last years, as it would enable several high-end applications, scalable twistronic devices, and pave the way to enticing quantum technologies. In this talk, I will introduce the growth via non-reducing chemical vapor deposition (CVD) of decoupled graphene on crystalline Cu films deposited on sapphire. The resulting graphene is lying atop a thin Cu_2O layer, and is charge neutral, low strained, and easy to transfer. Electrical transport measurements reveal unprecedented room temperature carrier mobilities for graphene grown on rigid substrates, exceeding 10^5 $cm^{-2}V^{-1}s^{-1}$ when encapsulated in hexagonal boron nitride [1], thus opening realistic pathways for graphene-based high-end applications, including the exploration of innovative quantum platforms. Finally, I will discuss the transformative potential of artificial intelligence (AI) in materials science by demonstrating artificial neural network (ANN) assisted growth of high-quality graphene [2].

9:00 AM EL03.03.03

Direct Synthesis and Chemical Vapor Deposition of Two-Dimensional Transition Metal Carbides and Nitrides (MXenes) Di Wang[1], Noah Mason[1], Francisco J. Lagunas Vargas[2], Chong Liu[1], Robert F. Klie[2] and Dmitri V. Talapin[1]; [1]The University of Chicago, United States; [2]University of Illinois at Chicago, United States

MXenes are a large family of two-dimensional (2D) transition metal carbides and nitrides that follow a generalized formula of $M_{n+1}X_nT_x$ (n = 1-4), where M stands for early transition metal (such as Ti, V, or Nb), X is C or N, and T is surface terminations (for example, -O, -F, and -Cl). Interest in 2D MXenes continues to grow because of their promising performance in energy storage, electromagnetic interference (EMI) shielding, and catalysis.
Most MXene synthesis methods are fundamentally top-down approaches, which involve the conversion of a MAX phase (A is typically Al or Si) precursor through selective etching of the A layers in hydrofluoric acid-containing solutions or other etchants such as Lewis acidic molten salts and HCl. Recent developments have begun to focus on bottom-up routes due to superior atom economy and a greater degree of synthetic control in such methods. We demonstrated two direct ways, bypassing the MAX phase intermediates, to prepare one of the most widely used MXenes, Ti_2CCl_2. One is based on the high-temperature reaction of a stoichiometric mixture of precursors. The other uses chemical vapor deposition (CVD). We further pushed MXene bottom-up synthesis to a new level by expanding the scope of MXene available through direct synthesis. We show C_2Cl_4 and other analogous similar precursors can directly synthesize high-purity Ti_2CCl_2 along with Zr_2CCl_2, and Nb_2CCl_2 MXenes. This method implies simple halocarbon molecules of varying stoichiometries can enable a general and scalable route to various MXenes. The high reactivity of molecular precursors increases the nucleation rate, so that the lateral sizes of MXene flakes remain small, on the order of tens of nanometers. The large surface-to-volume ratio helps with the solution procession of MXenes, and is ideal for surface functionalization of MXenes.
The direct synthesis routes save time and minimize hazardous waste production. Besides, these new routes offer synthetic modalities not compatible with traditional methods, especially in the cases where corresponding MAX phases are not available. Considering the extensive possibility of element combinations, the direct synthesis method could substantially expand the variety of the MXene family. These benefits are expected to improve the efficiency of scaling production and expedite converting lab-scale discoveries into industrial-level applications.

9:15 AM EL03.03.04

A Wafer-Scale Hybrid Dielectric Made from Single-Crystal Bilayer Hexagonal Boron Nitride for Two-Dimensional Electronic Devices Jaewon Wang[1], Hyeonwoo Lee[1], Jaemin Kim[1], Haeng Un Yeo[1], Cheol Hwan Yoon[1], Min Seok Yoo[2], Kitae Park[1], Joonki Suh[1], Chanyong Hwang[3], Tae-Sik Yoon[1], Minsu Seol[2], Hyung-Joon Shin[1], Zonghoon Lee[1], Changwook Jeong[1] and Soon-Yong Kwon[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Korea Research Institute of Standards and Science, Korea (the Republic of)

The wafer-scale integration of high-quality, ultrathin high-k dielectrics on two-dimensional (2D) semiconductors is critical for realizing high-performance 2D electronics. Van der Waals dielectrics, such as hexagonal boron nitride (hBN), are typically introduced to preserve the intrinsic properties of 2D semiconductors; however, synthesizing these dielectrics on the wafer-scale and integrating them with 2D semiconductors is challenging. In this study, we show that hybrid hBN/high-κ dielectric heterostructures can be created on wafer scales using a metal-organic chemical vapor deposition (MOCVD) of bilayer hBN epitaxially grown on Ni(111), followed by an atomic layer deposition (ALD) of high-κ dielectric materials. The utilization of wafer-scale single-crystal bilayer hBN as an interlayer between a high-κ dielectric and the 2D channel demonstrates interface scattering suppression in 2D transistor arrays on a wafer scale. Using a pulse-mode MOCVD system, in which precursors are injected sequentially with an interruption step, we achieve the high-throughput, spatially uniform growth of hBN on a wafer-scale. The unidirectional alignment of hBN originates from its epitaxial growth guided by the atomic stacking configurations of the hBN/Ni(111) crystal structures. Atomic-scale structural characterization and first-principle calculations confirm the stability of bilayer hBN nucleated by the Ni step. Additionally, we demonstrate the fabrication of spatially uniform hBN/high-κ dielectric stacks with an ultrathin metal seed layer, and a damage-free transfer method of the hybrid dielectric stacks using capillary force-assisted bubbling transfer, which successfully integrates onto the polycrystalline molybdenum disulfide (MoS_2) channel. Monolayer MoS_2 field-effect transistor arrays supported by the hybrid dielectric stacks show a significant enhancement in electronic performance and reliability, including the subthreshold swing, interface trap density, and carrier mobility.

Scalable Two-Dimensional Semiconductors—From Photo-Gating to Deep UV Optoelectronics Amalia Patane; University of Nottingham, United Kingdom

Two-dimensional semiconductors (2SEM) offer opportunities to advance modern science and technologies. However, transforming the semiconductor landscape requires high-quality materials with well-defined electronic properties, which are still difficult to control and scale. Here, these challenges are addressed by integration of growth, scanning probe microscopy and electron spectroscopy of 2SEM in ultra-high vacuum (UHV). We use a bespoke facility (EPI2SEM) for EPitaxial growth and In-situ analysis of 2SEM in UHV [1]. A centrosymmetric polymorph (D_{3d}) of gallium selenide (GaSe) is obtained by epitaxy onto large-area sapphire [2] and graphene/SiC [3] substrates. Epitaxial GaSe represents a scalable building block for nanoelectronics. We present two proof-of-concept devices. In our first type of device, the electric dipole at the interface of single layer GaSe and graphene is very sensitive to photogenerated charges in GaSe. The indirect nature of the band gap of GaSe and the heavy hole masses can retard band-to-band recombination and facilitate an accumulation of positive charge in GaSe, thus acting as a photogate for graphene. In the second proof of concept, the grown materials provide a platform for scalable optical sensors. The optical anisotropy and resonant absorption of GaSe in the UV spectrum are exploited for photon sensing in the UV-C spectral range, offering a scalable route to deep-UV optoelectronics [2].

10:30 AM EL03.04.02
Amplification of Interlayer Exciton Emission in Twisted Transition Metal Dichalcogenides Heterostructures

Chirag Palekar[1], Bárbara Rosa[1], Paulo de Faria Junior[2], Ching-Wen Shih[1], Aris Koulas-Simos[1], Imad Limame[1], Niels Heermeier[1], Frederico Sousa[3], Arash Rahimi-Iman[4], Leandro Malard[3], Jaroslav Fabian[2] and Stephan Reitzenstein[1]; [1]Technische Universität Berlin, Germany; [2]Universität Regensburg, Germany; [3]Universidade Federal de Minas Gerais, Brazil; [4]Justus-Liebig-Universität Giessen, Germany

Transition metal dichalcogenides (TMDC) heterostructures (HS) are obtained by stacking two or more different monolayers (ML). These structures host spatially indirect interlayer excitons (IX) with unique properties that depend on the twist angle and stacking order of two or more MLs [1]. However, the practical applications of IXs are limited by their weak oscillator strength, which leads to a significant reduction in emission. Therefore, innovative solutions to substantially improve the emission of interlayer excitons are desirable. Here we present two concepts to enhance the emission of interlayer excitons in twisted TMDC HSs for future use in nanophotonic devices. One concept is based on advanced WSe2/WSe2/MoSe2 heterotrilayer (HTL) systems. In this system, the interlayer exciton formed in the HTL region exhibits up to a 10-fold increase in photoluminescence yield compared to the heterobilayer (HBL) region on the same sample. Detailed optical and numerical investigations show that the interactions between the three layers significantly contribute to the formation and relaxation mechanisms of interlayer excitons, resulting in the observed luminescence enhancement [1]. The second concept utilizes light-matter interaction of TMDC HSs integrated into chirped distributed Bragg reflectors, which feature energetically separated cavity resonances. This configuration enables cavity-coupled emission of intra and interlayer excitons that are energetically separated in a WSe2/MoSe2 HSs. The chirped microcavity, in combination with TMDC HSs, shows potential for studying moiré physics and enhancing light-matter interactions in TMDC-based devices [2]. Overall, our approaches offer versatile tools for future studies and applications of TMDC HS using innovative layer and cavity designs.

Real-Time and Highly Sensitive Sub-Wavelength 2D Hybrid Perovskite Photodetectors and Sensors for Environmental and Healthcare Monitoring Rosanna Mastria[1,2], Karl Jonas Riisnaes[1], Agnes Bacon[1], Ioannis Leontis[1], Hoi Tung Lam[1], Mohammed Ali Saleh Alshehri[1], David Colridge[1], Tsz Hin Edmund Chan[1], Adolfo De Sanctis[1], Luisa De Marco[2], Laura Polimeno[2], Annalisa Coriolano[3], Anna Moliterni[2], Vincent Olieric[4], Cinzia Giannini[2], Steven Hepplestone[1], Monica Craciun[1] and Saverio Russo[1]; [1]University of Exeter, United Kingdom; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Università del Salento, Italy; [4]Paul Scherrer Institute, Switzerland

Layered (2D) perovskites, known for their enhanced stability under ambient conditions compared to their 3D bulk counterparts, are gaining significant attention due to their highly tuneable optical and electrical properties. This has sparked considerable interest in their potential for advanced 2D-photovoltaic applications. However, the full value of 2D hybrid perovskites in nano-scale optoelectronics has remained underexplored, primarily due to their sensitivity to environmental conditions and the solvents used in conventional semiconductor fabrication processes. This has posed challenges in developing competitive perovskite-based solutions for high-density and large bandwidth signal processing.
In this presentation, we showcase our development of nano-scale 2D-fluorinated phenethylammonium lead iodide perovskite (F-PEAI) planar photodetectors [1,2]. Remarkably, these devices are entirely fabricated under ambient conditions using standard electron beam lithography that involves solvents. Our photodetectors exhibit exceptional performance metrics, including a room temperature detectivity exceeding 5 × 10^17 Jones, a real-time photoresponse comparable to commercial 2 GHz Si photodiodes, an extraordinarily large linear dynamic range of

228 dB, and a photo-responsivity of approximately 1100 A/W. Notably, these devices maintain stability from room temperature down to 4 K and can be reliably fabricated on diverse substrates, including flexible and wearable media, without performance loss. This is a significant advantage over other 2D materials, such as graphene and transition metal dichalcogenides, which require planarization and atomically clean dielectrics.

Furthermore, we demonstrate the successful fabrication of planar nano-scale 2D F-PEAI photodetectors with sub-wavelength dimensions, smaller than one-fifth the wavelength of the detected light. This breakthrough opens new possibilities for high-definition imaging technologies using perovskites.[1]

Expanding on this innovation, we also explore the potential of 2D F-PEAI for sensing applications in aqueous environments [2]. By utilizing the unique properties of natural beeswax as a protective encapsulation layer, we have developed photodetectors with outstanding performance, including responsivity greater than 2200 A/W and detectivity of 2.4 × 10^18 Jones. The hydrophobic beeswax coating grants these sensors exceptional durability against prolonged immersion in contaminated water, extending the operational lifespan to over one year. Additionally, the biocompatibility and self-cleaning attributes of beeswax enable the same sensors to be effectively used for healthcare applications, such as monitoring human heartbeat through photoplethysmography, capturing clear systolic and diastolic signals.

The remarkable combination of ambient stability and exceptional optoelectronic properties of 2D F-PEAI, coupled with innovative beeswax encapsulation, heralds a new era of opportunities for multipurpose applications in sustainable electronics. Our work paves the way for the versatile and practical use of 2D perovskites in both environmental and healthcare monitoring, underscoring their significant potential in addressing key societal challenges.

11:00 AM EL03.04.04

Enhanced Photodetection Performance of *In Situ* Core/Shell Perovskite-MoS$_2$ Heterostructure Phototransistor

Jinwoo Sim[1], Sunggyu Ryoo[1], Joo Sung Kim[1], Juntae Jang[1], Tae-Woo Lee[1], Kyungjune Cho[2], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) are promising materials for various optoelectronic device applications due to their tunable band gap, simple fabrication, interesting excitonic properties, and chiral light-matter interaction from the spin-valley locking [1]. However, their atomic-level thinness results in low light absorption, which hinders the sensitive photodetection in 2D TMDCs-based photodetectors. Recent studies have integrated perovskite nanocrystals (PNCs) layer with high optical absorbance on 2D TMDC channel in order to increase the light absorption of 2D TMDCs [2]. Still, a remaining problem is the low carrier mobility and inefficient charge injection from the PNCs layer into the TMDC layer due to the long insulating ligands of the PNCs.

In this study, we address the shortcoming of conventional PNCs integrated on TMDC photodetectors by depositing in-situ core/shell perovskite onto the MoS$_2$ channel. In-situ core/shell perovskites are formed by efficiently splitting three-dimensional (3D) perovskite films with short ligands and minimized defects, which significantly improves charge transfer and light absorption efficiency [3]. First, we optically characterized the PNCs/MoS_2 heterostructure through UV-visible absorbance spectroscopy and time resolved photoluminescence. As a result, increased optical absorbance and efficient charge transfer from the PNCs to the MoS_2 layer was confirmed. Second, we observed that the photodetection performance of PNCs/MoS_2 phototransistors were enhanced compared to the MoS_2 phototransistors without PNCs layers. Specifically, PNCs/MoS_2 phototransistors' responsivity and specific detectivity reached the maximum values of 2.2×10^6 A/W and 9.0×10^{11} Jones, respectively, which were both high values compared to the previous reports. Due to the type-II band alignment of the PNCs/MoS_2 heterostructure, photogating and photoconductive effect synergistically contribute to photocurrent generation [4]. To further elucidate the photodetection mechanism of the PNCs/MoS_2 phototransistor, we changed the gate voltage while measuring the photo response of the device and we observed that the response time and the nonlinearity of the photocurrent to the incident light power increased at higher gate voltages. Both results indicate that photogating effect becomes more dominant at higher gate voltages. Our research improves the performance of the 2D MoS_2 photodetector through a simple process, which provides a promising approach for a low-cost, highly integrated, and stretchable photodetector based on 2D materials.

Self-Powered High-Performance WS_2 Visible-Light Photodetector Based on a Seamless Lateral p-i-n Homojunction

Jehwan Park, Seokjin Ko and Jihyun Kim; Seoul National University, Korea (the Republic of)

Transition metal dichalcogenides (TMDCs) have emerged as promising materials for nanometer-scale devices, exhibiting attractive properties such as high carrier mobility, low surface trap density, and strong light-matter interaction. Their potential applications in advanced field-effect transistors (FETs) and optoelectronic devices have sparked significant interest in semiconductor research. Manipulating the doping characteristics of TMDCs is crucial for controlling device properties and constructing complex structures. However, conventional doping techniques, including diffusion or ion implantation, have limited applicability to these materials. Consequently, p-doping via charge transfer, involving the interaction between a semiconductor and an electron-withdrawing agent, has gained widespread utilization. For tungsten-based TMDC materials such as WS_2, exposure to ultraviolet-ozone (UV-O_3) can induce the formation of sub-stoichiometric oxide WO_X ($X < 3$) with high electron affinity, resulting in effective p-doping. While existing research on p-n junction diodes has primarily focused on type-II-based heterojunction diodes, the performance of these devices is often limited by defects and nonuniformity at junction interfaces arising during the fabrication process. To overcome these limitations, high-performance two-dimensional p-n devices with homojunction have been developed as a promising alternative to eliminate defects by achieving atomically clean interfaces. Among these, p-type/intrinsic/n-type (p-i-n) junctions have been extensively utilized to attain high-speed response by effectively reducing junction capacitance by incorporating a wider depletion region.

