Understanding the reaction pathways in complex oxide synthesis is an ongoing goal in materials science. Clues to understanding these pathways can be gathered by monitoring the persistence of intermediate phases as impurity phases in the final sample. With the goal of better understanding the formation of impurity phases in $BiFeO_3$ thin film synthesis through the sol-gel technique, we have constructed a high-quality dataset of 340 synthesis procedures and outcomes extracted manually from 178 scientific articles. From this dataset, we built a decision tree model that reinforces important experimental heuristics for the avoidance of phase impurities, but ultimately shows limited predictive capability. Under the assumption that this limited performance is due to hidden variables and the need for more data, we used the text-mined dataset to inform several experiments aimed at reproducing results from the literature as well as proposing new syntheses to explore under-represented regions of the synthesis condition space. In our investigation, we identify important features in controlling phase purity that are corroborated by known heuristics in the field, such as annealing temperature and Bi:Fe metal ratio, as well as other less frequently studied indicators, such as solution stirring temperature and precursor solution concentration. We also highlight the limitations of building predictive models for complex synthesis tasks based on text-mined data alone, which may often be due to the incompleteness of synthesis descriptions in the literature. Nevertheless, we show how such a dataset can be made useful by informing new controlled experiments and forming a better understanding for impurity phase formation in this complex oxide system.

A Predictive Approach to Quantify the Role of Entropy in Metal Plasticity from Atomistic Simulations Soumendu Bagchi and Danny Perez; Los Alamos National Laboratory, United States

Thermally activated dislocation events significantly govern yield characteristics, especially temperature and strain-rate dependence of yield strength in metal plasticity. Generally being difficult to quantify directly, the entropic contributions are often approximated with empirical compensation rules to inform the activation energetics associated with a wide-range of dislocation driven plastic events, e.g. slip nucleation, cross-slips, kink-pair nucleation/migration and twinning, to name a few. Despite their popular use in crystal plasticity models, several recent investigations demonstrate significant anomaly with both empirical as well as harmonic approximations when entropic effects dominate defect pathways. In this talk, I will introduce a computationally simple predictive approach to quantify the rates of dislocation mediated events aided by atomistic simulation data. To exhibit the significance of entropic contributions and the approach's potential impact, we discuss a key scenario concerning crystal plasticity i.e., the nucleation of dislocations from surface steps, where currently existing approximations dramatically fails to reproduce the nucleation rates observed in direct MD. By accurately quantifying the change in vibrational entropy along the minimum energy pathway, we elucidate the non-trivial effects of anharmonic kinetics which is otherwise intractable with the existing empirical and harmonic approaches ubiquitous in modeling materials.

11:30 AM MD02.05.10
Navigating Phase Diagram Complexity to Design More Efficient Solid-State Synthesis Recipes Jiadong Chen[1], Sam Cross[2], Lincoln Miara[2], Yan Eric Wang[2] and Wenhao Sun[1]; [1]University of Michigan, United States; [2]Samsung Research America, United States

An emerging goal in the *ab initio* materials design community is to predict efficient synthesis recipes to novel functional materials. Precursor selection plays a major role in designing effective recipes, as there are many examples where a reaction can work from one set of precursors but not another. Here, we present a conceptual strategy to navigate high-dimensional convex hulls in the search of reactive precursors for more-efficient materials syntheses. The overarching strategy is to determine pairs of precursors where the reaction to a target material has large driving force and few competing phases. Using a high-throughput robotic synthesis laboratory, we design novel precursors for a diverse set of 32 quaternary oxide materials, and show that our DFT-guided precursors are substantially better at synthesizing the target oxides than naïve traditional precursors. This enables us to guide precursor selection for solid-state synthesis using information that is largely-available in high-throughput materials databases like the Materials Project.

11:45 AM MD02.05.11
Fully Automated Nanoscale to Atomistic Structure from Theory and Spectroscopy Experiments Davis G. Unruh, Venkata Surya Chaitanya Kolluru and Maria K. Chan; Argonne National Laboratory, United States

Computational investigation into the structural and electronic properties of a material begins with knowledge of the underlying atomistic structure. When investigating novel or non-stoichiometric materials, various experimental spectroscopic techniques can be used to probe the material. However, moving from the spectra to the oxidation state and atomic configuration requires searching a vast structural space, where it is critical to not only match the experimental data but to also minimize quantities such as the energy to ensure structures are physically plausible and realizable. To address this need, we have previously developed the FANTASTX code, a multi-objective evolutionary algorithm which performs structure search for a variety of spectroscopies using genetic algorithm and basin-hopping methods. While FANTASTX has demonstrated success with few-atom systems, a significant challenge in extrapolating to more complex large-scale systems is the presence of near-duplicates within the search space and the significant computational expense of first-principles calculations on large-scale systems. To address these issues, we have extended FANTASTX to automatically incorporate on-the-fly machine learning methods, including both structural fingerprinting and graph neural network methods, to both identify and eliminate structural duplicates prior to processing and replace the use of density functional theory as the geometric relaxation and energy prediction mechanism.

Automatic Discovery of High-Performance Quantum Dot Thermoset Nanocomposites Ozgur Keles, Birsen Sirkeci and Folarin Erogbogbo; San Jose State University, United States

More than 65 million tons of thermosets are used annually. Ten percent of this is used for fiber reinforced composites. Thermosets have higher stiffness, strength, and fire resistance than thermoplastics, which make them suitable for transportation, defense, electronics, construction, consumer product, piping, adhesive, and other applications. In addition, fiber reinforced thermoset composites dominate structural applications that demand high strength-stiffness and low density. However, thermosets are brittle. For example, the common thermoset epoxy is as brittle as window glass. Many different fillers–graphene, clay, rubber–have been used to enhance the toughness of epoxies. Yet, poor bonding, agglomeration, voids, misalignment, and waviness limit their effectiveness. An alternative filler without these problems is the two-dimensional (2D) quantum dots (QDs), such as graphene QDs. In this talk, I will explain potential origins of enhanced toughness and thermal conductivity in QD thermosets. I will discuss how the unique properties of QDs, such as photoluminescence, can be used for future applications, such as structural carbon fiber composite batteries. Furthermore, concepts on artificially intelligent high-throughput automatic processing-structure-property exploration towards faster discovery of sustainable nanocomposites will be introduced.

2:00 PM MD02.06.02
Discovering All-Organic Flexible High-Temperature Polymer Dielectrics with Virtual Synthesis and Machine Learning Rishi Gurnani[1], Stuti Shukla[2], Deepak Kamal[1], Chao Wu[2], Chris Kuenneth[1], Yang Cao[2], Gregory Sotzing[2] and Rampi Ramprasad[1]; [1]Georgia Institute of Technology, United States; [2]University of Connecticut, United States

A record-setting new polymer dielectric that displays the highest-ever electrostatic energy density (8.9 J/cc) at 200 C has been designed using advanced AI algorithms, and subsequently validated through synthesis and breakdown testing. This new flexible, all-organic polymer, polyoxanorbornene-1 (PONB1), beats the current industry standard for high energy density capacitors--biaxially oriented polypropylene (which degrades rapidly above 25 C)--by a significant margin of 3.5 J/cc. Concurrent developments, also by us, in polymer informatics played a key role in the discovery of PONB1. These developments include an advanced deep learning framework that reduces the time required for polymer screening by more than 50 times compared to traditional approaches, and two algorithms for generating realistic but never-before-synthesized polymers. Our progress, especially in the development of algorithms for polymer generation and in the real-world validation of PONB1, was made possible by lively collaboration and iteration with experimental colleagues. Looking forward, the polyoxanorbornene family--which includes PONB1--expands the scope and effectiveness of capacitor-based energy storage, a technology that may ultimately power the world's electrification. Given the results of our work, it is likely that other valuable candidates exist in our massive data set of never-before-synthesized polymers for many applications. We offer this data set to the community, as well as the open source code for our advanced deep learning framework.

2:15 PM MD02.06.03
Improving Deep Neural Network in Predicting Electron Ionization Mass Spectra by Molecular Similarity-wise Sampling Ryohei Yamaguchi, Shigenori Takeda, Toshifumi Kakiuchi and Yutaka Imamura; AGC Co., Japan

Mass spectrometry is an indispensable analytical tool to identify molecular species. A target molecule is often determined by comparing the mass spectrum with known spectra stored in a database. This approach is useful for detecting known molecules, but not applicable for novel molecules. To solve this issue, a recent study proposed to add machine-learning predicted spectra into the database in order to increase chemical space covered by the database. This method is expected to extend applicability of the knowledge-based searching system, but the coverage of the system would be still restricted by the predictability of the machine-leaning model. In this study, we therefore modified the machine-learning model by training our own dataset in addition to the original open data of mass spectroscopy.

First, we tried to extend the novel approach by adding our own dataset of fluorinated molecules to the open database composed of more than 200 thousand molecules; however, the limited additional dataset much less than the huge original datasets was not enough to improve the predictability of the machine-learning model for fluorinated molecules. We therefore applied a simple but powerful dataset sampling scheme that downsamples the molecular datasets in terms of molecular similarity. The molecular similarity between molecules in own and open datasets was evaluated by Tanimoto method with Morgan fingerprints, then the datasets with reduced data with low similarity were used for training the machine-learning model as the downsampled dataset. Additionally, the datasets exhibiting bit collision due to the limitation of Extended-Connectivity-Fingerprints (ECFP4) in representing molecular structures were eliminated to improve the training performance. Consequently, the model trained with the reduced dataset was found to overperform the original model for predicting mass spectra of extra fluorinated molecules, which demonstrated that the strategic learning with appropriate downsampling can improve the performance of deep learning models, even though additional data is limited.

3:30 PM MD02.06.04
Computer Vision and Artificial Intelligence for Smart Additive Manufacturing Grace Gu; University of California, Berkeley, United States

Additive manufacturing (AM) has made huge strides in the past decades, enabling the fabrication of multiscale and multi-material designs previously deemed infeasible. As AM spreads to the fields of aerospace, automotive, and medical fields, part quality and reliability become increasingly important. Improper settings of process parameters can lead to imperfections in the part; small imperfections in one layer can propagate into the rest of the build. In this work, we present a real-time monitoring and autonomous correction system enabled by computer vision and machine learning to diagnose the quality of parts and modify 3D-printing parameters iteratively and adaptively in real-time. Sensor technologies embedded in our platform are used to capture images during the printing process to train a machine learning model. Precise localization and semantic segmentation detection algorithms are implemented to shed light on the evolution of defects during real-time printing, specifying a quality profile at each layer of the print. This advanced detection system is capable of providing defect information for quality assessment and has the potential for further automated control as well as correction of AM systems.

3:45 PM MD02.06.05
Understanding Alloy Microstructure During Additive Manufacturing Through Meso-Scale Modeling Indranil Roy[1], Ying Yang[1], Alex J. Plotkowski[1] and Shuanglin Chen[2]; [1]Oak Ridge National Laboratory, United States; [2]CompuTherm, United States

In the recent years, as the additively manufactured alloys are gaining popularity in vehicle technology, space sector, and manufacturing industry, the effect of fast cooling rate (compared to conventional casting) on the microstructure evolution of alloys require detailed study. The mechanical properties of alloys depend on the final microstructure and elemental segregation. Although the dendritic growth of the primary phase is well studied, the eutectic microstructure modeling, especially lamella type is not well established. As Aluminum based alloys is a promising candidate for commercial vehicle application, we have selected them as our prototype material. The lamella eutectic structure in Al-based alloys, e.g., Al-Ce, Al-Mg is also often observed. Therefore, we developed a cellular automaton (CA) based modeling tool that simulates dendritic-eutectic combined solidification of Al-based alloys. CALPHAD approach is used to initialize the input material property parameters for the solidification model. The modeled microstructure is compared to experimental micrographs obtained from controlled additively manufactured samples that show significant similarity. Using this approach, multiple Al alloys with varying element and composition are studied which provides important insight into the precipitation behaviors of such alloys that ultimately results in better understanding of mechanical properties.

4:00 PM MD02.06.06
AI-Powered *In Situ* X-Ray Characterization for Laser Metal Additive Manufacturing Process Sen Liu, Vivek Thampy, Peiyu Quan and Christopher Tassone; Stanford/SLAC, United States

Energy materials research, development, and production are facing huge challenges as the world's energy infrastructure is changing in favor of renewable energy. Additive manufacturing (AM) has shown its promise to change the way how future energy materials and systems can be designed and delivered, such as producing 3D functional energy structures, saving materials waste and energy, reducing production cycle and cost, and achieving extraordinary mechanical system compactness. In recent years, laser AM has been applied for metal-ceramic composite, turbine molds and cores, advanced battery electrode architectures, GE LEAP engine parts, aerospace brackets, lattice heat exchangers, and power electronics. However, manufacturing "printable" high-quality parts are inherently difficult due to the fast cooling rate of laser-induced melt-pool and multi-physics effects are poorly understood. Excessive costs and lengthy certification cycles have hindered the application of AM in many industrial sectors.
The recent explosion of artificial intelligence (AI) and machine learning (ML) shows great potential in the breakthrough of laser AM process modeling. The AI-based approaches are an indispensable step to derive the complex metal alloy composition-process-structure-property relationships. In this study, it will present the results of artificial intelligence (AI)-based methods to process real-time X-ray diffraction and radiography of Aluminum alloy printing during the laser AM process at synchrotron radiation lightsource. Aluminum alloys are key materials in additive manufacturing (AM) technologies due to their low density and high strength-weight ratio for structural function. However, printing densified and defects-free Al alloy faces many challenges because of their low laser absorption, high thermal conductivity and AM fast cooling rate; they are characterized as highly crack sensitive or poor printability. Inoculation treatment offers a chance to solve this problem, where the grain refining inoculants are mixed into molten metals and act as heterogeneous nucleation catalysts during crystallization. Grain refinement was achieved by the contribution of Al3Ti nuclei and their coherent interfaces. Equiaxed grains accommodate the solidification shrinkage allowing the production of crack-free samples. The high-speed X-ray diffraction extracts subsurface phase transition and cooling rates from melted to solidified track. The X-ray radiography reveals the pore formation mechanism and fluid dynamics during laser melting. The effects of processing parameters and constituted composition on the phase transition and molten pool characteristics are analyzed. The electron microscopy characterization shows pore defects reduction and fine equiaxed grains for nanoparticle-reinforced Al alloy.

4:15 PM MD02.06.07
Machine Learning of Borophene-Boride Hetero-Structures for Borophene Synthesis Luqing Wang[1,2], Qunfei Zhou[1,2], Qiucheng Li[1], Joshua Paul[1,2], Mark C. Hersam[1], Pierre T. Darancet[2] and Maria K. Chan[2]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Borophene, two-dimensional (2D) boron, exhibits versatile properties which may lead to a variety of environmental and energy applications, such as CO_2 reduction, hydrogen and oxygen evolution reactions, nitrogen fixation, superconductivity, and so on. Also as a synthesized 2D material without a bulk layered counterpart, borophene structure cannot be predicted from bulk boron, and has polymorphic phases. These structural characteristics not only enrich the diversity of available materials properties, but also are informative for the fundamental understanding of 2D crystal structures and boron chemistry. However, a big challenge in borophene field is synthesis. Though borophene has been synthesized on several metal substrates, the strong interaction between borophene and substrates limit the achievement of free-standing borophene. Recently, it was found that boride is formed through the reconstruction of the top metal layer mixed with boron during borophene synthesis on Al(111). Metal borides have the potential to be superior substrates, compared to metals, for borophene synthesis and separation. Here to search for good substrates for borophene synthesis, we firstly generate a dataset of approximately 100 borophene-boride hetero-structures by density functional theory (DFT) calculations, then perform machine learning (ML) to analyze the interaction in the hetero-structures based on binding energy and charge transfer. For ML, random forest algorithm is used and features are initially imported from Matminer. Furthermore, we use the ML model in a larger dataset of hypothetical borides structures to predict good substrates. This work allows us to explore alternative routes of borophene synthesis. Also it will advance the understanding of the bindings with boron and explain the mechanism of determinants for borophene synthesis. What is more, this work is promising to solve the major challenge in borophene field which is the isolation of borophene from the substrates.

4:30 PM MD02.06.08
AI/ML Guided Exploration of Electronic Polymer Thin Films for Manufacturing Henry Chan[1], Jie Xu[1], Chengshi Wang[1,2], Aikaterini Vriza[1] and Rohit Batra[1,3]; [1]Argonne National Laboratory, United States; [2]The MathWorks, Inc., United States; [3]IIT Madras, India

Electronic polymers are emerging as the materials for novel electronics that are flexible, wearable, and printable. To realize these applications, it is crucial to understand the processing-structure-property relationships of these polymers and derive suitable processes to manufacture them into high quality thin films at scale. This task is challenging due to the complex interplay between thin film processing steps such as solution formulation, rheology, and post-processing, and the many tunable parameters associated with these steps. With the advancements in data-driven approaches and experimental instrumentations, autonomous materials acceleration platforms driven by AI/ML is beginning to revolutionize the discovery of materials. Here, we introduce an example of such platforms developed at our facility and demonstrate its success in simultaneously handling many experimental processing parameters and optimizing the conductivity and processibility of electronic polymer thin films. We will also outline various challenges and prospects related to small data and digital twins that facilitates the integration across physics-based simulations, ML models, and experiments.

4:45 PM MD02.06.09
A Sensitivity Analysis for an Electron Transport System with Uncertainty in the Underlying the Material Parameters—A General Approach Applied to the Specific Case of Wurtzite Gallium Nitride Yanyan He[1], John Chilleri[2], Michael Shur[3], Robert Kirby[4] and Stephen K. O'Leary[5]; [1]University of North Texas, United States; [2]New Mexico Institute of Mining and Technology, United States; [3]Rensselaer Polytechnic Institute, United States; [4]The University of Utah, United States; [5]University of British Columbia, Canada

The electron transport that occurs within semiconductors is often studied through the use of Monte Carlo simulations. The results of such a simulation are critically dependent upon the underlying material parameters associated with the specific material being examined. For a compound semiconductor, the critical material parameters are the effective masses, the non-parabolicity constants, the deformation potential, the phonon energies, and the elastic constants. It is often the case that many of these material parameters are not very well known or have a range of different reported values. In this study, we employ an uncertainty quantification technique that allows us to determine the effect of the uncertainty of the underlying material parameter values on the computed transport properties through the use of a Monte Carlo simulation approach. In order to make matters concrete, this technique is applied to the specific case of wurtzite gallium nitride, a material whose material properties remain less well known than that of the more traditional compound semiconductors, such as gallium arsenide. The broader consequences of this approach, for the constellation of compound semiconductor materials, is considered.

5:00 PM MD02.07.01
Automated Defect Analysis of CdSe Nanoparticles through Supervised Learning with Large Simulated Databases Corey H. Williams, Luis E. Rangel DaCosta, Mary Scott and Tofunmi Ogunfunmi; UC Berkeley, United States

In the development of advanced functional nanomaterials, knowledge of the precise atomic structure and its relationship to functional characteristics of a material can rapidly accelerate the design of new material systems. Transmission electron microscopy (TEM), in conjunction with machine learning tools for automated analysis, is a powerful platform for providing atomic-scale characterization of next-generation materials like nanoparticles for large sample populations. CdSe nanoparticles, a highly tunable quantum dot system, are attractive functional nanoparticles due to their broad range of photoemission over a small range of sizes and established synthesis protocols. However, it is yet unclear as to the precise role planar defects, like stacking faults, play in quantum dot synthesis, growth, and functional performance.

In this work, we reveal the relationship between defect density and functional performance in CdSe quantum dot systems with high-resolution transmission electron microscopy (HRTEM) and machine learning. We use large, simulated HRTEM image databases of CdSe to train high-accuracy neural networks with supervised learning techniques to measure the morphology and defect statistics of CdSe nanoparticles at the atomic- scale, providing a direct measurement of the joint distribution between quantum dot morphology and defect characteristics. Through supervised learning techniques with ground-truth simulated databases, we can automatically detect and count stacking faults in CdSe quantum dots. Access to ground-truth data also allows us to develop methods for predicting and measuring sources of uncertainty and error related to systematic sources of error such as nanoparticle misorientation. Atomic structure measurements are linked back to population-wide functional behavior through UV-Vis spectroscopy. Our techniques point towards robust workflows for high-throughput, atomic-scale characterization of advanced nanomaterial systems using HRTEM via neural network analysis and provide a route for high-accuracy defect analysis in nanoparticle systems.

5:00 PM MD02.07.02
STEM Image Analysis Based on Deep Learning—Identification of Vacancy of Defects and Polymorphs of MoS_2 Kihyun Lee, Jinsub Park, Soyeon Choi and Kwanpyo Kim; Yonsei University, Korea (the Republic of)

Identifying structural features in scanning transmission electron microscope (STEM) images of crystalline materials is important in studying structure-property correlations, but traditional methods for identification are often time-consuming and require expertise. Recent advances in deep learning for computer vision, in particular the use of convolutional neural networks (CNNs), holds promise for efficient high-throughput STEM image analysis. Here we investigate the generalizability of CNNs in identifying point defects and polymorphs in STEM images of transition metal dichalcogenides (TMDCs) in the presence of different levels of noise and aberrations. We focus on the application of ResUNet, a type of fully convolutional neural network, in identifying sulfur vacancies and different polymorphs of molybdenum disulfide(MoS_2). Based on these results, we provide a guideline on best practices to train a deep learning model to identify structural features of interest in STEM images.

5:00 PM MD02.07.03
Beyond Single Molecules: Intermolecular Interference Effects Louise Hyllested and Gemma C. Solomon; University of Copehagen, Denmark

Molecular electronics is a field that has been widely investigated over the last 25 years. Previously molecules have been found to function as rectifiers, diodes, and switches.[1][2][3] These have been observed in single molecules and self-assembled monolayers of molecules. One other interesting feature of some organic molecules is destructive quantum interference (DQI).[4] When DQI is present, a molecule will suppress the current across the junction, acting as an insulator. One challenge here is that the most common indication of DQI in experiments is low current, but this is also an indication of e.g., a weak connection to the electrodes. Therefore, we are interested in observing a more direct signatures, for example a sharp dip in the differential conductance, but this has of now only been observed for monolayers. Since the indirect indication of DQI has been observed for single molecules, while the direct signature (the sharp dip) has not – it must be that the step from single molecules to monolayers is not destroying DQI but for some reason making it more readily observable.

We have investigated the influence intermolecular interactions have on DQI effects for a group of conjugated and cross-conjugated molecules using density functional theory. We observe that intermolecular interactions can shift the energy of interference features. In the cases we considered, transitioning from a single molecule to a monolayer the interference feature is moved closer to the Fermi energy, thus making the DQI more pronounced and easier to observe for monolayers compared with single molecules.

If we can understand how and when DQI effects occur in monolayers, we take a step towards designing molecular materials with DQI effects for electronics applications such as large on/off switching, highly insulating materials, or dielectric materials.

5:00 PM MD02.07.04
Insight into the Reactivity of Electrocatalytic Glycerol Oxidation—The Strength of the Hydroxyl Group Bonding on Surface Minseon Park[1], Jeemin Hwang[2], Song Jin[3,4], Daehee Jang[1], Hyung Ju Kim[5], Won Bae Kim[1] and Min Ho Seo[6]; [1]Postech, Korea (the Republic of); [2]Korea Instutitute of Energy Research, Korea (the Republic of); [3]Gwangju Institute of Science and Technology, Korea (the Republic of); [4]Korea Institute of Materials Science, Korea (the Republic of); [5]Korea institute of Chemical Technology, Korea (the Republic of); [6]Pukyong National University, Korea (the Republic of)

Glycerol is a main byproduct originating from the transesterification process of vegetable oils and animal fat into biodiesel. The production of glycerol byproduct has become greater than the demand as the biodiesel production has increased. Its oversupply has significantly lowered the market price. Therefore, research on electrocatalytic glycerol oxidation reaction (EGOR) has been highlighted recently since it can generate both electricity and valuable chemicals. Glycerol can be used not only as fuel in direct alcohol fuel cells but also as reactants to produce valuable chemicals like dihydroxyacetone, glyceric acid, glycolic acid, and formic acid. However, it is not fully unknown for the reaction pathway on various catalysts due to the complexity of reaction intermediates. Most of the research focused on finding the mechanism for which desired target substance is produced. However, this work is done to comprehend a key mechanism that not only determines glycerol oxidation having various pathways but also might relate to the selectivity of each intermediate in oxidizing process. What to find the main descriptor that affects the glycerol electro-oxidation would be worthy for further design of the electrocatalyst. Combination studies of *ab-initio* computations and experiments to find the represent descriptor that affect the glycerol electro-oxidation was performed. The adsorption energies of OH and hydroxyl group in the glycerol at the catalyst surface were compared with calculating binding energies and a crystal orbital Hamilton population (COHP) analysis. As a result, the binding energy of OH and that between the hydroxyl group in glycerol and the catalyst surface were proposed as key descriptors to control the glycerol oxidation reaction in PtCu surface model. Both OH and hydroxyl group of the glycerol molecule were most strongly bound on the $PtCu_3$ surface. The alloy catalyst of Pt and Cu supported on porous carbon was used to support this data. (Pt/PC, Pt_3Cu/PC, PtCu/PC, and $PtCu_3$/PC) The mass activity of the glycerol oxidation experiment showed the same tendency as the result of the calculation, that the $PtCu_3$/PC sample showed the highest mass activity among other catalysts. Therefore, the stronger OH binds on the surface, the higher the reactivity of the glycerol oxidation. This study identified that the binding energy of OH on the catalyst surface is the key descriptor in the glycerol oxidation reaction. This is expected to be helpful in predicting and analyzing the reactivity of glycerol as well as various alcohol-based molecules. This research will pave the way for the design and development of future catalysts to produce value-added chemicals for electrocatalytic glycerol conversion reactions.

5:00 PM MD02.07.05
Ripplocation Boundaries and Kink Boundaries in Layered Solids Kaustubh Sudhakar and Michel Barsoum; Drexel University, United States

Ripplocations - best defined as an atomic scale ripple and characterized by oppositely signed ripplocation boundaries (RBs) – have recently been shown to be the underlying mechanism responsible for buckling in layered crystalline solids (LCS) such as graphite, mica, and the MAX phases. The malefactor for the deformation of LCS for more than half a century has been basal dislocations (BDs) which manifest themselves into kink boundaries (KBs) at high stresses. Since the inception of ripplocations, much work has gone into deciphering the fundamental deformation mechanism of LCS, and other layered systems such as steel sheets and playing cards. To develop a thorough understanding of the phenomena, we collected data via retrospective analysis of the literature on RBs and KBs that was carried out to date. Furthermore, to support this study we also provide new molecular dynamics (MD) data to analyze the deformation behavior in graphite through bending tests to substantiate our hypothesis. Based on this work, it is evident that KBs and RBs are distinctive in many ways; i) RBs are reversible in nature in that the system can return to its original state after deformation while KB formation only occurs when the material has been plastically deformed, ii) Atomical observations show that RBs have rounded edges as opposed to the sharp, pointy edges seen in KBs, iii) RBs are associated with high stresses at their surface which is absent in the case of KBs, and lastly iv) At extreme strains, RBs transform into KBs. By employing several - mostly past – and present investigations we intend to fundamentally unravel the differences between these atomic boundaries occurring in layered systems. The consequences of this study will help elucidate the deformation mechanics of layered systems in tens of orders of magnitudes, from the nanoscale to the geological scale.

5:00 PM MD02.07.06
Data-Driven Electrode Optimization for Vanadium Redox Flow Battery by Reduced Order Model Chao Zeng, Soowhan Kim, Edwin Thomsen, Yucheng Fu, Yunxiang Chen, Jie Bao and Zhijie Xu; Pacific Northwest National Lab, United States

The vanadium redox flow batteries are a promising energy storage technology for stationary applications (e.g., renewables integration) that offer a pathway to cost-effectiveness through independent scaling of power and energy as well as longevity. However, the flow non-uniformity and high pumping loss in cell reduce system efficiency and increase resistance. Many current research efforts are devoted to optimizing electrode configuration and screening electrode materials for flow uniformity and higher system efficiency. Current high-throughput laboratory-scale testing is time and material intensive for this purpose. An integrated experimental and numerical method are proposed to accelerate the optimization of electrode material and structure. Current state-of-art 780 cm2 interdigitated flow cell is paradigm for further optimization. Reduced order model is developed based on equivalent circuit model to represent full 3D model and is validated with experimental results. The reduced 2D model can significantly reduce computational cost and create large datasets for optimization. Based on the large datasets, statistical optimization is used to search for optimal combination of electrode dimension and properties. This date-driven method and statistical framework may serve as a general guideline for structure optimization and material screening for redox flow battery stacks.