This work first investigates the manipulation of p-doping in multilayer WS_2 (ML-WS_2) through the formation of WO_X using incremental UV-O_3 treatment times. Mechanically exfoliated ML-WS_2 flakes were dry-transferred onto a Ni plate and oxidized via UV-O_3 treatment with a flow rate of 8 L/min at 100 °C in 30 min intervals. The extent of p-doping by WO_X formation was examined at each step by measuring work function changes using Kelvin probe force microscopy until saturation was observed to optimize the p-doping of ML-WS_2 flakes. A lateral homojunction p-i-n

photodetector was fabricated based on the optimized UV-O_3 oxidation process. A ML-WS_2 flake was dry-transferred onto a Ni (20 nm) electrode pre-deposited on a p^{++}-Si/SiO_2 substrate for the p-type region contact and a Ti/Au (20/80 nm) electrode for the n-type region contact was formed after the transfer, where both electrodes were defined by electron-beam lithography and deposited using an electron-beam evaporator. The intrinsic region width was set to 3 μm. Thermal annealing was performed in high vacuum (~10^{-6} Torr) at 200 °C for 2 h to enhance the metal-WS_2 contacts. The p-type region of the ML-WS_2, located directly above the Ni electrode, was defined by electron-beam lithography and underwent UV-O_3 treatment for 3 h. After rinsing off the resist, the exposed ML-WS_2 comprising both p-type and intrinsic regions was subjected to an additional 1 h UV-O_3 treatment.
The fabricated p-i-n photodetector exhibited impressive performance with self-powered operation. It demonstrated a high responsivity of 496.30 mA/W under 530 nm light (power density of 12.33 mW/cm^2), with fast rise and decay times of 4.5 and 4.4 ms, respectively. Notably, the device showed an excellent rejection ratio of 221.56 under 530 nm and 780 nm light with a responsivity of 2.24 mA/W at 12.4 mW/cm^2, indicating the absence of defect levels responding to longer wavelengths. This work demonstrates that controllable p-doping of ML-WS_2 can be realized by manipulating the UV-O_3 treatment time without introducing severe defects and it is a promising approach for creating seamless lateral homojunction p-i-n diodes for optoelectronic applications.

Monitoring Structural and Electrical Properties of $PtSe_2$ Films for High Frequency Optoelectronics Pierre Legagneux; Thales Research & Technology, France

$PtSe_2$ exhibits high carrier mobility and infrared absorption which are particularly suitable for high frequency optoelectronics at the 1.55 μm telecom wavelength. We have studied $PtSe_2$ films grown by molecular beam epitaxy (MBE) to demonstrate high-frequency photodetectors and mixers. Optoelectronic mixers can mix high-frequency optical and electrical signals, enabling innovative applications such as radio-over-fiber communication systems, wideband radio frequency transceivers for radar systems and satellite payload. We first measured the optical absorption at 1.55 μm and the conductivity of $PtSe_2$ films as a function of the number of monolayers (ML) and focused our studies on thick (12-16 MLs) semimetallic films that exhibit both good IR absorption and high conductivity. These are key parameters for demonstrating highly efficient optoelectronic mixers. To this end, we have carried out in-depth studies on the growth of $PtSe_2$ by MBE. To evaluate the crystalline quality of $PtSe_2$ films, most groups measure the full width at half maximum (FWHM) of the in-plane Eg Raman peak. Eg FWHM ≤ 5 cm^{-1} was then an indicator of high crystalline quality. Monitoring not only E_g FWHM but also the FWHM of the out-of plane $A1_g$ peak, we have optimized the MBE growth of large-scale $PtSe_2$ films on sapphire substrates. By performing a post-growth annealing, we demonstrated that the E_g and A_{1g} FWHM values reach the exceptionally low values of 3.6 cm^{-1} and 3.5 cm^{-1} respectively, as well as a high conductivity of 1.6 mS. Based on these studies, we propose a new figure of merit showing that both Eg and A1g FWHM values are required to evaluate the crystalline quality of $PtSe_2$ films. We show that the electrical conductivity of our films can be efficiently predicted using the FWHM of the A1g peak. Furthermore, using X-ray diffraction and advanced transmission electron microscopy techniques, we have identified the correlations between the crystalline structure and the electrical conductivity of the $PtSe_2$ films.
A14ML $PtSe_2$ film of high crystalline quality was grown on a 2-inch sapphire wafer. We then fabricated $PtSe_2$ based coplanar waveguides to demonstrate photodetectors at 1.55 μm with a record bandwidth of 60 GHz and the first $PtSe_2$-based optoelectronic mixer with 30GHz-bandwidth.

11:45 AM ^EL03.04.07

Prevention of Photo-Induced Degradation in Monolayer TMDs Probed by THz Emission Spectroscopy Claudia Gollner, Chenyi Xia, Zhepeng Zhang, Fang Liu, Tony F. Heinz and Aaron Lindenberg; Stanford University, United States

Low dimensional transition metal dichalcogenides (TMDs) are at the front line for opto-electronic devices, valleytronics, or quantum emitters due to their extraordinary optical and mechanical properties, such as a sizeable bandgap, large exciton binding energies or strong spin-orbit coupling. However, many 2D materials with atomic-scale thickness suffer from oxidation and degradation effects under ambient conditions, which hampers their practical applications. In the case of MoS_2 and WS_2, it is understood that gradual oxidation appears along grain boundaries or sulfur vacancies when the monolayers are exposed to the environment for several months. It is further suggested that H_2O acts as a 'catalyst' and greatly speeds up the oxidation process. Recently, photo-induced oxidation in WS_2 monolayers was identified as the physical mechanism of oxidation in ambient air when the sample is excited with photon energies above the band edge. Thus, in order to realize robust TMD opto-electronic devices, it is necessary to further investigate in protection strategies for large scale 2D materials. Instead of encapsulating WS_2 monolayers (ML) with a preservative hBN coating, which is limited in its scalability, in this work, we exploit Au substrates to prevent photo-induced degradation in the 2D TMD material and probe the surface properties as well as charge carrier dynamics with THz emission spectroscopy.

We thereby excite the WS_2 monolayer above the band edge energy with 400 nm (3.09 eV) pulses and record the emitted THz transient with electro-optic sampling. Sampling the time variation and polarization of the radiated electric fields provide a contact free, quantitative method for determining the magnitude, polarity, directionality, phase and temporal variation of the source currents, which can reflect the structure symmetry, carrier diffusion, carrier drift, surface depletion or non-linear susceptibility.

The following samples are under investigation: (1) WS_2 monolayers grown by chemical vapor deposition (CVD) on Sapphire transferred to either a fused silica or gold substrate and (2) large-area gold-tape exfoliated WS_2 monolayers which are either transferred to a fused silica substrate or kept on the gold layer. The set of samples is chosen such that the study is independent of the defect state densities, caused by different fabrication methods. We report for the first time on THz emission from single layer TMDs pumped above resonance. We observe a surprisingly high THz signal from the ML, which is only five times lower than the signal from a reference bulk InSb sample for which the THz signal is ascribed to the Photo-Dember effect. The large THz signal from WS_2 on fused silica is attributed to resonant optical rectification as well as to a surface field-induced photocurrent. However, while the emitted THz field is stable when the environment is purged with N_2, resulting in a relative humidity of 0%, the THz signal vanishes under ambient environment within minutes and obvious optical damage of the sample is visible under the microscope. In contrast, in the case of WS_2 on a gold substrate, the THz signal remains stable under ambient conditions, and no optical damage can be observed under the microscope, although higher fluences are applied as compared to the fused silica samples. Moreover, pump polarization studies indicate that THz radiation is due to interfacial charge transfer from the TMD monolayer to the metallic substrate. We thus hypothesize that the enhanced stability of the gold substrate is due to quenching of the photoexcited carriers through nonradiative recombination in the gold substrate and thus, the number of excited carriers available for chemical reaction is greatly reduced.

This simple method of using a gold substrate to prevent photo-induced oxidation could pave the way for future electro-optic devices based on 2D TMD materials.

SESSION EL03.05: Inks and Nanofluidics

Scalable Production and Application of Printable 2D Nanoelectronic Inks Mark C. Hersam; Northwestern University, United States

Solution-processed 2D nanoelectronic materials are promising inks for printed applications including flexible electronics, batteries, and sensors. However, the polydisperse nature of nanomaterial dispersions following liquid-phase exfoliation poses manufacturing challenges, as incompletely exfoliated materials must be removed to achieve optimal properties. Incumbent separation schemes invariably rely on centrifugation, which is highly energy-intensive and limits scalable manufacturing. In contrast, this talk will explore cross-flow filtration (CFF) as a centrifuge-free processing method that improves the throughput of nanomaterial separations by orders of magnitude [1]. By tuning membrane pore sizes between microfiltration and ultrafiltration, CFF can also be used for efficient recovery of solvents and stabilizing polymers. In this manner, life cycle assessment and techno-economic analysis reveal that CFF leads to significant reductions in greenhouse gas emissions, fossil energy usage, water consumption, and specific production costs. To confirm that CFF produces electronic-grade nanomaterials, the performance of CFF-processed nanoelectronic inks in printed electronic, optoelectronic, and energy technologies will be delineated including photodetectors, optical emitters, supercapacitors, and batteries [2-5].

Nanofluidics—Exploring New Frontiers Aleksandra Radenovic; École Polytechnique Fédérale de Lausanne, Switzerland

In this talk, I will introduce two novel types of nanofluidic platforms. The geometry of the first nanofluidic platform combines the benefits of reduced sensing regions typically seen in 2D material nanopores with the asymmetric geometry of capillaries, resulting in ionic selectivity, stability, and scalability. The proposed nature-inspired growing method provides a flexible nanopore platform for various nanofluidic research applications, such as biosensing, energy science, and filtration technologies. The second nanofluidic platform with a large entrance asymmetry is designed for in-memory processing, which can be mass-produced and behaves as performant memristive charge threshold switches with discontinuous current-voltage characteristics. The device's performance and reliability enabled the building of a logic circuit composed of two interactive ionic channels and an electronic resistor, which opens the way to the design of nanofluidic neural networks for brain-inspired ionic computations.

2:45 PM EL03.05.03

Wafer-Scale Transistor Arrays Fabricated Using Slot-Die Printing of Molybdenum Disulfide and Sodium-Embedded Alumina Yonghyun A. Kwon, InCheol Kwak, Seonkwon Kim, Soo Young Cho, Seung Yeon Ki, Jihyeon You and Seonmi Eom; Yonsei University, Korea (the Republic of)

Two-dimensional materials made via solution processing could be used to create next-generation electronic devices at scale. However, existing solution processing methods typically have a trade-off between scalability and material quality, which makes them unsuitable for practical applications. Here we show that wafer-scale arrays of molybdenum-disulfide-based transistors can be fabricated using a commercial slot-die printing process. We create inks of molybdenum disulfide nanosheets and sodium-embedded alumina for printing of the semiconductor and gate dielectric layer, respectively. The transistors exhibit average charge carrier mobilities of 80.0 $cm^2 V^{-1} s^{-1}$ in field-effect transistor measurements and 132.9 $cm^2 V^{-1} s^{-1}$ in Hall measurements at room temperature. The high charge carrier mobility is attributed to the sodium-embedded alumina gate dielectric, which causes a band-like charge carrier transport in the molybdenum-disulfide-nanosheet-based thin-film networks. We use the transistors to create various logic gates, including NOT, NOR, NAND and static random-access memory.

SESSION EL03.06: Te-Based 2D Materials
Session Chairs: Carlo Grazianetti and Aleksandra Radenovic
Tuesday Afternoon, December 3, 2024
Sheraton, Second Floor, Back Bay C

3:30 PM *EL03.06.01
Chirality-Determined Fundamental Properties of 2D Tellurium Peide P. Ye and Chang Niu; Purdue University, United States

In this talk, we first review recent progress in synthesizing atomically thin Te two-dimensional (2D) films and one-dimensional (1D) nanowires. We will also overview the recent study on its quantum transport in the 2D limit and progress in exploring its topological features and chiral related physics. We envision the breakthrough in obtaining unexplored electrical, optical and spin-related magnetic properties of 2D Te deterimined by the structure chirality and handedness.

4:00 PM EL03.06.02
Topological Modulation of 2D Tellurium Giheon Kim[1], Jaeuk Bahng[1], Jaemo Jeong[1], Wonkil Sakong[1], Taegeon Lee[2], Daekwon Lee[2], Youngkuk Kim[1], Heesuk Rho[2] and Seong Chu Lim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

Trigonal tellurium (Te) is a semiconductor with a bandgap of 0.3 eV. Recently, theoretical calculations predicted the existence of Weyl points near the band edges, so it is referred to as a Weyl semiconductor. Due to the narrow gap, we can study transport properties near Weyl points through gate modulation, which was not possible with Weyl semimetals. Near the conduction band edge only, we observed a strong Hall effect with no magnetic field. Under the time-reversal symmetry, various mechanisms have been invoked to generate transverse voltage, such as skew scattering, side-jump scattering, and current jetting. Our careful investigation details that the transverse Hall voltage scales in parabolic to the longitudinal input current I(w), i.e., $V(2\omega) \sim I^2(\omega)$. Intriguingly, V(DC) is linearly proportional to $I^2(\omega)$ and display the same value with $V(2\omega)$. The results indicate that the Hall voltage of 2D Te has a topological origin of Berry curvature dipole (BCD). This effect arises due to the asymmetric distribution of Berry curvature in momentum space. At 4 K, 2D Te shows a much more significant on/off ratio, approximately 10^4

in the transverse direction, than 10 in the longitudinal direction. The high on/off ratio implies that the nonlinear Hall voltage (NLHV) is sufficiently gate-modulable and opens a new possibility for topological electronics.

Per- and Polyfluoroalkyl Substances (PFAS) Detection in Water Using 2D Nanomaterial-Based Field-Effect Transistor Sensors Yuqin Wang[1,2], Hyun-June Jang[1,2], Max Topel[1], Siva Dasetty[1], Yining Liu[1,2], Mohamed Ateia[3,4], Aaron Tam[5], Vepa Rozyyev[2,1], Ellie Ouyang[1], Wen Zhuang[1,2], Haihui Pu[1,2], Sang Soo Lee[2], Jeffrey Elam[2,1], Andrew Ferguson[1], Seth Darling[2,1] and Junhong Chen[2,1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States; [3]U.S. Environmental Protection Agency, United States; [4]Rice University, United States; [5]Oak Ridge Institute for Science and Education, United States

Widespread, persistent, and toxic per- and polyfluoroalkyl substances (PFAS) pose a major threat to both water systems and human health. Current PFAS detection methods are relatively expensive, slow, and complex. To combat PFAS contamination and meet increasingly stringent regulations of PFAS in drinking water, the development of highly sensitive and selective PFAS sensing techniques is imperative. 2D nanomaterial-based field-effect transistor (FET) sensors are strong candidates in water pollutant monitoring owing to their high sensitivity, tunable selectivity, fast response, and portability. We present a remote gate FET (RGFET) sensing platform featuring β-cyclodextrin (β-CD)-modified reduced graphene oxide (rGO) as the sensing membrane for perfluorooctane sulfonic acid (PFOS) detection in tap water with a reporting limit (~250 ppq) lower than the maximum contaminant level (4 ppt) set by the U.S. Environmental Protection Agency. The sensor exhibits excellent selectivity against common inorganic ions (e.g., Na^+, K^+, Ca^{2+}, Cl^-, HPO_4^-, SO_4^{2-}) and select organic pollutants (e.g., trichloroacetic acid) in tap water. Importantly, the reversible and rapid response (< 2 min) indicates the potential of RGFET for continuous inline monitoring of PFAS. Quartz crystal microbalance experiments provide further insights into the analyte adsorption behavior at the modified rGO sensing surface and emphasize the important roles of both analyte adsorption and charge properties of analytes and buffers in generating sensing signals. The binding nature between β-CD probe and PFOS or interferent molecules, as well as the spatially resolved selectivity revealed by molecular dynamics simulations, suggests rational probe engineering strategies for future selective capture probe design.

EL03.07.02

Band Alignment Study for CVD Grown Vertically Stacked Different Configurations of Monolayer MoS_2-ReS_2 Photodetector Gowtham Polumati[1], Barbara A Muñiz Martínez[2], Mauricio Terrones[3], Andres De Luna Bugallo[2] and Parikshit Sahatiya[1]; [1]Birla Institute of Technology and Science, Pilani – Hyderabad Campus, India; [2]Universidad Nacional Autónoma de México, Mexico; [3]University of Pennsylvania, United States

This work demonstrates different configurations of vertically stacked two step CVD (chemical vapour deposition) grown monolayers of MoS_2-ReS_2 and stacking significance in tailoring band type and hence charge migration phenomenon upon visible illumination. The MoS_2/ReS_2 heterostructure is popularly known for its high stability, greater light matter interaction due to high absorption coefficient, strong in-plane carrier mobility of MoS_2,direct bandgap of ReS_2 irrespective of the number of layers ,tunable transport mechanism upon different stacking configurations and greater responsivity of ReS_2 due to its high density of states .To better understand the issue of stacking for different configurations i.e. ReS_2-MoS_2(MoS_2 on top) or MoS_2-ReS_2 (ReS_2 on top), the optical properties are examined by micro-photoluminescence wherein it was interestingly observed a change in band type in accordance with stacking order for different stacking configurations i.e. Type-I for ReS_2 on top and Type-II for MoS_2 on top. Furthermore, the morphology was examined to confirm the stacking of vertical heterostructure by HR-TEM which clearly reveals the formation of ReS_2 on MoS_2 and vice-versa. Photodetection experiment was conducted for devices having different stacking configurations and it was noted that ReS_2 on top (Type-I) and MoS_2 on top (Type-II) exhibits responsivity of 400 A/W and 72 A/W respectively under visible illumination. It was clearly observed that the responsivity of Type-I band alignment is much higher than that of Type-II band alignment. The increment in the responsivity value when ReS_2 is on top (Type-I band alignment) is due to the effective separation of photogenerated carriers to MoS_2 and high symmetric crystallographic orientation that was confirmed by low temperature PL studies and extracted band structure. It is noted that suitable stacking plays a vital role in deciding suitable band alignment and accordingly the desired responsivity. The insightful study of such 2D vertically stacked heterostructure configurations are important to conveniently decide the best version of device in developing high responsive photodetectors.

EL03.07.03

Enhancing Hydrogen Storage Performance Using Electric Fields on 3D Graphene Ji Hoon Kim[1,1], Gyu Hyeon Shim[2], Vo Thi To Nguyen[1] and Ho Seon Ahn[1,1]; [1]Incheon National University, Korea (the Republic of); [2]AHN Materials Inc., Korea (the Republic of)

This study presents an innovative approach to enhancing hydrogen storage performance using electric fields applied to carbon-based materials. We developed a method for forming large-scale (> 4-inch diameter) 3D graphene networks via self-assembly at a superheated liquid-vapor interface. The porous network's morphology was modified by controlling the vaporization rate, surface temperature, and amount of discharged colloids, allowing for mass production with excellent electrical and mechanical properties. The 3D graphene, coated on Cu or Al foil, was optimized as a hydrogen storage medium. Rolled samples were placed in a cylindrical cell with an electrical rod at the center, creating a radial electric field. The application of an electric field resulted in changes to the surface charge distribution around the 3D graphene, enhancing the attraction between hydrogen molecules and the graphene surface. This electric field increases the adsorption energy by attracting the positive charge of hydrogen molecules, leading to a stronger binding and preventing easy desorption. By adjusting the electric field's strength and direction, hydrogen storage performance can be optimized. Utilizing 3D graphene at cryogenic temperatures allowed for significant improvement in hydrogen storage efficiency under low voltage conditions, demonstrating potential for high-capacity, high-density hydrogen storage systems suitable for commercialization. This research experimentally verifies reversible hydrogen storage mechanisms using electric fields, paving the way for advancements in energy storage technology and commercialization.

EL03.07.04

Influence of Cosmic Rays on Monolayer MoS_2 Transistor Sungjin Cho, Jongin Park and Yeonhoo Kim; Korea Research Institute of Standards and Science, Korea (the Republic of)

The space industry has steadily grown since the last century and has the potential to become an even larger industry in the future. The space industry pays significant attention to the effects of cosmic rays on devices in satellites or spacecraft. The environment of space in which satellites or spacecraft operate is harsh due to the presence of a large number of high-energy electrons, neutrons and protons. These particles, collectively known as

cosmic rays, travel through space at nearly the speed of light. Cases of satellite malfunctions caused by electronic damage from cosmic rays have been reported. Therefore, it is crucial to investigate the impact of cosmic rays on electronics within the space industry and to appropriately respond to the findings in order to ensure the success of space missions.
Two-dimensional(2D) MoS_2 has potential to serve as an alternative semiconductor material for future electronics due to its attractive semiconducting properties, including high mobility and a tunable band gap. Ultra-scaled transistors are of interest in the development of next-generation electronic devices, and devices utilizing a MoS_2 channel has been explored.
Herein, we investigate changes in the electrical characteristics of MoS_2 transistors before and after exposure to electron beam. A monolayer MoS2 transistor with a back gate was used for the investigation. Au electrodes were deposited by e-beam evaporator on monolayer MoS_2. These results could provide valuable insights into developing and fabricating suitable devices capable of operating in the extreme environment of space.

EL03.07.05
Space Irradiation Effects on Gas Sensing Properties of Graphene Jaeyeon Oh[1,2], Sungjin Cho[1], Jongin Park[1] and Yeonhoo Kim[1]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

With the surging interest in the space industry, the influence of cosmic rays on electronic devices is attracting enormous attention. Among them, research on electronic devices integrated with two-dimensional (2D) materials is particularly needed, since 2D materials possess an ultrathin structure with excellent radiation endurance. With this advantage, Graphene is also promising gas sensing material that can potentially replace commercialized metal-oxide semiconductors due to its excellent gas sensing properties at room temperature, as well as its mechanical and chemical stability. For these reasons, graphene-based gas sensors have been extensively explored for harsh environments such as nuclear reactors, outer space and high-altitude flights to effectively monitor air quality. However, the specific mechanism and the standard damage controls depending on detailed dosages have not been defined and discussed yet. The high-energy radiation from the space environment inevitably induces damage to the material's structure, morphology, and sensing performance, leading to significant degradation in the usability of these sensors in aerospace applications. Consequently, thorough investigations about the effects of space radiation on graphene gas sensors are crucial for advancing their further development and application.
Herein, we report the degradation evaluation of gas sensing properties of graphene layers subjected to the space radiation including electrons, protons and heavy ions. After electron beam irradiation, the changes of gas sensor response were calculated to be less than about 3%, 1.5%, and 1.5% for 5 ppm NO_2, 50 ppm NH_3, and 50 ppm H_2S, respectively. To fabricate the sensors, we used CVD grown-graphene synthesized on a Cu foil and transferred graphene onto the SiO_2 substrate by wet transfer method. After that, the layer was patterned by photolithography and reactive oxygen ion etching to form H-shaped pattern with a channel having a width of 10 μm. X-ray photoelectron spectrum (XPS) and Raman analysis were conducted before and after irradiation to examine the influence of radiation and its impact on the surface chemical bonding. The gas sensing performance change of graphene gas sensors in a space irradiation environment was also assessed. Gas sensing characteristics of the sensor were measured at room temperature using various gases such as 50 ppm CH_3COCH_3, 50 ppm C_2H_5OH, 100 ppm C_7H_8, 100 ppm CO, 1 % CO_2, 50 ppm H_2, 50 ppm H_2S, 5 ppm NO_2, and 50 ppm NH_3. The results showed that the sensor exhibited remarkable invariance even after exposure to high level of cosmic radiation, indicating its robustness and reliability for space applications. Ultimately, our study stands to greatly advance the space industry, bolstering the development of space technologies.

EL03.07.06

Large Area Growth of 2D-2D PtS_2/MoS_2 Heterostructure and Its Broadband Photodetector Study Gaurav Bassi and Mukesh Kumar; Indian Institute of Technology Ropar, India

Recently, transitional metal dichalcogenide (TMDC) materials have shown great potential in the optoelectronics and electronics field owing to their unique and favourable properties. However, developing high-performance broadband photodetectors in bare TMDC material is impeded due to their limited absorption and poor charge-carrier separation. However, recent advancement in van der Waals heterostructure fabrication has exhibited a new path to improve the device performance. In present work, we present a facile approach to fabricate a large area of PtS_2/MoS_2 heterostructure which demonstrates a broad spectral detection range from 400-1200 nm with high responsivity (30.2 AW^{-1}) and detectivity (1.12×10^{13} Jones) even under near infrared (NIR) 900 nm light illumination at moderate bias. Moreover, PtS_2/MoS_2 photodetector exhibits a much enhanced in responsivity (97 times) and detectivity (33 times) compared with bare MoS_2. A rise/fall time of 11 ms /10 ms for PtS_2/MoS_2 device exhibits its fast response speed. The X-ray photoelectron spectroscopy (XPS) measurements reveals the type-I band alignment between the PtS_2 and MoS_2 which further utilize to understand the charge carrier dynamics between the PtS_2 and MoS_2 interface. This work presents a simple strategy to synthesize scalable, high-performance broadband photodetectors for future optoelectronics applications.

EL03.07.07

Jet-Printed Solution-Processed MoS_2 Semiconductor and Jet-Printed Al Electrodes for Thin-Film Transistors
Woon-Seop Choi, Young-Jin Kwack, T. T. T. Thuy, Kim Yong Jae and Young Jik Lee; Hoseo University, Korea (the Republic of)

Recently, transition-metal dichalcogenides (TMDs) have attracted much attention as new materials for electronics devices, electrocatalysts, photocatalysts, sensors, batteries, and bio-applications. Most TMDs are two-dimensional (2D) materials with a single layer. Bonds between each layer are made up of Van der Waals bonds, while intra-layer atoms bind together as covalent bonds.
Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS_2 can be obtained from this method using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process. Even though there is sulfur in the precursors of the solution-process synthesis methods, supplementing the sulfur that is lost in the high-temperature CVD process is unavoidable.
Electrohydrodynamic (EHD) jet printing is a technique that uses electric fields to yield fluid flows for delivering solution/paste materials to a target substrate. EHD printing can create smooth areas or patterns with a large range of material viscosity, even with low-viscosity solutions or high-viscosity pastes, which are better by far than inkjet printing for this concern. Moreover, the merit of EHD jet printing is that MoS_2 TFTs can be patterned simply without using any shadow masks compared to other methods such as E-beam or thermal evaporation.
Directly printed transistors have been in the limelight due to low cost and an environmentally friendly technique. An electrohydrodynamic (EHD) jet printing technique was employed to pattern both MoS_2 active layer and Ag source/drain electrodes. Printed MoS_2 lines were patterned on a silicon wafer using a precursor solution of ammonium tetrathiomolybdate and ammonium molybdate in different solvent formulations. Simple thermal annealing with bottom-up thermolysis methods were used to make MoS_2 multi-crystalline, without CVD. These patterns were transferred on other SiO_2 substrates as semiconductors for TFT fabrications. On top of the patterned MoS_2, Ag paste was also patterned for source and drain electrodes using EHD jet printing, too. The electrical properties show improved mobilities of 9 to 48 cm^2/V s and reasonable on-off ratios of around 1.0×10^5 with solid output saturations and better hysteresis behaviors. This result could be important for practical TFT applications and could be extended to other 2D materials.

EL03.07.08

Solution-Based Synthesis of Ultrathin Quasi-2D Amorphous Carbon for Nanoelectrics Viet Hung Pham[1,2], Congjun Wang[1], Junseok Lee[1,2], Jennifer Weidman[1,2], Sittichai Natesakhawat[1,2] and Christopher Matranga[1]; [1]National Energy Technology Laboratory, United States; [2]NETL Support Contractor, United States

In the last decade, the research on carbonaceous two-dimensional (2D) materials has drawn a lot of interest from the aspects of both fundamental studies and practical applications. The atomic-scale thickness and unique layered structure make the materials in this family exhibit several distinct optical and electrical properties from their bulk counterparts. Previous studies have mainly focused on the crystalline graphene material. Recently, 2D amorphous carbon is emerging to attract increasing attention since it has shown great potential for applications in various fields. However, synthesis of wafer-scale 2D amorphous carbon with thickness approaching the atomic limit is a substantial challenge. Current approaches to prepare 2D amorphous films rely on the adoption of plasma-enhanced chemical-vapor deposition (CVD) or pulsed laser deposition, where the power provided by the excited species in plasma, or the energetic pulsed laser can lead to the formation of continuous films but is insufficient to promote their crystallization. For both methods, the spatial uniformity and area coverage of the prepared 2D amorphous films could be limited, and especially the film thickness cannot be precisely controlled with atomic level of precision, in particular beyond the first monolayer when the reaction can no longer be catalyzed by the substrate. These limitations have so far prevented their adoption in functional application demonstrations which require films with large-area homogeneity and precisely tunable thickness from monolayer to multilayers, ideally synthesized directly on device substate. Here we report the wafer-scale synthesis of ultrathin quasi-2D amorphous carbon with thickness down to 1–2 atomic layers from solution-processable carbon-dot precursors directly on noncatalytic substrates. The prepared one layer of coalesced carbon dots is an atomically thin, mechanically strong amorphous film predominantly composed of sp2 carbon with low surface dangling bond density, and their few-layer assemblies are robust nanodielectrics with low leakage current density and high breakdown field strength. This synthesis strategy is distinct from vacuum depositions, with substantial advantages in enabling a solution-based process that is not only scalable but can be repeated in a layer-by-layer fashion for producing freestanding membranes from 1–2 atomic layers to multi-layered stacks with precisely controlled nanometer thickness. The achieved macroscopic uniformity, atomic-level thickness control, and wafer-scale processability allow engineered incorporation of prepared quasi-2D amorphous carbon films as dielectric in nanoelectronic devices, where their unique structure and properties were exploited to enable enhanced device performance and uniformity.

EL03.07.09

Gate-Tunable Homojunction of 2D Semiconductor for Low-Power Electronics Kyungmin Yang, June-Chul Shin, Won Seok Choi and Gwan-Hyoung Lee; Seoul National University, Korea (the Republic of)

Recently, low power consumption in both the static and dynamic modes of operation has been crucial for the successful development of next generation electronic devices. However, continuous down-scaling of transistors faces a bottleneck due to power consumption issues, such as leakage current and operating voltage. In this regard, two-dimensional (2D) semiconductors have been considered as promising candidates for low-power transistors owing to efficient gate-tunability and absence of short channel effect even in the ultra-scaled size. Here, we demonstrate gate-tunable homojunction of 2D semiconductor for low-power electronics. The barrier within 2D homojunction is freely modulated by a graphene gate without any interference, such as Fermi-level pinning. Benefiting from the gate-tunable barrier, our device showed a very low off-current of 10^{-16} A/μm due to suppressed electron transport in off-state of 2D channel, indicating low power consumption in the static mode of operation. Furthermore, our device exhibited a low subthreshold swing of 58 mV/decade, which is close to the

Boltzmann limit. It is the first approach to measure an off-current and achieve an extremely low off-current using diode-like structure in 2D channel. Our 2D transistor with partial gate shows a great potential in low power electronics that request low off-current and subthreshold swing.

EL03.07.10

Pt Anchored MoS_2 Based Ascorbic Acid Sensor for Different Biomedical Application Arpita Biswas; Indian Institute of Technology Jodhpur, India

The ascorbic acid (AA), also called vitamin C, is an essential bioactive element that has a significant impact on various metabolic processes in human body. AA has an important role in the production of neurotransmitters, collagen and the elimination of harmful free radicals, and the absorption of iron by cells in intestines. Consequently, there is a critical requirement for a sensing platform that is extremely selective, sensitive, and cost-effective for detecting ascorbic acid (AA). In this study, we present the utilization of a Pt-anchored MoS_2 material for the highly effective detection of an AA biosensor. The chemical vapor deposition (CVD) method was employed to synthesize hollow rectangular structures of MoS_2, in response to the growing demand for a dependable detection platform. Next, we construct a chemiresistive biosensor using Pt-anchored MoS_2, which exhibits exceptional accuracy and excellent sensitivity in measuring AA. The experiments aimed to assess the performance of the device in the absence and presence of AA biomolecules. Later, the device selectivity was examined for various biomolecules, and the device was selective to AA. The Pt-anchored MoS_2 based device exhibited 125% response towards AA biomolecules at a concentration of 1 mM, surpassing all other devices and being 2.2 times greater than the response of the MoS_2 based device. The device has the capability to detect AA across a broad range of concentrations, spanning from 100 nM to 1 mM of AA. The selectivity of the sensor towards different biomolecules was also evaluated, and it was found that the sensor exhibits a high degree of selectivity towards AA molecules. The developed sensor exhibits a lower detection limit (LOD) of 70 nM and sensitivity of 10.03 $\mu A \mu M^{-1}$. This study show that Pt-anchored MoS_2 is an effective material for detecting AA, making it a promising choice for this application. This research aims to improve our abilities to monitor and detect AA, which will lead to advancements in environmental, biomedical, and industrial applications.