5:00 PM MD02.07.07
Application of Baysian Super Resolution to Spectroscopic Data Analysis Shunta Harada[1], Kota Tsujimori[1] and Jun Hirotani[2]; [1]Nagoya Univ, Japan; [2]Kyoto University, Japan

The number of data points of digitally recorded spectra have been limited by the number of multi-channel detectors employed, which sometimes inhibits the precise characterization of spectral peak shape. Here we describe a methodology to increase the number of data points as well as the signal-to-noise (S/N) ratio by applying Bayesian super-resolution in the analysis of spectroscopic data. In our present method, first the hyperparameters for the Bayesian super-resolution are determined by a virtual experiment imitating actual experimental data, and the precision of the super-resolution reconstruction is confirmed by the calculation of errors from the ideal values. For validation of the super-resolution reconstruction of spectroscopic data, we applied this method to the analysis of Raman spectra. From 200 Raman spectra of a reference Si substrate with a data interval of about 0.8 cm^{-1}, superresolution reconstruction with a data interval of 0.01 cm^{-1} was successfully achieved with the promised precision. From the super-resolution spectrum, the Raman scattering peak of the reference Si substrate was estimated as 520.55 (+0.12, -0.09) cm^{-1}, which is comparable to the precisely determined value reported in previous works. The present methodology can be applied to various kinds of spectroscopic analysis, leading to increased precision in the analysis of spectroscopic data and the ability to detect slight differences in spectral peak positions and shapes. So far, we have already confirmed that the present method is effective not only to Raman spectroscopy but also to electron energy loss spectroscopy (EELS), X-ray photoelectron spectroscopy and the electric signals.

5:00 PM MD02.07.08
A Workflow to Track Time-Resolved Dislocation Behavior in High Temperature Aluminum Holland Stacey, Naomi G. Mo, Lichao Fang and Leora E. Dresselhaus-Marais; Stanford University, United States

Studying dislocation behavior furthers our understanding of their effects on the mechanical, thermal, and electronic properties of materials. Previous observation-based research on dislocation motion has primarily been conducted with TEM and thus typically concerns dislocations near or at the surface (< 2 µm thick foils). While models for subsurface dislocation movement exist, many of these models have yet to be validated by experiments with comparable samples. Dark-Field X-Ray Microscopy (DFXM) is a new technique developed in the last decade to study subsurface dislocations. We use DFXM to track deep subsurface dislocations approximately 200 µm beneath the surface of single crystalline FCC aluminum at 96% of the melting temperature. In this work, we present a 5-step workflow to automatically track time-resolved dislocation movement in DFXM scans, including a Stationary Wavelet Transform (SWT) approach, convolution kernels, adaptive thresholding, structuring elements, and an image segmentation tool. This workflow allows us to identify and quantify the position of dislocations in DFXM images over time, paving the way to discovering more about dislocation dynamics at tri-junctions.

5:00 PM MD02.07.09
Investigation of Solidification in Supercooled Water Drops using Large Data Sets of Synchronized Optical Images and X-ray Diffraction Patterns Claudiu A. Stan[1,2], Armin Kalita[1], Maximillian Mrozek-McCourt[1], Thomas Kaldawi[1], Philip Willmott[3,2], N. Duane Loh[2], Sebastian Marte[1], Raymond Sierra[2], Hartawan Laksmono[2], Jason Koglin[2], Matt Hayes[2], Robert Paul[2], Serge Guillet[2], Andrew Aquila[2], Mengning Liang[2] and Sébastien Boutet[2]; [1]Rutgers, The State University of New Jersey, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Paul Scherrer Institute, Switzerland

The freezing of supercooled water drops is a complex example of rapid nonequilibrium solidification that includes dendritic crystal growth, changes in volume leading to mechanical deformation and fracture, and the formation of metastable crystal phases. It is also an important natural phenomenon that occurs in clouds and can trigger precipitation.

We investigated the freezing of water drops cooled by evaporation in vacuum. We imaged optically the freezing drops at high magnification with short light exposures, and we probed them simultaneously with ultrashort X-ray laser pulses. This approach provided a snapshot of a drop's state at both the micron scale and at the molecular scale, and had the temporal resolution needed to resolve a freezing process that is completed in approximately one millisecond. Since the X-ray lasers are pulsed and have sufficient energy to damage the drops, only one multiscale data point can be collected from a drop.

A major challenge in investigating a spontaneously freezing system with high resolution is the randomness of nucleation. Our experiment reduced greatly the range of nucleation times by using very rapid cooling, but even so the spread of nucleation times was comparable with the duration of solidification, and the nucleation statistics averaged the details of the freezing dynamics. We therefore collected large data sets of drops freezing at several average time delays, which each set containing a distribution of drops at different elapsed times after ice nucleation. The data contains more than 10000 simultaneous optical and X-ray measurements from single drops, and additional optical data from more than 40000 drops. At each average time delay, we had available thousands of data points to measure the distribution of the stages of freezing that could be observed experimentally.

Seven distinct stages of freezing were identifiable from the optical images, from supercooled liquid drops to drops that shattered due to the strain accumulated during solidification. We developed a kinetic model of freezing based on these stages, and we determined all the model properties (nucleation rate, stage durations, probability of shattering, etc.) though a complex fitting procedure that used the experimental distributions of freezing stages.

Using the optical images and the seven-stage freezing model, we sorted the X-ray diffraction data by the time elapsed from nucleation. Sorting improved substantially the temporal resolution of diffraction, and the resolution was sufficient to observe the increase in the intensity of high-index diffraction peaks, which indicated that long-range crystalline order in ice was largely formed in approximately one millisecond. The diffraction patterns also showed that during the first millisecond after freezing the ice had a hexagonal crystal structure with inhomogeneous strain and a grain size on the order of 100 nm.

Characterizing Dislocations by formulating the Invisibility Criterion for DFXM Dayeeta Pal and Leora E. Dresselhaus-Marais; Stanford University, United States

The motion and long-range interactions of dislocations are essential to understand the mechanical, electronic and thermal properties of materials, but their dynamics are difficult to measure. While transmission electron microscopy (TEM) has imaged dislocations for half a century, its limited field of view and sample thickness requirements may not be representative of bulk phenomena. To understand the “stochastic” dislocation dynamics in bulk crystals that govern their properties and dynamics, Dark Field X-ray Microscope (DFXM) has been developed to image deep subsurface dislocations. By imaging along an X-ray diffracted beam with an objective lens, DFXM images lattice distortions hundreds of micrometers beneath the surface of crystalline materials – mapping hierarchical structures of dislocations. While today’s DFXM can effectively map the line vector of dislocations, it still cannot quantify the Burgers vector required to understand dislocation interactions, structures, and energies. Our study formulates a theoretical model to establish the theory behind how DFXM images map information to deduce the Burgers vector of dislocations. By revisiting the “invisibility criteria” from TEM theory, we re-solve this formalism and extend it to the ray-optics models developed for DFXM in order to evaluate how the images acquired from different scans about a single {hkl} diffraction peak encode the Burgers vector within them. This work advances our understanding of DFXM to establish its capabilities to connect *bulk* experiments to dislocation theory and mechanics.

Optical Property Database of Inorganic Phosphor Seunghun Jang, Gyoung S. Na and Hyunju Chang; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Developing inorganic phosphor with desired properties has relied on time-consuming and labor-intensive material development processes. Moreover, the results of material development experiments depend significantly on the intuitions and experiences of each researcher. For efficient and reliable materials discovery, machine learning has been widely applied to various scientific applications in materials science. However, the prediction capabilities of machine learning methods fundamentally depend on the quality of the training datasets. In this work, we constructed a high-quality and reliable database that contains experimentally validated inorganic phosphors and their optical properties for data-driven research on inorganic phosphors. Our database includes 3,432 combinations of 27 dopant elements in 2,231 host materials. The database provides material information, optical properties, measurement conditions for inorganic phosphors, and metainformation. For the validation of the collected database, we preliminarily performed machine learning on the database and evaluated the prediction results.

5:00 PM MD02.07.12
Numerical Investigation of Using Mechanical Metamaterial as a Broadband Microwave Absorber Daniel D. Lim[1], Sangryun Lee[2], Jeong-ho Lee[1], Wonjoon Choi[3] and Grace Gu[1]; [1]University of California, Berkeley, United States; [2]Ewha Womans University, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

A porous structure composed of lossy materials enables advanced microwave absorption compared with non-porous material owing to its improved impedance matching and multiple internal reflection. Optimizing the internal geometry of lossy material-based porous structures leads to the active control of microwave absorption for desired target operating ranges while the mechanical strength and stiffness can be secured for practical applications. It has been shown that introducing porous, strong, and stiff mechanical metamaterial with a low density as a microwave absorber has a high potential to create a new kind of broadband absorber satisfying both the electromagnetic and mechanical requirements. So far, empirical approaches were employed to investigate the wave absorption characteristic of materials.There is currently a lack of understanding of the underlying physics of geometric features such as lattice structure, volume fraction, or unit cell length. Furthermore, there are challenges in exploring myriad input variables and visualizing the electromagnetic fields interacting with the structure.
Here, we investigate the effect of the geometric feature of the mechanical metamaterial on microwave absorption, using the microwave simulation using finite element analysis. By varying geometric features such as volume fraction, unit cell length, and lattice type of different mechanical metamaterials (octet-truss, body-centered cubic, cubic foam, and octet foam), we define different absorption mechanisms depending on the structural adjustments. The central finding is that low-density unit-cell (5-20% relative density) absorbs microwaves better than high-density structure, because microwaves going through more porous material enables impedance matching and improved internal multiple scattering effects. When the thickness of the whole structures is varied by changing the unit cell length of the mechanical metamaterial, different lattice structures show a similar response regardless of the lattice types at the subwavelength scale. Meanwhile, when the size of the total thickness of the structure is larger than the incident wavelength, it results in major variance in absorbance with different mechanisms based on the lattice type. Lastly, broadband microwave response (4-18 GHz) under the fixed unit cell length is examined to elucidate different microwave absorption mechanisms depending on lattice structures such as strut-based and facet-based geometries. This work can pave the way for expanding mechanical metamaterial as a broadband microwave absorber by defining the correlation between the geometric feature to the microwave absorption.

5:00 PM MD02.07.13
Determination of Contact Models for AFM Nanoindentation Without Tip Shape Knowledge by Machine Learning Linh T. Nguyen and Bernard H. Liu; National Cheng Kung University, Taiwan

Atomic force microscopy (AFM)-based nanoindentation provides local nanomechanical measurements of materials by acquisition and analysis of force-displacement (FZ) curves. However, the calculated nanomechanical properties usually contain uncertainty due to the use of contact model corresponding to the AFM tip shape and the nature of the tip-sample interactions. Therefore, the present study proposes a machine learning (ML) classification framework to suggest the appropriate contact model based on features of the FZ curves, and the information of tip shape is not required. The ML framework is performed using multiple ML classifiers and contact models; both balanced and imbalanced datasets are applied.
The testing results indicates that the quadratic discriminant analysis (QDA) classifier trained using both balanced and imbalanced datasets, provides the best predictive quality. In the balanced learning task, the ML classifier is trained and tested using more than 5000 sets of FZ curves of homogeneous materials, i.e., polydimethylsiloxane (PDMS), polymethyl methacrylate (PMMA), polyvinyl alcohol (PVA), and gold (Au). The practical feasibility of the proposed ML framework is examined by processing more than 200 sets of unseen FZ curves of a heterogeneous material, i.e., *Staphylococcus aureus* (*S. aureus*) bacteria. The QDA classifier outputs the use of the SND contact model with a testing accuracy of above 95.0%. In the imbalanced learning task, the ML classifier is trained and tested using several thousands of FZ curves of PDMS, PMMA, PVA, Au, *S. aureus*, and methyl-ammonium lead iodide perovskite ($MAPbI_3$). The QDA classifier suggests the use of the SND contact model with a testing accuracy of above 90.0% for each set of unseen FZ curves (~700 curves/set) of *S. aureus* and $MAPbI_3$, respectively. The results show that ML is an efficient approach to not only reduce the uncertainty

remain in the AFM measurements, but also speed up AFM data analysis.

5:00 PM MD02.07.14
Predicting Elastic Modulus of Materials without AFM Tip Shape Parameters and Contact Model Fitting Linh T. Nguyen and Bernard H. Liu; National Cheng Kung University, Taiwan

Atomic force microscopy is a commonly used technique to characterize the nanomechanical properties of materials. In this technique, the elastic modulus of a material is calculated by fitting an appropriate contact model into the force curve. However, the contact model fitting is a challenging task since such practical paramtertes of AFM tip are difficult to determine. Hence, the present study develops a machine learning (ML) regression framework to determine the elastic modulus of materials based on the force-displacement (FZ) features, without the need for both knowledges of tip parameters and process of contact-model fitting.
In the ML framework, FZ features are extracted and implemented into the ML regressor, which learns the relationship between these features and the corresponding elastic modulus values, and then outputs the modulus values for the unseen data based on the these FZ features. The robustness of the ML framework is examined using two groups of materials with elastic modulus spanning several orders of magnitude (from kPa to GPa): (1) homogeneous materials including polydimethylsiloxane, polymethyl methacrylate, and polyvinyl alcohol and (2) heterogeneous materials including *Staphylococcus aureus* and methylammonium lead iodide. The results show that, for all considered materials, Gaussian process regression (GPR) outperforms other ML regressors, i.e., random forest, support vector regression, and multiple linear regression (MLR). Specifically, the GPR model achieves a high testing coefficient of determination value, R^2, above 90% and 80.0% for homogeneous and heterogeneous materials, respectively. By contrast, the MLR model shows the worst prediction performance with an R^2 value of up to 50.0% and 35.0%, respectively. Overall, ML is a promising approach for calculating the nanomechanical properties of materials based solely on FZ features.

5:00 PM MD02.07.15
Optimization of Atmospheric Plasma Treatment Parameters for Hydrophilic Surface Functionalization of Non-Woven Fabrics Through Design of Experiment MiJeong Park[1], Hee Yeon Jeon[1], Jeong Hyun Kim[1], Dong Hoon Lee[1] and Young-In Lee[1,2]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]The Institute of Powder Technology, Korea (the Republic of)

The use of hydrophilic polymers is a promising technology in various application fields such as filters and oil-water separation membranes, but it is difficult to directly utilize them due to problems such as a very small number and low mechanical properties. Accordingly, various attempts have been made to modify the surface of the non-hydrophilic material to be hydrophilic. The plasma treatment method in which activated ions collide with the surface to be modified by supplying energy to the gas has the advantage of being able to modify the surface easily and simply without major damage to the surface of the polymer. Among them, atmospheric pressure plasma is attracting attention in that it can perform surface modification with only a plasma source and a substrate without a special device such as a vacuum system or solvent treatment. It is well known that the surface of the non-hydrophilic polymer is modified to be hydrophilic when plasma treatment is performed using a specific gas on the polymer surface, but the effect of each process variable and the optimized conditions are not discussed in detail.
Although the nonwoven fabric treated with atmospheric pressure plasma parameters as described above has many advantages, it has a problem, named the aging effect, in that the hydrophilic effect rapidly decreases over time. The aging effect is a phenomenon that occurs due to the characteristic that the reactors formed by plasma treatment return to their original state over time. Many studies have introduced various physicochemical methods in the plasma treatment process to solve this problem, when optimizing for improved conditions, a large problem arises in that a lot of time is additionally required because the effect over time for each condition must be reflected. Therefore, we propose a post-treatment method that uses the "design of experiment" to find the factor that has the greatest influence on the aging effect and reduces the decrease in the hydrophilic performance of the nonwoven fabric while maintaining the first optimized condition.
Design of Experiments (DoE) is a statistical technique for quickly optimizing the performance of experimental results using input process variables. By analyzing the results of the DoE experiment, it is possible to find out which factors have a statistically significant effect on the results, how and which factors are interdependent, and finally, the experimental conditions can be optimized for the purpose of the experiment. A process capability index is a tool for determining whether the results of a set of process results meet a specific quality. Experimental results conducted with optimized process variables can be statistically verified by confirming process consistency and process yield through process capability analysis.
In this study, a chain of experimental procedures based on various parameter combinations was performed using the DoE method, and the main factors that had the largest influence were found by quantifying the effect of each process variable of plasma treatment. In addition, based on the results, multiple regression analysis was used to optimize the experimental parameters under the conditions of maximizing the hydrophilicity of the polymer surface, and the excellence of the optimized conditions was shown statistically and physicochemically through process capability analysis and surface analysis. Finally, to evaluate the effect of reducing the effect over time, the estimation of hydrophilicity ability over time was also conducted. A series of experiments and analysis procedures were characterized by Minitab 20 software, X-ray photoelectron spectroscopy (XPS), Atomic Force Microscope (AFM), and contact angle analyzer.

Machine-Learning Interatomic Potential for Silicon Carbide: A Molecular Dynamics Study of Mechanical Properties Kenji Nishimura[1] and Ken-ichi Saitoh[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Kansai University, Japan

Silicon carbide (SiC) is a promising candidate for next-generation power electronics materials because of its superior electrical properties. However, SiC is a brittle material at low temperatures and is known to be a hard-to-work material. Thus, ductile mode machining, which yields a highly efficient and smooth machined surface, has been developed over several decades. To grind brittle materials in ductile mode, a basic understanding of the material's mechanical properties is necessary, that is, mechanisms of plastic deformation, phase transformation, and crystal defect formation. Specifically, since electronic materials require precise processing, mechanical phenomena occurring at the nanoscale should be focused on.
Quantum electronic structure calculations are highly accurate, but due to its high calculation cost, the computational scale is often limited to hundreds of atoms. That is why it is difficult to elucidate the mechanical properties including nanoscale phenomena at an atomistic point of view by means of first-principles calculations. Recently, some types of machine-learning interatomic potentials (ML-IAPs) have been proposed, which can reproduce the results of the first-principles calculations adequately without any empirical information or data, and have been applied to molecular dynamics (MD) simulations. It is expected for ML-IAPs to analyze crystalline defects in large systems with the same accuracy as the first-principles calculations.
In this study, we attempt to create a spectral neighbor analysis potential (SNAP) for SiC from reference data obtained by the first-principles calculations. The SNAP proposed by Thompson et al as one of ML-IAPs adopts bispectrum components as descriptors to express the energy of the atomic system. Then the SNAP potential for SiC we built is applied to MD simulations to examine its reproducibility. As a result, the SNAP potential developed in this study reproduces a lattice constant, elastic modulus, and bulk modulus with higher accuracy than any other empirical ones. We confirm that stable edge dislocation cores are generated as a dislocation dipole in crystalline 3C-SiC and they properly glide in a predicted slip plane. Additionally, the Peierls stress estimated by our MD simulations agrees well with that of the previous study.

5:00 PM MD02.07.18
Machine Learning for Predicting Emulsion Stability in Agrichemical Formulations Ryan Marson, Chris Roth, Wanglin Yu and Michael Tate; Dow, United States

Crop protection is a multi-million-dollar industry requiring complex formulations of multiple surfactants in a solvent, which must form stable emulsions prior to being dispersed. We outline a joint computational and experimental study undertaken within Dow to predict the stability of a given formulation. Data from thousands of high-throughput formulation experiments were compiled and analyzed for emulsion stability. This experimental data set was then used in combination with physical and chemical descriptors of the formulation components to train an ensemble of cluster-based machine learning models (e.g., Decision Trees, k-means, etc.) to predict whether a given formulation would be stable, some of which demonstrated cross-validation accuracies as high as 75%. We outline the details of this effort and discuss opportunities for continuous improvement of the models.

5:00 PM MD02.07.20
In-Situ Analysis of Convoluted Data at Large-Scale Facilitates Trygve M. Ræder; Technical University of Denmark, Denmark

Advances to electron microscopes and X-ray facilities have enabled tremendous leaps in the quality of experimental data over the past decades. This has lead to the development of experimental configurations and techniques that were not possible even five or ten years ago. Simultaneously, improvements in informatics and detectors have dramatically increased the rate of data acquisition. Data processing has in many cases become more challenging due to increased experimental complexity and data throughput despite advances to data quality. In particular, the challenge arises when using novel experimental configurations, as is often the case at X-ray free electron lasers. Successful execution and optimization of the experiment is frequently contingent on in-situ data analysis, and data-processing often becomes a bottleneck for the experiment as a whole. Most critically, as the number of collaborators grows with experimental complexity, the programming knowledge often does not scale in a similar fashion.

This poster will detail our approach to automating data analysis in-situ during an ongoing experiment. We have found that automatic and semi-automatic data processing have enabled faster feedback to guide experiments during an ongoing beamtime at X-ray free electron facilities, and empowered more team members to access convoluted results in an approachable manner. Automated data analysis also reduces the overall workload of the beamtime, allowing for more rest between shifts and less exhaustion. We believe our approach is generally applicable to electron microscopes and scanning probe microscopy in addition to X-ray science.

Towards Automatic Characterization of Nano-Energetic Material Response to Directed Energy Camden I. Boyle[1], Timothy Gaines[1], Alex Hurt[1], James Keller[1], Grant Scott[1], Stanton R. Price[2] and Matthew I. Maschmann[1]; [1]University of Missouri–Columbia, United States; [2]U.S. Army Research and Development Center, United States

Aluminum nanoparticles (Al-NPs) have garnered interest from researchers due to their low cost, naturally occurring passivating aluminum-oxide shell, and high energy density. The passivating oxide shell limits the achievable rate of reaction, thus restricting the possible applications for this material. Various proposed reaction mechanisms describe the escape of aluminum from the passivation shell. The first and most common is thermally driven diffusion which describes when a cluster of particles is irradiated, the temperature increase causes particles near sinter together. The melt dispersion mechanism proposes that volumetric expansion during rapid heating overcomes the yield stress of the shell, leading to shell rupture and spallation of the particle. Melt dispersion remains largely unobserved experimentally, and therefore not fully understood. However, if this mechanism was well understood and triggerable, the application space for aluminum nanoparticles would expand significantly.
To better understand these reaction mechanisms, single particle experimentation has been performed using targeted photothermal heating with a custom optical microscope setup equipped with a microscope camera, piezoelectric nano positioner, and diode laser. Experiments have been performed by irradiating particles or particle clusters while capturing optical and SEM images before and after irradiation. However, because particle composition, particle diameter, heating rate, and packing density are all contributing factors to reaction outcomes, the parameter space has become overwhelmingly large to explore using traditional experimental techniques. To combat this, automation has been employed to accelerate the experimental throughput allowing for more efficient and effective exploration of this parameter space. Automation was achieved by coordinating the microscope setup using a control computer and API calls to carry out experimentation without the need for human intervention. Likewise, computer vision techniques have been used to measure distinctive features from images captured before and after directed energy excitation of nanoenergetic particles. These features are used to describe the reactions in the pursuit of creating an automated nanoenergetic material reaction characterization model. Combined, these endeavors can autonomously collect and analyze experimental data to better inform researchers and physical models.

Optimizing Biomimetic Cellular Structures Inspired by the Sea Glass Sponge Using a Surrogate Model and Multi-Jet Fusion Printing Ailin Chen, Sangryun Lee and Grace Gu; University of California, Berkeley, United States

Architected cellular structures have great significance in the biomedical industry because, when compared to completely dense metallic implants, orthopedic prostheses with a porous structure can provide better stress shielding and osseointegration. The considerable skeletal structure observed in the sea glass sponge demonstrates great yield strength and buckling resistibility during compressive testing. This structure's biomimetization gives cutting-edge inspiration for lightweight constructions with superior compression characteristics. However, finding, fabricating, and testing the best design in conventional ways, on the other hand, is both costly and inefficient. In our study, we trained a neural network using massive datasets produced from finite element analysis (FEA) and achieved a coefficient of determination over 94% on relative density and von mise stress prediction. The FEA model is validated by experiments, and the specimens are printed using the Multi-jet Fusion (MJF). It is a novel additive manufacturing process for the powder bed fusion of thermoplastic polymers. Next, an active deep learning-based optimization technique is used to investigate the best spacing between the diagonal lines and the frames in the sponge structure. Later, the optimized structure will be applied to the close cellular structure and tested for its mechanical properties improvement. This study takes advantage of the performance and power of computer algorithms and additive manufacturing processes to discover optimal biological designs in structural applications and broaden the spectrum of materials available.

5:00 PM MD02.07.24
Multiscale Mechanisms of Twisted Carbon Nanotube Yarns Probed *In Situ* by Soft X-Rays During Tensile Loading Philip M. Jean-Remy[1], Daniel Malone[1], Adam Golder[2], Alexander Schwartz[1], Cheng Wang[2], Eric R. Meshot[1] and Xavier Lepro Chavez[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Advanced Light Source, United States

Resonant soft x-ray scattering (R-SoXS) can help realize the promise of data driven research in hierarchical materials whose structure spans multiple length-scales, such as carbon nanotube (CNT) assemblies. Our prior work demonstrated the wealth of high-resolution and statistical data R-SoXS provides about chemical and structural morphologies across different length scales in CNT materials.[1] CNTs are known as the strongest 1D material due to their covalent *sp*^{2} carbon bonds, hexagonal lattice, and cylindrical shape. However, piecing together CNTs into assemblies has proven to be so far a failed strategy to achieve the same elite performance metrics as individual CNTs. This highlights a critical deficiency in understanding the effects that the processing of individual nanostructures has on the performance of their derived macroscale assemblies, thereby hindering the development of a process-structure-performance map for these materials.

In this work, we propose a new method to decouple the distribution orientation of nanoscale tortuosity and the macroscale twist of CNT dry-spun yarns under applied loads via *in-situ* R-SoXS probing at high energy (1300 eV) and low energy (280 eV), respectively. With this decoupling enabled by *in-situ* R-SoXS, we gain new insights on the deformation mechanisms of these yarns which have been structurally reinforced with a novel vapor-phase polymer that is subsequently self-crosslinking.[2] Further, we examine how both the distribution orientation of the nanoscale tortuosity of CNT bundles and the macroscale twist of the yarns evolve as a function of applied load for different processing conditions, including yarns with plasma-enhanced surface reactivity prior to the polymer reinforcement. Better understanding of the multiscale structural behavior of CNT yarns as a function of processing will allow advances for the manufacture at large scale of products based on ultra-strong, flexible, conductive fibers for aerospace, defense, communications, wearables, and biomedical industries.

5:00 PM MD02.07.26

Using Machine-Learning and Deep-Learning to Discover Relationships in Intercalation Compounds Joseph S. Fenton[1], Ryan Aguilar[1], Iman Ellahie[1], Heidi G. Paisley[1], Jordyn A. VanOrman[1], Jack R. Vitek[1], Kaci L. Kuntz[2] and Natascha Knowlton[1,2]; [1]Rowland Hall, United States; [2]The University of Utah, United States

Intercalation refers to the insertion of guest species into the interlayer space of a host material. This can create drastically different properties in the resulting compound and therefore, intercalation can be used to tune the properties of a material. Layered materials such as graphite are common host structures because of their large van der Waals gap between layers; this allows for the insertion of guest species, resulting in graphite intercalated compounds (GICs). As guest species insert, the interlayer space may expand or contract, the guest may donate electrons (n-doped) or accept electrons (p-doped) from the host--resulting in an increased conductivity of the GIC, and may insert with different staging--where a stage I intercalation compound has molecules inserted in between each host layer while a stage II is every other layer, and so on. Thusly, intercalation is a powerful tool, as it provides a unique avenue to tune and engineer the properties of a material.

However, because of the vast combinations of guest and host compounds as well as the variations in staging, understanding the relationships between guest, host, and GIC properties are incredibly complex and challenging. However, machine learning (ML) and deep learning (DL) provide a route to elucidate the complex relationships between the properties of guest species, graphite host, and intercalated compounds. Here, we successfully employ these techniques to elucidate structure-property relationships in GICs. This work has application toward improving efforts in engineering materials without needing to test every possible combination; thereby, materials can be strategically selected to synthesize for specific applications, including medical, optoelectronic, and energy storage (*Inorg. Chem. Front*., 2016, 3, 452; *Adv. Mater*., 2019, 1808213).

Example: Strategies for Synthesis of GICs
By training on input parameters (donor/acceptor of the intercalant, stage, in-plane conductivity, and interlayer spacing of the GIC), we predicted thermodynamic values for the enthalpy of formation, $\Delta H_f \pm 5\%^{,}$ with 40% accuracy and entropy, $\Delta S \pm 5\%$, with 80% accuracy. These results allow for the calculation of Gibbs Free Energy, ΔG_f, for the formation of a GIC. Furthermore, because of the dependance of on temperature, we can determine the conditions which a GIC will form—including temperature, pressure, and applied voltage. This is significant for the broader materials community, since these ML- and DL-discovered relationships provide a new tool to guide the parameters for the synthesis of GICs. Furthermore, these relationships create the possibility of predicting and discovering new GICs.

In summary, with this work, we successfully used ML to elucidate structure-property relationships between intercalants, graphite host, and GICs, including thermodynamic values, which could be relevent to efficiently synthesizing GICs. With DL, we utilized the individual properties of guest species, graphite, and GICs to predict composite characteristics of GICs. More broadly, this research can lead to facilitating more sustainable efforts in material design for intercalation compound

5:00 PM MD02.07.28

Origin of the Onset Temperature in Solid-State Ceramic Synthesis Shibo Tan[1], Gabrielle Kamm[2], Karena Chapman[2] and Wenhao Sun[1]; [1]University of Michigan, United States; [2]Stony Brook University, The State University of New York, United States

Temperature plays a crucial role in solid-state synthesis, but there are currently no mechanistic theories to predict the optimal temperature to carry out a solid-state reaction. A variety of recent observations suggest that transient liquid intermediates provide a diffusion media for solid-state reactions at subsolidus temperatures. Here, we hypothesize that in a solid-state reaction $A + B \text{->} AB$, the precursors A and B first melt into a metastable liquid phase before transformation into the solid AB product phase. In this theory, the onset temperature of a solid-state reaction derives from the extension of liquidus curves into the metastable eutectic region of a Temperature-Composition phase diagram. We validate this theory by combining *in situ* XRD synchrotron observations with a thermal gradient heater, which produces temperature-time-transformation curves for a solid-state reaction that largely agree with the theory of a metastable liquid intermediate. To more readily predict the reaction onset temperature, we present with a strategy to combine DFT convex hulls with CALPHAD approaches to rapidly estimate the high-temperature liquidus curves of phase diagrams at minimal computational cost.

5:00 PM MD02.07.29

Clinical and Forensic Characterization of Exhaled Breath—Multiscale Computational Studies for the Metrics of Aerosol Particle Capture Veruska Malavé, Kavita Jeerage, Edward J. Garboczi and Tara Lovestead; National Institute of Standards and Technology, United States

Exhaled breath research consists of the study of gases, water vapor, volatile organic compounds, as well as aerosol particles. This research field typically involves the implementation of state-of-art methodologies for both novel technology and metric test analysis. This is particularly the case when collecting, detecting, and measuring exhaled submicrometer aerosol particles. Particle matter is produced in the lungs due to mechanical disruption of the airway lining fluid, which consists of water, lipids, proteins, and non-volatile compounds. Drugs of abuse, for instance: amphetamines, cocaine, and tetrahydrocannabinol (THC), have been detected in exhaled aerosol particles in conjunction with potential biomarkers of health or disease. Particles can be deposited in surgical masks, electret filter devices, and impaction filter devices; however, the absorptive properties of masks and some filters can hinder recovery for instrumental laboratory analysis. *Future development and adoption of exhaled breath sample tests and aerosol particle collection based on the particle fraction of breath require a deeper understanding of how human factors interact with device design, as a collector method, to influence particle deposition*. Robust multiscale computational methods, such as computational fluid dynamics (CFD) in conjunction with computational fluid particle dynamics (CFPD) numerical models, can support the design, optimization, and prototype development of these breath devices while aiding the interpretation of human subject exhaled breath studies that are not yet fully comprehended. In this work, the development and application of a three dimensional (3D) multiscale CFD-CFPD model of a single impact filter is carried out to aid *understanding of the complexity phenomena of the dynamics, transport, and deposition of submicrometer particles in exhaled breath*, the macroscale domain. The focus is on numerical simulations informing about the exhaled breath velocity profile as well as the local transportation, deposition, and distribution of submicrometer polydisperse particles in exhaled flow in a single-impact filter of a commercial breath aerosol capture device. This fluid dynamics and discrete phase computational approach is novel in terms of how depicting (a) exhaled breath and particle deposition within an aerosol collection device and (b) fluid breath dynamics of submicrometer polydisperse particles deposited in a filter by means of impaction. This study highlights needed decoupling strategies to characterize the influence of the size of particle as well as their concentration distribution and human (e.g.: flowrate and breath volume) and device factors. The goal of this study is to aid reproducibility and laboratory analysis of particle collection when human subject breath analysis is involved. This work will contribute to developing crucial standardized metrics that will promote pathways to advance public health and safety while offering a mean for a deeper comprehension of exhaled breath particle research.

Exploring the Reaction Mechanisms in Sol-Gel Synthesis of BiFeO3 Thin Films Using Chemical Reaction Networks Viktoriia Baibakova, Kevin J. Cruse, Carolin M. Sutter-Fella, Anubhav Jain and Samuel M. Blau; Lawrence Berkeley National Laboratory, United States

BiFeO3 thin films have potential applications in memory devices and photovoltaics due to their multiferroic properties [1]. They can be synthesized through spin-coating of a sol-gel [2], but this process is complex and can result in impurity phases that negatively impact physical and device properties. In this study, we aim to improve our understanding of the mechanisms involved in sol-gel synthesis of BiFeO3 by using chemical reaction networks [3]. We also seek to propose a different method for managing precursor materials in synthesis recipe databases that can produce defining features effectively processed by machine learning models. We present preliminary results obtained from constructing and analyzing the reaction network for the reaction between bismuth(III) nitrate pentahydrate and 2-methoxyethanol. For instance, our study suggests that replacing the nitrites and water in the outer layer of bismuth with 2-methoxyethanol may be hindered by kinetics, but becomes easier once hydrogen bonds are weakened. This finding may help explain why the reaction does not occur at room temperature in experiments [4]. We also report our efforts to explore preferred chemical routes based on energy gain using high-throughput computations with xTB [5] and QChem [6]. Additionally, we discuss alternative representations of materials that can be used to improve the success of chemical reaction networks and contribute to a data-driven understanding of the effects of different chemical components on the outcome. Our findings contribute to a more predictive and mechanistic understanding of the sol-gel synthesis process, which could lead to the production of high-quality BiFeO3 thin films.

The Study on Intelligentization of Heat Treatment Conditions for Alloy Steel Using Artificial Intelligence Kyeonghun Kim[1], Uro Heo[1], Jeong Hyeon Kwon[1], Seongtak Kim[2] and Hae Woong Yang[1]; [1]Pohang Institute of Metal Industry Advancement, Korea (the Republic of); [2]Korea Institute of Industrial Technology,, Korea (the Republic of)

The cold forging heat treatment process is known to be a decisive factor in the mechanical properties of products. In the case of alloy steel used in cold forging, coarsening and refinement of crystal grains occur according to changes in alloy composition and heat treatment conditions, which directly affect mechanical properties, so proper heat treatment conditions according to the material are very important. However, most of the processes, such as changing the heat treatment pattern and inspecting and confirming before input, are currently performed manually, which takes a lot of time and has a disadvantage in that productivity is low. Also, depending on the experience, know-how and proficiency of the operator, some deviations in the process occur. In this study, atypical data collected in the heat treatment process (quenching and tempering) was preprocessed after removing invalid columns by setting optimal variables. Random Forest Regressor, Gradient Boosting Regressor, Extra Trees Regressor, and Bayesian Ridge were used as experimental models for preprocessing results, and heat treatment calculation results were derived through data such as alloy components and external environment. In order to evaluate the consistency of these calculation results, as a result of conducting a regression analysis (comparative verification) with the actual heat treatment material, the result value within the error range was confirmed.

Vanadium Dioxide-Containing Formulations for Smart Windows Applications, Synthesized and Characterised via Automation for Multi-Objective Optimisation Mohammed F. Amin[1,2], Yee Fun Lim[1] and Ivan P. Parkin[2]; [1]Agency for Science, Technology and Research (A*STAR), Singapore; [2]University College London, United Kingdom

Smart windows have been proposed as a solution to improve the energy efficiency of buildings. VO_2 is a phase change material that has shown promises because it stable during synthesis and allows EM waves to penetrate the building at cold temperature or reflect at high temperatures [1].
To fully optimise a smart window: the phase change should occur at 27°C (transition temperature), be transparent and uniform. Typical synthesis and characterisation routes are time consuming because finding an optimum requires extensive exploration of large search spaces, including but not limited to reagents, stoichiometry, reaction, and conditions analysis methods [2]. In this work, we aim to minimise manual experimentation and optimise VO_2

properties by combining automated experimentation and ML to converge to the three objectives.
We first utilized an automated machine chemical synthesis tool (Zinsser), which has robotic tools to mix reagents, dopants, coat the substrate, and anneal 15 samples in approximately 8 hours. Additionally, the Zinsser measures the UV-vis spectra for transparency data. Transition temperature data is then measured using a custom-built, robust, automated measurement set-up which consists of a 4-point probe, thermal camera, and a heating bed. Finally, the uniformity, is measured in high throughput with HPS. Consequently, we have collected a large dataset that can be used in multi-Objective optimisation processes.
Results obtained are in line with an operational smart window, both functionally and compositionally (XRD). Over 90% of the entire process yielded target material and was completed without human interaction, allowing us to generate a large and varied dataset which will drive ML-based optimisation.
Bayesian optimisation has been tested with synthetic a dataset by varying parameters and implement different regression algorithms to achieve the best RMSE and R^2 scores, as well as minimise the number of iterations. The experimental results obtained will undergo pre-processing and scaling before optimisation using open-source Python library, scikit-optimize (*skopt*) [3].

5:00 PM MD02.07.36
Database of Computed Properties for Color Center Defects in Silicon Vsevolod Ivanov[1], Alexander Ivanov[2], Jacopo Simoni[1], Prabin Parajuli[1], Thomas Schenkel[1] and Liang Z. Tan[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Brown University, United States

Color center defects in silicon are emerging as a promising platform for realizing a number of applications in quantum information science (QIS), including quantum sensing, single-photon sources, and integrated quantum communication between quantum computer nodes. Several well-studied defects such as the G-center, W-center, and T-center, possess some of the necessary attributes for these applications, including narrow linewidths, emission in the telecommunications band, long electron spin coherence times, and coupling between spin and optical degrees of freedom. Despite this, no known defect is perfectly suitable for QIS applications, and in fact different devices can require defects with expressly distinct sets of properties. We report the publication of a searchable online quantum defect database containing the computed properties of over 5000 distinct silicon defect structures. Formation energies, defect energy levels, ground and excited spin states, zero phonon lines, and electric dipole matrix elements are provided for each defect, which are then used to screen for candidate defects with emission within the telecommunications band, non-trivial spin state, and strong optical coupling. Additionally, a machine learning approach is applied to predict defect properties directly from structural data.

This work was supported by the Office of Fusion Energy Sciences and the Molecular Foundry, a DOE Office of Science User Facility, supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

Steps Towards Convergence Informatics—Enriching the Groundwater Chemical Composition Data Alexey Gulyuk[1,2], Akhlak-ul Mahmood[1], Paul Westerhoff[3] and Yaroslava G. Yingling[1]; [1]North Carolina State University, United States; [2]STEPS research center, United States; [3]Arizona State University, United States

The problem of reusing available natural resources and, particularly, removing various chemical pollutants from water sources is a topic that currently receives a lot of attention. Utilization of various agents (nanoparticles, hydrogels, or solvents) opens new paths to recovery the dangerous wastewater pollutants like hydrogen, phosphorus, or heavy metals.

The very first step for developing water cleaning strategies requires assessing full chemical composition of a target water source. In practice, extensive water quality analysis involves analyzing enormous amounts of data and requires rigorous data preparation and several preprocessing steps.

Here we want to present our vision of how the combination of experimental and ML- derived data can help to facilitate the increased accuracy of data analysis for further advances in clean water sustainability. Particularly, we focus on assembly, analysis, and completion of the water chemical composition dataset, which became one of cornerstones of the project. Data enrichment tools utilized in this work rely on Machine Learning algorithms and enable elements of Convergence Informatics, thus advancing data-driven research with the end goal of finding the most effective water treatment compounds and agents.

5:00 PM MD02.07.40
Evaluating Extended Length Scale Structures in Aqueous Solutions of Sodium Nitrate and Sodium Nitrite Yihui Wei[1], Emily Nienhuis[2], Sebastian T. Mergelsberg[2], Trent Graham[2], Gregory K. Schenter[2], Carolyn Pearce[2,3] and Aurora Clark[1,2]; [1]The University of Utah, United States; [2]Pacific Northwest National Laboratory, United States; [3]Washington State University, United States

Relating electrolyte solution structure, from local solvation to that of the extended ion networks, to the solubility and reactivity is of interest due to its relevance in the processing of industrial wastes. X-ray total scattering, for pair distribution function analysis, is one key method to access structures across multiple length scales in these materials, while readily allowing for complementary experimental and computational efforts. In this work we used computation methods to unravel the molecular origin of multiscale correlations observed in the experimentally obtained X-ray pair distribution functions of dilute to concentrated $NaNO_2$ and $NaNO_3$ aqueous solutions. Two graph theory approaches, polyhedra identification and geodesic pathway analysis, combined with Molecular Dynamics simulations were utilized to identify the organizational motifs composed of intermolecular networks and their concentration-dependent evolution. The growing population of extended ion networks is found to be responsible for the change of atom pair correlations while bulk water structure remains unperturbed.

Voxelized Atomic Structure Potentials for Molecular Dynamics—Determining Mass Diffusion Coefficient in Ti-Al Alloys Mayur P. Singh, Matthew C. Barry and Satish Kumar; Georgia Institute of Technology, United States

Prediction of dynamical properties of materials through Molecular Dynamics (MD) simulations comes with the established problems such as exponential increasing computational cost with increasing size, limited time scale, and inaccuracy of results from using empirically derived interatomic potentials compared to first principles Density Functional Theory (DFT) simulations. Neural Network Interatomic Potentials (NNIPs) have lower computational cost and comparable accuracy to the first principles calculations. However, one problem faced by NNIPs is the creation of mostly simplified or expert-guided *ad hoc* selection of the salient material structure descriptors to describe interatomic forces, when in actuality these interactions happen on complex 3D atomic structures. In this work, we introduce the Voxelized Atomic Structure (VASt) potential for Molecular Dynamics. VASt is a framework for creating interatomic potentials through the voxelization of the atoms in an atomic structure. This creates a 3D representation of the structure, which can be trained in a Convolutional Neural Network with 3D convolutions. We use the VASt potential in MD simulations to calculate the mass diffusion coefficient of two-component systems. Performance of many metallic alloys are highly dependent on the mass diffusion coefficient of the components, notably Ti-Al alloys. We consider a 2-component system of Al and -Ti and study the diffusion of Al into -Ti in a wide range of temperature, i.e., 300-1500 K. Overall, our approach has great potential to predict diffusive, mechanical and thermal properties of multi-component systems.

EGBO: Evolutionary-Guided Bayesian Optimization for Materials Discovery Kai Yuan Andre Low[1,2], Yang Bai[2], Khoo Zi Hui Jonathan[2], Made Riko I[2], Eleonore Vissol-Gaudin[1], Huiqing Xie[2], Albertus D. Handoko[2], Vijila Chellappan[2], Jianwei Jayce Cheng[2], Fengxia Wei[2], Yee Fun Lim[2] and Kedar Hippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, Singapore

The development of Materials Acceleration Platforms has enabled High-Throughput (HT) materials experimentation towards solving materials grand challenges with large decision spaces, multiple conflicting objectives and complex constraints. The implementation of existing state-of-the-art Bayesian Optimization called q-Noisy Expected Hypervolume Improvement (qNEHVI) is able to solve noisy constrained multi-objective problems with batch evaluations, appropriate for HT experimentation. However, the stochastic sampling approach used to generate candidates leads to inefficient exploration of the search space and inability to fully resolve the Pareto Front, reducing the number of good solutions that can be tested experimentally. In this work, we develop a new algorithm specifically designed for materials discovery using a hybrid framework called Evolution-Guided Bayesian Optimization (EGBO) that introduces selection pressure via evolution to rapidly navigate the exploration-exploitation trade-off. We demonstrate this on multiple multi-objective benchmark problems, both synthetic and real-world, and show that EGBO is able to efficiently resolve the Pareto Front [1]. Asides from hypervolume, we present other metrics that are specifically relevant to assessing optimization for material science problems such as scalability, consistency and feasibility. We demonstrate this on a closed-loop experimental workflow that explores Cu-Sb-S compositional space to optimise its photoelectrocatalytic hydrogen evolution from water,. The multiple-objective optimization model discovered optimum experimental conditions after only nine cycles of integrated experiments-machine learning loop. Photocurrent testing at 0 V *vs.* reversible hydrogen electrode (RHE) confirmed the expected correlation between the materials properties and photocurrent. An optimum photocurrent was observed on $Cu_9Sb_{45}S_{46}$ in the form of single layer coating on F-doped SnO_2 (FTO) glass with corresponding bandgap of 1.85 eV and 63.2% Cu^{1+} species content [2].

Adaptive X-Ray Diffraction with Automated Phase Identification Nathan Szymanski[1,2], Christopher Bartel[1,2], Yan Zeng[2], Mouhamad Diallo[1,2], Haegyeom Kim[2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The speed by which machine learning models can be evaluated creates novel opportunities to integrate them directly with experiments. In this presentation, we will demonstrate how the effectiveness of X-ray diffraction (XRD) can be improved by using machine learning to analyze data on the fly so that the diffractometer can be autonomously steered toward features that accelerate phase detection. This is accomplished by training a neural network to propose which phases best match a given XRD pattern, quantify the uncertainty related to each proposed phase, and pinpoint the features in the pattern where these phases differ most. By leveraging early experimental data from a rapid XRD scan on an unknown sample, the neural network can effectively narrow down the list of possible phases from thousands to only a handful. To distinguish between these few phases, the neural network controls the diffractometer in real time such that high-resolution measurements are focused on regions containing features that are unique to each phase. Scans are performed adaptively until all phases can be identified with high confidence. We show that this method significantly boosts the accuracy of impurity detection on multi-phase samples while cutting their measurement time in half. Because adaptive XRD scans are fast but accurate, they can be used to characterize chemical reactions where short-lived intermediates appear. As a proof of concept, we demonstrate that all phases can be successfully identified by adaptive XRD during the synthesis of a common solid electrolyte. These findings showcase the advantages of in-line machine learning for materials characterization and point to the possibility of more general approaches for adaptive experimentation.

Characterizing 2D Materials with Semi-Supervised Learning and Convolutional Neural Networks Chengyin Wu, Isaiah A. Moses and Wesley Reinhart; The Pennsylvania State University, United States

The unique and fascinating properties exhibited by 2D materials have triggered tremendous interest in their research. Characterization of 2D materials is often performed using Atomic Force Microscopy (AFM) which generates topographic images of synthesized samples. However, the height maps from AFM are usually processed by manual analysis with specialized software such as ImageJ to extract information like thin film coverage, thickness, or descriptions of morphology. This process is inefficient since each image generated by AFM must be analyzed one by one in a time-consuming postprocessing step. Therefore, developing a method to automatically process the AFM images by Machine Learning (ML) can improve workflow efficiency. Meanwhile, utilizing computational metrics can provide some useful information other than numerical data, such as correlating thin film patterns with experimental parameters or overall thin film coverage by different vapor deposition methods for further physical properties investigation.
In this study, we explored the use of statistical learning models and Convolutional Neural Networks (CNN) to automate the AFM postprocessing workflow for samples of WSe2 grown by Metal-Organic Chemical Vapor Deposition. We first developed a semi-supervised ML scheme to propagate the sparse labels of thin film coverage to the rest of the dataset. In this step, we also learn abstract representations of the unlabeled data and identify qualitative features of AFM height maps that are not obtained in the conventional workflow. In the next step, we evaluated different CNN architectures to design

optimized models for our image processing workflow. After training, we achieve significantly better performance than using statistical learning alone. The automated workflow can also augment the traditional image analysis by providing searchable abstract representations. We anticipate this approach can be applied to all kinds of 2D materials for high-throughput characterization.

9:00 AM MD02.08.03
Machine Learning for Predicting Structure- and Environment-Dependent Degradation Behavior of Biopolymers Jessica N. Lalonde[1,2], Babetta Marrone[2], Stefan Zauscher[1] and Ghanshyam Pilania[2]; [1]Duke University, United States; [2]Los Alamos National Laboratory, United States

Plastics derived from fossil fuel feedstocks have become essential to modern life around the world, but the detriment to the environment and human health throughout their entire materials life cycle continues to be a significant challenge. Materials design of bio-based alternatives to conventional plastics are often limited by time- and resource-intensive experimental screening for optimum degradation rates, thermal processing ranges, and durability. In this work, we employ machine learning (ML) as a powerful data-enabled technique to explore the structure-property-processing relationships of a diverse family of bio-derived polyesters, poly(hydroxyalkanoates) (PHAs), in a quantitative and efficient way. We conduct a thorough literature review of varying PHA structures and compositions, degradation environments, and experimental conditions to explore a broad suite of variables affecting the overall degradation rate of the PHA biopolymers. Individual data entries, including over 1,700 unique data points from more than 200 different sources were collected from peer-reviewed journal articles, published book chapters, and other open-source formats to create a ML dataset unique to PHAs to predict the degradation rate in a variety of real-world environments. We demonstrate how this curated database of PHA samples can be used to employ a robust ML approach that is capable of both: (1) regression for prediction of the degradation rate of the PHA samples, and (2) classification of samples into different categories of degradation profiles at specific timepoints. A random forest (RF) decision tree algorithm was used for semi-quantitative predictions of two degradation parameters which capture the key features of the database to predict the weight loss over time for each sample. We show this novel approach to parameterization of the features to develop a degradation profile for each sample can be used to compare PHA samples with vastly different degradation timescales. Using this approach, we achieve a highly accurate and physically meaingful model. By demonstrating the potential of ML-informed experimental materials design process for PHAs, we present a generalizable framework for biopolymer materials design for other types of biopolymers in addition to PHAs, with potential impacts of helping to push the biopolymer materials design process forward.

9:15 AM MD02.08.04
Experimental Design for High Fidelity Polymer Solubility Data to Improve Machine Learning Capabilities Mona Amrihesari, Joseph D. Kern, Amari Murry, Ramamurthy Ramprasad and Blair K. Brettmann; Georgia Institute of Technology, United States

Recently developed machine learning approaches to understanding material properties provide new opportunities for studying and developing new knowledge about polymers. The vast application of polymers and their sensitivity to many parameters like molecular weight, temperature, morphology, etc. requires developing high throughput experimentation methods that lead to accurate results. This will be vital for developing any prediction model in data science analysis. Although polymer informatics has significantly improved in recent years, using artificial intelligence and machine learning techniques, a significant hurdle in the polymer informatics area is the lack of complete and sufficiently detailed databases. One example where this is a challenge is in developing a dataset for polymer solubility and dissolution, where the classification of “soluble” or “insoluble” is sensitive to molecular weight, concentration, temperature, heating/cooling rate, and other factors that are not always reported or well-controlled. To overcome the challenges with the current dataset on polymer solubility, in this work, we apply turbidity measurements with precise temperature control using a Crystal16 parallel crystallizer and develop an experimental design to maximize usable data from a single sample, while still controlling for the factors that impact the kinetics of polymer dissolution. With this method, the experiments are possible to do in reproducible and time-effective ways while also collecting time-resolved dissolution data continuously throughout the experiment. This approach produces detailed results in a controllable manner allowing us to develop a more information-rich data set for predicting the polymer solubility using machine learning techniques.

9:30 AM MD02.08.06
Developing Robust Neural Networks for High-Resolution TEM Image Analysis Katherine Sytwu[1], Luis E. Rangel DaCosta[2] and Mary Scott[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Neural networks are promising tools for high-throughput and accurate transmission electron microscopy (TEM) analysis of nanomaterials. However, these powerful analysis techniques have yet to move past proof-of-concept into wider adoption. Notably, neural networks perform poorly on data that is “out-of-distribution” from its training data. Given the wide variety of microscope conditions and potential samples yet limited types of local features typically seen in TEM images, it is unclear what sort of images would be classified as different, or "out-of-distribution," from others. Without an idea of what training protocols are needed for a robust network, one would need to either retrain neural networks for every dataset one wants to analyze, or acquire/label a large dataset of TEM images that spans every sample/imaging condition, both of which prohibit wider usage of neural networks for analysis of TEM images.

Here, we investigate how the choice of training dataset influences neural network performance in the context of an automated characterization pipeline. We curate and label high-resolution TEM image datasets of nanoparticles under controlled imaging and material parameters, including magnification, dosage, nanoparticle size, and nanoparticle material. By training and cross-validating neural networks with these curated datasets, we not only identify under what conditions these neural networks generalize, but also uncover the biases that arise when test data differs from training data. As an example task, we focus on segmentation, or pixel-wise classification, of atomically-resolved crystalline nanoparticles against an amorphous TEM substrate background. We find that neural networks generalize well across images of different nanoparticle sizes, but are sensitive to images taken with different electron dosages. Networks tested on images taken with a higher electron dosage than the training set underestimate nanoparticle size, and vice versa. Synthetic image augmentation can help with small perturbations in microscope and sample conditions, but is not a viable strategy to cover a wide variety of conditions. In general, images taken with different microscope conditions are more likely to be flagged as out-of-distribution, implying that neural-network-aided analysis may be more feasible for in situ datasets whose microscope conditions are heavily controlled. Our results point towards the need for additional testing of data-driven algorithms to account for generalizability across multiple datasets.

[1] This research was supported by an appointment to the Intelligence Community Postdoctoral Research Fellowship Program at Lawrence Berkeley National Laboratory, administered by Oak Ridge Institute for Science and Education (ORISE) through an interagency agreement between the U.S. Department of Energy and the Office of the Director of National Intelligence (ODNI).

Toward Automated Characterization of Disordered Materials by Integrating Atomistic Simulations, Machine Learning and X-ray Absorption Spectroscopy Wonseok Jeong, Wenyu Sun, Yu-Ting Hsu, Fikret Aydin, Xiao Chen, Michael Bagge-Hansen, Liwen Wan, Michael Nielsen and Tuan Anh Pham; Lawrence Livermore National Laboratory, United States

Optimizing material performance requires accurate knowledge of local composition and structure at atomic scale. Spectroscopic techniques such as X-ray Absorption Near-Edge Structure (XANES) have been widely used for material characterization. However, extracting chemical information from experimental probes can be intractable in heterogeneous systems. In this work, we discuss how atomic simulation is integrated with machine learning techniques and XANES calculations to understand chemical speciation of amorphous carbon nitride systems as a case study. We discuss the development of machine learning (ML) potentials that can efficiently explore a large configurational space of amorphous carbon nitrides. The ML potentials are then combined with statistical methods to elucidate the most representative local structures, such as carbon and nitrogen hybridization, and how they evolve with chemical compositions and density. Our simulations indicate that structure of amorphous carbon nitrides is highly complex, exhibiting non-linear and unexpected behavior at medium density and nitrogen concentration. Structural analysis is then combined with XANES simulations to establish a relationship between local structure and spectroscopic signatures, which in turn, is used to provide high-fidelity interpretation of experimental measurements. Development of ML models, including a transformer model, for describing structure-spectrum relationship will also be discussed.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Funding was provided by LLNL Laboratory Directed Research and Development (LDRD) Program Tracking No. 22-ERD-014.

10:30 AM MD02.08.08

Robustly Describing Atomically Dispersed Catalysts Using Deep Learning Assisted Microscopy Analysis Haoyang Ni[1,2], Jacob Smith[3,2] and Miaofang Chi[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Oak Ridge National Laboratory, United States; [3]North Carolina State University, United States

Atomically dispersed catalysts (ADCs) are a recently emerging category of catalysts where metal atoms are anchored on substrates in a mononuclear or monomolecular form[1]. Due to the size reduction, better catalytic performance is expected from the higher specific activity and utilization of atoms[2]. However, heterogeneous atomic configurations, such as dimers, trimers, and clusters, can form during synthesis[3] or catalytic reactions[4]. These different atomic configurations can contribute differently to the overall catalytic performance. Therefore, it is necessary to characterize the local structure of adsorbed metal atoms in ADCs to understand the origin of the observed catalytic performance.

Annular dark field (ADF) scanning transmission electron microscopy (STEM) has been used to characterize the local structure of ADCs and identify the presence of different atomic configurations[5]. ADF STEM allows metal atoms to be intuitively distinguished via image contrast against the background contrast of bulk support. The continued development of STEM instruments permits the automatic acquisition of many ADF images to allow researchers to build statistics of ADCs dispersions and capture their structural evolution in different operant environments[5]. However, the identification and counting of different atomic configurations are normally performed through either manual labeling or conventional thresholding methods, which become a bottleneck for data analysis.

Here, we present a deep-learning-based algorithm for atom configuration identification and categorizing in ADCs. We propose a convolutional neural network structure – AtomNet- consisting of four consecutive residual neural networks as the backbone. A pipeline of automatic generation of synthetic datasets that can mimic different imaging conditions, such as magnification, dwell time and resolution, is designed to train the neural network. Applying trained AtomNet to synthetic and real STEM images shows the high accuracy of atom identification under different imaging conditions and different materials systems. On a desktop with GPU support, an image with size 1024*1024 only needs milliseconds to process, which outruns most in-situ STEM image acquisition time. Therefore, live feedback on atom positions and configurations can be achieved and applied to time-of-flight analysis.