EL03.07.11

Layer-Dependent Growth of Large Area 2D $MoSe_2$ Films for Supercapacitor Applications Praveen Kumar, Sudhir Kumar, Debabrata Pradhan and Prasana K. Sahoo; Indian Institute of Technology Kharagpur, India

The large-area growth of two-dimensional molybdenum diselenide ($MoSe_2$) has garnered significant research attention due to its diverse applications in electronics and energy storage devices. This study explores the continuous synthesis of layered-controlled $MoSe_2$ films over centimeter-scale areas using the atmospheric pressure chemical vapour deposition (APCVD) method using selenium and molybdenum trioxide as solid precursors. Using optical microscopy, atomic force microscopy, and Raman spectroscopy, we characterized the as-synthesized 2D $MoSe_2$ films. Remarkably, we achieved large-area $MoSe_2$ growth on SiO_2/Si substrates across different precursor amounts. However, the surface morphology, thickness, and crystallite size of $MoSe_2$ domains were significantly influenced by the precursor quantity. Of particular interest, $MoSe_2$ multilayers synthesized with a higher precursor quantity (20 mg) exhibited enhanced electrochemical performance. Upon illumination, the areal capacitance values experienced a substantial increase, rising from 96 (in the dark) to 115 $\mu F/cm^2$ at a current density of 5 $\mu A/cm^2$.This enhancement can be attributed to light absorption and the generation of photogenerated electron-hole pairs under an applied voltage, resulting in additional charge carriers. These carriers contribute to energy storage and capacitance, potentially allowing for the accumulation of more electrolyte ions at the contact interface. This work highlights the potential for optimizing 2D $MoSe_2$ layer number for improved energy storage applications.

Keywords: CVD, $MoSe_2$, 2D Materials, AFM, and Supercapacitor

EL03.07.12

Graphene Field-Effect Transistor-Based Bioelectronic Tongue for Bitterness Evaluation Using Agonism and Antagonism of Bitter Taste Receptor Kyung Ho Kim and Oh Seok Kwon; Sungkyunkwan University, Korea (the Republic of)

Bitterness can provoke unpleasant sensations in humans, posing challenges for food acceptance and medication adherence. Thus, effectively identifying and masking bitter tastes is crucial for enhancing palatability in food and ensuring compliance in pharmaceuticals. This study focuses on leveraging agonism and antagonism of bitter taste receptors at the molecular level to achieve these goals. The research involves developing a bioelectronic tongue capable of characterizing agonism and antagonism of human bitter taste receptors, specifically hTAS2R16 and hTAS2R31. These receptors are expressed using an Escherichia coli system and embedded into nanodiscs (NDs). Subsequently, hTAS2R16- and hTAS2R31-NDs are immobilized on graphene field-effect transistors (FETs) to create the bioelectronic tongues. The developed system demonstrates high sensitivity, detecting bitter agonists such as salicin and saccharin at concentrations as low as 100 femtomolar (fM) in real-time, with exceptional selectivity. Furthermore, the dose-response curves indicate that the antagonists of hTAS2R16 and hTAS2R31 shift the curves and decrease the K values, illustrating effective antagonism-based masking of bitter taste. In conclusion, this bioelectronic tongue shows promise for accurately identifying bitter tastes and evaluating bitterness masking strategies based on the agonism and antagonism of hTAS2Rs. These advancements hold significant potential for improving the sensory properties of foods and enhancing medication palatability in various industries.

Fabrication of n-Type MoS_2 by Atomic Hydrogenation and TFT Application Kousaku Shimizu and Kecheng Li; Nihon University, Japan

MoS_2 thin films prepared by peeling from a single crystal or Molecular Beam Epitaxy are usually n-type semiconductors. They are known to be p-type when deposited by sputtering. We have clarified that when sputtering is used, oxygen is automatically doped, and an acceptor level is formed, resulting in a p-type. We fabricated MoS2 thin films using a sputtering method to extend this technique to larger areas. In this paper, we report the results of converting the thin film to n-type by hydrogenation using the hot-wire method and fabricating TFTs, thereby opening new possibilities in the field of materials science and semiconductor technology.
With utmost precision, we deposited 20 nm of molybdenum sulfide at room temperature at 100 W, 1.0 Pa, using the sputtering technique. The atomic hydrogen treatment, a key part of our research, was meticulously performed by the hot-wire method using a tungsten wire. Hydrogen gas was introduced into the vacuum chamber, and hydrogen was pyrolyzed with a tungsten wire heated to 1600°C to generate atomic hydrogen. This was followed by annealing at 200°C for 1 hour in air, ensuring the highest level of accuracy in our experimental process.
The fabricated n-type transistor had a mobility of 61.26 cm2/Vs, a threshold voltage of 0.724 V, and a subthreshold swing of 288 V/dec. Compared to the data from the atomic oxygen treatment reported previously[1], the performance was almost equivalent. We believed that it became n-type because the atomic hydrogen was introduced into the film by the atomic hydrogen treatment combined with the oxygen taken up in the MoS2 film to form water, and the water evaporated when annealed and was removed from the film.
The above demonstrated that CMOS devices can be easily fabricated.

Highly Sensitive Gr/Si Hetero Device for DNA Detection via Field-Effect Tunable Schottky Barrier Sung Hyun Kim and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

In this study, we present a highly sensitive graphene-based hetero device designed for the detection of target DNA sequences. The core structure of the device comprises an N-type silicon substrate overlaid with a graphene layer, whose quality is confirmed by Raman spectroscopy data showing a 2D/G peak ratio of 1.76. The graphene surface is bio-functionalized by immobilizing antibodies specifically tailored to capture target DNA sequences. The K3 peptide is adsorbed onto the graphene surface through π-π stacking interactions, enhancing the bio-functionalization process. Upon the introduction of the dCas9-E3 protein, significant changes are observed, demonstrating the high sensitivity of the device to biomolecular interactions.

The device functions as a field-effect tunable Schottky barrier, where the field effect is utilized to modulate the Schottky barrier height, enhancing the sensitivity and selectivity of the device. Further performance analysis includes I-V measurements conducted at 3V under varying conditions. The device demonstrates its capability to operate effectively even at low analyte concentrations, achieving a current response of up to 500% at 100 pM target DNA in reverse bias, underscoring its high sensitivity and efficacy.

Measurement data reveal distinct electrical characteristics when exposed to different concentrations of target DNA, specifically at 10 nM and 100 nM. The device shows a marked increase in current response proportional to the DNA concentration. These results indicate that the device can reliably detect varying levels of DNA, making it suitable for applications requiring precise quantification.

Comparative studies with existing literature highlight the superior detection sensitivity of our graphene-based hetero device. The device's Schottky barrier measurements before and after the introduction of target DNA further illustrate its efficiency and reliability. The integration of encapsulation and PCB board connection enhances the device's robustness and practical applicability, ensuring stable operation in various environmental conditions.

Our graphene-based hetero device offers a robust and highly sensitive platform for detecting target DNA sequences. By leveraging the unique electrical properties of graphene, π-π stacking interactions for bio-functionalization, and field-effect modulation of the Schottky barrier, we have developed a highly responsive and reliable sensor. Our graphene biosensor is promising as a platform for advanced semiconductor applications, enabling highly sensitive and precise electronic biosensing technologies.

EL03.07.15

Enhancing Performance of Single-Bridge Channel Field Effect Transistors Through MoS2 Doping on Graphene and Integration with Hexagonal Boron Nitride Jiale Cao[1], Arthur McClelland[2] and Tingying (Helen) Zeng[1]; [1]InnoBridge Institute, United States; [2]Harvard University, United States

This reearch presents the design and manufacturing of a Single Bridge Channel Field Effect Transistor (SBCFET) using 2D materials, which includes the integration of graphene as the channel and hexagonal boron nitride (h-BN) as the gate dielectric and the doping technique on graphene with Molybdenum disulfide (MoS2). The combination of MoS2 and graphene shows the unique electrical properties, such as the high carrier mobility of graphene with the MoS2, which significantly enhances the performance of SBCFETs' mobility. This study shapes a strong comparison between the current SBCFET and the conventional FinFET fabrication with the improvement of doping techniques.The shorter gatelength design and modification of carrier concentration of graphene positively affecst the mobility of the transistor. The MoS2-enhanced doping graphene SBCFETs demonstrates advanced performances in current control and higher carrier mobility. Our research shows a significant improvement over conventional silicon-based FETs. The fabrication process includes the Scotch tape method for obtaining high-quality materials including graphene, MoS2, and h-BN. This methodology builds a solid foundation for precise doping and layering techniques for the device fabrication. Additionally, Electron-beam lithography (EBL) is used for nanoscale patterning, and atomic layer deposition (ALD) for gate dielectric formation with the h-BN. The results of this study highlights the potential of MoS2 and graphene integration in enhancing the mobility of next-generation transistors. This study provides valuable insights into the practical application of 2D materials in semiconductor devices, paving the way for future innovations in the field of nanoelectronics.

EL03.07.16

Viable Fabrication of Edge-Contacted Monolayer MoS_2 Field-Effect Transistors Enabled by Interfacial Chemical Analysis Chia-Chun Lin[1], Naomi T. Paylaga[2], Chun-Chieh Yen[1], Yu-Hsuan Lin[3], Kenji Watanabe[4], Takashi Taniguchi[4], Shao-Yu Chen[3] and Wei-Hua Wang[1]; [1]Academia Sinica, Taiwan; [2]National Central University, Taiwan; [3]National Taiwan University, Taiwan; [4]National Institute for Materials Science, Japan

Edge contacts offer significant advantage for enhancing the performance of semiconducting transition metal dichalcogenides (TMDCs) devices by interfacing with metallic contact from the lateral side, allowing encapsulation of the whole channel material [1-3]. However, a viable fabrication of electrical edge contact to TMDCs remains a great challenge for high device performance, featuring lack of viable interfacial chemistry characterization by conventional method. The characterization of the interfacial chemistry at the metal–2D semiconductor edge interface represents a major bottleneck owing to negligible cross section in characterizing nominally 1D structure by measuring from top of the edge contact. Here, we present a directional angled etching technique to fabricate slanted edge structure of TMDCs, thereby allowing determining explicit chemical information at the metal–MoS_2 edge interface. The slanted edge structure enables significant cross section for the conventional X-ray photoemission spectroscopy (XPS) to perform element analysis, revealing dominance of pristine MoS_2 layers and an atomically thin, uniform substoichiometric MoS_x interfacial layer, indicating simple chemical environment and clean interface. By optimizing the contact interface, we achieve high-quality slanted edge contact to monolayer MoS_2 transistors encapsulated by hexagonal boron nitride. The transport data of the monolayer MoS_2 device shows efficient charge injection at the edge contact owing to thermionic and tunneling effect, attributed to a clean Au–MoS_2 edge interface and ideal transport characteristics. The demonstrated edge contact method offers a viable approach to fabricate encapsulated 2D material devices which is crucial for both fundamental study of 2D materials and high-performance electronic applications.

The Development of Nanochannel Memristor Through Ag Ion Intercalation in h-BN/MoTe2 Heterostructures

Junsun Son and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

Memristors based on 2D materials have attracted attention as next-generation memory devices due to their high

data processing performance and low power consumption. Current research on memristor devices is actively progressing through the utilization of various 2D materials. In particular, h-BN with its excellent insulation and chemical stability, plays a crucial role in heterojunctions with other 2D materials. Combining it with TMD materials such as $MoTe_2$, WS_2, and MoS_2 can maximize the performance of memristor devices.
In this study, we utilize hexagonal boron nitride (h-BN) and transition metal dichalcogenides (TMDs), which play a crucial role in enhancing the electrical properties of memristors. This study involves fabricating memristors with vertical structures by stacking TMD materials, such as $MoTe_2$, on h-BN flakes and analyzing their electrical properties through ion intrercalation processes. As we change e-beam lithography recipe, such as acceleration voltage and develop time, and reactive ion etching recipe with SF_6 gas to pattern the nanochannels improving the performance of memristors by controlling the width and depth of the nanochannels. Our results show that Ag ion intercalation through h-BN nanochannels maximizes the on/off ratio of memristors and induces stable phase transitions.
As AI technology expands and the demand for high-performance memory devices increases, investments in memristor-based technology have grown, leading to the growth of memristor memory. The potential applications of TMD-based nanochannel memristors in next-generation neuromorphic devices have been identified, and they will contribute to groundbreaking technological advancements in the IT field. This research suggests the potential for developing neuromorphic artificial synaptic devices based on memristors, contributing to innovations in IT technologies. We expect it will significantly contribute to the practical application of memristor devices and play a key role in future artificial intelligence and neuromorphic computing systems.

EL03.07.18

Mimicking Heterosynaptic Plasticity Using 2D Oxide Based Memristors Tien Dat Ngo[1], Je-Jun Lee[2], Won Jong Yoo[1] and Min Sup Choi[3]; [1]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Chungnam National University, Korea (the Republic of)

In this study, we achieve precise thickness controllable oxidation using UV-ozone treatment with different chuck temperatures. With precisely controlled WO_x thickness by UV-ozone treatment, monolithic few-layer WO_x/WSe_2 memristors are fabricated. The postsynaptic responses of the topmost single-layer oxidized WSe_2 and fully oxidized WSe_2 memristors exhibit opposite behaviors, which can be applied to mimic the heterosynaptic plasticity. We explore the feasibility of using each oxidation-layer-controlled memristor as a hardware accelerator by showing pattern recognition rates of 84% and 71% for the 1L and 9L WO_x-based devices, respectively, assessed through CIFAR-10 pattern recognition task. We also examine the applicability of a synaptic cell composed of devices with oppositely switched characteristics. Consequently, the synaptic weight, defined as the difference in conductance between two synaptic devices, can be either increased (potentiated) or decreased (depressed) by simultaneously updating both devices with the same voltage signal. This weight update concept achieves a moderate recognition rate of 85.94% when using an MNIST pattern-based recognition task.

EL03.07.19

Back-End of the Line Compatible Growth of Wafer Scale MoS_2 Bilayer for Neuromorphic Device Application Prashant Bisht, Junoh Shim and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

The back end-of-line (BEOL) compatible and scalable growth of two-dimensional (2D) transition metal dichalcogenides for device applications has been the most challenging task for their industrial adoption. In this study, 2D MoS_2 bilayer has been synthesized across 4-inch SiO_2/Si substrate using plasma enhanced chemical vapor deposition (PECVD) technique at temperature below 350 °C. Raman and photoluminescence (PL) spectra show the formation of pure and high-quality bilayer MoS_2. The growth is optimized by varying the PECVD parameters such as plasma power, Ar/H_2S gas ratio, seed layer thickness, growth time and substrate temperature.

The AFM and HRTEM reveal the morphological and structural characteristics of the film. XPS measurements gives the chemical state and composition of the as-grown film. Filed effect transistor (FET) characteristics of the as fabricated device on the MOS_2 film show an Ion/Ioff ~10^3 and a mobility of 0.2 $cm^2V^{-1}s^{-1}$. Further, the FET device exhibits essential synaptic behaviour such as short-term plasticity, long term and short-term potentiation and depression with high linearity and stability.

EL03.07.20

Development of Asymmetric Lateral and Vertical Configuration Flexible Micro-Supercapacitors from MXene and Laser Induced Porous Graphene (MXene-LIPG)

Sanju Gupta[1,2]; [1]The Pennsylvania State University, United States; [2]Gdansk University of Technology, Poland

Associated with the rapid development of layered materials beyond graphene, two-dimensional transition metal carbides *i.e.,* MXenes derivatives have been exploited and exhibited unique physical/chemical properties that hold promise for applications in electrochemical energy storage and conversion systems, especially micoscale devices [1]. Current microfabrication of micro-supercapacitors often involves multistep processing and time-consuming lithography protocols. In this study, we report a facile method of fabrication to develop an asymmetric MXene-based micro-supercapacitor, which is flexible and current-collector-free. Specifically, the interdigitated device architectures are designed while fabricating scalable laser-induced porous graphene (LIPG) onto flexible substrates created. The electrode materials consisted of titanium carbide MXene ($Ti_3C_2T_x$) and LIPG, which are both 2D layered materials that contribute to the faster ion diffusion in the interdigitated electrode architectures. The MXene-based asymmetric micro-supercapacitor operates at ≥ 1 V working voltage window with polymer gel or aqueous electrolytes while retaining > 85% of the initial capacitance after five thousand cycles, and exhibiting an energy density of 7.3 mW h cm^{-3} at a power density of 0.14 W cm^{-3}. Further, these MSCs can show a high level of flexibility during mechanical bending. Utilizing the ability of $Ti_3C_2T_x$-MXene electrodes to operate at negative potentials in aqueous electrolytes, it is shown that using $Ti_3C_2T_x$ as a negative electrode and LIG as a positive electrode in asymmetric architectures appears to be a promising strategy for increasing both stored energy and power densities simultaneously. We also fabricated and characterized vertical (or traditionally parallel) asymmetric MXene || LIPG (< 1V, 3 mW h cm^{-3} at a power density of 0.1 W) and symmetric LIPG || LIPG (< 0.8 V, <1 mW h cm^{-3} at a power density of < 0.01 W) and MXene || MXene (1V, 3 mW h cm^{-3} at a power density of 0.1 W) devices. The intrinsic relationship among microscopic structure, physicochemical properties, and applications for termination-tailored MXene derivatives is emphasized [2]. *The author (S.G.) acknowledges the support from an internal Grant (Nobelium Award under IDUB).