Data-Driven Modeling and Adaptive Optimization of Floating Zone Crystal Growth Process Applying Gaussian Mixture Model and Reinforcement Learning Shunta Harada[1], Yusuke Tosa[2], Ryo Omae[2], Ryohei Matsumoto[2] and Shogo Sumitani[2]; [1]Nagoya Univ, Japan; [2]Anamorphosis Networks, Japan

Materials process has been upgraded, automated, and efficiently optimized by applying various kinds of informatics algorithms and the field of “process informatics” were emerging. Although parameters for most materials processes are time-independently given, which means that a set of input parameters gives a single output, some materials processes are manually controlled according to the information obtained during operation. For example, in crystal growth by the optical floating zone (FZ) method, an operator monitors the status of the melt in a furnace with a camera and changes the inputs to maintain suitable conditions for single-crystal growth. In the present study, we predicted the dynamics of crystal growth by the optical FZ method using Gaussian mixture model (GMM) and optimized the operation trajectory by reinforcement learning for automated operation.
There are two characteristics in the operation data of the material manufacturing process which requires adaptive control according to the process states including FZ crystal growth process. One is that the amount of data for learning is limited, and so-called "big data" cannot be collected. It is unrealistic to run thousands of experiments for automation. The other is that the operation trajectories are not identical, but they are all similar trajectories. An operation is carried out according to the process states, and it is natural to control refering to the similar operations which once succeeded. Therefore, it is necessary to construct a prediction model in a limited parameter space with a limited amount of data. Considering these characteristics of the operation data, we selected to apply for the prediction of the dynamics by GMM in the present study. GMM is a model that can predict nonlinear dynamics near the training trajectories with high sample efficiency. In order to validate the predication of the dynamics by GMM, we created an emulator of FZ crystal growth process and generated virtual operation trajectories. As a result, from only five training trajectories, we successfully predicted the operating dynamics using GMM with better precision than one obtained by using linear regression or neural networks.
<!--StartFragment -->Once the prediction model for the dynamics of the operation trajectory with high accuracy is constructed, it is possible to generate an

ideal operation trajectory by reinforcement learning. In the present study, the control model was trained using proximal policy optimization (PPO). In reinforcement learning, it is generally important to appropriately define a reward function that quantifies whether state is good or bad. In order to accurately control the operation of the FZ crystal growth by reinforcement learning from the dynamics predicted by GMM, the reward function should be properly designed. As a result, we have reveald that not only the error from the ideal shape of grown crystal considering the necking process but also the error from the training trajectories should be minimized in the reward.
Finally, by applying GMM and PPO, we succeeded in achieving an operation trajectory that is closer to the ideal one than one manually controlled.<!--EndFragment -->

S/TEMfit—A Tool for Real-Space Analysis of Large-Scale S/TEM Images Ewout van der Veer, Ruben Hamming-Green, Beatriz Noheda, Majid Ahmadi and Bart J. Kooi; University of Groningen, Netherlands

The analysis of atomic resolution (scanning) transmission electron microscopy images has been a topic of much research interest in recent years due to its ability to locally determine material properties such as elastic strain, electric polarization, phase distributions, etc. Real-space techniques, in particular, have taken flight to circumvent the limitations of traditional methods like geometric phase analysis. In this context, several software packages have been developed, including Atomap, STATstem and mpfit. Although these tools have shown great utility in the analysis of highly idealized images containing relatively few atoms, they tend to fall short on larger images and those with defects like out-of-zone or amorphous regions. This precludes the accurate analysis of, for example, highly strained epitaxial thin films.
We demonstrate the analysis of such strained films consisting of $BaTiO_3$ grown on a $SrTiO_3$ substrate using a Sn-doped $SrTiO_3$ buffer layer with tunable lattice parameter using an in-house developed software package—called S/TEMfit. The package is designed for the *a posteriori* analysis of as wide a range of S/TEM images as possible in a performant and automated manner. It is fundamentally based on principal component analysis for image filtering, a thresholding procedure for atom detection and 2D Gaussian fitting.
We show that S/TEMfit allows us to visualize continuous strain relaxation in our film and resolve inter-layer lattice parameter differences down to at least 2 pm, despite the presence of significantly defective regions in the images. It further allows us to image electric polarization and identify different structural phases in the image.

Transfer-Learning Strategies for using Simulated and Experimental Datasets in Machine Learning for Automated HRTEM Characterization Luis E. Rangel DaCosta[1], Katherine Sytwu[2], Catherine Groschner[1] and Mary Scott[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Supervised machine learning techniques offer the potential for high-accuracy, automated analysis of high-resolution transmission electron microscopy (HRTEM) data, providing precise atomic scale characterization of next-generation nanomaterials. However, it can be difficult and expensive to train accurate neural network models which are generally applicable and robust to a wide variety of experimental conditions. Curating sufficient high-quality experimental data to train and develop models with supervised learning techniques is prohibitively expensive and prone to human error and biases. Alternatively, simulated datasets are cheaper to produce and can compete with and even outperform the use of experimental data in neural network training, despite not capturing all fine details of experiment with a given forward model. When both synthetic and experimental data streams are available, it can be advantageous to use all aggregated data for training neural network models, but it is still unclear how to best incorporate multiple datastreams arising from distinct sources when training models.

In this work, we address the challenges of developing experimentally robust and general neural network models to analyze HRTEM data at atomic resolution by using mixed simulated and experimental data streams. Models trained in multiple phases with multiple datastreams can accrue the benefits of each: robust performance and generalization given by large simulated datasets covering a variety of experimental conditions, and well-tuned high-performance on target datasets given by experimental data. We isolate strategies for curating a mix of simulated and experimental HRTEM datasets for training neural networks with good generalization behavior in data-efficient manners through a comparative study of various fine tuning and transfer learning strategies for training neural networks. We observe that, with sufficient experimental data, fine-tuning/transfer learning after pre-training on simulated data can improve the performance of a model beyond what is achievable by training solely with experimental data. The final performance ability is not necessarily tied to how well a model performs after the pre-training stage. In other scenarios, fine-tuning a model on a specific experimental dataset offers only marginal gains in performance at a significant sacrifice to its ability to generalize well to other experimental datasets. Common data augmentation strategies, like sampling non-orthogonal rotations of a training image, further improve performance but again at a sacrifice to generalization. These results point towards pragmatic lessons for producing and deploying machine-learning-based automated characterization tools at low cost and with stronger guarantees on measurement accuracy in scientific environments.

Data-Driven Characterisation of Materials for Fins and Surfboards Pawel Kryzanowski and Marc In het Panhuis; University of Wollongong, Australia

Surfing waves with surfboards for sport of leasure is practiced in many coastal areas around the world. Surfboards consisting of balsa wood started to spread from Hawaii to mainland USA and Australia. Modern surfboards with a foam core were introduced at the end of the 1950’s.

The mechanical characteristics of surfboards (and fins) most valued by surfers is mechanical stiffness and is generally referred to as flex. During characteristic surfing manoeuvres (bottom turns) a surfboard (and its fins) will bend either due to the shape of wave or the force exerted on the board by the surfer or a combination of both effects.

However, development of new materials for surfboards and fins are almost entirely based on subjective experiences (feedback from surfers) rather than scientific data.

In this presentation we show that data-driven approaches (using sensors) can be used to develop new materials for fins and surfboards that improve performance for surfers. We present the development and field-testing of a working prototype of a surfboard with inbuilt electronics and a set of instrumented fins. We demonstrate that data collected in real-time via telemetry during surfing waves can be used as a research tool for developing new materials for surfboards and/or fins.

Autonomous Workflows for an Accelerated Design of Battery Electrodes and Interfaces Ivano Eligio Castelli; Technical University of Denmark, Denmark

The development of automated computational tools is required to accelerate the discovery of new functional materials, to speed up the transition to a sustainable future. Here, I address this topic by designing new battery electrodes for different intercalation battery chemistries. These workflows are implemented in the framework of Density Functional Theory, using MyQueue and the Atomistic Simulation Environment (ASE). In the first part, I describe a fully autonomous workflow, which identifies materials to be used as intercalation electrodes in batteries, based on thermodynamic and kinetic descriptors like adsorption energies and diffusion barriers [1]. A substantial acceleration for the calculations of the kinetic properties has been obtained due to a recent implementation of the Nudged Elastic Bands (NEB) method, which takes into consideration the symmetries of the system to reduce the number of images to calculate. Moreover, we have established a surrogate model to identify the transition states, which can further reduce the computational cost to at least one order of magnitude [2, 3]. We have applied this workflow to discover new cathode materials for Mg batteries as well as solid state electrolytes for Li, Na, and Mg all-solid-state batteries [1, 3]. In the second part of my talk, I discuss how nanostructured materials can positively impact the Li-ion battery solid/electrolyte interface towards a controlled formation of the Solid Electrolyte Interface (SEI) [4, 5] and to adjust the volume expansion in Si-anodes during battery cycling [6].

Unifying Molecular and Textual Representations via Multi-task Language Modelling Dimitrios Christofidellis, Giorgio Giannone, Jannis Born, Teodoro Laino and Matteo Manica; IBM Research Europe, Switzerland

Neural language models have achieved impressive results in various natural language understanding and generation tasks.
Recently, advances in language models have been successfully transferred to the chemical domain, proposing generative modeling solutions to classical problems from molecular design to synthesis planning.
These new methods have shown potential for optimizing chemical laboratory operations, initiating a new era of data-driven automation in scientific discovery.
However, despite these recent successes, specialized models for each chemical task are typically needed, requiring problem-specific fine-tuning and neglecting tasks' dependencies.
However, the lack of a unified representation between the information expressed in natural language and chemical representations is the main limiting factor in the interaction between humans and the models. Inspired by recent advances in generative transfer learning, we explore a multi-task language model that can tackle a large variety of tasks in the chemical and natural language domains.
We rely on mono-domain, frozen encoder models and jointly fine-tune a decoder on multiple domains.
In doing so, we relieve the cross-domain training from computationally expensive, data-hungry pretraining, leveraging the power of language models trained on unstructured data.
Furthermore, we apply multi-task learning to increase model expressivity and information sharing between modalities.
In this way, our model handles chemical and natural language concurrently and can solve numerous chemical and natural language-based tasks using a single set of weights.
We quantitatively evaluate our method against state-of-the-art baselines, exploring different strategies to adapt and fine-tune cross-domain language models.
Our work paves the way for robust and efficient language models accelerating discovery in physical sciences.

8:50 AM MD02.09.04
Growing Strings in a Chemical Reaction Space for Searching Retrosynthesis Pathways Federico Zipoli, Carlo Baldassari, Matteo Manica, Jannis Born and Teodoro Laino; IBM Research Zurich, Switzerland

Machine learning algorithms demonstrated remarkable accuracy in predicting the outcomes of chemical reactions, often outperforming human experts. Simultaneously, a high level of precision was achieved in the single-step retrosynthesis prediction problem. However, designing a synthesis pathway leading to a given product is a challenging task that runs up against the limits of many currently available ML-driven algorithms. Like the game of chess, retrosynthesis route prediction entails putting together a series of steps to create a given product from existing substances, with the goal of optimizing the synthesis efficiency by taking advantage of specific strategical game rules like protection, deprotection, FGI, etc. Because current machine learning models are trained on single reaction steps, they lack knowledge of these strategy rules. Here, we recast the retrosynthesis problem as a string optimization problem, capitalizing on the homology between the chemical reaction space and a multidimensional geometrical space. If we think of chemical reactions as multidimensional vectors (fingerprints), then a synthesis in this space is a string that involves three or more connected fingerprints. An extensive corpus of chemical synthesis, comprising approximately 1.2M examples, was extracted and added as strings to the chemical reaction space. We use the Euclidean metric to minimize the distance between the trajectory of the growing retrosynthesis string and the existing strings. By doing so, we aim to assemble steps that, in the chemical reaction space, will grow along paths more similar to existing retrosynthesis, thereby inheriting the strategic guidelines compiled by domain experts. We integrated this approach into the RXN platform (https://rxn.res.ibm.com/) and present the method's application to complex synthesis as well as its ability to produce better synthetic strategies than current methodologies.

9:05 AM MD02.09.05

Structure–Property Relationships for Electron Trapping in Amorphous Oxides Cameron Chevalier[1,1], Alex Greaney[1] and Mahesh R. Neupane[2]; [1]University of California, Riverside, United States; [2]U.S. Army Research Laboratory, United States

Amorphous oxides are promising functional materials for use in a number of next generation electronics applications, both because of their ability to accept and immobilize electrons in multilayer devices, and because of the tunability of the amorphous atomic packing. In this talk, we present our multi-scale approach to modeling the macroscopic electronic properties of materials that are inherently structurally inhomogeneous. For this, we link classical molecular dynamics simulations with small-scale high fidelity density functional theory calculations of electronic structure to generate an effective "representative volume" sampling of the amorphous material. Using the same approach, we study the distribution of trapping probabilities from impurity and stoichiometric defects in a-Al_2O_3, and use machine learning methods to identify structural outliers, or packing defects, in these systems.

9:20 AM *MD02.09.06
Operator Learning for Predicting Fracture Paths in Brittle Random Media Ariana Quek and Johann Guilleminot; Duke University, United States

We present an operator learning approximation framework for brittle fracture. The proposed approach aims to alleviate the computational cost associated with full-scale, phase-field simulations in studying brittle fracture in heterogenous materials. Our strategy relies on the combination of dimensionality reduction and learning between function spaces. We first explore optimal strategies to encode and decode smooth and non-smooth physical fields, including the use of linear and nonlinear reduction techniques. A probabilistic learning technique is subsequently leveraged to map between the latent spaces. The accuracy of the method is finally demonstrated considering fracture path simulations in a random medium exhibiting stochastic spatially varying toughness.

Deposition of Boron Nitride by Micro Hollow Cathode Discharge Claudia Lazzaroni, Manoel Jacquemin, Hiba Kabbara, Alice Remigy, Ovidiu Brinza, Guillaume Lombardi and Vianney Mille; LSPM CNRS USPN, France

In this presentation, we propose an alternative synthesis method to deposit thin film material hexagonal boron nitride (h-BN) assisted by microplasma source. h-BN thin films are the focus of interest for electronic and optoelectronic applications due to its wide band gap semiconductor (and 2D layered structures). In other hand, microplasmas have attracted growing attention in recent years because of possible applications in various fields such as surface treatment, light sources and nanomaterial synthesis. They can be generated at high pressure which is a favourable condition to better dissociate N_2 molecules, a prerequisite to the synthesis of nitride materials at lower temperatures compared to conventional processes.

Our deposition reactor is composed of two chambers and the micro-plasma is located at the junction between them. The plasma source is generated by a micro hollow cathode discharge (MHCD) which consists of an anode-dielectric-cathode sandwich through which one hole of 400 µm in diameter is drilled. The injected gas is an argon/nitrogen mixture. The higher pressure chamber (several tens of mbar), favors the production of high density plasma, and consequently high nitrogen dissociation, while the lower pressure chamber (several mbar) limits the nitrogen recombination. The polarizable and heating substrate holder is located in the lower pressure chamber where the boron precursor (BBr_3) and hydrogen are injected. The polarization of the substrate holder with a DC positive voltage of several hundreds of volts allows the discharge to be expanded from the hole to the substrate. Suitable conditions can be defined to achieve the BN growth. We report the growth of BN on silicon and sapphire substrates at temperatures below 1000°C and present the characterizations of the different BN deposited. The synthetized BN type depends of the nature of the substrate, the deposition duration, the gas compound and the distance between the MHCD source and the substrate. This latter has a major role on the stoichiometry and the stability of the deposited films.

8:15 AM NM01.01.02
Engineering Light-Activated Microswimmers for Controllable Motion and Interparticle Interactions John A. Castaneda[1], John G. Gibbs[1] and Jennifer Martinez[1,2]; [1]Northern Arizona University, United States; [2]Los Alamos National Laboratory, United States

Inspiration for new materials often comes from observations of natural phenomena, such as the swarming of flocks of birds and schools of fish. That dynamic and concerted motion of the natural world can also be observed at the micron and nanoscale, where collections of engineered and self-propelled nano- or micron-particles "swim" in viscous fluids. These active matter microswimmers consume energy and through that catalysis exert mechanical motion. Beyond creating materials that can actively control and manipulate their environment, active materials hold promise for new applications in both the synthetic and living worlds, if only their catalytic activity and subsequent motion can be precisely engineered.

An example of artificial, nonbiological microswimmers is a catalytic Janus particle that has surface-asymmetry with specific physico-chemical properties at different locations upon the particle. Controlling this asymmetry may allow one to engineer these kinds of dynamics exhibited but here we are interested in self- propulsion. Two primary methods have been established for self-propulsion: (1) ejection of bubbles, akin to jet- propulsion, and (2) sustained creation of temperature or concentration gradients. As the scale decreases, only the latter appears possible, but this method requires high catalytic activity of the particles as well as asymmetry in either the shape or materials properties of the particles themselves. These Janus microswimmers are synthesized with a catalytic material (e.g., bulk metal gold or platinum) selectively deposited on one side of micron-particle. The morphology of the particle enables the sustained thermodynamic gradient that induces motion.

Unfortunately, bulk metal surfaces are not nearly catalytically active nor selective enough to enable future applications in active matter, particularly as the active matter particle decreases in size. Metal nanoclusters, however, because of their ultrasmall size, unique packing and high surface to volume ratios, tend to have far higher photocatalytic and substrate selectivity than do nanoparticles or bulk surfaces of similar compositions.

To date, there are two primary limitations in the field of active matter that we can, eventually, overcome using clusters as the catalytic booster: (1) low overall catalytic efficiency, which should be overcome with the high catalytic activity of clusters; and (2) little ability to tune the directionality of the active matter motion. The latter should be overcome by directional deposition of different clusters within the same titanium dioxide (TiO2) micron-particle; wherein the motion of the particle would change as a function of which cluster is activated. Clusters and their activation will differ by bandgap/wavelength of excitation or catalytic selectivity/reagent addition. The successful extrapolation from our results suggests that differing sized nanoclusters, with different band-gaps, may tune the light needed for TiO2 activation, thus creating an important knob for coupling active matter to the environment.

In this talk, I will focus on the approach, design and fabrication of my microswimmers to achieve the catalytic activity required for propulsion. I propose that it is possible to engineer photoactive microswimmers for desired motion directly from a metal oxide photocatalyst, magnetic materials and combing these microscale swimmers with other nanoscale structures through: (1) Physical Vapor Deposition (PVD) and Glancing Angle Deposition (GLAD) with electron beam and thermal evaporating systems; (2) Constructing microswimmers from photoactive material such as TiO2 that gives a more effective level of control in comparison to traditional catalysts since the activity, intensity of propulsion can be turned on-and-off using UV light; (3) Creating microswimmers with a coating of precise nanoclusters. Combined, these ideas allow for the creation of active microswimmers that exhibit controllable collective motion and behavior.

8:30 AM *NM01.01.03
Distinct Chemical and Physical Properties of Janus Nanosheets Peiran Wei and Emily Pentzer; Texas A&M University, United States

Janus particles have recently garnered significant attention for their distinct properties compared to particles that are homogeneously functionalized. Moreover, high aspect ratio Janus particles that are rod-like or planar (i.e., nanosheets) are especially intriguing considering their interfacial properties as well as their ability to assemble into higher-order and hybrid structures. To date, major challenges facing the exploration and utilization of 2D Janus particles are scalability of synthesis, characterization of tailored chemical functionalization, and ability to introduce a diverse set of functionalities. Herein, a facile method to access Janus 2D graphene oxide (GO) nanosheets by combining a Pickering-type emulsion and grafting-from polymerization via ATRP is reported. Janus GO nanosheets bearing PMMA on one face as well as the symmetrically functionalized analogue are prepared, and the chemical, thermal, structural, surface, and interfacial properties of these materials are characterized. Time-of-flight secondary ion mass spectrometry coupled with Langmuir−Blodgett films is shown to be an ideal route to conclusively establish asymmetric functionalization of 2D materials. This work not only provides a facile route for the preparation of Janus nanosheets but also demonstrates the direct visualization of polymer grown from the surface of GO.

9:00 AM *NM01.01.04
Surface Engineering of Patterned Polymer-Tethered Nanoparticles Eugenia Kumacheva; Univ of Toronto, Canada

Patterning of colloidal particles with chemically or topographically distinct surface domains (patches) has attracted intense research interest. Surface-patterned particles act as colloidal analogues of atoms and molecules, serve as model systems in studies of phase transitions in liquid systems, behave as 'colloidal surfactants' and function as templates for the synthesis of hybrid particles . The generation of micrometer- and submicrometer-sized patchy colloids is now reached the state of the art, however surface patterning of nanoparticles with dimensions of the order of tens of nanometres remains a challenge.

We develoepd a strategy for surface patterning nanoparticles by utilizing thermodynamically driven segregation of polymer ligands from a uniform polymer brush into surface-pinned micelles following a change in solvent quality. The methodology offers the ability to control the dimensions of patches, their spatial distribution and the number of patches per nanoparticle, in agreement with a theoretical model. The versatility of the strategy is demonstrated by patterning nanoparticles with different dimensions, shapes and compositions, tethered with various types of polymers and copolymers and subjected to different external stimuli. These patchy nanocolloids have potential applications in fundamental research, the self-assembly of nanomaterials, diagnostics, sensing and colloidal stabilization.

Scale-Up Production of Janus Graphene by Interfacial Nano-Reactor for Enhanced Oil Recovery Applications Sehoon Chang, Gawain Thomas and Wei Wang; Aramco Americas, United States

As an emerging enhanced oil recovery (EOR) technology, nanofluid flooding has been developed for the oil displacement or injectivity improvement in oil reservoirs. However, current nanofluids with conventional nanoparticles show relatively low efficiency for EOR, especially with low concertation under laboratory condition. The research aims to investigate a new type of nanomaterials, Janus nanofluids, as highly effective alternative nano-agents for EOR applications under reservoir conditions and introduce a new cost-effective scale-up synthesis method for industrial applications. A lyotropic liquid crystal phase as a novel “interfacial nano-reactor” system has been demonstrated to synthesize Janus nanomaterials at numerous liquid-liquid interfaces. Compared to the conventional bi-phase reaction system, the new “interfacial nano-reactors” could greatly enhance the efficiency of the interfacial reaction by more than a million times, and thus allow production of Janus nanomaterials in mass quantity at low cost for industrial applications. Large quantities of Janus graphene nanosheets have been successfully synthesized via this method and characterized by scanning electron microscopy (SEM), Langmuir-Blodgett (LB), contact angle, fluorescence imaging and interfacial tension (IFT) measurements. With a low concentration of Janus graphene nanosheets in nanofluid formula, microfluidic imaging and core-flooding experiments have been performed to evaluate the efficiency of the nanofluids for oil displacement in carbonate reservoirs.

The Janus graphene nanosheets with proper hydrophilic/hydrophobic functionalization can be directed and assembled onto the interface of water and oil, which has been characterized by microfluidic imaging. The Janus graphene nanosheets can significantly lower the interfacial tension (IFT) values between brine and crude oil at simulated reservoir conditions. The core flooding measurements have demonstrated that the Janus nanofluids at ultra-low concentrations (less than 0.01 wt %) remarkably promote oil displacement in simulated carbonate reservoirs. A novel scale-up method for mass production of Janus graphene nanosheets at low-cost (about one million times more efficient than the conventional bi-phase method) has been demonstrated. The novel Janus graphene nanofluids have been utilized for improving efficiency of oil recovery at ultra-low concentration (less than 0.01 wt%).

10:30 AM *NM01.01.06
Synthesis and Self-Assembly of Janus Au-Fe_3O_4 Nanoparticles Shan Jiang; Iowa State University of Science and Technology, United States

We have developed methods to fabricate Janus nanoparticles. In one example, Janus Au-Fe_3O_4 dumbbell nanocrystals (< 20 nm) were synthesized with the hydrophobic ligands coated on the Au lobe and negatively charged hydrophilic ligands coated on the Fe_3O_4 lobe. We can control the self-assembly of nanoparticles in aqueous solutions by systematically balancing the hydrophobic and hydrophilic moieties. The strong interparticle plasmonic coupling displayed a red-shift in surface plasmon resonance, with larger structures formed by Au-Au-Fe_3O_4 assembly extending into the near-infrared region.

11:00 AM NM01.01.07
Scalable Continuous Flow Synthesis of Janus-Like Gold-Polystyrene Particles with Tailored Morphology and Optical Properties Julia S. Seifert and Robin N. Klupp Taylor; Institute of Particle Technology (LFG), Germany

A wide range of Janus and, more broadly, patchy particles, have been reported over the last decade. Impressive control over single particle and collective properties has motivated interest from numerous application fields. Nevertheless, commercial exploitation is currently held up by a considerable lack of techniques to produce such particles on a large scale. In this contribution, we give details of a simple process for the synthesis of Janus-like and patchy particles which is both highly tunable in terms of the product morphology and properties, and also scalable. Our approach, which produces gold patches on polystyrene core particles, is based on a continuous flow process realized as a cascade of two millimeter scale T-mixers. Such an arrangement is an excellent compromise between high mixing intensity and scalability. In the first mixer the core particles, which are positively charged, are heterocoagulated with a small number (typically fewer than four) ultrafine negatively charged gold nanoparticles. The latter function as seeds for an electroless gold plating reaction initiated at the second T-mixer resulting in typically < 20 nm thick conformal gold patches. Simple variations of the reaction and process conditions enable us to tailor the coverage, thickness and density of the patches, thus accessing a wide range of Janus-like and patchy morphologies. Moreover, the local surface plasmon resonance of gold nanostructures offers the possibility of product particles with tunable visible and near-infrared properties as well as a convenient means to investigate and optimize the synthetic process. Regarding the latter, in the present contribution we will introduce a process-property function which relates a dimensionless parameter representing the amount of gold precursor per seed to the optical properties and metal patch morphology. Moreover, we will show how this relationship is affected by the concentration of other key parameters like the reducing agent, chloride ion concentration and core particle size.
The high tunability of optical product properties mentioned above makes our Janus-like particles relevant for various application fields, e.g. in pigments, sensors or theranostics. In this context, we demonstrate how particle concentration and sample volume can be scaled-up with our continuous flow set-up. We will also demonstrate that the necessary post-synthetic treatment (washing, stabilization etc.) can be achieved without significant reduction in product properties.

11:15 AM NM01.01.08
Hierarchically Grown Nanostructure for Suppressing Leaching in Fiber Optic Chemical Sensing Adil Alshoaibi; King Faisal University, Saudi Arabia

Owing to fiber-optic pH sensing, phenolphthalein immobilized SiO2 nanoparticles (P-SNPs) and phenolphthalein immobilized SiO2–TiO2 nanoparticles (P-STNPs) are synthesized by low-temperature sol-gel route. The P-SNPs revealed hierarchical structure, surface roughness (Ra) 7 nm, surface area ~442 m2/g, n (refractive index) 1.37 at 550 nm which is significant for pH sensing. The P-STNPs exhibited granular structure, low Ra 3 nm, surface area ~219 m2/g, n around 1.52 at 550 nm. Both matrices are thermally stable around 250 C. The P-SNPs and PSTNPs sensitivity is calculated ~22 counts/pH and 19 counts/pH with the determination coefficient (R2) ~ 0.99.
The pka value of P-SNPs is measured ~9.5 and time response 0.11s within pH 12 without leaching which is higher than P-STNPs (9.1) and 3.9 s with leaching. Experimental findings suggested P-SNPs have the potential for practical usage in intense basic media.

11:30 AM NM01.01.09
Synthesis of Patchy Nanoparticles by Atomic Stencils for Scaled-up Self-Assembly Chansong Kim, Ahyoung Kim, Lehan Yao, Eric Yang, Yu-Shen Liu, Xiaoying Lin and Qian Chen; University of Illinois, Urbana-Champaign, United States

In this talk, we will discuss our recent work in developing and implementing a universal atomic-stencil method to prepare polymer-patched gold nanoparticles (NPs) with different shapes and patch patterns at a superior monodispersity and synthesis yield. The facet-dependent adsorption energy of ligands allows for selective attachment of block copolymer onto different sites of NPs, including the hard-to-achieve facet patches. We demonstrated our synthesis method is universally effective for diverse shapes of NPs from simple faceted polyhedral to complicated-crystalline spherical NPs. As a result, we were able to achieve a wide library of facet-specifically decorated patchy NPs. Furthermore, scaled-up assemblies (tens of micrometers) of the patchy NPs were also made through a careful control of solvent evaporation, which show novel mechanical and optical properties. We expect that our study will provide the groundwork for high-quality patchy NPs and their assemblies which are crucial for practical applications in diverse areas.

11:45 AM NM01.01.10
Correlated Electrostatic Interactions in High-Capacitance Zwitterion Containing Thin Films Loren G. Kaake; Simon Fraser University, Canada

Given their oppositely charged ends, zwitterionic small molecules are perhaps the smallest example of a Janus nanomaterial. We have synthesized an imidazolium and trifluorosulfonoimide based zwitterionic molecule that can be doped into conventional polymers like poly(methyl methacrylate) (PMMA). At low zwitterion doping levels, the films act as expected under an applied electric field, including zwitterions provides a small but measurable increase to the capacitance. However, above a critical concentration, the zwitterions begin to interact electrostatically with each other. This interaction results in a sharp increase in the thin film capacitance, approaching that of an electrostatic double layer. Polarized optical microscopy and grazing angle wide angle x-ray scattering shows a dramatic increase in the overall film crystallinity, presumably as a result of electrostatically driven ordering of the zwitterionic molecules. The high capacitance of the thin films can be used to create both n-type and p-type field effect transistors that operate below 5 V, demonstrating the utility of zwitterion containing thin films as high capacitance ambipolar electrolyte dielectric materials.