EL03.07.21

Non-Epitaxial Growth of Single-Crystalline Two-Dimensional Transition Metal Dichalcogenides Below Back-End-of-Line Temperature Limit for Monolithic Three-Dimensional Integration

Doyoon Lee, Kiseok Kim, Seunghwan Seo, June-Chul Shin, Jungel Ryu and Jeehwan Kim; Massachusetts Institute of Technology, United States

As modern silicon-based transistor is approaching its scaling limitation, monolithic three-dimensional (M3D) integration has recently been developed to continue Moore’s law. Even though M3D integration provides higher device density with more efficient heat management than conventional 3D integration by eliminating the need for the complex through-silicon-via process, its low thermal budget is the key limitation.

Two-dimensional (2D) semiconductors, such as transition metal dichalcogenides (TMDs), are considered as promising channel materials for M3D integration, because their processing temperature can be lower than the back-end-of-line (BEOL) temperature limit, typically below 400 °C, and their performance is not degraded at atomic thickness. However, M3D integration using 2D TMDs has heavily relied on the transfer process due to their

high growth temperature. To avoid the transfer process, direct growth of TMDs on amorphous oxide-coated silicon substrates at low temperatures has been investigated, but achieving single-crystalline TMDs on an amorphous substrate is fundamentally challenging due to the absence of a crystalline substrate for epitaxial growth and the low growth temperature.

Here, I demonstrate the growth of single-crystalline TMDs on amorphous oxide-coated silicon substrates below 400 °C by using confined-growth method, in which a-SiO_2 mask is patterned on an a-HfO_2-coated silicon substrate. Owing to the growth selectivity, single-domain TMDs selectively grow within the HfO_2 trench when the trench dimensions are optimized. Additionally, the dangling bonds at the edge and corner of the SiO_2 mask reduce the activation energy for nucleation, allowing for lower growth temperatures. To demonstrate M3D integration with direct growth, a vertical CMOS structure was fabricated. First, WSe_2 was grown using the confined-growth method, followed by pMOS fabrication. MoS_2 was then grown on top of the pMOS tier at a temperature below 400 °C, after which nMOS fabrication was completed. The results showed that the underlying pMOS tier was not degraded after the nMOS process. Furthermore, the devices exhibited excellent performance compared to previously reported TMD-based CMOS via transfer and direct growth, thanks to their single crystallinity.

Graphene Thin-Film Technology for Neural Interfaces Jose A. Garrido[1,2]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]ICREA, Spain

Establishing a reliable bidirectional communication interface between the nervous system and electronic devices is crucial for exploiting the full potential of neurotechnology. Despite recent advancements, current technologies evidence important shortcomings, e.g. lack of focal stimulation, low signal-to-noise ratio, etc. Thus, efforts to explore novel materials are essential for the development of next-generation neural interfaces. Graphene and graphene-based materials possess a very attractive set of physicochemical properties holding great potential for implantable neural interfaces. This presentation provides an overview on the technology and applications of graphene-based thin film devices aiming at developing neural interfaces for an efficient bidirectional communication with the nervous system.

8:30 AM EL03.08.02

Chemically Etched Silver Decorated Titanium Carbonitride MXene (Ag/Ti_3CN) for Enhanced Electrochemical Detection of Cortisol in Biological Fluid Atul Sharma[1,1], Madhurya Chandel[2], Agnieszka M. Jastrzebska[2] and Sameer Sonkusale[1,1]; [1]Tufts University, United States; [2]Warsaw University of Technology, Poland

Stress and unhealthy lifestyles have an undue effect on people’s physical and mental health. As a key hormone responsible for maintaining the normal functioning of human systems, cortisol plays a vital role in regulating physiological activities and monitoring psychological stress. Various nanomaterials, mainly two-dimensional (2D) nanomaterials, hold great promise in developing rapid electrochemical sensors due to their high surface area, excellent conductivity, and tunable properties. MXenes, a 2D transition metal carbide/nitride or carbonitrides, exhibit transformative characteristics related to their physical, chemical, and environmental properties, making

them attractive candidates for sensor applications. The design of metal-doped MXene-based electrochemical sensors holds the potential to revolutionize biomarker monitoring. A novel material based on the chemical etching of Al from the (Ti_3AlCN) MAX phase without oxidation resulted in silver-decorated (Ag/Ti_3CN) MXene, which showed enhanced electrochemical properties. The fabrication of Ag/Ti_3CN was characterized using FTIR, XRD, SEM, AFM, and XPS techniques. The resulting MXene-based composite is used as a multilayer electrochemical sensor for highly sensitive cortisol detection to achieve a sub pg/mL detection limit. Fabrication of the disposable and miniturized cortisol sensor is realized on the in-house produced porous laser engraved graphene electrode (PLEG) on thin polyimide (PI) films. The laser engraving employs a CO_2 laser to directly pattern porous and multilayered graphene onto a thin PI surface. The Raman spectrum of the PLEG electrode exhibited three distinguished peaks (D, G, and 2D peaks), confirming the formation of graphene. The fixed ratio of Ag/Ti_3CN dispersed into the water was sonicated (15 min), drop-casted onto an electrochemically cleaned PLEG electrode, and dried. Later, the electrode surface (Ag/Ti_3CN/PLEG) was washed to remove the unbound fraction. To quantify cortisol, a differential pulse voltammetric signal was deployed to capture the oxidation current of metabolized cortisol due to the nanozyme activity of the Ag/Ti_3CN composite using a wireless readout. This was attributed to silver-catalyzed cortisol metabolism and Ag/Ti_3CN MXene's excellent conductivity and large electroactive surface area, facilitating charge transfer at the electrode surface and enhancing electrocatalytic activity for cortisol detection. Under optimal experimental conditions, the proposed MXene-based sensor electrodes could detect cortisol in a broad concentration range from 0.10 pg/mL to 100 pg/mL with a good correlation of ($R^2 = 0.9891$, n=3). The higher sensitivity and notable LOD of 0.012 pg/mL cortisol, with good repeatability and reproducibility. The real-time application of the proposed MXene sensor electrodes was confirmed by testing in buffer and spiked artificial saliva samples with excellent recoveries from 97.8 to 102 % (n=3), demonstrating the practicality and reliability of the platform.

Graphene Biosensors—High-Resolution Monitoring of Loop Mediated Amplification Reaction Renan Villarreal, Diego Fernando Jaramillo Calderon, Sorin Melinte, Omar Nyabi, Pierre Vandenberghe and Jean-Luc Gala; Université Catholique de Louvain, Belgium

Graphene-based field effect transistors (GFETs) are considered one the most promising electrical sensing technology among the next generation of electronic biosensors. These biosensors can detect biomarkers such as molecules and pathogens by measuring changes in electrical signals due to variations in the electronic environment around the transistor channel. It has been shown that these biosensors present advantages such as high sensitivity, rapid response, real-time monitoring, low power consumption, and reduced noise levels. Here, we report on progress with functionalized commercial GFETs (graphene/nanoparticle hybrid devices) for loop-mediated isothermal amplification (LAMP) detection. The products are detected via Dirac point shifts with a differential scheme using compact electronic boards, suited for point-of-care testing.

Transforming Healthcare with Innovative Sensing Applications Using 2D Nanomaterials Ashish Mathur; University of Petroleum and Energy Studies, India

The integration of 2D nanomaterials into healthcare bioelectronics is revolutionizing diagnostics and therapeutics technologies. Since graphene's isolation in 2004, research on 2D materials has burgeoned, spanning protective

coatings to biochemical sensing. Graphene, transition metal dichalcogenides (TMDs), black phosphorus, MXene and other 2D materials [1] offer unique properties such as high surface area, exceptional electrical conductivity, and biocompatibility. Their atomic thinness, flexibility and biocompatibility enables seamless integration into electronics devices. This integration facilitates advanced bioelectronics for chemical, biochemical, and neurobiological sensing applications. In this comprehensive review we provide an overview of the research conducted at the **Sensor Fabrication Lab (SFL) @ UPES** across three primary domains: 1) Development of electrochemical sensors 2) Biosensors for Healthcare 3)Agriculture &pesticide area. Our primary emphasis is on harnessing on variety of 2D nanomaterials to tackle pressing healthcare issues, encompassing the early identification of ailments like cervical, breast, and prostate cancer, alongside the development of biosensors for glucose detection. Furthermore, we delve into the utilization of electrochemical sensors to monitor water pollution caused by compounds like dibenzofuran, chloropyrifos, heavy metals (such as arsenic and fluoride), and antibiotics etc. T

9:15 AM *EL03.09.01

2D Materials for Neuromorphic Computing Devices Max C. Lemme[1,2]; [1]RWTH Aachen University, Germany; [2]AMO GmbH, Germany

2D Materials are one of several material classes considered for resistive switching (RS) devices, potential game-changers for neuromorphic computing hardware [1]. Such ”memristive” devices can be switched between two or more resistive states in a volatile or non-volatile way [2], and may be used in computing-in-memory architectures [3], cross-bar arrays [4], or as electronic synapses [5].

Semiconducting molybdenum disulfide (MoS_2) has been investigated intensively as a RS material. The physical origin of the switching has been attributed to different mechanisms: bias-induced migration of sulfur vacancies and grain boundaries, lattice distortion, reversible modulation of MoS_2 phases, and ion migration. Here, I will discuss different MoS_2 device configurations that depend on the material growth conditions and lead to different RS behavior and mechanisms.

Cross-point devices, where two metal electrodes are separated by one or several MoS_2 layers oriented perpendicular to the electrodes, are probably the best-studied devices. We show that the choice of electrodes and even the choice of their deposition method can influence the switching behavior and reliability. In particular, metal-organic chemical vapor deposited (MOCVD) MoS_2 with sputtered Al top-electrodes show significantly reduced variability, with high yields of up to 95% and competitive endurance, retention, and switching speeds compared to the state-of-the-art [6].

Vertical MoS_2 films can be grown under certain conditions by thermal conversion of thin molybdenum films. Here, the van der Waals gaps between the vertical layers facilitate electric-field-driven ion movement [7], leading to non-volatile RS. I will show volatile RS in a device combining a SiOx layer with vertically aligned MoS_2. The devices exhibit repeatable threshold switching at low switching voltages below 1 V, switching times below 400 ns, and endurance of close to 6000 cycles [8].
Similar ion transport in van der Waals gaps can be observed in lateral two-terminal devices based on MOCVD MoS_2. I will show experiments on silver (Ag) ion migration in lateral MoS_2 memristors that do not require higher "forming" voltages for their initial RS event. These Pd/MoS_2/Ag devices show volatile switching with ultra-low threshold voltages of 0.3 V and 100-600 ns switching [9].

Furthermore, I will present a study on the current conduction mechanism in memristors with MOCVD-grown hexagonal boron nitride (h-BN) as the active material. The devices were electrically measured in their low and high resistance states in a wide range of temperatures. We propose the formation and retraction of nickel filaments along boron defects as the RS mechanism, with defect-mediated transport in the high resistive state. The devices exhibit low cycle-to-cycle variability of 5% and a large On/Off current ratio of 10^7 [10].

Finally, I will discuss the parasitic effect of resist residues, which could potentially lead to misinterpretations of RS in 2D materials [11].

All experiments are corroborated with transmission electron microscopy, Raman spectroscopy, and through other analytical means.

This work has received funding from the German BMBF through grants 03ZU1106xx (NeuroSys) and 16ME0399/16ME0400 (NEUROTEC II).

MoS_2 on Nanogap Architecture for Reservoir Computing Roshni S. Babu[1], Ioannis Zeimpekis[1,2], Sujaya Kumar Vishwanath[1] and Dimitra G. Georgiadou[1,2]; [1]University of Southampton, United Kingdom; [2]Optoelectronics

Research Centre, United Kingdom

Reservoir computing (RC) is a brain-inspired neuromorphic computing algorithm derived from recurrent neural networks (RNNs). Unlike RNN, in RC networks, only the weights connected to the output layer need to be trained. This approach allows RC networks to perform fast and energy-efficient temporal data analysis and prediction with low training costs[1]. Recently, there has been a growing interest in exploring nanodevices to construct physical RC systems. Among these nanodevices, memristors have gained a lot of attention due to their low power consumption, high integration density, adaptability, and nonlinear characteristics, all of which align with the requirements of reservoir computing. In this work, we introduce a new class of 2D memristors, employing coplanar nanogap electrodes, with molybdenum disulfide (MoS_2) as the active material, to facilitate the development of an efficient RC system.

Molybdenum disulfide, a layered transition metal dichalcogenide, exhibits a range of electrical, mechanical, and optical properties[2]. In this work, the MoS_2 is directly grown onto a Si/SiO_2 substrate by a two-step process. First, a template of the MoO_3 layer is deposited on a Si/SiO_2 wafer using the atomic layer deposition (ALD) process. The MoO_3 film is subsequently converted to MoS_2 through vapor sulfurization. MoS_2 film is later transferred onto a coplanar nanogap electrode array with the aid of a polystyrene film[2]. The coplanar electrodes of Au and Al separated by a nanogap of 10 nm are prepared by adhesion lithography[3]. The structural characteristics of MoS_2 film are observed using ellipsometry, Raman spectroscopy, and Atomic Force Microscopy (AFM).

The utilization of MoS_2 in memristors with nanogap electrodes has shown significant potential for low operating voltage (-4V to 4V), mainly due to their low dimensionality. The key synaptic characteristics, including excitatory postsynaptic current (EPSC), paired-pulse facilitation (PPF), spike-timing-dependent plasticity (STDP), and frequency-dependent plasticity, are successfully emulated with these devices. Moreover, when used as a physical reservoir, the MoS_2 memristor was able to implement 16 states of 4 bits in a reservoir computing approach. The device-to-device (10 devices) and cycle-to-cycle (10 cycles) variability is also examined. The device was further tested by reproducing four commonly observed neural firing patterns in the human brain, such as bursting, adaptation, tonic, and irregular firing, which underscores the practical potential of this nanoscale memristor.

In conclusion, memristive devices based on MoS_2 2D materials integrated with nanogap electrodes are excellent candidates to be implemented in emerging technologies for neuromorphic computing. Overall, our findings suggest that these devices are a promising avenue for developing efficient, low-power reservoir computing systems, bringing us closer to a future, where computational systems mimic the remarkable efficiency and adaptability of the human brain.

10:30 AM *EL03.09.03
Two-Dimensional Materials for In-Sensor and Near-Sensor Computing Tania Roy; Duke University, United States

In-sensor computing requires devices that can perform sensing along with storing the sensed information. New devices, such as optoelectronic synapses, can sense light and store the information as tunable conductance states. Two-dimensional (2D) materials enable such devices because of their superior optoelectronic properties. These devices are designed to optimize light sensitivity and electronic properties, allowing them to be integrated to perform vector matrix multiplication at the sensor node. Memristive devices with 2D materials are also used to form synaptic crossbar arrays, which can be heterogeneously integrated with CMOS devices. The back-end-of-line compatibility of 2D materials allows for the possibility of a 3D integrated neuromorphic system for edge AI.

11:00 AM EL03.09.04

Wafer-Scale Ferroelectric Transistors for Efficient Temporal Signal Processing by Delay-Coupled Physical Reservoir Computing Yingyi Wen, Songwei Liu, Jingfang Pei, Yang Liu, Pengyu Liu, Lekai Song and Guohua Hu; The Chinese University of Hong Kong, Hong Kong

Recurrent neuron networks (RNNs) are well-suited for temporal signal processing owing to its recurrent connections. Amongst them, reservoir computing (RC) is of particular interest with fast and low-cost training. However, the long-term iteration of the reservoir costs considerable computation power, thus far hindering the application of RC. Realizing RC with physical nonlinear systems emerges as a promising solution to address this problem, where specifically designed physical nonlinear systems can be employed as the reservoir. Recent advances show that ferroelectric field effect transistors (FeFETs) with nonlinear switching and short-term memory are promising for the design and implementation of physical RC systems.

In this work, we present wafer-scale fabrication of $MoS_2/BaTiO_3$ FeFETs via a full solution process for the physical realization of RC. To develop the FeFETs, $BaTiO_3$ (BTO) film is first deposited on silicon wafer as the ferroelectric layer via a chemical solution deposition method. Specifically, a wafer-scale ~300 nm BTO film can be obtained after pyrolysis and crystallization. Large-area and continuous MoS_2 film is then deposited by spin-coating a MoS_2 dispersion on the ferroelectric BTO film. The dispersion contains few-nanometer thick MoS_2 nanosheets prepared by electrochemical exfoliation. Following this fabrication method, $MoS_2/BaTiO_3$ FeFETs with a short-term memory (memory fading time ~5 seconds) are developed. This short-term memory may originate from the retention degradation behavior of BTO as a result of the defects caused by the solution process. Besides, a memory window of ~10 V and an on/off ratio of ~10^3 are demonstrated. With these suitable switching and memory characteristics for physical RC system realization, our FeFETs can be used to design the reservoir layer of physical RC systems. Particularly, a delay-coupled physical RC framework is designed in our work utilizing the memory effect of our $MoS_2/BaTiO_3$ FeFETs to simplify the reservoir layer. With this in mind, we design a hardware RC system for processing time series and temporal signals. Briefly, a raspberry pi is used for time-multiplexing, input, and output; ADC, DAC and TIA are integrated and used for communication between the raspberry pi and the analog reservoir layer implemented with our $MoS_2/BaTiO_3$ FeFETs. We prove that this hardware RC system after training can successfully forecast Mackey-Glass time series.