SESSION NM01.02: Janus Nanomaterials—Structure/Property

Session Chairs: Zhifeng Ren and Christopher Wirth
Wednesday Afternoon, April 12, 2023
InterContinental, Fourth Floor, Telegraph Hill

1:30 PM NM01.02.01
Correlated TERS and KPFM Imaging of the SeMoS Janus Monolayer Crystals Ziyang Gan[1], Antony George[1], Andrey Krayev[2] and Andrey Turchanin[1]; [1]Institute of Physical Chemistry, Jena University, Germany; [2]Horiba Scientific, United States

We report the first time nanoscale, tip enhanced Raman scattering (TERS) imaging of the SeMoS Janus monolayers crystals both as-grown on gold foil and transferred from the growth substrate to the gold-coated silicon wafers. Due to the preferential enhancement of the out-of-plane modes in the gap-mode of TERS, the TERS spectra of SeMoS differ from the conventional Raman spectra reported earlier [1, 2]. The $A_1^1$and A_1^2 out-of-plane modes are shown to be the first and the second strongest Raman peaks in TERS, while in conventional Raman spectroscopy the A_1^2 mode is extremely weak. Interestingly, the red shift of the spectral position of A_1^2 mode correlates with a decrease of the contact potential difference in Kelvin probe force microscopy (KPFM) images.. While the TERS maps mostly show the Raman spectra characteristic to the high quality SeMoS Janus monolayers, we observed in some cases narrow, below 20-30 nm, areas that featured a peak at 406 cm^{-1} which could be interpreted as the A' band of MoS_2. The ability to detect the nanoscale imperfections in Janus monolayer crystals is a mandatory condition for optimizing their synthetic routes. TERS imaging cross-correlated with KPFM measurements demonstrate the applicability for the nanoscale assessment of the structural homogeneity of both the as-grown and transferred SeMoS Janus monolayer crystals.

Janus Particle-Laden Fluid Interfaces—Microstructure, Rheology and Stability Sepideh Razavi, Dimitrios Papavassiliou and Elton Corriea; University of Oklahoma, United States

The behavior of colloidal particles in vicinity of fluid interfaces has intrigued scientists since the early 1900s. The large binding energy, relative to the thermal energy, causes particles to irreversibly adsorb at the interface, a useful attribute in the engineering of interfacial systems in various applications including pharmaceutics, food stabilization, oil recovery, and personal care products. The use of Janus particles in interfacial applications is of particular interest since they combine the colloidal-scale properties of particle stabilizers (i.e., large desorption energy from fluid interfaces) with the molecular-scale properties of surfactants (i.e., tunable amphiphilicity). In many such applications, interfacial materials become subjected to deformations that produce compression/expansion and shear stresses. Therefore, it is important to understand the impact that the Janus character brings to interfaces. In this talk, I will review our findings on how Janus particles influence the stability and rheology of fluid interfaces. I will discuss the impact of particle amphiphilicity on the capillary interactions, the resulting interfacial microstructure, and their connection to the flow behavior. Building on this information, I will present our research in understanding the dynamics of complex interfacial systems comprised of colloidal particles and surfactant molecules under an applied stress, especially in elucidating the rich physical mechanisms that affect their synergism at interfaces.

2:15 PM *NM01.02.03
Active Surface Agents—Swimmers at Fluid Interfaces Jiayi Deng[1], Mehdi Molaei[2], Nicholas Chisholm[3] and Kathleen Stebe[1]; [1]University of Pennsylvania, United States; [2]The University of Chicago, United States; [3]Worcester Polytechnic Institute, United States

Active colloids, self-propelled microscale objects, have generated tremendous excitement because of their ability to swim, interact, and self-organize. Active colloids interact with boundaries, fundamentally changing their swimming behavior. However, the effect of fluid interfaces on active colloid motion is unknown. Fluid interfaces are highly non-ideal, complex domains that impose constraints that alter swimming behavior. We study bacteria as model active colloids to understand these constraints and their implication. Bacteria attach to interfaces with pinned contact lines, which fix the angle of the cell bodies at the interface and constrain the arrangement of the flagellum. As a result, similar bacteria have different trapped configurations and widely different swimming behaviors. Interfacial stresses further constrain the interfacial flow via diverging Marangoni stresses-surface tension gradients- that dictate divergence-free motion or incompressibility in the interface.
We focus on swimming behaviors and hydrodynamics of *Pseudomonas aeruginosa* PA01 at aqueous- hexadecane interfaces. The bacteria can swim adjacent to the interface, or they can adsorb directly and swim in an adhered state with complex trajectories that differ from those in bulk in both form and spatio-temporal implications. To understand their impact on interfacial transport, we visualize the interfacial flows generated by PA01 in pusher modes and find flow fields with unexpected symmetries that differ significantly from their bulk fluid counterparts. Analysis reveals that these flow fields can be decomposed into two dipolar hydrodynamic modes associated with incompressible interfaces. The relative importance of these modes is determined by the cell bodies' trapped configurations.
Hydrodynamic theory allows us to understand this flow field fundamentally and to explore its implications on mixing in the interface. Our aim is to advance the concept of an *Active Surface Agent*, an active colloid trapped at fluid interfaces whose motion and trapping state can be designed to promote mixing and structure formation. This concept represents an important and largely untapped degree of freedom for interfacial engineering. By understanding how biological swimmers move at fluid interfaces, we can develop design rules for artificial biomimetic systems to promote transport at fluid interfaces with broad implications in chemical engineering processes.

Magnetic Janus Microrobots for Cellular Manipulation Fatma Ceren Kirmizitas, Sudipta Mallick, Max Sokolich and Sambeeta Das; University of Delaware, United States

Inspired by the biological motors at the micron and nanoscale, various microscale robots have been developed that can be actuated in cellular environments and are on the same length scale as biological motors. However, motion at such low length scales is hard to control due to thermal fluctuations. In our group we have developed microscale robots that can be actuated using magnetic fields in dense cellular environments. In this work we will present the fabrication and manipulation of magnetic Janus microrobots which can be navigated in tight channels mimicking blood vessels. We will also demonstrate automated control of microrobot motion and its application for cellular manipulation. This precise wireless control of Janus microrobots is also able to transfer cells against fluid flows.

3:30 PM NM01.02.05
Study on the Low-Damage Atomic Layer Etch of Various Two-Dimensional Materials Dongryul Lee[1] and Jihyun Kim[2]; [1]Korea University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

In the recent processes of nano-electronics and ultra-integrated semiconductors, good electrical/chemical properties of ultra-thin materials are essential. Silicon is an appropriate material with manufacturing and doping potential that is suitable for commercial processes, but it has limitations in electrical properties due to the short-channel effect in application to ultra-integrated and scale-downed devices that advance every year. Two-dimensional (2D) materials, incorporating graphene, hexagonal boron nitride, and transition metal dichalcogenide materials are suitable for the nanometer-scale processes owing to their atomic-scale thickness and excellent electrical/optical properties. In addition, the surface dangling bonds and defect sites of the exfoliated/grown thin film are nominal in the atomically-flat surfaces of 2D materials. 2D materials can be applied as a component of a next-generation semiconductor that is sensitive to malfunction.
Numerous studies of 2D material-based nano-electronics and optoelectronic devices with outstanding electrical/optical performances have been reported. However, applying the 2D materials to commercial dry- and wet-etch processes is limitary because of the chemical/mechanical stability due to their atomically clean surface. In the past, radicals with physical energy have been used to break a stable surface state, but there are two restrictions. 1) Precisely controlling the etch thickness is difficult. 2) The properties of the material deteriorated by the surface damage caused by energetic ions. Therefore, to apply 2D materials as a commercial semiconductor, introducing an atomic-layer etching (ALE) technology that cuts off one or two layers while suppressing damage and precisely controlling the etching rate is necessary.
In this study, a plasma-based ALE method with low damage was demonstrated and proved applicable to various two-dimensional materials (Graphene, h-BN, MoS_2, $MoTe_2$, WSe_2, WS_2). Atomic force microscope analysis was proceeded to confirm the precisely controlled etching rate of 1 to 2 layers and the roughness of the surface. The crystalline quality of the etched region was analyzed by Raman spectroscopy measurement. Through the fabrication of few-layer-thick 2D material-based field-effect transistors with ALE technology identifies the possibility of application to electronic devices. This ALE technology has high versatility as it can be progressed by the conventional dry-etch equipment of commercial semiconductor processes. The traditional gas used in the etching causes little damage to the polymer mask, this ALE can be arranged to self-aligned and selective etch processes. Our work can contribute to the introduction of a commercial electronic device manufacturing process with 2D materials. More details of our work will be discussed in the presentation.

3:45 PM NM01.02.06
β-Ga_2O_3 Metal-Semiconductor Field-Effect Transistor with High Breakdown Voltage Applied h-BN Slant Field-Plate Jeongmin Kim, Dongryul Lee and Jihyun Kim; Seoul National University, Korea (the Republic of)

The fast growth of green energy, electric vehicle, and aerospace industries has necessitated the development of power electronics technology, encouraging the research into wide bandgap semiconductor materials. Wide bandgap semiconductors are suitable for high-power and radio frequency (RF) applications due to their fast switching and excellent breakdown characteristics allowing high-voltage or high-current operations. Beta gallium oxide (β-Ga_2O_3) is an ultrawide bandgap (4.9 eV) semiconductor material one of the five phases of the gallium oxide family. Baliga's figure of merit (BFOM) is a parameter representing the relative performance of semiconductor materials as a power device, and the BFOM of 3444 for β-Ga_2O_3 demonstrates its superior characteristics compared to silicon carbide (340) and gallium nitride (870). The metal-oxide-semiconductor field-effect transistor (MOSFET) is the basic building block of integrated circuits, where the interface between the channel and the dielectric material is critical to its performance. Compared to that of silicon-based MOSFETs, the performance of β-Ga_2O_3-based MOSFETs is far more degraded by the high trap density of the interface between the gate oxide to the channel. Metal-semiconductor field-effect transistor (MESFET) structure was introduced to resolve this problem. In a MESFET, the channel is switched on and off by the electric field induced by the bias applied at the top-gate, where the Schottky barrier at the contact between the gate metal and the semiconductor minimizes the gate leakage current. In RF devices, the MESFET structure is suitable due to its lack of the oxide dielectric layer, leading to low capacitance level owing to the Schottky contact, and far less interface traps. In a MESFET, however, concentration of the electric field occurs at the edge of the interface between the gate metal and the semiconductor. This electric field concentration acts as a point of electrical breakdown, instigating premature breakdowns. The electric field concentration can be alleviated, and thereby increasing the breakdown voltage, by the implementation of the field-plate structure. In this research, a gate field-plate structure using hexagonal boron nitride (h-BN), a two-dimensional material with high thermal conductivity and excellent insulating performance, is adopted for a MESFET with a β-Ga_2O_3 channel. Although the electric field concentration is relieved by the h-BN field-plate structure, the junction where β-Ga_2O_3, h-BN, and gate metal meet still experiences the concentrated electric field which induces reduction in the breakdown voltage. A slant field-plate structure was designed to reduce the angle of h-BN sidewall in contact with the gate metal and Silvaco simulation software was utilized to predict the lateral distance of the h-BN edge to the source electrode to optimize the attenuation of electric field concentration. Electron-beam lithography and downstream plasma etching techniques were used to etch the part of h-BN to reduce the angle of the h-BN sidewall by the undercut induced by the isotropic etching. Ni/Au gate was deposited on β-Ga_2O_3 and h-BN by electron-beam lithography and electron-beam evaporation. The angle of the h-BN sidewall was measured to be approximately 30° by atomic force microscopy and the breakdown characteristic of the device assessed by the 3-terminal breakdown measurement showed improvement compared to that of the conventional gate field-plate structure. The application of the slant field-plate structure can be expected to realize the full potential of β-Ga_2O_3 as a power device.

4:00 PM NM01.02.07
Non-Oxidized Bare Metal Nanoparticles in Air—Negatively Charged Surface with Excess Electrons Transferred from Two-Dimensional Electride Athira Thacharon and Sung Wng Kim; Sungkyunkwan University, Korea (the Republic of)

Athira Thacharon[1], Sung Wng Kim[1]
Department of Energy Science, Sungkyunkwan University, Republic of Korea[1]

Instability of metal surface toward oxidation has been of classical issue, but still important in fundamental science and practical applications. Passivation of metal surface with additional moieties or post-treatments have been considered as the most prominent solutions for impeding oxidation, especially in the field of nanoscience and technology. Indeed, non-oxidized bare metal nanoparticles (NP) in air have been hardly realized. Here, we report oxidation-resistant bare metal NPs in air by mimicking the cathodic protection in nanoscale using electride as an electron source [1]. Cu NPs grown on electrides are thoroughly investigated by atomic scale observations and chemical analyses combined with theoretical calculations revealing that ultra-high oxidation-resistant behavior is originated from the large work function difference between Cu and electride, inducing negatively charged surface state on Cu NPs. Furthermore, we developed a rational approach for non-oxidized bare metal NPs by wet chemical solution process employing electride as an electron-donating agent to reduce diverse metal precursors in alcoholic solvents [2]. Atomic-scale structural and chemical analyses confirm all synthesized bare Cu, Ag, and Sn nanoparticles are ultra-stable in ambient air, exhibiting no trace of metal oxides. These obtained results suggest a revolutionary breakthrough for rational protection of Cu and other metal NPs against oxidation in ambient air for various practical applications such as heterogeneous catalysts [3].

Surface Patterning of Au Tetrahedra with Block Copolymer Patches Xiaoying Lin[1], Chansong Kim[1], Thi Vo[2], Haihua Liu[3], Tommy Waltmann[2], Jiahui Li[1], Sharon Glotzer[2] and Qian Chen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Michigan–Ann Arbor, United States; [3]Argonne National Laboratory, United States

Patterning of nanoparticles with distinct surface patches has attracted intense research interest through the past decade. Here, we demonstrate the synthesis of patchy tetrahedra focused on the thermodynamic and scaling behaviors of amphiphilic block copolymers. By engineering the surface chemistry via facet-selective ligands and controlling polymer-solvent interactions, the copolymers form different patterns on the surface of Au tetrahedra, including vertex-patches, edge-patches, and clover-like patches. We also demonstrate the controlled clustering of the patchy tetrahedra and study their plasmonic coupling properties. Our study expands the fundamental studies on the polymer behaviors on nanoparticles with novel geometry and sophisticated surface chemistry and shows as a promising strategy for the design of functional nanomaterial and composites.

Two-Phase Janus Nanoparticles Obtained from Thin Fe/Au Bilayers Chen Errera and Eugen Rabkin; Technion–Israel Institute of Technology, Israel

Metallic Janus nanoparticles (NPs) are usually synthesized employing wet chemistry methods. Such NPs are thermodynamically unstable at elevated temperatures due to interdiffusion and reactions between constituent metals. In this study, we fabricated thermodynamically stable Janus NPs containing face centered cubic Au-based and body centered cubic Fe-based phases employing a solid state dewetting (SSD) of thin Fe/Au bilayers deposited on sapphire substrate. We found that the size distribution and morphology of the Janus NPs can be varied by changing the overall compositions, the deposition order of individual sub-layers, and the SSD parameters. The combination of Au, which is an inert, conducting, optically active at the nanoscale and biocompatible metal, along with the ferromagnetic Fe, results in unique set of properties that can be utilized in the opto-magnetic and sensing applications. In particular, by selective etching of Fe we obtained single-phase Au NPs with unusual shapes, enhancing their optical response

Metal-Metal Phosphide Synthesis—Selective Phosphidation of Ag-Cu Nanocrystals Xiao Ma and Abdessadek Lachgar; Wake Forest University, United States

The incorporation of phosphorous into metal nanoparticles is an important strategy to affect material's structure and bonding, its electronic structure, and its catalytic property. Colloidal synthesis, hot injection in particular, is well known for its versatility and can be an alternative approach for Janus nanomaterials synthesis.
In this work, we present the colloidal synthesis of metal-metal phosphides, by preparing metal-metal nanoparticles followed by selective phosphidation. We applied this strategy to convert Ag-Cu to Ag-Cu_3P. Ag-Cu nanoparticles were prepared using $W(CO)_6$ as the reducing reagent as previously described by Quan *et al*.[1] Phosphidation of Cu nanoparticles was performed using tris(trimethylsilyl)phosphine and trioctylphosphine as previously reported by Schaak *et al*.[2] Partial phosphidation of the Cu-Ag nanoparticles led to the formation of Ag-Cu_3P nanocrystals. The materials before and after phosphidation were used as electrocatalysts for hydrogen evolution in 0.1 M NaOH. The onset potential of Ag-Cu_3P is 200 mV smaller than that for Ag-Cu, indicating that incorporation of phosphorus into metal-metal nanocrystals not only enhances their stability but also their catalytic activity. The phosphidation conversion described here can be achieved when substituting Cu by Ni, Co, Fe, and substituting Ag by Au if the Janus metal-metal can be obtained.

5:00 PM NM01.03.02
Integration of Mesopores into Paper Materials Using Sol-Gel Chemistry Dominik Richter, Joanna Mikolei and Annette Andrieu-Brunsen; Technische Universität Darmstadt, Germany

Cellulose based materials are beneficial economically and ecologically due to their renewability, recyclability and biodegradability. The hierarchical porosity of cellulosic fibers in paper is a prerequisite and key factor to optimize application potential e.g. in the field of lab-on-chip-technology, sensors, point of care diagnostics, etc. The reason for this impact of fiber structure is its influence on capillary fluid imbibition, wettability, or mechanical stability of paper. Upon paper production, porosity can be drastically reduced, especially on the mesoscale. Attempts to reintroduce porosity into paper often come with the use of environmentally problematic chemicals or great technical effort. Here, we present a method to modify cellulose fiber and thus paper porosity by coating with (mesoporous) silica using sol-gel chemistry and evaporation induced self-assembly (EISA) combined with dip-coating. Applying different sol-gel solution compositions using two different types of cellulose fibers, namely cotton linter and eucalyptus fibers, not only mesoporosity was designed into paper but systematic insights into the mechanism of pore formation and fluid flow control were obtained. The modified paper sheets were characterized with respect to their porosity, silica distribution and fluid imbibition using small-angle x-ray scattering (SAXS), argon and krypton gas sorption, and confocal laser scanning microscopy (CLSM) to localize the silica coating relatively to the fiber structure within the paper sheet. The combined characterization techniques reveal that successful mesopore formation within paper has been achieved, that specific surface area can be adjusted by sol-gel chemistry and dip-coating which allows to adjust fluid transport velocity in paper. Interestingly, mesopore formation thereby relies on a synchronization of solvent evaporation rate, critical micellar concentration and paper-intrinsic capillary fluid imbibition velocity. The simple process allowing tuning of fluid imbibition and designing nanoscale pore space for application engineering in paper together with the fundamental mechanistic understanding is expected to impact the design of future hybrid materials for new sensing or separation devices.

5:00 PM NM01.03.03
Smart Catalytic Nanomaterials towards Green Chemistry Ji Yang and Ji Su; Lawrence Berkeley Lab, United States

Direct molecular transformation into desired structures without extra chemical transformations represents an ultimate goal in designing chemical processes, which highly depends on the development of advanced catalytic nanomaterials. Our vision is based on tailoring coordination microenvironment of a reactive atom at the atomic level to develop “reaction-matched” catalytic nanomaterials for green chemical transformations. Here, we demonstrated single-site Au with controllable coordination configurations for distinct ethanol conversion pathways. A functional nanomaterial to exclusively produce acetaldehyde from ethanol dehydrogenation was established, in which Au site was immobilized by oxygen vacancy on TiO_2; another two catalytic materials with cation vacancy-embedded Au active site on ZrO_2 or CeO_2 would give complex product distributions (C4+). By employing advanced spectroscopic studies, we attributed the distinct ethanol conversion pathways to unique electronic configurations of Au sites and vicinal coordination atoms. The concept of coordination configuration engineering demonstrated here will give unique insights and provide feasible pathways into rational design of smart catalytic nanomaterials, approaching the vision of green chemical transformations.

5:00 PM NM01.03.04
Viral-based Janus Particles for Nanomotor Assembly Xi Ding and Elaine D. Haberer; University of California, Riverside, United States

Viral nanoparticles are monodisperse, self-assembled biomaterials. Their structure and chemistry, including exact shape and site-specific functional groups, is genetically encoded and known with atomic scale precision, establishing a benchmark unrivaled by synthetic nanoparticles. Importantly, the biodiversity of viruses is vast, including an array of geometries and surface chemistries. Of specific interest, here, are viruses with asymmetric capsid proteins, like the M13 bacteriophage, that can serve as programmable bio-derived Janus particles. The M13 is a high aspect ratio, 880 nm long and 6.5 nm diameter filamentous virus. It contains approximately 2700 copies of p8 major coat protein along its length and 5 copies of p3 minor coat protein at the proximal end of the filament. Each of these proteins can be modified to create a low-symmetry template with peptide affinity for two different materials. In addition, using simple chemical exposure, this filamentous template can undergo a shape transformation to form 150 nm rods or 50 nm spheres, while maintaining site-specific affinity. The capacity for extreme modification of morphology combined with the asymmetric placement of the p3 and p8 on the viral surface make the M13 bacteriophage a potentially powerful scaffold for Janus particle assembly. In this work, the asymmetric Janus-like structure and functionality of the M13 bacteriophage capsid was used to create nanoswimmers. A cysteine-rich peptide fusion was inserted into the minor coat protein (p3) at the virus tip and Pt nanoparticles were attached via metal-thiol bonding. Using a brief chloroform treatment, the shape of the hybrid organic-inorganic Janus materials was transformed from filament to spheroid. The size and morphology of the resulting nanomaterials were characterized. The viral-based Janus particles were fluorescently tagged and exposed to low concentrations of H_2O_2 to fuel self-propulsion. Using confocal fluorescence microscopy, the nanomotor trajectory was explored, diffusion coefficients were measured, and particle motion was correlated to size and shape.

5:00 PM NM01.03.05
Multidimensional Characterization Approaches for Janus and Patchy Particles Julia S. Seifert, Andreas Völkl, Paola Cardenas Lopez, Johannes Walter and Robin N. Klupp Taylor; Institute of Particle Technology (LFG), Germany

Janus and, more broadly, patchy particles open up many opportunities as anisotropic components of tailored functional materials. Nevertheless, their promise brings with it significant challenges, in particular the characterization of their often rather complex morphologies. Improvements in this area are especially needed to support the development of large-scale processes to synthesize Janus and patchy particles, which, just like isotropic particles, tend to have broader morphological dispersity than when produced in the minute quantities often used for basic scientific studies.
We have developed various scalable continuous flow processes to synthesize Janus-like particles by coating dielectric core particles with patches of as silver or gold. Due to the localized surface plasmon resonance of the metal nanostructures, their morphology has a direct influence on their optical properties, leading to resonances in the visible and near-infrared spectral regions. To improve the later and target the product particles towards applications, it is necessary to optimize the process. The target here is to narrow the distributions of coating thickness, coverage and density. However, this can only be possible, if these parameters can be routinely and accurately measured. In this contribution, we will demonstrate how we use three different characterization techniques to extract complementary information from our complex particle system.
Firstly, we will show how automated analysis of scanning electron micrographs can be performed to investigate the metal patch yield (fraction of core particles possessing a patch), thickness and coverage. Here a significant challenge is the random orientation of the particles, meaning that statistical corrections need to be applied to account for possible “hidden” patches. Next, as an ensemble characterization technique we perform multiwavelength analytical ultracentrifugation. This technique has proven itself to be very powerful for the multidimensional characterization of anisotropic particles. Here we will show how the metal to core particle mass ratio can be determined and, taking the thickness distribution determined by microscopy, an estimate of the patch coverage distribution obtained. Finally, we will show how a new technique, single particle extinction and scattering, can be used to identify the patch yield (fraction of core particles possessing a patch) and reveal trends in patch coverage and density.

5:00 PM NM01.03.06
Automated Local Polymer Writing into a Mesoporous Silica Thin Film Using a Commercially Available Fluorescence Microscope and Oxygen Tolerant PET-RAFT Robert Lehn, Claire Förster and Annette Andrieu-Brunsen; TU Darmstadt, Germany

Functionalization of mesoporous material with polymers to modify its attributes e.g. ion transport or wettability is a much-studied field. A localized functionalization can then be used for e.g. lab-on-a-chip devices with hydrophobic barriers and hydrophilic reaction chambers or janus membrane-like structures for fluid-based material separation. One way to produce locally confined polymer functionalization is to use light-induced polymerization in combination with local illumination. The use of photomasks allows for locally restricted illumination and is well suited for mass production but lacks flexibility when developing new patterns. A direct “writing” of polymer with a precisely controlled local illumination is needed for rapid prototyping in research and development. While the use of UV-induced polymerization is well-known, the development of visible light-induced methods made the usage of commercially available fluorescence microscopes with laser illumination for polymer writing possible. A key step to make this approach more feasible was the development of an oxygen tolerant polymerization, making special equipment for the control of reaction conditions, like a glove-box, unnecessary. Here, we present an oxygen tolerant photoinduced electron/energy transfer reversible addition–fragmentation chain transfer polymerization (PET-RAFT) in combination with a commercially available fluorescence microscope (Nikon Ti2-E) for automated precise and flexible micrometer-scale polymer writing into mesoporous silica thin films. Optimization of illumination time and power was performed resulting in the ability to "write" any given monochromatic pixel image with a chosen polymer into the mesoporous silica film within a reasonable time frame. Three monomers with varying attributes were tested with the system (DMAEMA, MEP, METAC). A consecutive polymerization of all three monomers in close proximity as well as a re-initiation of polymerization with a different monomer at the same spot for the functionalization with block-copolymers was successfully performed.

5:00 PM NM01.03.08
X-Ray Induced Photodynamic Therapy With CsI(Na)@MgO Nanoparticles Zhizi Feng; University of Georgia, United States

Photodynamic therapy (PDT) is an emerging therapeutic approach to kill tumor cells by using photosensitizer (PS, both singular and plural) molecules that can be activated by light to produce reactive oxygen species (ROS), most important singlet oxygen ($^1O_2$). Only the combination and co-localization of light and PS can cause cell death, which is highly selective. Also PDT may be applied repeatedly without resistance, and can be used with chemotherapeies and immunotherapies for synergistic therapies. But the limited tissue penetration restrains PDT from the mainstream cancer treatment options. X-ray induced photodynamic therapy (X-PDT) combines the advantages of radiotherapy and PDT, potentially solves the challenge of conventional photodynamic therapy for deep-penetrating cancer therapy, and is applied by us and other groups for cancer treatment. Herein, we report a streamlined X-PDT strategy based on CsI(Na)@MgO nanoparticles and 5-aminolevulinic acid (5-ALA). The combination of CsI(Na)@MgO-and-5-ALA can kill cancer cells with the existence of X-ray, because CsI(Na)@MgO nanoparticles produce strong ~410 nm X-ray luminescence, which matches the Soret band of PpIX. While 5-ALA is a photosensitizer approved by FDA, converted to protoporphyrin IX (PpIX) in mitochondria of cancer cells. So after X-ray irradiation, protoporphyrin IX (PpIX) converted from 5-ALA can produce ROS in mitochondria with the ~410 nm X-ray luminescence caused by CsI(Na)@MgO nanoparticles, causing damages to mitochondria, and synergizes with DNA-targeted irradiation. While scintillator nanoparticles and photosensitizer are administered separately, the approach forgoes issues such as self-quenching or uncontrolled release of photosensitizers. When tested with 4T1 cells *in vitro*, the combination of CsI(Na)@MgO and 5-ALA elevated radiation-induced reactive oxygen species (ROS), which enhance damages to mitochondria, DNA, and lipids, and eventually reduced cell proliferation and clonogenicity. When tested in 4T1 models *in vivo*, the combination of X-PDT with the CsI(Na)@MgO and 5-ALA significantly improved tumor suppression and animal survival comparing with radiation therapy (RT) alone. After treatment, the scintillator nanoparticles, made of low-toxic alkali and halide elements, were efficiently excreted, causing no detectable harm to the hosts. Overall, separately administering CsI(Na)@MgO nanoparticles and 5-ALA represents a safe and streamlined X-PDT approach with a potential in clinical cancer treatment.

5:00 PM NM01.03.09
Polycation Stabilized Electrohydrodynamic Co-Jetted Janus Nanoparticle for Drug Delivery. Albert Chang and Joerg Lahann; University of Michigan–Ann Arbor, United States

Currently, poorly water-soluble drugs account for a major portion of the market-available drugs or potential drug candidates in pharmaceutical research setting. They usually require additional surfactants for solubility while also suffer from poor and high variably in bioavailability, thus limit their effectiveness in providing oral or parenteral administration. One drug delivering strategy involves exploiting hydrogels for its biocompatibility and sustainable delivery. However, existing hydrogel formed by either polymer or protein are usually hydrophilic, thereby having low compatibility and dosing efficiency with hydrophobic drugs. Nanoparticle albumin bound (NAB) technology is an efficient encapsulating method that allowed the inclusion of hydrophobic molecules into protein structure. In this work, we report the coupling of NAB technology with the adaptive electrohydrodynamic co-jetting to produce polycation-stabilized Janus nanoparticles (JNPs) for co-delivery of hydrophobic drugs. Quantitative and qualitative analysis by scanning electron microscopy (SEM) and structure illumination microscopy (SIM) show and corroborated distinct compartments in JNPs with good monodispersity at sub 200 nm in diameter. The JNPs have positively charged surface and maintained size stability for extended period characterized through dynamic light scattering (DLS). Kinetic studies of drug release show that the JNPs are pH-responsive and display different releasing profile in various settings. Our finding suggests that the polycation-stabilized NAB-JNPs is a platform that can be tailored for co-delivery of hydrophobic drugs. Furthermore, we envision that the positively charged nanoparticles can add additional mucoadhesive properties owing to its positively charged surface for targeting and adhesion that can be elucidated in further *in vitro* and *in vivo* studies for insight on therapeutic effects.

Fast Responsive Optically Functionalized Mesoporous Gold Nanostructures for pH Sensing Adil Alshoaibi; King Faisal University, Saudi Arabia

Two different routes turkivish and sol-gel methods are used to synthesize sodium citrate and polyethylene glycol functionalized gold nanostructures. Field emission scanning electronmicroscope (FESEM) analysis confirms spherical-shaped gold nanoparticles (AuNPs) and self-assembled Au nanodendritic (AuNDs) structures. Highresolution transmission electron microscopy (HRTEM) confirmed the spherical and dendritic morphology with particle sizes 9 nm of AuNPs and 3 nm of AuNDs, respectively. An atomic force microscope (AFM) shows average surface roughness (Ra) ~2.5 nm of AuNPs which is reduced to 1.5 nm in AuNDs. The AuNPs and AuNDs show heterogeneous chemical bonding and thermal stability at high temperatures. Brunauer-Emmett-Teller-based surface area is calculated at around 18 m2/g for AuNPs and 54 m2/g for AuNDs. The creosol red immobilized AuNPs (CR-AuNPs) and AuNDs (CR-AuNDs) sol demonstrate pka around 8.9 and 9.2 at 575 nm, respectively. The CR-AuNDs sol exhibit a time reaction 0.5 s which is relatively high than CR-AuNPs ~0.6 s. Both Au-structures show non-leachable behavior.

SESSION NM01.04: Janus Nanomaterials—Application

Interactions and Chemical Reactivities Between a Janus Tubular Aluminosilicate and the Cement Matrix—Case of Nuclear Waste Stabilization

Estelle Puel, Antoine Thill, Fabienne Testard, Celine Cau Dit Coumes and Arnaud Poulesquen; Commissariat à l’énergie atomique et aux énergies alternatives, France

This work deals with the conditioning of non-incinerable radioactive oil, issued from the nuclear industry, and which is still deprived of an appropriate treatment. The investigated strategy consists in using Janus particles with dual affinities for cement and oil to encapsulate oil in cement.
The chosen Janus particles are hybrid nano-clays (hybrid aluminosilicate imogolites) with tubular shape[1]. Their Janus character come from the specific properties of their internal and external surfaces. The internal surface of the nanotubes being covered by Si-CH_3 groups, this one is hydrophobic and can trap and stabilize hydrophobic compounds. The external surface formed by alumina surface is on the contrary hydrophilic and positively charged up to pH~10. It thus has good affinity for the mixing water used for cement hydration.

In this presentation, after a brief demonstration of the favorable interaction between oil and imogolite[2], we will focus on the impact of hybrid imogolites in the cement formulation with respect to oil incorporation and Portland cement hydration[3].

Previous research work shows that Pickering emulsions can be formed between oils and hybrid imogolites[2]. The stabilization mechanism is a two steps process. The first one consists in a fast stabilization of the water/oil interfaces by the nanotubes, controlled by the hybrid imogolites adsorption (pendant droplet technique). The second step shows that the adsorption allows to form a solid/gel layer that evolves slowly with time generating a stable gel structure between the drops. Direct Pickering emulsions incorporate oil up to 60% by volume by only adding a mass fraction of hybrid imogolite materials lower than 1 wt%. These emulsions stabilized by an original Janus particle have a typical behavior of both gel and Pickering emulsion, allowing to efficiently encapsulating oils.

Hexadecane was used as a non-radioactive surrogate of the contaminated oil. Hydration of cement pastes with variable contents of imogolites and / or oil was monitored using isothermal microcalorimetry. Unlike hexadecane, hybrid imogolites were shown to retard the hydration process. The delay depended both on the imogolite and water contents. To understand the mechanism involved in this delay, a simplified system, consisting in hybrid imogolites and tricalcium silicate $3CaO.SiO_2$, the main constituent of Portland cement, was thoroughly investigated. Hydration of tricalcium silicate was stopped by the solvent displacement method after increasing periods of time and the solid fraction of the paste samples was characterized by solid state NMR (^{29}Si and ^{27}Al), XRD and TGA. Imogolites were progressively destabilized under the highly alkaline conditions set by the cement paste, releasing aluminate ions to the solution, which were consumed to precipitate an aluminum-substituted calcium silicate hydrate (referred as C-A-S-H phase). This early precipitation of C-A-S-H could be responsible for the delay in cement hydration, since it is known that C-A-S-H particles do not act as nucleation and growth sites for further calcium silicate hydrate (C-S-H)[4,5]
The role of this C-A-S-H phase formation for the affinity with oil of the hydrated hybrid cement paste is still to be explored.

Acknowledgments: The authors gratefully acknowledge the French Alternative Energies and Atomic Energy Commission (CEA) and the FOCUS research program for funding.

Exploring the Janus Structure to Improve Kinetics in Sulfur Conversion of Li-S Batteries Jun Hyuk Moon and Donghee Gueon; Sogang University, Korea (the Republic of)

Lithium-sulfur batteries, which have a larger theoretical capacity compared to lithium-ion batteries, have been attracting attention as a next-generation energy storage system. A typical cathode of a lithium-sulfur battery uses sulfur loaded on a porous or high specific surface area carbon support. During charging and discharging, the electrolyte soluble lithium polysulfide (LiPS) is converted to an electrically insulating solid lithium sulfide (Li_2S), where random deposition of lithium sulfide on the cathode substrate sluggish complete conversion of sulfur. Many previous efforts to introduce metal compounds to strongly adsorb LiPS and/or to promote conversion do not entail morphological control over Li_2S deposition. In this study, we introduce a Janus structure of a metal compound/carbon to simultaneously control the growth of Li_2S as well as promote the adsorption/conversion of LiPS. The Janus particles are prepared by directional thermal deposition of MoO_3 onto CNT-agglomerated spherical particles. Under potentiostatic discharge, we observe that Li_2S is deposited predominantly on MoO_3-coated regions on CNT particles, accompanied by high discharge capacity. As the deposition of Li_2S is microscopically controlled, the diffusion path of ions/charges in the electrode is preserved. Moreover, it is confirmed that the adsorption and catalytic properties of MoO_3 are greatly promoted by its lithiation during the charge/discharge process. Janus particle cathode cells achieve excellent performance, especially under kinetically limited conditions, such as ultra-high C-rates or high cathode sulfur densities.

Dynamic Optical Structures for Sensing Based on Complex Janus Emulsions Timothy M. Swager; MIT, United States

This lecture will focus on the design of systems wherein reconfiguration of complex liquid Janus emulsions (droplets) and related materials can be triggered chemically, biochemically, or with magnetic fields. The utility of these methods is to generate new transduction mechanisms by which chemical and biological sensors can be developed. Complex liquid Janus droplets behave as optical lens systems and small changes in surface tensions can change focal lengths or cause systems to switch between optically transmissive or scattering states. Central to this scheme is that the fluids in the droplets have different densities and hence are aligned by the earth’s gravity. The induced optical changes can be triggered with chemical, photochemical, or biochemical stimuli and thereby create new generations of sensors. Demonstrations of these methods for the detection of enzyme concentrations, pathogens, and antibodies will be presented. Janus droplets containing birefringent liquid crystals (LCs), including chiral nematic phases, have been prepared and designer surfactants cause either planar of vertical anchoring at the water-liquid crystal interface. The liquid crystals can be used for precise positioning of magnetic particles and biomolecular elements. Magnetic particles can be used to create novel optical functions, including steering of light and selective reflection, which will be detailed.

9:45 AM *NM01.04.05
Janus Nanomaterials: Design, Synthesis and Applications for Oil Industry Wei Wang; Aramco Americas: Aramco Research Center-Boston, United States

Anisotropic nanomaterials composed of two halves of different structure, chemistry, or polarity, known as Janus nanomaterials, have distinct properties compared to symmetrically functionalized analogues and therefore have recently been paid significant attention in many applications such as electronic thin films, drug delivery, sensors, optics, oil/water separation membranes, photoactivated micromotors, photocatalysts, and interfacial modification. However, it remains a big challenge to synthesize the Janus nanostructures in large quantity with precise turnability of surface property. In this review, we summarize and discuss rational design and fabrication of Janus nanostructures, especially the methods for scale-up synthesis. Current progress on application of the Janus nanomaterials for oilfield chemistry in oil industry is discussed and prospected.

Transducing Metal Catalyst Reactivity to Selective Chemical Sensing with Pentiptycene Metallopolymer/Single-Walled Carbon Nanotubes Suprastructural Complexes Shao-Xiong Lennon Luo, Haosheng Feng and Timothy M. Swager; Massachusetts Institute of Technology, United States

Single-Walled Carbon Nanotubes (SWCNTs) possess desirable electronic properties to function as the transducer material in a chemiresistive sensor. However, pristine SWCNTs make poor chemical sensors as they lack the functionalities for the selective molecular interaction with target analytes. Our group has demonstrated that catalysis can be a powerful design principle for chemical sensing. By taking advantage of the high reactivity and chemoselectivity of the metal catalysts, we can build chemical sensors with high sensitivity and selectivity that mirror the catalytic processes. To this end, it is essential to develop a general methodology for the seamless integration of metal catalysts in SWCNT-based chemiresistors that can facilitate the effective transduction of the desired chemical interactions to electrical sensing readouts.
In this project, we show that by using a family of pentiptycene-containing conjugated polymers, which are found to effectively bind SWCNTs to form stable dispersions, we can chelate metal catalysts to form suprastructural complexes that are capable of translating the reactivity of the embedded metal catalysts to the selective detection of gas analytes. Chemiresistive chemical sensors constructed based on these metallopolymer/SWCNT complexes find applications in diverse areas such as environmental monitoring and health diagnostics. In particular, we demonstrate that by incorporating a methane oxidation catalyst in these metallopolymer/SWCNT complexes, we can detect the potent greenhouse gas in high humidity at room temperature, overcoming the weakness in most chemiresistive methane sensors. Moreover, we have built a sensitive and selective sensor for the detection of ammonia in breath, which is an important biomarker for the screening and monitoring of chronic kidney disease. For better utility, wearable sensors can also be realized by immobilizing the metallopolymer/SWCNT complexes on flexible substrates. Furthermore, by varying the metal catalysts and tuning the polymer ligand structures, these hybrid sensory nanomaterials can be readily derivatized to construct sensor arrays for the accurate classification and differentiation of analytes in a complex mixture.

10:45 AM DISCUSSION TIME

11:00 AM NM01.04.08
Effective Optical Nanoparticles and Nanocomposites Based on a Carbon Nanotubes-Organic–Inorganic Nanohybrid for Industrial Pollutant Removal Adil Alshoaibi; King Faisal University, Saudi Arabia

Improving the optical properties of zinc oxide to meet the practical requirements of photocatalytic reactions and solar cells is an ongoing challenge. To address this challenge, different nanostructures of ZnO were prepared from an organic–inorganic-CNTs nanohybrid. The nanohybrid was formed through intercalation of the long chain fatty acid $C_{17}H_{35}COOH$ and carbon nanotubes into Zn–Al nanolayered structures. X-ray diffraction revealed an increase in the interlayer spacing of the Zn–Al layered double hydroxides from 0.75 nm to 2.1 nm after admixing with the CNTs and organic fatty acid. Thermal analyses and FTIR confirmed the formation of the CNTs–C18–Zn–Al nanohybrid. Three different thermal treatments were used to transform the nanohybrid into nanostructures of doped zinc oxide nanoparticles and zinc aluminum oxide nanocomposites. As a result of changes in the nano size and structure, the band gap energy of the products decreased from 3.3 eV to 1.8 eV, to give efficient photocatalysts. The nanomaterials were used to purify water through the photocatalytic degradation of colored pollutants under UV light. A kinetic study showed that water purification was achieved within a short time, demonstrating the effectiveness of the nanomaterials. The nanohybrid and its derivatives are attractive materials for designing-efficient photocatalysts for pollutant degradation.

Development of Nano-prodrug&Hydrogel for Locoregional Therapy Liu Zhixiang; Tohoku university, Japan

Malignant skin ulcerations are caused by skin cancer or metastatic spread to the skin, resulting in the loss of epithelial tissues. In the present study, we aimed to develop nano-prodrug@hydrogel materials for locoregional therapy of malignant skin ulcerations. Compared to drugs in the molecular state, nano-prodrugs (NPDs), which are composed of only prodrug molecules, have high pharmaceutical activity due to high permeability to the tissue. Polydopamine nanoparticles (PDA-NPs) are introduced into poly(N-isopropylacrylamide) (pNIPAM) hydrogel to fabricate a PDA-NPs/PNIPAM hydrogel system. PDA-NPs, as a near infrared (NIR) sensitive material, can be heated under 808 nm NIR light and shrink the temperature sensitive pNIPAM hydrogel. Thus, this system is designed that can use NIR light to rapidly excite and release NPDs on demand. Here, we reported the fabrication of PDA-NPs/pNIPAM hydrogel loaded with SN-38-cholesterol nano-prodrugs (SN-38-chol NPDs).
SN-38-chol NPDs were prepared by reprecipitation method.The size of the NPDs was about 120 nm . PDA-NPs/pNIPAM hydrogel drug delivery system loaded with SN-38-chol NPDs was successfully fabricated . The drug loading of the SN-38-chol NPDs@hydrogel was about 0.05 mg/g (drug weight/hydrogel weight), indicating a good drug loading capacity of the system. To evaluate *in vitro* cytostatic activity, SN-38-chol NPDs dispersion and SN-38-chol NPDs@hydrogel were applied to HCT-116 (human colon cancer) cell at the same final concentration and incubated for 48 h. As a result, SN-38-chol NPDs dispersion and the SN-38-chol NPDs@hydrogel showed similar cytostatic activity

Structural and Chemical Mechanisms Governing the Stability and Electronic Properties of Inorganic Janus Nanotubes Ivano Eligio Castelli; Technical University of Denmark, Denmark

One-dimensional inorganic nanotubes hold promise for technological applications due to their distinct physical/chemical properties. Still, so far advancements have been hampered by difficulties in producing single-wall nanotubes with a well-defined radius. In this work, based on Density Functional Theory (DFT), we investigate the formation mechanism of different prototypes of inorganic nanotubes formed by the intrinsic self-rolling driving force found in asymmetric 2D Janus sheets. We show that for isovalent Janus sheets, the lattice mismatch between inner and outer atomic layers is the driving force behind the nanotube formation. At the same time, in the non-isovalent case, it is governed by the difference in chemical bond strength of the inner and outer layers leading to steric effects. From our pool of candidate structures, we have identified a handful of nanotubes with a preferred radius below 15 Å, which we hypothesize can display distinctive properties compared to their parent 2D monolayers. We investigate electronic properties and show that many of these nanotubes exhibit sizable band gaps and size-dependent electronic properties. Moreover, we observe that the flexoelectricity in these nanotubes is significantly larger than those of other nanotubes and their 2D counterparts. This work opens up an avenue of structure-property relationships of Janus nanotubes and demonstrates exciting new properties, which can accelerate the green transition to a more sustainable future.

8:30 AM *NM01.05.03
Assembly and Propulsion of Magnetic Janus Particles Bhuvnesh Bharti; Louisiana State University, United States

Janus particles are widely considered as a fundamental building block for fabricating intricate machines able to perform complex functions at sub-micron scale. Due to their dual surface functionality, these particles have dissimilar surface interactions with surrounding particles and medium. The inherent asymmetry of Janus particles can drive their assembly into complex phases and/or generate net force on the particles inducing a motion. In this talk I will present the use external magnetic field as to tool to direct the assembly and propulsion of Janus particles suspended in ferrofluids. First, I will show how the intrinsic anisotropy in magnetic interactions combined with the asymmetry of the Janus particles can induce unusual magnetic interaction energy landscape around the particle. By combining patchy and non-patchy particles, we modulate these interactions to construct clusters with morphologies resembling colloidal molecules. I will discuss the assembly of such clusters, their programmability by manipulation of patch size, their in-situ tunability using the magnetic field, and I will show a technique to permanently bind them once assembled. Secondly, I will demonstrate how to use time-periodic magnetic fields to drive the coherent dynamic surface rolling of Janus particles in the ferrofluids. I will show how external field allows controlling characteristics of the active motion such as rolling, rotation, speed, and direction of motion of the Janus particles. Our experimental results display the potential in microstructuring at the single cluster level as well as controlling active motion and collective behaviors of the Janus colloids, using a single external magnetic field. The simplicity and versatility of the approach stems from exploiting the anisotropy of magnetic interactions combined with the asymmetry of the Janus particles enabling a precise control over both the equilibrium assembly and non-equilibrium motion of the particles.

9:00 AM *NM01.04.06
Optical Manipulation of Janus Particles Using Optical Nanofibers Sile Nic Chormaic; OIST Graduate University, Japan

Janus particles, which are small composite particles, are of interst for biomedical applications, where they act as actuators, carriers, or imaging agents. One major technical challenge is efficient manipulation of Janus particles. Long-range methods depending on chemical reactions or thermal gradients have limited precision and depend on the environmental fluid. Here, we demonstrate the optical manipulation of Janus particles consisting of silica microspheres half-coated with gold in the evanescent field of an optical nanofiber. The Janus particles have faster propulsion along the nanofiber compared to pure dielectric particles of the same size.

InterContinental, Fifth Floor, Sutter

10:30 AM *NM02.01.01
2D Polymers and Their van der Waals Heterostructures for Electronic and Ionic Devices Yu Zhong; Cornell University, United States

Artificial van der Waals (vdW) solids assembled from 2D crystals represent a new type of materials that can be engineered at the atomic scale. 2D polymers, made by cross-linking molecules into a 2D network, are not only an emerging library of 2D building blocks for making vdW solids but also offer unlimited structural tunability on the molecular level. In this talk, I will introduce an approach to synthesizing monolayer 2D polymers on a large scale. This approach allows for scalable and facile integration of 2D polymers into electronic and ionic devices. The 2D polymer films can serve as the thinnest semipermeable membranes, which deliver a record high osmotic power generation density. Furthermore, I will show the programmed assembly of hybrid 2D heterostructures using 2D polymers and inorganic 2D materials. This approach allows for integrating versatile molecular building blocks into layered nanomaterials to develop ultrathin electronic, ionic, and electrochemical devices.

11:00 AM *NM02.01.02
Manufacturing 2D Materials at Low Temperatures and High Spatial Selectivity Zakaria Al Balushi; University of California, Berkeley, United States

The multitude of 2D materials in regard to composition, crystal structure and layer thickness leads to a variety of material properties covering all of the components necessary to address voltage, interconnect, energy, and dimensional scaling issues in a variety of applications. For 2D materials to be technologically competitive, it is imperative to develop manufacturable materials deposition protocols with spatial selectivity and low temperatures at any location on demand without wafer transfer processing. In this talk, a low temperature spin coating process will be discussed to form transition metal dichalcogenides at low temperatures using a modified spin coating technique from low decomposition temperature molecules. Furthermore, to achieve spatial selectivity of grown 2D materials, this talk will also describe a novel process to spatially measure and modulate the surface energy of van der Waals surfaces at growth temperatures to achieve selective area growth of 2D materials into a variety of form factors.

SESSION NM02.02: Nanoscale Imaging and In Situ Spectroscopy I
Session Chairs: Kwabena Bediako and Fang Liu
Tuesday Afternoon, April 11, 2023
InterContinental, Fifth Floor, Sutter

1:30 PM *NM02.02.01
Spatiotemporally Following Ions and Carriers and Heat (oh my!) at the Nanoscale in Few-layer Materials Hannah L. Weaver[1], James Utterback[1], Livia Belman-Wells[1], Stephanie Hart[1], Leo Hamerlynck[1], Rongfeng Yuan[1], Cora Went[2], Dipti Jasrasaria[1], Joeson Wong[2], Alex King[3], Elena Vasquez[1], Eran Rabani[1], Harry A. Atwater[2], Adam Weber[3] and Naomi S. Ginsberg[1]; [1]University of California, Berkeley, United States; [2]California Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

Electronic, thermal, and ionic transport are all important to the myriad roles that 2D materials play in science and technology and particularly in electrochemistry. I will describe our recent work to characterize each type of transport using the single umbrella of time-resolved optical elastic scattering microscopy. This approach allows these different forms of energy flow to be imaged separately and together, with temperature change sensitivity down to 0.1 K. I will separately show results imaging the co-evolution of excitons and heat in few layer MoS_2 and results imaging the redistribution of ions in an electrolyte during an electrochemical reaction. I will finally describe efforts to unite these two separate foci so that ion intercalation and electrochemistry can be characterized simultaneously with electronic and thermal transport.

2:00 PM *NM02.02.03
Hot Carrier Dynamics & Many-Body Effects in TMD-Based Electrochemical Cells Revealed Using Nonlinear Spectroscopy & Theory Yusef R. Farah, Rachelle Austin, Thomas Sayer, Andres Montoya-Castillo, Justin Sambur and Amber T. Krummel; Colorado State University, United States

Commercial hot carrier devices have not yet been realized, in part due to the poor understanding of how operational device conditions impact hot carrier dynamics. Single monolayer transition metal dichalcogenides (2D TMDs) are promising active materials for hot carrier devices due to their broad and large visible light absorption, atomically thin geometry, and slow hot carrier cooling. To push hot carrier devices towards being a disruptive technology, one must understand the tuning parameters available in the devices and how to predict behaviors of the 2D TMDs. In this talk, I will describe efforts in combining theory with experiment to characterize and describe hot carrier dynamics in a monolayer (ML) MoS_2-based electrochemical cell. Results from in operando spectroscopy, including steady-state photocurrent spectroscopy and transient absorption spectroscopy, will be presented. We have built a model electrochemical cell in which ML MoS2 makes intimate contacts with an electron selective solid contact and a hole selective electrolyte contact. All measurements are made as a function of applied potential. Photocurrent and absorbance measurements performed simultaneously as a function of applied potential reveal which optical states generate charge carriers first. In operando transient absorption measurements provide signatures of hot carrier extraction and the time scales associated with hot carrier extraction and charge carrier dynamics. We observe the extraction of hot carriers within 50 fs and high photocurrent yields in our device that exceed photocurrent yields observed in bulk MoS_2. Throughout this work we monitor the formation of excitons and trions as a function of applied potential. Finally, the experiments are interpreted within a theoretical framework that allows for: 1. the origin of the experimental observations to be described and 2. A streamlined modelling approach taken to describe many-body effects that are observed in the experiments.

2:30 PM BREAK

3:00 PM *NM02.02.04
Ultrafast Charge Carrier and Polaron Dynamics in 2D-Transition Metal Chalcogenides Hirendra N. Ghosh; Bhabha Atomic Research Centre, India

Research on two-dimensional (2D) transition metal dichalcogenides (TMDC) have gained incredible interest and importance in recent times, attributable to their fascinating optical, electronic and mechanical properties. They offer both fundamental and technological implications in various advanced electronic, optoelectronic and gas sensing devices, energy storage systems, photovoltaics and photo-catalysis. To optimize the efficiency of any devices it is very important to understand the ultrafast charge carrier dynamics of these 2D TMDC materials. In the present talk we will discuss photo-excited charge carrier dynamics of few TMDC materials with the aid of Femto-second broad-band pump-probe spectroscopy and Femtosecond Terahertz spectroscopy. We have discussed free-carriers, exciton and other quasi particles like bi-exciton and trion dynamics in TMDC on excitation with ultrafast laser pulse.

3:30 PM *NM02.02.05
Spatial and Temporal Imaging of Exciton Transport in Two-Dimensional Heterostructures Libai Huang; Purdue University, United States

Charge-transfer (CT) excitons at hetero-interfaces play a critical role in light to electricity conversion using nanostructured materials. However, how CT excitons migrate at these interfaces is poorly understood. Atomically thin and two-dimensional (2D) nanostructures provide a new platform to create architectures with sharp interfaces for directing interfacial charge transport. Here we investigate the formation and transport of interlayer CT excitons in van der Waals (vdW) heterostructures based on semiconducting transition metal dichalcogenides (TMDCs) employing transient absorption microscopy (TAM) with a temporal resolution of 200 fs and spatial precision of 50 nm.

We have investigated interlayer exciton dynamics and transport modulated by the moiré potentials in WS$_2$-WSe$_2$ heterobilayers in time, space, and momentum domains using transient absorption microscopy combined with first-principles calculations. Experimental results verified the theoretical prediction of energetically favorable K-Q interlayer excitons and unraveled exciton-population dynamics that was controlled by the twist-angle-dependent energy difference between the K-Q and K-K excitons. Spatially- and temporally-resolved exciton-population imaging directly visualizes exciton localization by twist-angle-dependent moiré potentials of ~100 meV. Exciton transport deviates significantly from normal diffusion due to the interplay between the moiré potentials and strong many-body interactions, leading to exciton-density- and twist-angle-dependent diffusion length. These results have important implications for designing vdW heterostructures for exciton and spin transport as well as for quantum communication applications.

We have also imaged the transport of interlayer CT excitons in 2D organic-inorganic vdW heterostructures constructed from WS$_2$ layers and tetracene thin films. Photoluminescence (PL) measurements confirm the formation of interlayer excitons with a binding energy of ~ 0.3 eV. Electron and hole transfer processes at the interface between monolayer WS$_2$ and tetracene thin film are very rapid, with time constant of ~ 2 ps and ~ 3 ps, respectively. TAM measurements of exciton transport at these 2D interfaces reveal mobile CT excitons, with diffusion constant of ~ 1 cm^{2}s^{-1}. The high mobility of the delocalized CT excitons could be the key factor to overcome large CT exciton binding energy in achieving efficient charge separation.

SESSION NM02.03: Nanoscale Imaging and In Situ Spectroscopy II

Wednesday Morning, April 12, 2023
InterContinental, Fifth Floor, Sutter

8:00 AM *NM02.03.02
Exciton Propagation in 2D Semiconductors Alexey Chernikov; TU Dresden, Germany

Transport of photoexcited charge carriers in semiconducting solids plays a central role from both fundamental and technological perspectives. In two-dimensional systems with strong Coulomb interaction the propagation of optically injected carriers is dominated by excitons instead of free electrons or holes. These correlations determine the flow of energy stored in the electronic system and can facilitate transport of information encoded in spin or pseudospin degrees of freedom.

In this talk I will present recent studies focused on propagation of mobile exciton quasiparticles in semiconducting van der Waals monolayers and hybrid perovskite materials. In these systems, the electron-hole correlations present a particularly interesting case combining the properties of Wannier-Mott excitations in inorganic semiconductors with high exciton binding energies that are more characteristic for Frenkel-like states in molecular crystals. I will discuss non-linear and anomalous diffusion, indications of quantum transport for excitons, as well as high-density propagation phenomena in van der Waals heterostructures at the Mott transition.

8:30 AM *NM02.03.03
Probing Excited State and Charge Transfer Dynamics at 2D Interfaces Keshav M. Dani; Okinawa Institute of Science and Technology, Japan

Mechanistic Insights into 2H to 1T Phase Transitions in Transition Metal Dichalcogenides by *In Situ* Optical Microscopy Juhwan Lim, Jung-In Lee, Christoph Schnederman, Manish Chhowalla, Akshay Rao and Arturo Medina; University of Cambridge, United Kingdom

Phase engineering of transition metal dichalcogenides (TMDs) allows for the tuning of electric and optical properties and enhancement of the device performance. The most well studied example of this kind of phase transformation is use of charges and intercalating lithium ions to change semiconducting octahedral (2H) TMDs to metallic trigonal prismatic (1T) phase using n-butyllithium (n-BuLi).
In this study, we optically tracked the chemically-induced 2H to 1T phase transition of MoS_2, $MoSe_2$, WS_2, and WSe_2 in n-BuLi in real time, using in-situ optical reflectance interferometric contrast microscopy (RICM). The different optical properties of 2H- and 1T- TMD allow us to quantify reaction dynamics of mechanically exfoliated mono-, bi-, and multilayer flakes in diffraction limited resolution (~200 nm). We show that mechanism of the phase transformation is dependent on the transient metal atom present, as MoS_2, $MoSe_2$ exhibit a single spatially propagating phase front for the conversion, while WS_2 or WSe_2 has no wavefront or two wavefronts propagating closely, respectively.
These observations are correlated with cyclic voltammetry(CV) and electrochemical measurements to build a mechanistic picture of the phase transformation reaction in different TMDs. In electrochemical measurement, MoX_2(X= S/Se) has electrical potential for a phase transition closer to the redox potential of n-BuLi(1V), while WX_2 have lower potential (MoS_2 : -0.07 V, $MoSe_2$: +0.08V, WS_2 : +0.22V, WSe_2 : +0.2V, versus Li/Li^+). This correlates to the optical observation of a more spontaneous phase transition for MoX_2. Additionally, the potential difference between phase transition and conversion is discrete for MoX_2, while close or overlapped for WX_2(MoS_2 : ~0.5V, $MoSe_2$: ~0.3V, WX_2: < 0.1V). This could be incorporated with the light-driven phase transition which only MoX_2 displayed discrete 1T phase while WX_2 undergo conversion reaction. We also carefully examined each flake with different phase in ex-situ, such as the change of A-exciton PL, arising of Raman J peaks, and shifts of Raman peaks, and suggest systematic interpretation for this behavior. This study could suggest mechanistic insight of phase transition by incorporating the correlation between electrochemical- and chemical- reaction, for application in phase engineering, chemical exfoliation and energy application of TMDs.