Given the scalability and low-cost of the $MoS_2/BaTiO_3$ FeFETs, we envisage our $MoS_2/BaTiO_3$ FeFETs based hardware RC system with further specific reservoir layer design and delay-coupled RC model training can achieve temporal signal processing for, for instance, pattern recognition from IoT sensor and healthcare data, and tracking dynamical motions in wearables and soft robotics.

Encryption and Privacy Safeguarding via True Random Number Generation Using Structurally Metastable Solution-Processed 1T’ $MoTe_2$ Yang Liu[1,2], Yingyi Wen[1], Pengyu Liu[1], Songwei Liu[1], Lekai Song[1], Jingfang Pei[1] and Guohua Hu[1]; [1]The Chinese University of Hong Kong, Hong Kong; [2]Shun Hing Institute of Advanced Engineering, Hong Kong

Cryptography is of critical importance in the modern electronics era when the exponentially growing data is at risk of being attacked and sabotaged. True random numbers play a critical role in secure cryptography, where the generation relies on a stable and readily extractable entropy source. Here, from solution-processed structurally metastable 1T' $MoTe_2$, we prove stable output of featureless, stochastic yet stable conductance noise at a broad working temperature with minimal power consumption for true random number generation. We prove cryptographic applications of the random numbers in secure encryption and privacy safeguarding.

We start with $MoTe_2$ exfoliation vie electrochemical exfoliation (ECE). This gives scalable few-layer thick monoclinic 1T' $MoTe_2$ nanosheets that are structurally metastable. This structural metastability can potentially induce volatile, stochastic polarization of the underlying ferroelectric dipoles that can lead to stochastic noise in the electronic properties of the 1T' $MoTe_2$ nanosheets., With this understanding, we develop simple vertically structured devices where the 1T' $MoTe_2$ nanosheets are sandwiched between gold electrodes, and then probe the current noise from the devices as the entropy for true random number generation. Notably, we prove stable conductance noise probing with an ultra-low voltage (0.05V) and an ultra-low power consumption (0.05μW) at a broad working temperature from 15K to 370K. Our detailed characterizations and statistical analysis of the conductance noise characteristics indeed suggest that the noise arises from the volatile stochastic polarization of the underlying ferroelectric dipoles in the 1T' $MoTe_2$ nanosheets. Further, as proved in our experiments and indicated by our Monte Carlo simulation, the ferroelectric dipole polarization is a reliable entropy source with the stochastic polarization persistent and stable over time. This allows us to design a simple circuit to extract this stable entropy noise for the true random number generation. Particularly, the circuit is designed without compromising the randomness of the noise such that the generated true random numbers can successfully pass the NIST test. Exploiting the conductance noise, we achieve high throughput generation (1M bit/s) of random numbers.

Using the random numbers, we prove common cryptographic applications, for example, password generation and data encryption/decryption (including pictures, audios, and videos). Besides, particularly, we show a privacy safeguarding approach to sensitive data that can be critical for the cryptography of neural networks. Briefly, to prove privacy safeguarding, the random numbers are injected as noise to the target sensitive data for masking. We demonstrate that the noise can disrupt the feature detection capability of well-trained Resnet variant models while the perturbations are not discernible to the human eyes. Our safeguarding approach therefore can serve as a novel privacy protection measure to avoid the leakage of the critical data without causing destructive interferences to the neural networks.

Switching in Atomic Memristors—The Role of Defects and Interfaces Nicholas D. Ignacio[1], Saban Hus[2] and Deji Akinwande[1]; [1]The University of Texas at Austin, United States; [2]Oak Ridge National Laboratory, United States

Memristors utilize a phenomenon known as resistive switching where the electrical resistance of a material can be modulated between a high-resistance state and a low-resistance state with each able to be maintained with zero-power supply provoking strong interest for memory and neuromorphic computing applications. Memristors based on 2D materials are especially interesting as they promise the enabling of low power, high density, and scalable computinng technology. The vertical metal-insulator-metal (MIM) device architecture is thought to be operated on the migration of metal atoms into intrinsic vacancies of the atomic layer. We previously reported the first observation of this phenomenon with 2D materials in a vertical MIM device configuration and uncovered the one-to-one correlation between gold atom substitution into sulfur vacancies within nonvolatile changes in resistance within a vertical Au/MoS_2/Au memristor [1][2]. Subsequently we developed a dissociation-diffusion-adsorption model to describe the kinetics of resistive switching, and in this work, we expand the model to further describe the role of defects in the 2D material and include the role of imperfections in the electrode surface [2]. We study the Ag/hBN/Ag vertical atomic memristor with scanning tunnelling microscopy (STM) for imaging, spectroscopy, and transport measurements to characterize the defect sites of hBN in addition to the underlying Ag surface and emulate an MIM structured device at an atomic scale. We see that changes in the defect states cause critical differences in the switching performance of monolayer hBN based memory devices as the switching voltage and power consumption are tied to the local defect structures in the hBN layer. Furthermore, the defect sites on the Ag electrode including grain boundaries, atomic steps and individual vacancies act as low-energy dislocation sites for Ag atom dissociation. The insights gained from this work can be used to extend the functional behavior of atomic memristive devices in future memory or neuromorphic computing applications. [1] R. Boosting Functional Diversification of 2D Materials—From Multiresponsive Hybrid Heterostructures to Neuromorphic Logics Paolo Samori; Université de Strasbourg, France

Engineering the interfacing of 2D semiconductors with molecules by making use of principles of supramolecular chemistry represents a powerful strategy to impart multiresponsiveness to 2D materials with the ultimate goal of generating multifunctional hybrid systems for applications in electronics beyond CMOS through the functional diversification following a “more than Moore” strategy. [1]
In my lecture I will present our recent findings on the non-covalent functionalization of 2D materials to engineer hybrid systems via the controlled interfacing of their two surfaces either in a symmetric or asymmetric fashion with molecular switches, thereby imparting additional properties to MoS_2, back phosphorous or WSe_2, rendering 2D material-based transistors capable to respond to as many as four different independent stimuli.[2] Such a strategy enabled to execute complex function thereby emulating neuromorphic-based cognitive processes.[3]

Our modular strategies relying on the combination of 2D materials with molecules offer a simple route to generate multifunctional coatings, foams and nanocomposites with programmed properties to address key global challenges, to ultimately improve the quality of life on our planet.

2:00 PM EL03.10.02

A Highly Sensitive Flexible Humidity Sensor Based on $Ti_3C_2T_x$ MXene/Bentonite Thin Film Hiroya Morotomi[1], Yuki Matsunaga[2], Lijun Liu[3], Hisashi Sugime[4] and Jun Hirotani[1]; [1]Kyoto University, Japan; [2]Nagoya University, Japan;

[3]Osaka University, Japan; [4]Kindai University, Japan

Humidity sensors are widely used for health, industrial, and agricultural monitoring. For the accurate sensing and quick response, sensing layer materials are significant in humidity sensors. In recent years, MXenes, 2D transition metal carbides, and nitrides have been attracted much attention for susceptible and conductive humidity sensors [1]. MXenes are known to have strong hydrophilicity due to their surface functional groups and high electrical conductivity. In this study, we introduce clay mineral layer materials, bentonites, to enhance the water adsorbent. Bentonites have one Al octahedral nanosheet and two Si tetrahedral nanosheets, showing negative charge imbalance. Some cations, such as Na^+ and Ca^{2+}, are intercalated to compensate for this charge imbalance. Due to these intercalated cations, bentonites show ionic conductivity and strong water adsorption. Furthermore, bentonites are also known to exhibit strong O_2 absorbance to prevent MXenes oxidation in previous research [2], which is advantageous for long-term utilization.

MXene/bentonite thin films were fabricated by vacuum-assisted filtration, and these films were carefully transferred onto a plastic substrate. We have measured the sheet resistance of MXene/bentonite thin film with various mixing ratios using the four-point probe method in ambient environment. By increasing the MXene ratio from 0 wt% to 100 wt%, the sheet resistance is gradually increased and exhibits the maximal value around the MXene ratio of 25 wt%, and then sheet resistance is decreased over 25 wt% MXene content. We performed impedance measurements to clarify the factors that cause such sheet resistance changes, and we found that electronic conduction is dominant in MXene-rich film (67 wt% MXene). On the other hand, ionic conduction is dominant in bentonite-rich film (10 wt% MXene).

The humidity sensing abilities of the MXene/bentonite thin film in the relative humidity (RH) range from 10% to 90% were studied. Bare MXene thin film shows the sensitivity of 5.14 %, however we found that MXene-rich film (67 wt% MXene) exhibit high sensitivity of 1.04×10^2 %, which is about 20 times sensitivity enhancement. This is probably because more water molecules are absorbed by increasing humidity, and interspaces between the MXene flakes are enlarged, increasing intra-flake resistance.

PDMS—A Versatile Platform for Determining Young's Modulus in Ultrathin 2D Materials Luana de Avila and Bernardo R. Neves; Universidade Federal de Minas Gerais, Brazil

The elastic modulus, or Young's modulus, is a critical mechanical property that influences material suitability for various applications. This extends to 2D materials such as graphene, transition metal dichalcogenides (TMDs), boron nitride, talc, and others. However, conventional indentation techniques, effective for bulk materials, face challenges when applied to ultrathin 2D materials due to substrate effects. An alternative method involves the fabrication of well-defined circular holes on a rigid substrate, where the 2D material flake is deposited and a subsequent nanoindentation experiment is carried out at the center of the suspended 2D membrane [1]. Although successful, such procedure requires sophisticated lithography and transfer techniques which may hinder its wide applicability.

Here, to address this issue, we propose an innovative approach using polydimethylsiloxane (PDMS) as a compliant substrate for atomic force microscopy-based force curves. Our method relies on an analytical model for plate deformation on an elastic foundation initially developed by Timoshenko and Woinowsky-Krieger in the late 1950s [2]. By measuring three easily accessible parameters—the flake thickness, applied force, and resulting deformation—we accurately determine the Young's modulus of ultrathin materials [3]. Remarkably, this approach yields excellent agreement with existing literature for various tested 2D materials, including graphene, TMDs, and

talc.
PDMS serves as an ideal choice for the compliant substrate due to its widespread use in mechanical exfoliation and transfer of 2D material flakes. Moreover, PDMS possesses a well-known or easily measurable Young's modulus (a requirement for our analytical model). The simplicity of our approach allows researchers to measure force curves directly on freshly exfoliated flakes while still on the PDMS surface, streamlining Young's modulus determination.
As the variety of ultrathin materials continues to expand, our proposed platform holds significant promise. By making Young's modulus determination accessible and efficient, we contribute to the rapid development of applications for these remarkable materials.

MOCVD of Magnetic 2D Materials Cecilia Mattevi; Imperial College London, United Kingdom

The discovery of long-range magnetic order in atomically thin two-dimensional (2D) materials is a new emerging field promising for future applications in ultra-compact low-power spintronics, memory technologies, neuromorphic computing etc. The family of 2D magnets is rapidly expanding and the van der Waals and non-van der Waals chalcogenides of chromium are emerging as materials with air stability and high temperature magnetic transitions. In this talk, I will present our work on the MOCVD (metal organic chemical vapour deposition) synthesis of different crystal phases of chromium di-chalcogenides and on the characterizations of their magnetic and electronic properties. The synthesis precision, represented by the phase selectivity, is achieved by the combination of the kinetic control of the synthesis and chemistry of the chosen precursors. We demonstrate the phase selectivity of either trigonal prismatic or octahedral phases grown on epitaxial substrates, and we map the magnetic properties at different temperatures. Finally, we demonstrate the integration of 2D chromium dichalcogenides in devices.

4:00 PM EL03.11.02
Growth and Characterization of Fe-Ni Flux-Grown Hexagonal Boron Nitride Michael J. Mastalish[1], Santosh Karki Chhetri[1], Ashby Philip John[1], Elena Lotti[1,2], Tallisen Scott[1,3], Alton Holscher[1], Nathan Sawyers[1], Mohammad Hafijur Rahaman[1], Evans Addo-Mensah[1], Casper McPherson[1], Janet Obaemo[1], Kenji Watanabe[4], Takashi

Taniguchi[4], Jin Hu[1] and Hugh Churchill[1]; [1]University of Arkansas, United States; [2]University of Massachusetts Dartmouth, United States; [3]Oberlin College, United States; [4]National Institute for Materials Science, Japan

The growth of high quality Hexagonal Boron Nitride (hBN) crystals is a process that has attracted much interest in recent years. It is a transparent, insulating van der Waals material, and it is commonly used in nanoscale devices as a gate dielectric, tunneling barrier, and as an encapsulating layer for air sensitive devices. Here, we present a novel growth method for hBN synthesized at the MonArk NSF Quantum Foundry facilities at the University of Arkansas. This method uses a Fe-Ni flux at atmospheric pressure, and this talk summarizes our characterization of the resulting crystals.

The bulk crystals yield Raman spectra matching those reported in the literature for other hBN crystal growth methods. Upon exfoliation, we obtain cathodoluminescence spectra for thin flakes, and we compare the energies of the peaks with those reported in the literature. By fabricating parallel-plate capacitor devices, we obtain the dielectric constant and breakdown voltage for a range of thicknesses. We then use hBN synthesized by the Taniguchi and Watanabe group at NIMS to fabricate similar devices and compare the results obtained from both sources. These results establish that hBN crystals grown at the MonArk Quantum Foundry are high quality crystals that have properties comparable to those from other widely used growth facilities.

4:15 PM EL03.11.03

Two-Dimensional Silicon Carbide—Growth and Applications Sakineh Chabi, Luis Payan, Jose Castro and Nishan Shrestha; The University of New Mexico, United States

Two-dimensional silicon carbide (2D SiC) exhibits intriguing physical properties due to its unique electronic structures, direct wide band gap feature, and quantum confinement effects. These properties include exceptional thermal and mechanical capabilities, as well as strong light-matter interactions, positioning 2D SiC as a promising material for various applications ranging from nanoelectronics and optoelectronics to high-temperature applications and extreme environments.

Stacked SiC nanosheets or heterostructures combining 2D SiC with other 2D materials such as graphene present additional intriguing possibilities. For instance, unlike bulk SiC, which is diamagnetic, multilayer SiC in AB stacking exhibits interesting ferromagnetic properties due to interlayer interaction. However, realizing the full potential of 2D SiC in practical applications requires extensive experimental investigation, as many of these properties are yet to be fully explored.

In this presentation, I will discuss our latest advancements in understanding and exploiting the physical properties of 2D SiC, as well as its growth mechanisms. Both bottom-up and top-down approaches have been utilized to grow 2D SiC and other related materials such as non-stocichiomteric silicon carbide structures.

Synthesis of Two-Dimensional Single Crystalline Silver Nanosheets for Low-Temperature Sintering

Seungyeon Kim, Young-Seok Song, Sneha S. Bhise and Tae-Wook Kim; Jeonbuk National University, Korea (the Republic of)

Recently, there has been a growing interest in flexible electronic devices within the electronics industry. Consequently, some electronic components based on polymer substrates such as Polyethylene Terephthalate (PET), Polyimide (PI), and Polyethylene Naphthalate (PEN), as well as organic groups or nanoscale building blocks, are being applied. However, these components cannot maintain their functionality and stability at high temperatures above a certain threshold. Therefore, research on metal filler materials that can be sintered at low temperatures below 200 °C is necessary. Silver (Ag) nanoparticles are readily sintered, facilitating easy bonding at

the interfaces between metals such as copper (Cu) [1]. This allows for the formation of sintered metals with bulk melting temperatures, making them more useful than solder over a wide temperature range [2]. However, research has primarily focused on using Ag nanoparticle paste to bond with other metals and organic materials.
In this study, we propose synthesizing Ag nanoparticle-decorated Ag nanosheets, which enhance electrical performance through sintering under conditions below 200 °C, focusing on the low-temperature performance of submicron-sized particles. We synthesized large silver nanosheets at room temperature and atmospheric pressure by mixing silver nitrate, poly (vinyl pyrrolidone), sodium chloride, hydrogen peroxide, and ammonium hydroxide. The silver nanosheets exhibited shapes such as triangles, truncated triangles, hexagons, or polygons, with edge sizes ranging from 1 µm to approximately 50 µm and thicknesses proportional to their size, ranging from 10 to 100 nm. During this process, we controlled the reduction rate of Ag^+ ions to Ag^0 using hydrogen peroxide (H_2O_2). This allowed us to regulate the formation and growth rate of Ag clusters into Ag nanosheets, thereby controlling the size and surface morphology of the nanosheets. Synthesis with a high concentration of H_2O_2 resulted in smooth-surfaced Ag nanosheets, while synthesis with a low concentration of H_2O_2 produced Ag nanosheets decorated with Ag nanoparticles.
The Ag nanoparticle-decorated Ag nanosheets synthesized under these conditions had an edge size of approximately 5 µm, a thickness of about 30 nm, and the decorated Ag nanoparticles had a diameter of roughly 70 nm. Films fabricated using these nanosheets demonstrated successful sintering, with the sheet resistance decreasing from 25.5 Ω/sq to 4.4 Ω/sq after 30 minutes at a low temperature of 100 °C. Films fabricated using these nanosheets demonstrated successful sintering, with the sheet resistance decreasing from 25.5 Ω/sq to 4.4 Ω/sq after 30 minutes at a low temperature of 100 °C. This represented a two-fold reduction in resistance compared to films made with Ag nanosheets lacking nanoparticles. Thus, we confirmed that we could control the size, thickness, and surface morphology of micron-sized large silver nanosheets. These findings suggest that such nanosheets can be effectively utilized as 2D metal nanofilms and as efficient metal fillers.

4:45 PM EL03.11.05
Facile Chimie Douce Route Towards Ferrimagnetic $PtSe_2$ Materials Kirill Kovnir; Iowa State University of Science and Technology, United States

Se-containing materials often synthesized by solution-assisted from toxic and expensive organo-Se precursors. We are reporting a facile alternative utilizing elemental Se which is cheap and non-toxic. Elemental Se reagent has a drawback of low solubility and reactivity resulting in sluggish kinetics at low temperatures. A process of elemental Se activation was developed resulting in stable solution of multiple Se^{2-}/Se^{1-} species in dynamic equilibrium. The developed activated Se precursor allows us to produce few-layers thick $PtSe_2$-based nanomaterials at near room temperature. The developed synthetic method opens ways for controlled incorporation of 3d transition metals into $PtSe_2$ intra- and interlayer space. The resulting M-$PtSe_2$ materials exhibit ferrimagnetic properties with atypical temperature dependences of coercivity.

5:00 PM EL03.11.06
Integration of Graphene with Chitosan Membranes for Peripheral Nerve Regeneration Domenica Convertino[1], Luca Scaccini[2], Neeraj Mishra[1], Antonella Battisti[3], Marco Cecchini[3], Ilaria Tonazzini[3] and Camilla Coletti[1,1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Scuola Normale Superiore, Italy; [3]Consiglio Nazionale delle Ricerche, Italy

The employment of graphene in tissue engineering has been recently exploited for the repair and regeneration of nerve tissue. Among the possible applications, graphene-based materials display a great potential as peripheral neural interfaces, especially for their unique electrical, optical and physical properties[1–4].
The integration of graphene with flexible biocompatible substrates represents a central point for the development of high-quality graphene-based nerve conduits. Many graphene-based nerve conduits use graphene flakes,

however, the use of chemical vapor deposition (CVD) graphene would be promising due to its higher resistance to degradation, that avoids flakes release in the bloodstream[5].
In this work we present recent results on graphene (G) integration with flexible supports made of chitosan and glycerol-blended chitosan[6,7].The membranes were prepared in their isotropic flat form (FLAT) and with directional micro-topographies presenting different levels of symmetry [gratings (GR) and scalene triangles (SCA)]. We discuss the challenges encountered in CVD graphene integration with these supports. Different transfer techniques were tested to choose the best one in terms of yield of number of good samples, focusing mainly on graphene continuity. The micropattern and graphene integration was assessed using optical microscopy and Raman spectroscopy.
Then we report preliminary results on the scaffolds' interaction with a glial Schwann cell (SC) line *in vitro*. We performed adhesion and single cell migration experiments, observing that the presence of graphene reduced the guidance effect of the patterns, acting like a masking layer that impedes the cells from feeling the pattern. However, the interaction of SCs with scaffolds was highly boosted by graphene, inducing an increased adhesion in the graphene coated substrates.

Overall, our results aimed at understanding the possibility to integrate graphene with micro-structured polymeric membranes. Additional efforts have to be made to optimize the transfer process in order to obtain a repeatable transfer of high-quality large-scale CVD graphene. The substrates will be then tested to study their effects on the different players involved in nerve regeneration.

Characterization of AA Domain and Electrical Property in Low-Angle Twisted Bilayer Graphene (tBG)

Myunghoon Choi[1], Hanaul Noh[1], David Velarde[1], Yun Yu[2], Gilbert Min[1] and Stefan Kaemmer[1]; [1]Park Systems Incorporated, United States; [2]George Mason University, United States

Manipulating the interlayer twist angle provides an effective method for adjusting the electronic characteristics of two-dimensional (2D) van der Waals (vdW) materials. Since the magic angle 1.1 degree of twisted bilayer graphene (tBG) is known for its remarkable electronic characteristics, various degrees of tBG have been studied to understand the underlying mechanisms . While previous studies examining the effects of interlayer twist on chemical reactivity have been reported, they have primarily focused on large twist angles (≥7 degree).
The evolution of vertical conductivity in tBG with respect to twist angle at low-twist angles (< a few degrees), reveals several intriguing characteristics including vibration mode modulation, changes in electronic structure, and electron-photon coupling behavior. The competition among interlayer vdW interactions, atomic and electronic reconstruction becomes notable at small twist angles. The distance between AA domains, where the carbon atoms are directly aligned on top of each other, are highly relevant to the twist degree. Consequently, this leads to an enlargement or shrinkage of all other domains. AA domain is known as high energy state and flat electronic band.<!--![endif]---->
<!--[endif]----> Recently, conductive atomic force microscopy (cAFM) has been extensively utilized for studying tBG due to its high sensitivity to local conductivity variations and high spatial resolving power. This capability allows for the precise identification and characterization of stacking domains and their conductivity properties. In 2019, researchers investigated the transition in tBG from incommensurate to commensurate domain structures, unveiling unique electronic transport behaviors. In 2020, a study demonstrated nonmonotonic vertical conductivity in tBG, while another explored symmetry breaking in 2022. Additionally, researchers presented two metastable reconstruction states in small-angle twisted monolayer–multilayer graphene in the same year.

In this study, we employ cAFM to characterize the moiré pattern of low-twist angle tBG and investigated its conductivity under both positive and negative potentials. The tBG sample investigated here is fabricated via graphene cutting using cAFM, Our measurement reveals current maps of moiré patterns in two distinct scales within the sample. The local twist angles are accurately determined and uncovered deviations from intended values during fabrication. Moiré pattern simulations are employed to compare experimentally detected AA wavelength and domain sizes, representing the methodology of understanding of tBG's structural complexity. More details will be presented on the poster.

Mechanocatalytic Synthesis of Graphene Quantum Dots Yuxuan Ye[1,2]; [1]Institute for Functional Intelligent Materials, Singapore; [2]National University of Singapore, Singapore

Nanometer-sized fragments of graphene, in other words, graphene quantum dots (GQDs) have gained extensive research interest due to their intriguing physicochemical properties. In the past two decades, GQDs have been reported to possess various characteristics and in different applications depending on how they were synthesized. For the top-down approach, there are mechanical and chemical methods of cutting graphite into small pieces; for the bottom-up approach, pyrolysis is nowadays a widely used method of producing highly functionalized graphene quantum dots. The common synthesis methods as mentioned above usually rely on chemical activations. The functional groups inherited from such chemicals like potassium hydroxide and citric acid may not be avoided. The inflexibility and instability in functionalization control has produced GQDs with sometimes controversial characteristics and has hindered the study on its intrinsic properties.

In this study, we explored ultrasonication as a new bottom-up method for GQDs synthesis. Following a methodologically simple procedure, blue-color fluorescent and 1-to-3-nanometer-sized GQDs were produced from benzene as the carbon source. TEM, AFM, PL analysis, and other related characterizations were conducted. Owing to the violent chemical excitation through ultrasonication, our method does not rely on the intrinsic chemical activity of the precursors. Instead, we are allowed to choose various precursors that provide functionalities as needed, no matter whether the reactions are thermodynamically favourable. Several other precursors like pyridine and acetophenone were attempted and produced GQDs with varied PL characteristics.

Tunability of the Superconductivity of $NbSe_2$ Films Grown by Two-Step Vapor Deposition Huihui Lin and Meijuan Chang; National University of Singapore, Singapore

Layered metallic transition-metal dichalcogenides (TMDCs) are ideal platforms for exploring their fascinating electronic properties at two-dimensional limits, such as their charge density wave (CDW) and superconductivity. Therefore, developing ways to improve the crystallization quality of TMDCs is urgently needed. Here we report superconductively tunable $NbSe_2$ grown by a two-step vapor deposition method. By optimizing the sputtering conditions, superconducting $NbSe_2$ films were prepared from highly crystalline Nb films. The bilayer $NbSe_2$ films showed a superconducting transition temperature that was up to 3.1 K. Similar to the salt-assisted chemical vapor deposition (CVD) method, superconducting monolayer $NbSe_2$ crystals were also grown from a selenide precursor, and the growth strategy is suitable for many other TMDCs. Our growth method not only provides a way to improve the crystalline quality of TMDC films, but also gives new insight into the growth of monolayer TMDCs. It holds promise for exploring two-dimensional TMDCs in fundamental research and device applications.

An Inexpensive and Rapid Route to Printable Phosphorene Quantum Dots from Red Phosphorus Michal Pawlus, James Robinson and Adam Clancy; University College London, United Kingdom

Black phosphorene is a very promising two-dimensional material composed of a single sheet of black phosphorus. Black phosphorene exhibits fascinating characteristics, such as in-plane anisotropy, tunable band gap and high carrier mobility. As a consequence of these properties, black phosphorene has shown a great potential to be utilized in a diverse array of applications – ranging from electronic and optoelectronic devices to the energy storage and energy conversion. Black phosphorene quantum dots (bPQDs) are a zero-dimensional variety of black phosphorene with lateral widths under 100 nm. The additional quantum confinement and higher proportion of edges versus their one- and two-dimensional counterparts makes them an intriguing tunable candidate material for many applications. Unfortunately, to date bPQDs have been exclusively formed from expensive individual sub-gram black phosphorus crystals.

In this work, an inexpensive, rapid and scalable synthesis of black phosphorene quantum dots from widely-available low-cost red phosphorus is demonstrated. Initially, the red phosphorus powder material is ball-milled to obtain black phosphorus nanodomains, and subsequently an etching pathway utilizing lithium electride-containing ammonia solution allows for the conversion to black phosphorene quantum dots through removal of defective regions. The result is a salt of bPQDs which spontaneously dissolve at room temperature in several solvents as individual monolayer quantum dots. These solutions can be cast to give isolated individual bPQDs on a range of substrates. Ball-milled samples were analyzed using various analytical techniques, such as Raman spectroscopy and x-ray diffraction, which revealed that red phosphorus was converted into black phosphorus. Additionally, optimal conditions for the ball milling of red phosphorus powder were determined. Conclusively, the formation of the black phosphorene quantum dots after etching was evidenced using microscopy, such as atomic force microscopy.

Hyperspectral Line Imaging Analysis of Defects in Atomically Thin Semiconductors Seungjae Lim[1], Tae Wan Kim[1], Taejoon Park[1], Seonguk Yang[2,2], Hosung Seo[1], Joonki Suh[2,2] and Jae-Ung Lee[1]; [1]Ajou University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Transition Metal Dichalcogenides (TMDs) are van der Waals 2D semiconductors with exotic physical properties originating from its 2D nature. Especially, monolayer TMDs have a direct bandgap which makes them promising for optoelectronic applications. For practical applications of these materials, several challenges need to be addressed: uniform and large-scale growth, high-yield fabrication of device structures, and large-scale characterization of the materials. The Metal Organic Chemical Vapor Deposition (MOCVD) method has been used for wafer-scale growth of TMDs, and researchers have demonstrated the device applications of TMDs such as classical logic gates, neuromorphic devices, gas sensors etc. However, syntheized TMD monolayers are often exhibit spatial heterogeneity such as non-uniform photoluminescence (PL), carrier mobility, and hysteresis, primarily due to defect distribution. Therefore, characterizing these spatially distributed defects is crucial for the practical application of TMDs.

In our presentation, we investigate the defect formation-related variation of optical properties in monolayer WS2 flakes. Using MOCVD, we achieved stoichiometry-dependent growth of WS2 monolayer flakes by adjusting the sulfur precursor injection without altering other growth conditions. We observed that WS2 flakes exhibit uniform PL intensity with an increasing the sulfur/tungsten precursor ratio. By utilizing Hyperspectral Line Imaging (HSLI), we statistically analyzed the spectral properties of WS2 monolayer flakes. Similar to PL intensity, W-rich flakes exhibit the most inhomogeneous distribution of exciton peak positions compared to S-rich flakes. We further examined the optical response after chemical treatment, observing contrasting behavior in W-rich and S-rich flakes, which we attributed to different types of defects. By comparing with defect formation energy calculations using density functional theory, we identified sulfur vacancy defects (V_s) as the dominant defect in W-rich flakes and chalcogen antisite defects (S_w) as the most prevalent defect in S-rich flakes. To demonstrate the large-scale applicability of HSLI, we conducted similar analysis on WS2 monolayer films and successfully characterized W-rich and S-rich samples on a sub-centimeter scale.

EL03.12.06

p-Doping of 2D materials by Phosphorus Ion Implantation Munkyung Kim and Jihyun Kim; Seoul National University, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) are considered as next-generation materials to replace silicon. TMDCs consist of atomically thin crystal layers with dangling-bond-free surfaces that exhibit high mobility, which is advantageous over silicon that exhibits decreased mobility at nanoscale thickness. However, efficient doping processes for TMDCs are yet to be fully established. Various doping processes such as electrostatic doping, charge transfer doping, and incorporation of impurity atoms during growth have been investigated but these methods are typically challenged by the lack of precise control over the doping location, concentration, or depth. Ion implantation is a doping method that is widely used in conventional silicon-based processes and has become essential for fabricating advanced devices and integrated circuits since it offers precise control over the doping concentration and depth and is compatible with existing semiconductor fabrication processes.

In this study, phosphorus ion implantation was conducted to enable the p-type doping of WSe_2, which intrinsically exhibits ambipolar transport characteristics which can be effectively tuned to either n- or p-type. WSe_2 flakes were mechanically exfoliated from a bulk WSe_2 crystal and transferred onto a sapphire substrate. 150 nm SiO_2 layer was deposited on the WSe_2 flakes on the sapphire substrate using high-density plasma chemical vapor deposition process. The SiO_2 layer was deposited to minimize defects generated by high energy ion collision and to control penetration depth of phosphorus ions in WSe_2. The optimal implantation energy to effectively introduce phosphorus dopants into the WSe_2 flakes was determined using the Monte Carlo simulation. After the ion implantation process, the samples underwent rapid thermal annealing (RTA) under an Ar gas environment to heal the possible damages induced by the ion implantation process and to ensure the stable incorporation of the dopants into the crystal lattices of the WSe_2 flakes. The RTA process was performed under temperatures ranging from 600 °C to 900 °C with 100 °C increments to investigate the effect of the annealing temperature in the activation of the phosphorous dopant in WSe_2. The effectiveness of the phosphorus ion implantation and thermal annealing process on the p-doping of WSe_2 was investigated through structural and electrical analyses. The change of crystallinity of the WSe_2 lattice structure was analyzed systematically before and after ion implantation and thermal annealing using Raman spectroscopy. Transmission electron microscopy imaging technique was also utilized before and after thermal annealing to verify the restoration of the lattice structure. Electronic devices based on the p-doped and intrinsic WSe_2 crystals were fabricated and their current-voltage characteristics were investigated to analyze the change in the transport characteristics and carrier concentration using a semiconductor parameter analyzer. The detailed process and results will be given during the presentation.

This study demonstrates the effective p-type doping of WSe_2 through phosphorous ion implantation and thermal annealing, illustrating the efficacy of the widely used ion implantation technique for the TMDCs and diversifying their doping methods. This work lays the groundwork for enabling precise doping in future nanoelectronics based on TMDCs.

EL03.12.07

Development of a Versatile and Rapid MAX Phase Synthesis System to Obtain 2D MXenes Mitsuru Inada, Daisuke Nishine and Mahito Yamamoto; Kansai University, Japan

MXene is an attractive two-dimensional nanomaterial with potential applications in energy storage, biosensors, and catalytic electrodes MXene is a transition metal carbide or nitride, and many combinations have been proposed. However, only a limited number of combinations of MXene have been realized. In general, MXene is obtained by etching the MAX phase, but the synthesis of the MAX phase is not easy because it requires annealing for several hours under high temperature and pressure conditions. Therefore, it is desirable to establish a simple

and easy method for synthesizing the MAX phase.
We have developed a simple and cost-effective MAX phase synthesis system that does not require complicated equipment. In addition, the system can synthesize a MAX phase in less than one minute. This means that the power consumption for synthesis is also very low. The system is based on induction heating (IH). The system is pressureless, and the MAX phase can be synthesized simply by heating the sample in a vacuum or an inert gas atmosphere such as argon. Rapid heating by induction heating induces a self-propagating high temperature synthesis (SHS) in the sample. This SHS propagates throughout the sample in just a few seconds. Therefore, the total heating time is less than one minute. Since this system is a pressureless method, the synthesized MAX phase can be easily flaked off and thus easily etched into MXene. Another feature of this system is that it can synthesize different types of MAX phases, such as M=Ti and M=V. Especially for the titanium based MAX phases, the synthesis of Ti_3AlC_2 and Ti_2AlC can be controlled by the synthesis conditions. Details of the developed system and the synthesis of M=Mo, Nb, and Cr MAX phases will be presented at the meeting.