Electroless Excitation of Semiconductors through Semiconductor-liquid Interfaces Shengyang Li, Kexun Chen, Ville Vähänissi, Hele Savin and Jani Oksanen; Aalto University, Finland

Electrochemistry of inorganic semiconductors has been studied extensively in the context of photoelectrocatalysis (e.g., water splitting, CO_2 reduction), corrosion and microfabrication technologies. On the other hand, little attention has been placed on studying the possibility of electroless excitation of semiconductors through semiconductor-liquid interfaces. We recently showed that electroless excitation takes place during metal-assisted chemical etching (MACE) of Si by using two different approaches. In the first approach,[1] a charge carrier collecting p-n junction structure coated with silver nanoparticles (AgNPs) was used to convert the chemical energy released during MACE to electricity using an electroless approach, i.e. without using any counter electrode, reaching a power density of 0.43 mW/cm^2. In the second approach,[2] we designed both n- and p-type Si photoconductors covered with AgNPs to probe their response to MACE. The experiments show that both n- and p-type photoconductors exhibit a strong response to MACE, seen as a significant increase of the currents through the photoconductors when exposed to the etching solution. All these experimental results imply that electroless excitation of Si takes place during MACE.
In this presentation, we discuss the origin of these findings and the possibility to generalize the mechanisms of electroless excitation of semiconductors to other fuel-oxidizer systems. In particular, we discuss a framework for describing the thermodynamic and kinetic properties of the charge flow across the semiconductor-liquid interfaces during electroless excitation, aiming to establish the limits for the thermodynamic feasibility of the process.

Phase Transitions of Excitons in Two Dimensions Xiaoyang Zhu; Columbia University, United States

An exciton is a quasi-particle consisting of an electron and a hole bound by the Coulomb potential. It is a solid and excited state analog of the hydrogen atom. Excitons are fundamental to semiconductors and determine a range of processes involving the conversion of light to charge or charge to light. As bosonic particles, excitons can form quantum phases, e.g., Bose-Einstein condensates (BECs). Unlike their 3D counter parts, the Coulomb and exchange interactions are poorly screened in 2D> This results in large exciton binding energies and strong dependences of semiconductor bandgaps on charge carrier concentrations. In 2D transition-metal dichalcogenide (TMDC) heterojunctions, charge separation across the interface results in interlayer excitons with lifetimes five orders of magnitude longer than those of their intralayer counterparts. Both the dipolar nature and long lifetime make interlayer excitons ideal models for the exploration of many body interactions and phase transitions. Moreover, moiré pattern formation and site-specific interlayer hybridization result in periodic potentials for interlayer exciton arrays that may serve as quantum simulators. We show the sensitivity of moiré trapped excitons to local strain, from 0D unstrained QD arrays to 1D strained wires. With increasing exciton density, inter-exciton interaction leads to two distinct phase transitions: from trapped excitons in the moiré-potential to the modestly mobile exciton gas as exciton density increases to $n \sim 10^{11}$ cm^{-2} and from the exciton gas to the highly mobile charge separated electron/hole plasma for $n > 10^{12}$ cm^{-2}. We explore the ordering of interlayer excitons into quantum phases using trilayer structure as predicted in recent theory.

Quantifying Energy Level Alignment at Monolayer MoS_2/Electrolyte Interface Rafael Almaraz, Justin B. Sambur and Justin Toole; Colorado State University, United States

Transition metal dichalcogenides (TMDs) have unique optical and electronic properties for photo-electrocatalysis applications. The fundamental problem is that the interfacial energetics of TMD/electrolyte interfaces in photoelectrochemical cells are poorly understood. The weakly screened Coulomb potential leads to a large exciton energy and a strong renormalization of the bang gap energy as a function of carrier concentration. Hence, my talk will focus on quantifying how the conduction and valence band energies move as a function of applied potential in an electrochemical cell. To do so, we utilize potential-dependent spatially resolved absorption spectroscopy to quantify the energy levels of monolayer MoS2 in electrochemical cells. The spatially resolved measurements are necessary to distinguish monolayer from few layer-thick material on the sample and, therefore, simplifies data interpretation. I will discuss how we 1) use optical data to extract the carrier concentration of the semiconductor as a function of applied bias and 2) construct band energy diagrams as a function of applied potential.

10:45 AM NM02.03.08
Probing of the Electrical Response of the Air/Graphene/Liquid Interface without the Presence of any Underlying Substrate Rodrigo G. Lacerda; Univ Federal de Minas Gerais, Brazil

Graphene is a crystalline 2D material and considered the thinnest possible membrane. Because of its high chemical stability, combined with its physical properties, graphene is promising in a variety of applications. Particularly, liquid/graphene interfaces have been exploited for bio-applications on cellular flow sensing, liquid sensing, DNA sequencing, and transparent windows in liquid cells. In such devices, understanding the interaction between water and graphene is crucial for building up novel and smart bio-interfaces. Additionally, the study of reactivity and structure of water at the graphene interface has also generated intriguing questions and controversial results. For instance, several experimental works demonstrate that the charge transfer process that happens between graphene and water molecules is highly dependent on the underlying substrate. Thus, it would be highly desirable to elucidate the above discussion by probing the electrical response of a suspended graphene membrane in contact with water without the presence of any substrate. We also believe that a precise understanding of the electrochemical behavior of water/graphene interface would be fundamental for developing novel and superior electrical, mechanical and optical devices. In this work, we develop a microfluidic platform that integrates suspended graphene membrane windows (with electrical contacts) with buried fluid channels to probe the electrical response of a graphene membrane in contact with water [1,2,3]. The platform design provides a direct probing of the electrical response of the air/graphene/liquid interface without the presence of any underlying substrate.

I will present a detailed study of the water-induced electromechanical response in suspended graphene atop a microfluidic channel. The graphene membrane resistivity rapidly decreases ~ 25% upon water injection into the channel, defining a sensitive "channel wetting" device – a *wetristor*. The physical mechanism of the *wetristor* operation is investigated using two graphene membrane geometries, either uncovered or covered by an inert and rigid lid (h-BN multilayer or PMMA film). The *wetristor* effect, namely the water-induced resistivity collapse, occurs in uncovered devices only. AFM and Raman spectroscopy indicate substantial morphology changes of graphene membranes in such devices, while covered membranes suffer no changes, upon channel water filling. Our results suggest an electromechanical nature for the *wetristor* effect, where the resistivity reduction is caused by un-wrinkling of the graphene membrane through channel filling, with an eventual direct doping caused by water being of much smaller magnitude, if any. The *wetristor* device should find useful sensing applications in general micro- and nano-fluidics and provides novel insights on the interface interactions of 2D materials with liquids.

Nanoscale Photoemission Spectroscopy as a Local Voltage Probe of Operating 2D Material Devices Søren Ulstrup; Aarhus University, Denmark

Understanding electronic and structural mechanisms that define intrinsic and extrinsic performance limits of two-dimensional (2D) materials integrated in functional device architectures is essential for the realization of truly 2D technologies. Obtaining such insights demands a probe that is capable of visualizing electronic structure on mesoscopic length scales and during operating conditions of devices.

Here, I will demonstrate the ability to visualize the energy- and momentum-dependent quasiparticle dispersion in 2D devices composed of graphene supported on a hexagonal boron nitride (hBN) dielectric and a graphite back-gate. The charge carrier-dependent spectral function of graphene is resolved using angle-resolved photoemission spectroscopy with nanoscale spatial resolution (nanoARPES) while the back-gate voltage is tuned. I will discuss how such measurements directly reveal the doping-dependent renormalized Fermi velocity of Dirac quasiparticles and elucidate electron-phonon and electron-plasmon interactions in graphene [1,2]. Position-resolved measurements of the graphene Dirac cone in the presence of an electrical transport current provide a map of the local electrostatic potential, which is combined with the local doping to estimate the spatially-dependent carrier mobility of graphene on hBN [3,4]. The work demonstrates the powerful concept of unifying spectroscopic and transport measurements on 2D materials, which allows for a simultaneous noninvasive local measurement of composition, structure, many-body effects and carrier mobility in the presence of high current densities and tunable charge carrier concentrations.

Optically Excited States and Their Dynamics in Atomically Thin Semiconductor Heterostructures Tony F. Heinz; Stanford University and SLAC National Accelerator Laboratory, United States

Combining semiconductor monolayers of van-der-Waals materials by stacking leads to a wide variety of new excited electronic states, which have the potential for various optoelectronic and electrochemical applications. In this paper, we will review recent progress in understanding the fundamental nature and dynamics of the interlayer excited states, the so-called interlayer excitons, that are supported in transition metal dichalcogenide heterostructures. In particular, we will discuss how time-resolved ARPES measurements, carried out in collaboration with the group of Keshav Dani, provide a methodology for directly imaging both the electron and hole component of these interlayer states in momentum space. This methodology allows us to track the ultrafast dynamics of the charge transfer processes leading to the formation of interlayer excitons, as well as the exciton decay dynamics.

We will also describe the new interlayer states that arise in semiconductor heterotrilayers, particularly in angle-aligned $WSe_2/WS_2/WSe_2$ stacks. In these materials, we find that symmetrical interlayer excitons can be created. These states exhibit much weaker exciton-exciton interactions than those seen in bilayers, since excitons in the former have no static dipole moment, while the latter have a substantial dipole moment. The so-called quadrupolar excitons in the trilayer structure can be continuously tuned by an external electric field to the dipolar limit, thus creating a material with a programmable exciton-exciton interaction. For the symmetric structure, we see at high exciton density signatures of a transition to a staggered dipolar phase. This phase transition is driven by attractive interaction between oppositely aligned interlayer exciton dipole moments. We will discuss the evidence for this new excitonic phase, the significant and distinctive influence of moiré effects in these trilayer structures, and the potential applications of such novel excited states.

3:30 PM *NM02.05.02

Theoretical Treatment of Electrocatalytic Reactions on 2D Transition Metal Dichalcogenides under Electrochemical Conditions Taylor Aubry[1], Elisa Miller-Link[1,2], Derek Vigil-Fowler[1] and Jao Van de Lagemaat[1,2]; [1]National Renewable Energy Laboratory, United States; [2]Renewable And Sustainable Energy Institute, United States

Two-dimensional semiconductors such as MoS2 and WSe2, etc. are known (photo)electrocatalysts for the electrochemical reduction of water to form H2, CO2 to form C1 and higher products, N2 to form NH3, and other relevant reactions for a future low-carbon economy. These reactions are complex and involve multiple steps. When performed on the 2-dimensional systems, they are often catalyzed by defects or step edges or to need a semiconductor to metal phase transition to be efficiently catalyzed on intact basal planes. The reactions also involve multiple electron and proton transfer events that are often thought to happen in an intricately coupled manner. At the same time, it is known from experiment that electrochemical conditions, such as electrical bias, strongly modify the electronic properties of the (photo)electrocatalyst by effects such as bandgap renormalization, non-uniform shifts of catalyst and molecular electronic states with applied potential, phase transitions, and other effects that can radically alter the energetics and kinetics of the steps involved. Also, these materials can have very strong light-matter interactions that modify their electrochemical behavior. This complexity makes it hard to make predictions about the electrocatalytic behavior of these materials.

In this contribution, we investigate the above-mentioned reactions using density functional theory calculations performed in the Grand Canonical Ensemble, as implemented in the JDFTx software package that can accurately address realistic electrochemical conditions (electrified interfaces, dielectric response, ionic strength, etc.) while still fully treating spin- polarization and other electronic effects. We study the reaction pathways, intermediate energies and the electronic properties of the intermediate complexes to gain a better understanding of the electrochemical reduction reactions in their actual microenvironments. We find that the electrochemical conditions modify electrocatalytic pathways in a non-trivial manner and that the local structure of the 2-D semiconductor changes considerably during the reaction sequence. We investigate the bonding environment between catalytic site and substrate and find that effects such as pi-back bonding to the transition metal sites and local relaxation of the microenvironment are essential in understanding the reaction pathway and the dependence of the reaction thermodynamics on electrochemical bias. Most significantly we find that traditional methods of calculating intermediate state energies in vacuum environment, while informative to study intermediate conformation, are not able to treat the reaction particulars well and, in many cases, the wrong reaction step can be identified as rate limiting.

Lastly, in this contribution, we connect our theoretical calculations to experiments performed in our group and in the literature and talk about the implications of the new theoretical insight on our understanding of fuel-forming reactions on 2-dimensional semiconductors and other related electrocatalytic systems. We demonstrate that it is essential to more fully treat the electrochemical microenvironment in order to model and understand these complex multi-step reactions and that local bias effects are much more important than previously understood and cannot be ignored or approximated by simple Coulomb approximations. This new insight has the potential to alter our understanding of electrocatalytic reactions in (photo)electrochemical systems considerably.

4:00 PM NM02.05.03

Disentangling Spectral Signatures of 2D Material Interfaces Under Bias—Cracking the Mysterious Case of the Shifting A Exciton in Monolayer Transition Metal Dichalcogenides Thomas Sayer[1], Yusef R. Farah[2], Rachelle Austin[2], Justin Sambur[2], Amber T. Krummel[2] and Andres Montoya-Castillo[1]; [1]University of Colorado, Boulder, United States; [2]Colorado State University, United States

A fundamental challenge in elucidating, controlling, and exploiting nonequilibrium relaxation in condensed phase systems is the ability to employ physically transparent models to assign and interpret the spectral signatures of processes spanning charge and energy transfer, quasiparticle formation, and even chemical reactivity. Two-dimensional materials, such as transition metal dichalcogenides (TMDs), offer one such challenge, especially under applied fields. In this talk, I will discuss our critical assessment of the ability of a physically intuitive Hamiltonian, consisting of an infinitely heavy exciton immersed in a fermi sea of conduction band electrons, to capture and offer an interpretation of the spectral features in the linear and transient absorption optical signals of this material under an applied bias. We leverage our analysis to identify, physically, how trion formation moves, broadens, and resizes the "A exciton" absorption of our working device. We further unify the interpretation over various sources of such TMD spectral shifts: applied bias, fluence, and (TA) delay time. Our work thus delineates open questions that are only now becoming possible to address with theory and experiment about the interplay of spectral signatures of various quasiparticles, and identifies the underlying physical process responsible for previously misidentified spectral features in 2D materials that changed with applied voltage, fluence, and time.

4:15 PM NM02.05.04

Dynamics, Hybridization and Thermalization of Phonons in Optically Excited Twisted TMD Bilayers Johnathan Georgaras and Felipe H. da Jornada; Stanford University, United States

One primary limitation to implementing van-der-Waals (vdW) stacked materials in future nanodevices is the management of heat between layers. Recent experiments and calculations show that heterostructures of transition metal dichalcogenide (TMD) bilayers are surprisingly inefficient heat conductors. They display a thermal boundary conductivity across layers as small as 1.4 W $m^{-1}K^{-1}$ – comparable to the thermal resistance of 300nm of glass. This is particularly relevant to the dynamics of excitons in TMD bilayers, which are typically initialized optically first as an intralayer exciton, but quickly relax within ~50 fs into a spatially separated interlayer exciton, releasing phonons with a non-thermal distribution. Here, we evaluate the role of individual phonons and interfacial twist angle in the interlayer heat transfer. We focus on initial phonons created by the relaxation of intralayer excitons in twisted TMD bilayers and explore the mode- and time-resolved phonon dynamics, including phonon-phonon interactions, from first-principles-parametrized atomistic calculations. These methods give insight into the effects of atomic relaxation and the formation of strain solitons in these large-scale moiré TMDs, elucidating how one might engineer more efficient interlayer heat transfer.

4:30 PM *NM02.05.05

Coherences and Populations in Mixed Classical–Quantistic Bosonic Systems—A Many–Body Perspective Andrea Marini; Istituto di Struttura della Materia and Division of Ultrafast Processes in Materials (FLASHit) of the National Research Council, Italy

Excitons are routinely used to interpret a wealth of physical concepts [3], both at equilibrium and out–of–equilibrium. The commonly accepted picture is simple: a photo–excitation creates a bound electron–hole pair that evolves as a population in time inducing an observable induced field and governing the carriers distribution. Phonons [1, 7] are equally ubiquitous in condensed matter physics. The electron–phonon interaction is at the basis of the description of such disparate phenomena. There are few key differences between excitons and phonons. Excitons are not exact bosons while phonons are. On the other hand one of the most successful approach to calculate phonons is based on Density–Functional Perturbation Theory, a semi–classical approach where atoms are treated within the classical Born–Oppenheimer approximation. On the contrary excitons are obtained from a fully quantistic theory.

In this talk I will discuss how the external field (in the case of excitons) and trajectories (in the case of phonons) are just different manifestations of coherence. I will, then, discuss their link with the Many–Body Green's function concept. I will also investigate the processes that lead to a coherence transfer to the quantistic dynamics leading to the formation of real populations and, eventually, macroscopic phenomena. I will first describe three different aspects of the excitonic physics: the photo– induced band insulator to excitonic insulator (EI) transition [5], the ultrafast rise time of the transient

absorption in an MoS2 monolayer [6] and the discovery of the exciton internal structure by means of exciton–phonon coupling [4]. In the case of phonons I will discuss the clear and sharp distinction between the coherent, classical, trajectory concept and the quantistic fluctuations [2]. I will then conclude my talk by describing the rich physics of a paradigmatic
mixed classical–quantistic system, the Semi–classical Swing where classical fields oscillate immersed in a quantistic liquid. The different aspects discussed will contribute to give an unconventional description of the excitonic an phononic states opening the path to further theoretical and experimental investigations.

Engineering Topological and Atomic Defects for Electrochemical Reactions in 2D Materials Bryan J. Kim, Kaidi Zhang and Kwabena Bediako; University of California, Berkeley, United States

Understanding the factors that govern interfacial electron transfer and manipulating these interfacial reactions is vital for the design of new materials for energy conversion. 2D materials offer immense tunability and potential as electrochemical interfaces. Stacking multiple 2D layers is demonstrative of such tunability, as shown in trilayer graphene (TLG) systems. Natural TLG exhibits two distinct stacking modes (ABA and ABC), which we show here to possess different reaction kinetics for an outer-sphere redox reaction. We also show that the introduction of topological defects, such as interlayer twists between individual graphene layers, produces artificial stacking modes (AAA and AAB) that act as electron transfer reaction hotspots. Such topological defects unlock an additional degree of freedom to tune the electrochemistry. The electrochemistry of other 2D materials can similarly be improved by introducing atomic defects, specifically sulfur vacancies in MoS2. By irradiating monolayer MoS2 with a Raman laser, we show that sulfur vacancies emerge that act as reaction hotspots for electrocatalytic reactions such as the hydrogen evolution reaction.

5:00 PM NM02.06.02
Fabrication and Application of Fluoropolymer-Modified Electrocatalysts to Produce NH_3 with High Faradaic Efficiency from Nitrate Reduction Profulla Mondol[1], Dipak Panthi[2], Adan J. Ayala[1], Samuel Odoh[1] and Christopher Barile[1]; [1]University of Nevada, Reno, United States; [2]Boise State University, United States

Ammonia (NH_3) is an extremely important chemical feedstock and is used extensively in the fertilizer, pharmaceutical, and dye industries.[1-2] As a result, NH_3 is the fifth most produced chemical in the world by volume.[3] Additionally, NH_3 has recently been considered as an alternative renewable fuel in fuel cells.[4] The most well-established route to generate NH_3 on an industrial scale is the Haber-Bosch process.[5]
In light of the enormous energy footprint of the Haber-Bosch process (1-2% of global energy consumption), alternative green routes of generating ammonia (NH_3) are needed.[2] The electrochemical reduction of NO_3^- from waste streams is a promising method to produce NH_3 using renewably sourced electricity. However, catalyst selectivity is a grand challenge that hinders NO_3^- to NH_3 conversion technologies.
In this work, we fabricate Nafion-modified (6 mm thickness) Cu catalysts for NO_3^- reduction. Although Nafion composites are commonly used to facilitate proton transfer, this research investigates electrodes covered by Nafion overlayers, which possess unique reactivity. We find that Cu versions of these catalysts reduce NO_3^- to NH_3 with a Faradaic efficiency of up to (91 ± 2) % making them among the most selective catalysts reported. We also investigated the effect of polymer hydrophobicity by using PVDF polymer on NH_3 production efficiencies. Voltammetry studies, surface-enhanced Raman spectroscopy, and density functional theory calculations indicate that the Nafion overlayer activates the N-O bond of a key Cu-NO intermediate, thus facilitating NH_3 production.
Lastly, we tested the practicality of the Nafion-modified Cu electrode by using it to remove NO_3^- from a real-world groundwater sample. We obtained groundwater from Silver Springs, Nevada, which is in an agricultural valley 30 miles east of Reno, Nevada. This catalyst can remove 97 % of the initial NO_3^- within one hour of electroreduction.

5:00 PM NM02.06.03
Restacking-Resistant 3D MXene/Metal Selenide Microspheres Fabricated by a Ultrasonic Spray Pyrolysis for Energy Storage Application Seung Keun Park and Oh Hong Geun; Chung-Ang University, Korea (the Republic of)

Two-dimensional (2D) MXenes are considered as promising electrode materials for energy storage, owing to their high electronic conductivity and low diffusion barrier. Nevetheless, similar to most 2D materials, MXene nanosheets easily restack during the electrode preparation, which degrades the electrochemical performance of MXene-based materials. A novel synthetic strategy is proposed for converting MXene into restacking-resistant 3D balls coated with metal selenide. This strategy involves the preparation of metal oxide@ carbon/MXene microspheres via a ultrasonic spray pyrolysis and subsequent selenization process. Such 3D structuring effectively inhibits interlayer restacking, increases the surface area, and promote ion transport, while maintaining the attractive properties of MXene. Furthermore, combining metal selenides and carbon with 3D MXene microspheres provides more ion storage sites and enhances the structural stability of the electrode. The resultant 3D microspheres exhibit excellent electrochemical performance in potassium-ion batteries. This structural design strategy will inspire the development of 2D materials with excellent performance in the energy field.

5:00 PM NM02.06.04
Non-destructive Fabrication of Highly Dispersed Low-dimensional Nanocarbon Paste for Li-ion Battery Electrodes Jungmo Kim; Korea Electrotechnology Research Institute, Korea (the Republic of)

Application of 1-D and 2-D nanocarbon materials (i.e. carbon nanotubes (CNTs), graphene) in the Li-ion battery electrodes has long been the topic of interest, owing to the potential of enhancing the performance and stability of the batteries. The expectations has grown further with the successful commercialization of multi-walled CNTs (MWCNTs) as the conductive agents in Li-ion battery (LIB) cathodes, and the industries are currently making approaches to use single-walled CNTs (SWCNTs) and graphene as the next step.
In order to fully utilize SWCNTs and graphene as the components in the LIB electrodes, the materials must be prepared in a highly-dispersed state while maintaining their morphological and crystallographic characteristics. Unfortunately, the conventional procedures used for the MWCNTs are ineffective in the cases of SWCNT and graphene, and alternative strategies are required.
Herein, I introduce an efficient and effective method to disperse SWCNTs and graphene and demonstrate the application strategy of the low-dimensional nanocarbon materials as the conducting agent as well as current collector.
In the first part, non-oxidative debundling and exfoliation of SWCNT and graphene using charge transfer phenomena during chemical intercalation process is explained. The nanocarbon materials are charged when they are exposed to electron solutions formed by dissolving alkali metal in hexamethylphormamide (HMPA), and can be directly dispersed by introducing shear forces, resulting in highly dispersed paste with nanocarbon material content up to 1 wt%. The re-dispersion into other solvents commonly used in the industries are also showed.
In the second part, the application of the highly dispersed nanocarbon materials as the LIB electrode component is shown:
i) Facile fabrication of free-standing nanocarbon current collector; the free-standing film nanocarbon current collector allows significant weight reduction of the batteries, and can be extensively applied to the highly-stable flexible batteries;
ii) The production strategy for a nanocarbon-coated micro silicon particle and their application as the LIB anode active material; the coating allows enhanced cyclic stability as well as the increased energy density as the result of tightly formed percolation networks, suppressing the random formation of SEI layer.

5:00 PM NM02.06.05
An Efficient Method of Screening Chemical Receptors for the Electrochemical Detection of Biocides Haney Lee[1] and Hyeonseok Yoon[2,1]; [1]Department of Polymer Engineering, Graduate School, Chonnam National University, Korea (the Republic of); [2]School of Polymer Science and Engineering, Chonnam National University, Korea (the Republic of)

Biocides are any substances capable of eliminating, neutralizing, preventing, or controlling the harmful effects of any organism, whether it be through chemical or biological means. Biocides have been used for decades in many different industries, including those that produce food, drink, cosmetics, medicines, and household goods. A major issue is that some biocides may have unintended negative effects on human health. The potential for severe lung injury caused by isothiazolinones (ITZs) exposure has made pulmonary toxicity a pressing concern in recent years. Here, we describe the DFT-based evaluation of the recognition efficacy of several small-molecule-based chemical receptors that we designed for a specific ITZ. We also conjugated chemical receptors to graphene and tested their ability to detect biocides on an electrochemical platform. A statistical method for determining correlations in multivariate data was also used to check if the responses of the synthesized receptors immobilized on graphene could isolate the target ITZ from the interferences.

Electrochemical Storage Performance of N-doped $CoSe_2$/MXene Composites— Application for Sodium and Potassium Ion Batteries Oh Hong Geun, Seung Keun Park and Youngjae Yoo; Chung-Ang University, Korea (the Republic of)

Sodium and potassium have attracted much attention as next-generation energy storage systems to replace lithium based on abundant resources. However, sodium and potassium have a sizeable ionic radius than lithium. Therefore, electrode design for their practical application is essential and currently faces significant challenges.
This research synthesized a unique two-dimensional structured composite derived from MXene nanosheets and a metal-organic framework. First, a Co-based zeolitic framework (ZIF-67) was deposited on the surface of MXene nanosheets. After selenization, the ZIF-67 transformed into N-doped $CoSe_2$. This unique structure can improve the electrons and ion transportation owing to shorten pathways and provide sufficient space to accommodate the volumetric expansion of the active materials during the cycling. Also, the N-doped carbon matrix and MXene nanosheets can improve the robustness of the electrode materials. Therefore, the composites exhibited an increased electrochemical performance in sodium-ion and potassium-ion batteries.

Tunnel Oxide Passivated Contact on Silicon Photoelectrodes for Tandem Photoelectrochemical Water-splitting Devices Choongman Moon[1], Filipe Martinho[2], Gihun Jung[1], Jaehyuk Koh[1], Hajijafarassar Alireza[2], Canulescu Stela[2] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Technical University of Denmark, Denmark

Crystalline silicon has been considered one of the most promising materials for the bottom cell of a tandem photoelectrochemical (PEC) water-splitting device because of its appropriate band gap (1.12 eV) as well as the industrial maturity. The tandem PEC water-splitting device, especially when made of earth-abundant materials, would be a sustainable way of producing hydrogen fuels; thus, considerable efforts have been made to acquire the best performance out of the large band gap top cell and Si bottom cell. Despite these efforts, there have been only a few studies that enable unassisted solar water splitting by using a tandem PEC device with a silicon bottom cell because 1) the photovoltage from the tandem device is not sufficient to drive the water splitting reaction by itself, and 2) poor thermal stability of a Si bottom cell severely limits the choice of the top cell material and processing conditions. Therefore, improving the photovoltage and thermal stability of the Si bottom cell would provide a great opportunity to realize tandem PEC devices for solar fuel applications.

In this work, we report silicon photoelectrodes based on a tunnel oxide passivated contact (TOPCon), which exhibits superior properties as a potential bottom cell for a monolithic tandem device. Our TOPCon Si photoelectrodes yielded photovoltages in the range of 640 - 650 mV in both photocathode and photoanode configurations under a broad range of pH (0 – 14) conditions of working electrolytes, which are the highest values reported for photoelectrodes based on crystalline silicon. Furthermore, the TOPCon device retained its superior property after thermal annealing at 600 °C for 1 hour in air. The capability of operating in the both configurations (photocathode and photoanode) over a broad range of pH and high thermal stability provides great flexibility in the design of a tandem PEC device: TOPCon Si is capable of stable operation in any pH and is compatible with a top cell semiconductor of any type (n-type or p-type) that may require a high processing temperature. As a preliminary study of a monolithic tandem device based on TOPCon Si, we tested wired tandem devices using a $BiVO_4$ photoanode or halide perovskite photocathode as a large band gap counterpart of TOPCon Si photoelectrodes to show the feasibility of unassisted solar water splitting. The $BiVO_4$-TOPCon Si and perovskite-TOPCon Si tandem devices yielded solar-to-hydrogen conversion efficiencies of 0.24 and 3.6 %, respectively. Notably, STH efficiency from perovskite-TOPCon Si (3.6 %) is one of the highest values from tandem PEC devices based on earth-abundant elements.