Effect of Reduction Annealing on the Structural and Electrical Properties of α-MoO_3 Thin Films Sandipani Ghosh, Jessica Fink, Fahad Munshe, Md.Zulkernain Haider and Kartik C. Ghosh; Missouri State University, United States

Two-Dimensional Layered Molybdenum oxide (α-MoO_3) is gaining significant research interest due to its tuneable bandgap and diverse structural, chemical, electrical, and optical properties which are greatly influenced by the various growth parameters and synthesis. In this work, we report the effect of reduction-annealing on the structural and electrical properties of few layers of MoO_3 thin films on Si/SiO_2 substrate synthesized by Pulsed Laser Deposition method under a vacuum pressure of 10^{-4} mbar. The structural properties of MoO_3 films were analysed under different annealing conditions using X-ray diffraction. The films have nanocrystalline structure with a preferred orientation along (0 2 0) direction. The sample annealed for 10 hours shows the formation of highly crystalline orthorhombic α-MoO_3 with prominent peak shifts indicating reduction in unit cell volume. Field emission scanning electron microscopy and energy disruptive spectroscopy provide a comparative analysis of the detailed microstructures of the films and their elemental composition. Raman spectroscopy revealed the formation of the orthorhombic α-MoO_3 layered structure, indicated by the characteristic peaks at 667, 820, and 995 cm^{-1} for the O-Mo-O and the Mo=O stretch vibrational modes respectively. UV-Vis spectroscopy measurements indicated that the energy band gap of the MoO_3 films was approximately 3.25 eV. Reduction annealing introduced oxygen vacancies, leading to an increase in the electrical conductivity of MoO_3 to the order of $10^{-4}\ \Omega^{-1}\ cm^{-1}$. Nevertheless, preliminary FET characteristics measurements, including I_{DS} vs V_{DS} at various gate voltages, demonstrate that the samples retained their semiconducting behaviour.

Influence of Defects on the Valley Polarization Properties of Monolayer MoS_2 Grown by Chemical Vapor Deposition Faiha Mujeeb MC and Subhabrata Dhar; Indian Institute of Technology Bombay, India

Two-dimensional transition-metal dichalcogenides (TMDs) offers valley degree of freedom, which can be exploited to design next-generation valley-based electronics or “valleytronics”. The broken inversion symmetry, together with strong spin-orbit coupling, results in the valley-dependent optical selection rules in monolayer (1L)-MoS_2. This property enables an exciton to sustain its valley character throughout the time of its existence. In fact, valley polarization approaching 100% has been reported in exfoliated 1L-MoS_2 samples, whereas 1L-MoS_2 films grown by the chemical vapor deposition (CVD) technique, which is frequently used to grow large-area films on different substrates, show only moderate polarization values (less than 50%). Since large area coverage of the monolayer film has to be ensured for any practical application of the material, it is imperative to understand the reason for the moderation of valley polarization in CVD-grown 1L-MoS_2. Note that the optical and electrical properties of CVD-grown layers often suffer from the presence of a high density of sulfur vacancy defects (V_S) and the residual strain. Since the valley and spin properties are closely related to the crystal symmetry, both the strain and the defects are expected to have certain impacts on the valley polarization (VP) property of 1L-MoS_2 grown by the CVD technique. The involvement of small wavelength phonons in valley de-polarization of 1L-MoS_2 is an unsettled issue. A recent theory suggests that the long-range part of the electron-hole exchange interaction can virtually transfer excitons between *K* to *K'* valleys without directly involving any phonon [1]. In this process, the momentum scattering of the excitons can influence the spin-flip scattering rate through Maialle-Silva-Sham (MSS) mechanism. The presence of defects can influence the momentum relaxation rate of the excitons and hence can affect the valley depolarization.

Here, our temperature dependent polarization resolved photoluminescence spectroscopic study experimentally demonstrates, the above mechanism as the most dominant intervalley exciton transfer process in CVD grown monolayers, where momentum scattering of excitons by the air molecules attached to V_S plays significant role [2]. Interestingly, the momentum scattering rate is found to be proportional to the cube root of the defect density. Intervalley scattering of excitons through Γ-valley also contributes to the valley de-polarization process specially when the layer has tensile strain or high density of V_S defects as these perturbations reduces K to Γ-energy separation. Band-structural calculations carried out within the density functional theory framework confirm this finding. Experimental results further suggest that exchange interactions with the physisorbed oxygen molecules can also result in the intervalley spin-flip scattering of the excitons, and this process becomes important when the defect density is sufficiently high.

EL03.12.10

Flash-Within-Flash Synthesis of Gram-Scale Solid-State Materials Chi Hun (William) Choi[1], Jaeho Shin[1], Lucas Eddy[1], Victoria Granja[1], Kevin Wyss[1], Bárbara Damasceno[1], Hua Guo[1], Guanhui Gao[1], Yufeng Zhao[2], C. Fred Higgs III[1], Yimo Han[1] and James Tour[1]; [1]Rice University, United States; [2]Corban University, United States

Sustainable manufacturing that prioritizes energy efficiency, minimal water use, scalability, and the ability to generate diverse materials is essential to advance inorganic materials production while maintaining environmental consciousness. However, current manufacturing practices are not yet equipped to fully meet these requirements. Here, we describe a flash-within-flash Joule heating (FWF) technique—a non-equilibrium, ultrafast heat conduction method—to prepare 10 transition metal dichalcogenides (TMDs), 3 Group-XIV dichalcogenides, and 9 non-TMD materials, each in under 5 seconds while in ambient conditions. FWF achieves enormous advantages in facile gram scalability and in sustainable manufacturing criteria when compared to other synthesis methods. Also, FWF allows the production of phase-selective and single-crystalline bulk powders, a phenomenon rarely observed by any other synthesis method. Furthermore, FWF $MoSe_2$ outperformed commercially available $MoSe_2$ in tribology, showcasing the quality of FWF materials. The capability for atom substitution and doping further highlights the versatility of FWF as a general bulk inorganic materials synthesis protocol.

EL03.12.11

Atomic-Scale Insights into Mastering Epitaxial Growth of 2D Transition Metal Dichalcogenides Chengyang Li, Fangyuan Zheng, Jiacheng Min, Yi Wan and Li Lain-Jong; The University of Hong Kong, Hong Kong

The epitaxial growth of two-dimensional (2D) transition metal dichalcogenides (TMDCs), such as MoS_2, on sapphire substrates is a crucial method for producing large-area single-crystal films. While both step-edges and surface symmetry of the substrates have been proposed as controlling factors, the underlying fundamentals remained unclear. This paper presents our recent efforts to control the epitaxial growth of MoS_2 monolayers by manipulating the sapphire surface at the atomic scale. By growing MoS_2 on C/M-plane sapphire, we discovered that the sulfur evaporation rate dictates whether atomic-edge guided epitaxy or van der Waals epitaxy occurs. Specifically, we found that a high sulfur evaporation rate leads to the formation of S-terminated atomic edges, which inhibits edge nucleation, whereas a low sulfur evaporation rate results in O/Al-terminated atomic edges, thereby promoting edge nucleation. Specifically, a high sulfur evaporation rate creates S-terminated atomic edges that inhibit edge nucleation, while a low sulfur evaporation rate results in O/Al-terminated atomic edges that promote edge nucleation. By precisely controlling the step height to ensure a single-exposed atomic surface, we successfully synthesized 2-inch scale single-crystal MoS_2 thin films using van der Waals epitaxy. Our experiments reveal that over a 2-inch wafer, the van der Waals epitaxy mechanism allows better control of MoS_2 alignment (~99%) compared to the step-edge mechanism (<85%). Our findings highlight how atomic-level thermodynamics govern the nucleation modes of TMDCs, providing a pathway for precisely fabricating wafer-scale single-crystal 2D materials.

EL03.12.12

Operando Scanning Electron Microscopy Study of Support Interactions and Mechanisms of Salt-Assisted TMD Growth Jinfeng Yang[1], Ye Fan[1], Ryo Mizuta[1], Amarvir Chana[1], Jack Donoghue[2], Sarah J. Haigh[2] and Stephan Hofmann[1]; [1]University of Cambridge, United Kingdom; [2]The University of Manchester, United Kingdom

Salt enhanced chemical vapour deposition of 2D transition metal dichalcogenides (TMDs) is widespread, and while many mechanisms including vapour-liquid-solid (VLS) mediated growth have been suggested, gaining a more detailed understanding remains challenging. We employ operando scanning electron microscopy (SEM) [1] to resolve the entire process of salt-assisted CVD of two widely studied TMDs, namely WS_2 and MoS_2, focusing on a model system of individual, small (<100 μm), sapphire supported sodium tungstate (Na_2WO_4) salt particles.[2] We reveal support interactions that lead a salt particle to develop a lateral halo interface, that we propose is driven by sodium aluminate formation and surface eutectic melting above 630 °C. This hot salt corrosion dictates the salt wetting as well as Na and W transport, and thus upon gaseous sulphur precursor exposure dominates the spatio-temporal WS_2 nucleation and mono- and multi-layer domain expansion kinetics, all of which we can directly track by secondary electron (SE) contrast with a conventional In-Lens detector. Unlike to a conventional VLS mechanism, large (>20 μm) monolayer WS_2 formation does not involve the salt droplet directly attached to the growth facets, rather the salt droplet drives WS_2 layer growth in the vicinal halo interface region with a continuous supply of W. Sapphire supported, salt-assisted MoS_2 growth shows similar behaviour. We systematically also explore support interactions on SiO2, MgO and graphite. Our insights here make a strong case that support interactions should be considered in much more detail for a deeper understanding of salt-assisted TMD CVD and when discussing the opportunities and trade-offs of processing opportunities that salts can bring.

EL03.12.13

Layer-Dependent Chemical Reactivity of MoS_2 Zifan Wang[1], Tina Mihm[1], Jiaxuan Wen[2], Sahar Sharifzadeh[1], Keji Lai[2] and Xi Ling[1]; [1]Boston University, United States; [2]The University of Texas at Austin, United States

Two-dimensional (2D) materials offer a unique platform to expand the horizons of various disciplines, including physics, chemistry, materials science and engineering. One intriguing aspect of these materials is their distinct properties compared to their bulk counterpart, largely due to the quantum confinement effect at atomically thin region. Particularly, the thickness dependent physical properties of 2D materials have been extensively studied in the past two decades. Yet, little study is performed on the thickness dependent chemical properties. In this work, we report on the layer-dependent chemical reactivity of MoS_2 in a nitridation reaction. Our findings show that the reactivity of MoS_2 decreases with the decrease of the number of layers. This behavior is attributed to the layer-dependent binding energy of NH_3 at sulfur vacancies of MoS_2, as supported by theoretical calculations. The reaction results in the formation of MoN crystals across all thicknesses of MoS_2. Detailed atomic-level investigations using transmission electron microscope (TEM) reveal distinct morphologies of the reaction products. Specifically, MoN nanoplates are observed from the reaction products of monolayer MoS_2, and the continuity of the MoN film increases with the increase of the number of layers. This work demonstrates 2D materials to be a powerful avenue for advancing our understanding of materials chemistry.

EL03.12.14

Application of 4D-STEM and Multi-Slice Ptychography for Depth Sectioning of Lateral and Vertical 2D Heterostructures Grown by CVD

Oliver Massmeyer[1], Jürgen Belz[1], Badrosadat O. Dogahe[1], Robin Guenkel[1], Max Bergmann[1], Michael Heuken[2], Gerd Bacher[3], Andrey Turchanin[4], Andreas Beyer[1] and Kerstin Volz[1]; [1]Philipps-Universität Marburg, Germany; [2]Aixtron, Germany; [3]Universität Duisburg-Essen, Germany; [4]Friedrich-Schiller-Universität Jena, Germany

Two-dimensional (2D) materials have the potential to transform semiconductor technology. Their rich compositional and stacking diversity, especially when deposited as heterostructures, allows tailoring of material properties to enable a wide range of device applications.(1) A prominent class of these 2D materials are the transition metal dichalcogenides (TMDCs). With improved synthesis and fabrication capabilities, heterostructure concepts have been developed that show promising material properties for ultrathin optoelectronic devices. While these heterostructures can be fabricated by mechanical pattern transfer for small areas with high precision, these approaches are difficult to up-scale. Therefore, alternative approaches such as chemical vapor deposition (CVD) have been developed to fabricate 2D materials and their heterostructures.(2) Depending on the process parameters, several growth modes can dominate and thus a variety of structure combinations can be created. Since optical and electronic properties typically depend on the orientation, high-resolution measurements of the number of layers and the atomic structure of each material can help to understand the macroscopic optical measurements and guide the optimization of growth processes towards the desired layer structures.

We have studied CVD grown vertical and lateral heterostructures of WS_2/MoS_2 and $WSe_2/MoSe_2$. These structures are transferred to electron-transparent grids specialized for scanning transmission electron microscopy (STEM) either by a PMMA(3) transfer process or directly by growth of the material on SiN grids. The samples are characterized in an aberration-corrected JEOL 2200 FS STEM operating at 80 kV and 200 kV in conjunction with a fast pixelated pn-CCD detector, allowing the samples to be analyzed by 4D-STEM(4). In addition to conventional high-resolution STEM imaging, the chemical composition is determined by energy dispersive X-ray spectroscopy (EDX) and the orientation alignment within the heterostructures is resolved by scanning nanobeam diffraction (SNBD).

Although EDX, HR-STEM and SNBD provide a huge insight into the actual structure of the heterostructure, including the formation of defects such as vacancies and anti-sites within the 2D layers, the formation of grain boundaries between domains of different crystal orientations, the epitaxial relationship between the 2D layers in the heterostructure(5-6) as well as elemental interdiffusion at the lateral heterointerfaces, these techniques only provide a projected view of the total structure. Therefore, to further analyze the vertical heterostructures, we explore the possibilities of multi-slice ptychography using the py4DSTEM(7) software package to obtain depth sectioning of the atomic structure within the vertical and lateral heterostructures in bi- and tri-layer regions of the samples. The depth sectioning provides useful additional information on the formation of defects such as screw dislocations originating from buried layers and clarifies the location of lateral interfaces within the vertical heterostructures.

Our recent progress in the analysis of vertical and lateral 2D heterostructures and our improved understanding of the growth of the 2D heterostructures by CVD will be discussed in the presentation.

Indirect-to-Direct Bandgap Crossover and Room-Temperature Valley Polarization of Multilayer MoS2 Achieved by Electrochemical Intercalation Min-kyung Jo[1,2], Eunji Lee[3], Jeongyong Kim[3], Kibum Kang[2] and Seungwoo Song[1]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Monolayer (1L) group VI transition metal dichalcogenides (TMDs) exhibit broken inversion symmetry and strong spin-orbit coupling, offering promising applications in optoelectronics and valleytronics. Despite their direct bandgap, high absorption coefficient, and spin-valley locking in K or K' valleys, the ultra-short valley lifetime limits their room-temperature applications. In contrast, multilayer TMDs, with more absorptive layers, sacrifice the direct bandgap and valley polarization upon gaining inversion symmetry from the bilayer structure. We demonstrate that multilayer MoS2 can maintain 1) a structure with broken inversion symmetry and strong spin-orbit coupling, 2) a direct bandgap with high photoluminescence (PL) intensity, and 3) stable valley polarization up to room temperature. Through the intercalation of organic 1-ethyl-3- methylimidazolium (EMIM+) ions, multilayer MoS2 not only exhibits layer decoupling but also benefits from an electron doping effect. This results in a hundredfold increase in PL intensity and stable valley polarization, achieving 55% and 16% degrees of valley polarization at 3 K and room temperature, respectively. The persistent valley polarization at room temperature, due to interlayer decoupling and trion dominance facilitated by a gate-free method, opens up potential applications in valley-selective optoelectronics and valley transistors.

SESSION EL03.13: 2D Materials-Based Devices II
Session Chairs: Cinzia Casiraghi and Saptarshi Das
Thursday Morning, December 5, 2024
Sheraton, Second Floor, Back Bay C

8:00 AM *EL03.13.01

Graphene Nanoribbon Junctions as Elementary Components of Nanoelectronic Circuits Oleg Yazyev; École Polytechnique Fédérale de Lausanne, Switzerland