5:00 PM NM02.06.08
Density Functional Theory Study of the Adsorption of N_xO_y Functional Groups on Diamond (100) Surfaces Jenille Cruz[1], Ruzmetov Dmitry[2], A G. Birdwell[2], Elias Garratt[2], James Weil[2], Pankaj Shah[2], Tony Ivanov[2], Michael Groves[1] and Mahesh Neupane[2]; [1]California State University, Fullerton, United States; [2]DEVCOM Army Research Laboratory, United States

Diamond's unique structural, thermal, and electronic properties make it an interesting material for high-field, high-frequency device applications, such as radio-frequency field-effect transistors, power amplifiers, and communication satellites. Recent experimental evidence suggests that adsorbing N_xO_y functional groups on hydrogen-terminated diamond surfaces could play an important role in improving device parameters, such as current density and threshold voltage. In this study, we performed Density Functional Theory (DFT) calculations of N_xO_y functional groups adsorbed on bare and hydrogen-terminated diamond (100) surfaces. The adsorption energies were calculated to predict the most favorable structure. Band structures and density of states will be reported to explain the electronic properties of the most favorable system for device design. Nudge Elastic Band calculations will also be reported for the adsorption pathways to form these most stable absorbate configurations. Overall, this research will present several models of N_xO_y functional groups adsorbed on bare and hydrogen-terminated diamond (100) surfaces and will provide critical insight into surface electronic properties of diamond surfaces for surface doped diamond devices.

5:00 PM NM02.06.09
Mechanisms of Gas Intercalation, Transport, and Selectivity in Nanoconfined Ionic Liquids Revealed by Molecular Dynamics Simulations Fikret Aydin, Stephen E. Weitzner, Amanda Muyskens, Alexander Abelson, Steven F. Buchsbaum, Tuan Anh Pham and Eric R. Meshot; Lawrence Livermore National Laboratory, United States

Understanding gas transport through confined ionic liquids (ILs) becomes important for a wide range of emerging energy related technologies. The structure and dynamics of IL filling under confinement have been characterized previously [1]; however, the mechanisms governing gas transport and selectivity remain largely unknown, specifically a detailed understanding of the effects of the IL type, morphology and charge state of the nanopores on the gas separation is still missing. Here, we investigate the mechanism of CO, CO_2, N_2, O_2 or NH_3 transport and selectivity in widely/commonly used imidazolium-based ionic liquids, specifically a 1-butyl-3-methylimidazolium cation (bmim) with either hexafluorophosphate (PF6) or acetate (Ac) anion confined in carbon nanotubes (CNTs) with a diameter of 2.1 nm by using molecular dynamics simulations and enhanced free energy sampling methods. The two ILs have been identified using an informatics-based approach that enables an efficient screening of IL candidates to be used in electrochemical systems [2]. Our simulations provide free energy surfaces associated with selective interaction of various gases with ILs and reveal the underlying mechanism of specific gas selectivity. Our simulations show that the gas selectivity in these systems can be explained by the competition between a complex interplay between confinement, charge state of CNTs and type of IL. Our findings can provide insight into the conditions that optimize selectivity of gas molecules transporting through IL-CNT systems, which in turn may assist practical design and fabrication of real electrochemical systems.

Mechanistic Studies of the Nitrogen Reduction Reaction on 2D-Transition Metal Dichalcogenides in Realistic Media; Understanding the Effects of Electrified Interfaces Taylor Aubry, Logan M. Wilder, Derek Vigil-Fowler, Elisa Miller-Link and Jao Van de Lagemaat; NREL, United States

Improving electrocatalysts is a promising strategy towards clean and sustainable production of many globally important fuels and chemicals. Yet, to date, poor catalyst performance has limited their implementation in a variety of energy conversion technologies such as hydrogen evolution, CO2 reduction, and nitrogen reduction, among others. Two-dimensional (2D) transition metal dichalcogenides (TMDCs) are a class of materials that are advantageous for (photo)electrocatalysis due to their high surface area, favorable electronic transport properties, efficient light absorption, and highly tunable electronic structure. One important albeit challenging reaction to catalyze is the nitrogen reduction reaction (NRR) ($N_2 + 6H^+ + 6e^- \rightarrow 2NH_3$), which is highly desired to enable sustainable ammonia production for fertilizers and energy storage. Although 2D materials have shown promise for NRR, their activity and selectivity are hampered by competitive H_2 generation, poor N_2 solubility in aqueous media, and slow reaction kinetics. In order to engineer them for optimal performance, improved mechanistic understanding of the NRR on 2D-TMDCs is necessary.
In this work, perform density functional theory (DFT) calculations on the 6-step NRR pathway while considering the effects of solvent and applied potential. We use a joint-DFT software package (JDFTx) that employs continuum solvation models to handle solvent interfaces and grand-canonical DFT for fixed potential calculations, thereby more accurately describing the true behavior of electrochemical systems. We focus on one of the most widely studied and particularly promising TMDCs for NRR; MoS_2. We determine the catalysts active sites and selectivity over the hydrogen evolution reaction. We find that applied potential modifies the reaction mechanism for the NRR, an effect we believe is due to the ability of N_2 to undergo p-backbonding with the d-metals in the TMDC catalyst. This work highlights the importance of treatment of electrified interfaces in studying electrocatalytic systems. With improved understanding of how tuning TMDCs can impact NRR, the goal is to guide future catalyst design and generate competitive catalysts for NRR and other important reactions.

5:00 PM NM02.06.12
A Comparison of Vertically Aligned Graphene with Various Graphene Forms for Biosensing Applications Abdulrahman Al-hagri[1,2], Selvakumar Palanisamy[1] and Matteo Chiesa[1,2]; [1]Khalifa University, United Arab Emirates; [2]The Arctic University of Norway, Norway

Vertically aligned graphene nanosheet arrays (VAGNAs) have a large surface area, superior electron transport properties, excellent mechanical strength, high chemical stability, and enhanced electrochemical activity, making them highly suitable for supercapacitors, batteries, fuel cell catalysts, etc. We fabricated VAGNAs terminated with a high-quality bilayer graphene sheet without needing an additional catalyst using plasma-enhanced chemical vapor deposition [1]. A new electrochemical biosensor for detecting dopamine (DA) biomolecules (in human serum and drug samples) is reported in this study based on VAGNAs. Graphene structures of various types were compared with VAGNAs for their electrochemical behavior towards DA sensing. The fabricated VAGNAs-based sensor provided a highly selective and sensitive option with a detection limit of 2 nM and response range of up to 326.3 µM

compared to other graphene material (prepared by various methods) based biosensors. This finding strongly indicates that VAGNAs can be used as a real-time biosensor to detect DA at low levels.

5:00 PM NM02.06.13
General Synthesis of Inorganic/Reduced Graphene Oxide Nanocomposites and Their Applications in Lithium Batteries Wanyu Zhang, Zhe Su, Shan Yi and Donghui Long; East China University of Science and Technology, China

Two-dimensional (2D) graphene and its derivatives are promising candidates for electrochemical applications due to their versatility. Hitherto, various metal oxides have been decorated onto graphene sheets to form composite artificial materials with unprecedent characteristics and performances, taking fully advantages of 2D graphene and ultrafine metal oxides in a synergistic manner [1,2]. However, the adhesion of rigid inorganic nanoparticles generally induces more wrinkled and agglomerated structure, possibly due to the formation of inhomogeneous compressive stress during the synthesis, leading to limited application potential.
Herein, for the first time, we present a general heterogenous nucleation and diffusion-controlled growth route to synthesize dozens of sandwich structured metal oxide/reduced graphene oxide (rGO)/metal oxide nanocomposites [3], and further confirm their applications in both lithium metal and lithium sulfur batteries. The details are as follows: (1) Such sandwich structured materials could be applied as solid-state electrolyte to optimize lithium-ion conduction by interconnected amorphous organic–inorganic interphases with polyethylene oxide in lithium metal batteries[4]; (2) Furthermore, tailored metal oxide/sulfide heterostructures on rGO surface with rational balancing of strong adsorption and high catalytic activity could also be prepared through adding thiourea in the precursor solution, enabling an unrestricted adsorption-diffusion-conversion of polysulfides in lithium sulfur batteries[5].

8:00 AM *NM02.07.01
Multidimensional Metal Sulfide Electrocatalysts for CO_2 and CO Conversion to Alcohols Jesus M. Velazquez; University of California, Davis, United States

Electrocatalytic production of oxygenate and hydrocarbon fuels from sequestered CO_2 and green H_2 is a promising carbon-neutral technology that can be readily coupled with solar, wind, or hydroelectric power. The development of solid-state synthetic pathways of electrochemically active materials that address the growing dichotomy of simultaneously increasing energy demands and carbon emissions is an imperative that has progressively affected energy-related research efforts. To this end, our work establishes structure—function relationships for solid-state materials within the multinary chalgogenides comprised of MX_2 (M = Mo, W; X = S, Se) and Chevrel-Phase (CP) $M_yMo_6X_8$ (M = alkali, alkaline, transition or post-transition metal; y = 0-4; X = S, Se, Te) chalcogenides. The molybdenum sulfide structures from both families exhibit exceptional promise as CO_2R catalysts. Furthermore, we have identified the CP catalyst framework as being selective towards the electrochemical reduction of CO_2 and CO to methanol (only major liquid-phase product) under applied potentials as mild as -0.4 V vs RHE. Reactivity toward the electrochemical reduction of CO_2 and CO to methanol is correlated with the increased population of chalcogen states, as confirmed via X-Ray Absorption Spectroscopy. Overall, this work seeks to unravel optimally reactive small-molecule reduction catalyst compositions.

8:30 AM *NM02.07.02
Electrochemical Nitrogen and Proton Reduction using 2D Transition Metal Dichalcogenides Elisa Miller-Link; National Renewable Energy Laboratory, United States

We use 2D transition metal dichalcogenide (TMDC) catalysts to facilitate the nitrogen (N_2) reduction to ammonia and proton reduction to hydrogen via dark electrocatalysis. These two reduction pathways are very important to understand and control for NH_3 and H_2 electrochemical production, where both products can be used as energy carriers, for energy storage, and as direct fuels. TMDCs are good catalyst candidates for these electrochemical reduction reactions because they can be reduced to 2D, where their quantum confined properties are easily manipulated for various applications. Transition metal-based catalysts offer a unique opportunity to exploit the d electrons and orbitals as well as chalcogenide plane for N_2 activation and/or H^+ adsorption, where we specifically compare theoretically and experimentally MoS_2, TiS_2, and VS_2. In addition, the 2D TMDC catalysts are highly tunable 2D catalysts, where the band energetics, surface functionalization, defects, and phase can be tuned to control the reduction mechanisms. Also through various attempts and iterations to generate NH_3, we have many lessons learned about experimental and theoretical approaches for N_2 reduction that will be communicated.

9:00 AM NM02.07.03
Local Atomic Environment of Single-Atom Pt in Metallic TMDC Nanosheets Boosts Catalytic Performances of Li-O_2 Batteries Joo-Won Lee and Sohee Jeong; Korea Institute of Science and Technology, Korea (the Republic of)

2D Transition metal dichalcogenides (TMDCs) show changeable electronic properties corresponding to the polytype and chemical modification at the atomic level of 2D TMDCs. Metallic TMDCs comprising the trigonal structure (1T or 1T' phase) have been investigated as efficient catalysts due to their

proper electrochemical properties compared to semiconducting TMDCs with the 2H phase. These metallic TMDCs catalysts have been prepared by atomic-scale chemical modifications such as single-atom doping. However, a detailed role of single-atom doping in TMDCs is still ambiguous because it is unclear that the enhanced catalytic activities stem from whether the metallic properties or electrochemical properties of single-atom.
Here, we report the facile one-pot synthesis of metallic WSe_2 few-layer nanosheets. Subsequent solution treatments at room temperature enabled isolated incorporation of single atoms such as Rh, Pd, Ir, and Pt into metallic WSe_2 nanosheets. Extensive experimental analysis reveals that considerably high Pt content (~5 wt%) was doped in metallic WSe_2 nanosheets (Pt_{SA}-WSe_2). Local atomic structure of Pt_{SA}-WSe_2 was proved through X-ray analysis including XPS and XPDF, which supports that single-atom Pt is individually distributed inside of WSe_2. For efficient Li-O_2 batteries, cathode materials are required to overcome the sluggish kinetics of oxygen evolution reaction (OER) and oxygen reduction reaction (ORR). Pt_{SA}-WSe_2 shows enhanced ORR/OER activities by dissociative oxygen adsorption on the W sites of the basal planes as well as single-atom Pt sites in metallic WSe_2, which is demonstrated through experimental analysis and DFT calculations as well. Eventually, Pt_{SA}-WSe_2 shows the enhanced Li-O_2 battery performances with the capacity of 27,000 $mAhg^{-1}$ and stable discharge/charge cycles of 350.

Tuning of Physical and Chemical Properties of Graphene by Electrolyte Gating Matěj Velický, Martin Jindra, Ghulam Abbas, Martin Kalbáč and Otakar Frank; The Czech Academy of Sciences, Czechia

Electrolyte gating is an efficient way of controlling physical and chemical properties of two-dimensional (2D) materials.[1,2] However, despite its advantages over the more traditional dielectric gating, commonly used in condensed matter physics and electrical engineering, electrolyte gating has not been adopted at a significant scale by researchers outside the electrochemistry field.

We will demonstrate the power of electrolyte gating on a newly developed in situ spectroelectrochemical technique, which allows application of potential through a microdroplet electrochemical cell with a simultaneous Raman spectroscopy measurement.[3] Using this technique, we can monitor localized electrochemical and spectral responses of the basal planes of monolayer graphene with varying levels of disorder. Charge doping-dependent Raman G band shifts as well as cyclic voltammetry of a redox mediator both reveal contributions from two distinct processes, originating from the pristine and defective areas on the basal plane surface. This indicates the existence of two independent charge transfer processes with slower and faster rates on the same surface, each restricted to the defect-free and defect-rich areas, respectively.

In order to frame our results with a wider context, we evaluate the available literature on electrolyte doping of graphene using in-situ Raman spectroelectrochemistry measurements and draw conclusions on its limitations, applicability, and efficiency.

10:30 AM NM02.07.06
Large Scale Integration of 2D material for Memristors Clotilde Ligaud[1], Lucie Le Van-Jodin[1], Bruno Reig[1], Clémence Hellion[1], Pierre Trousset[1], Jean Coignus[1], Céline Vergnaud[2], Hanako Okuno[3], Djordje Dosenovic[3], Stéphane Cadot[1], Rémi Gassilloud[1] and Matthieu Jamet[2]; [1]CEA-Leti, Univ. Grenoble-Alpes, France; [2]Université Grenoble Alpes, CEA, CNRS, CEA, Grenoble INP, IRIG-Spintec, France; [3]University Grenoble Alpes, CEA, IRIG-MEM, France

2D materials are promising candidates for next generation devices. Their various properties combined with their intrinsic thinness and flexibility could enable the realization of high-performance devices. For instance, MoS_2 has demonstrated switching behavior [1] which allow the manufacturing of memristors [2] or high cut-off frequency RF switches[3]. Nevertheless, the high growth temperature of 2D material by physical or chemical methods prevents their fabrication directly on partially processed integrated circuits. An intermediate transfer step from the growth substrate to the final substrate is necessary to achieve their large-scale integration. Today, most publications are based on individual devices with a great lack of reproducibility and statistics. In this work, we report the successful large-scale integration of MoS_2 in memristors reaching the current state of the art.
In this work, bottom electrodes are patterned on a 200 mm wafer. About 250 dies of 1 cm^2 were thus obtained. On each die are designed several structures such as van der Pauw, Hall bar, RF switches, memories… By transferring and patterning MoS_2 and top electrodes on the dies, vertical memories are performed with the following structure: bottom electrode/2D material/top electrode.
Planar bottom electrodes are made of a stack of Ti/AlCu/Ti/TiN, performed with standard deposition and patterning processes. The 2D material consists of three monolayers (ML) of MoS_2 grown by Atomic Layer deposition on 200 mm SiO_2/Si wafer. MoS_2 is transferred above by wet transfer method using polystyrene as support layer. Then 2D material is patterned using deep UV lithography and plasma etching. Finally, top electrodes are deposited by ebeam evaporation and patterned by photolithography and lift-off. Three metallic electrodes are tested: Ag, Ni and Cr/Au.
An in-depth TEM study is performed on the stack SiO_2/MoS_2/Ag. It shows the very good quality of the device. It confirms the preservation of each of the three MoS_2 layers and the clean interfaces with electrodes. A study of Raman spectroscopy at each step of the process confirms the MoS_2 preservation. Optical and electronic microscopy images confirmed the quality of the devices.
Finally, several devices are tested by electrical measurements. Direct current characterization demonstrates resistance-switching behavior. Several cycles are observed on several devices with Ni and Au as top electrodes. Set (switching from OFF to ON state) and Reset (from ON to OFF state) cycles are reproducible between devices. The Set voltage is roughly 2V whereas the reset voltage is around -1V. Except for the first cycle during which the OFF-state current is lower than during the other cycles, the I_{ON}/I_{OFF} ratio is around 10^4. Several cycles (7) are obtained on the devices.
In summary, we developed a large-scale 2D material integration process compatible within standard microelectronics clean room facility. With this process, we were able to manufacture MoS_2-memristors reaching the current state of the art.

10:45 AM NM02.07.07
2D MXenes Monolayers are More Thermally Stable than Multilayers Hui Fang[1], Claudia Pereyra[1], Anupma Thakur[2], Babak Anasori[2], Andrew M. Rappe[1] and Zahra Fakhraai[1]; [1]University of Pennsylvania, United States; [2]Indiana University−Purdue University Indianapolis, United States

2D MXenes have demonstrated potential applications in optoelectronic devices. The thermal stability of these ultrathin films must be carefully considered due to ambient humidity, unavoidable heating caused by light absorption, current flow, *etc.* Here, we use in-situ spectroscopic ellipsometry to study $Ti_3C_2T_x$ MXenes oxidation and evaluate the resultant structures using AFM. We demonstrate that degradation can be dramatically suppressed upon heating in ambient conditions, after various pre-heat treatments in a vacuum. Contrary to conventional wisdom, our work shows that $Ti_3C_2T_x$ MXene monolayers are more thermally stable than their multilayer counterparts. We discuss how to improve thin film stability through thermal drying in a vacuum and establish the appropriate conditions for each type of film. Density functional theory calculations elucidate possible reasons for the improved stability of monolayers. Our findings provide important design rules for $Ti_3C_2T_x$-based devices, which is very important for the further market application of MXenes.

11:00 AM NM02.07.08
Moiré-Based Topological Defects for Tunable Electrochemistry Kaidi Zhang, Kwabena Bediako and Bryan J. Kim; Univerrsity of California, Berkeley, United States

Interfacial electron-transfer reactions underpin the interconversion of electrical and chemical energy. At electrode–electrolyte interfaces, atomic defects like vacancies and step edges are frequently implicated as active sites that mediate reactivity by introducing high densities of localized electronic states. However, these sites are challenging to deterministically synthesize and control at an atomic level. Moiré superlattices of atomically thin layers generate flat electronic bands and associated localized states that are precisely tunable by the interlayer twist angle. Here we show systematic, >80-fold control over the interfacial electron-transfer rate constant by controlling the stacking configuration and moiré angles in few-layer graphene. At small angles of twisted graphene, the kinetic modulation is governed by well-defined `topological' defects of the moiré superlattice, consisting of atomic configurations that cannot be realized independently of the moiré. These topological defects mediate outer-sphere electrochemical reactions with rates comparable to bulk metals, notwithstanding their consisting of only three atomic layers. Moiré superlattices therefore serve as an unparalleled platform for systematically interrogating and exploiting the dependence of electron-transfer rates on electronic structure.

11:15 AM *NM02.07.09
Accelerating Electrocatalysis on 2D Working Electrodes with a Backside Gate C. D. Frisbie; University of Minnesota, United States

Heterogeneous catalysis is well-known to be sensitive to electron accumulation or depletion on surfaces, but electron density is usually controlled by chemical doping (e.g., promoters) in the case of thermocatalysis, or electrochemical potential in the case of electrocatalysis. The recent advent of ultrathin two dimensional (2D) catalysts prepared either by exfoliation or thin film growth methods opens up a third approach — the transverse field effect, so central to silicon CMOS technology—to modulate the carrier density in a catalyst or electrocatalyst. In this approach the 2D catalyst material is deposited on top of a metal/dielectric stack (the “gate”) to make a capacitor; application of a voltage between the catalyst and the metal causes positive or negative charge to accumulate in the catalyst, depending on the sign of the voltage. This charge in turn tunes the reactivity of active sites, accelerating rates of reaction on the catalyst top surface. This talk will describe some early results for outer-sphere and inner-sphere electrochemical reactions at 2D working electrodes with a backside gate electrode. In particular, we show that a backgate voltage can significantly lower the required overpotential for H_2 evolution at 10 mA/cm^2 at MoS_2 electrodes. In general, 2D working electrodes with a backside gate provide a novel platform for fundamental investigations in electrochemistry.

1:30 PM *NM02.08.01
Exploring Dynamical Many-body Effects on Optoelectronic Properties of Low-Dimensional Materials Diana Qiu; Yale University, United States

In low-dimensional and nanostructured materials, the optical response is dominated by correlated electron-hole pairs---or excitons---bound together by the Coulomb interaction. Understanding the energetics and dynamics of these excitons is essential for diverse applications across optoelectronics, quantum information and sensing, as well as energy harvesting and conversion. By now, it is well-established that these large excitonic effects in low dimensional materials are a combined consequence of quantum confinement and inhomogeneous screening. However, many challenges remain in understanding their dynamical processes, especially when it comes to correlating complex experimental signatures with underlying physical phenomena through the use of quantitatively predictive theories. In this talk, I will discuss how excitons in low-dimensional and nanostructured materials, such as monolayer transition metal dichalcogenides and layered perovskites, differ from typical bulk materials. In particular, we will look at how long-range quantum interactions can give rise ultrafast energy transport in low dimensions and explore the transfer of spin, charge and chirality across heterointerfaces. Finally, we will explore the kinetics of phase transitions that accompany Li intercalation in layered van der Waals materials, which has promising energy storage applications and can drive the formation of new charge density wave (CDW) phases.

2:00 PM *NM02.08.02
Polarons in Two-Dimensional Materials—Boron Nitride and Beyond Feliciano Giustino; The University of Texas at Austin, United States

The polaron is an emergent quasiparticle that consists of an electron dressed by a cloud virtual phonons. Polarons arise from the interaction between electrons and phonons in solids, and are responsible for a plethora of unusual properties. Very recently, new spectroscopic capabilities have enabled the direct observation of polarons in several important 3D materials, shedding light on quantum many-body effects that were previously inaccessible. In contrast with these advances in the physics of polarons in 3D bulk materials, very little is known about polarons in 2D atomic crystals. It is currently unknown whether polarons can form in 2D materials, whether they are localized and to what extent, how they respond to probes such as electric and magnetic fields, and whether they exhibit collective phenomena such as Bose-Einstein condensation and superconductivity.

In this talk I will present recent work aimed at answering some of these questions by developing an *ab initio* theory of polarons in 2D materials. I will show that the physics of polarons in 2D is fundamentally different from their 3D counterparts as the effective Coulomb interaction between electrons and phonons becomes short-ranged. This effect alters the energetics and localization of polarons and gives rise to a critical condition for the existence of polarons in 2D which has no counterpart in bulk 3D materials.
To illustrate these concepts, I will first discuss *ab initio* calculations of polarons on bulk and monolayer hexagonal boron nitride (h-BN). Then I will present an *ab initio*-inspired model of polarons in realistic 2D materials which links widely available materials properties, such as dielectric constants and carrier effective masses, to the atomic-scale properties of polarons. This theoretical framework naturally identifies the most important materials descriptors of polaronic properties in 2D, and is suitable for high-throughput screening of two-dimensional polarons.

Excitation Transfer in Atomically Thin Materials Andreas Knorr; Technische Universität Berlin, Germany

Atomically thin semiconductors and hybrid structures constitute a remarkable playground for exciton physics in two dimensions. This involves optically accessible (bright) as well as spin- and momentum-forbidden (dark) excitonic states including intravalley and intervalley excitations. The nonlinear, coherent and incoherent exciton dynamics induced by light pulses results from the interplay of intrinsic exciton-exciton and exciton-phonon interactions. Here, we present applications of the theory to:
-biexcitons and exciton-exciton scattering induced coherence decay,
-detection of exciton wave function dynamics in time resolved ARPES, and
-different charge-, Dexter- or Förster-type transfer processes in atomically thin semiconductors functionalized with organic molecules, graphene or metal nanoparticles.
A comparison to experiments is provided throughout the talk.
This work is done in coilaboration with Malte Selig, Florian Katsch, Dominik Christiansen, Manuel Katzer, Lara Greten, Robert Salzwedel and Henry Mittenzwey (TU Berlin).

4:00 PM *NM02.08.04
Structural Design of Optical Selection Rules in Two-Dimensional Semiconductors Sivan Refaely-Abramson; Weizmann Institute of Science, Israel

Excited-state processes in functional materials are essential for emerging applications, from energy conversion to quantum information science. The associated transport and relaxation mechanisms are coupled to optical selection rules, directly related to the underlying material structure. In this talk, I will discuss our theoretical approach to compute excited-state phenomena in structurally-complex two-dimensional semiconductors from first-principles. I will present our recent study relating non-analytical discontinuities in the excitation energies with the early stages of excited-state propagation, and discuss an extension to compute exciton scattering and transport. I will further show our recent research on exciton complexity in transition metal dichalcogenide, relating electro-optical and magneto-optical signature to the presence of atomic defects and heterostructure composition.

4:30 PM *NM02.08.05
Interplay Between Structural and Electronic Properties of TMDC Heterostructures Felipe H. da Jornada[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The synthesis of quasi-two-dimensional materials, such as monolayer transition metal dichalcogenides (TMDCs), opened the door to the study of new classes of systems with nanoscale dimensionality confinement and weak electronic screening, leading to strongly enhanced electron interactions. However, the interplay between the structural details in such twisted bilayer structures (including atomistic relaxation effects), extrinsic fields, and doping on the excited-state properties of such materials is poorly understood, and often relies on empirically fitted continuum models. In this talk, we present results obtained from recent formalisms and methods we developed to bridge these effects and phenomena.

I will discuss how moiré effects can lead to large localization of excitons and the emergence of excitons with qualitatively different spatial distributions. I will also discuss a formalism our group recently developed to understand excitons in moiré materials, which can bridge the atomistic and moiré length scales from first principles. I also first show how the thermal conduction between a pair of vertically stacked 2D materials can be engineered with the interfacial twist angle. I will also show a novel heat transport regime, aided by electron-phonon interactions, which effectively increases the interfacial thermal conductivity by almost two orders of magnitude.

SESSION NM02.09: Current Understanding and Theoretical Description of the 2D Electrode/Electrolyte Interface II

Observing Floquet-Bloch States in van der Waals Semiconductors Vivek Pareek[1], David Bacon[1], Xing Zhu[1], Yang-Hao Chan[2], Fabio Bussolotti[3], Nicholas Chan[1], Joel Perez Urquizo[1], Kenji Watanabe[4], Takashi Taniguchi[4], Michael K. Man[1], Julien Madéo[1], Diana Qiu[5], Kuan Eng Johnson Goh[3,6], Felipe H. da Jornada[7] and Keshav M. Dani[1]; [1]Okinawa Institute of Science and Technology Graduate University, Japan; [2]Academia Sinica, Taiwan; [3]Agency for Science, Technology, and Research (A*STAR), Singapore; [4]National Institute for Materials Science, Japan; [5]Yale University, United States; [6]National University of Singapore, Singapore; [7]Stanford University, United States

Floquet engineering has generated much interest in recent years as a powerful approach to manipulating the electronic structure and topology in the material and manifest quantum states otherwise inaccessible in equilibrium. Typically, an intense optical field is used to create the Floquet states in materials1–3. Despite its potential, the experimental realizations of Floquet engineering using optical fields have been challenging due to detrimental effects such as multi-photon absorption, heating, and scattering. Recently, oscillating bosonic fields within the material, such as excitons or phonons, have been proposed as an alternate route to Floquet engineering4. In the case of the exciton, its presence in the material alters the original ground state Hamiltonian by dynamically changing the many-electron screened-exchange interaction. This results in a time-dependent coupling that oscillates periodically at the exciton frequency and is responsible for driving the Floquet states in the material. So far, such proposals of Floquet engineering driven

by quasi-particle fields, such as excitons, have not been achieved experimentally.
In this work, using time-resolved angle-resolved photoemission spectroscopy (tr-ARPES), we show that the valence band in monolayer tungsten disulfide (WS2) gets replicated in energy due to the oscillating field generated by excitons. We find that the strength of the exciton-driven Floquet effect is two orders of magnitude stronger than the optically driven counterpart. Consequently, we observe that the exciton-driven Floquet replica of the conduction band hybridizes with the bare valence band resulting in a distinct Mexican-hat-like dispersion with a local dip at the center of the valence band. This work also reproduces the predicted changes in the band structure for the BEC to BCS transition in non-equilibrium excitonic insulators. Our findings open new avenues to Floquet engineering using quasi-particle fields such as excitons, phonons, or plasmons.

Electrostatic Gating to Tailor Interfacial Charge Transfer at 2D MoS_2 Electrodes Sonal Maroo and Kwabena Bediako; University of California Berkeley, United States

Tailoring electron transfer dynamics across solid-liquid interfaces are fundamental to electrical and chemical energy interconversion. Marcus–Gerischer[1] formalism suggests that the electronic states of the electrode around the Fermi level have a significant influence on the rate of electron transfer. Studies have also shown that the faster electron transfer kinetics observed on introducing defects is due to localized enhancements in the electronic states around the fermi level that are available to participate in the reaction. Electrostatic gating in field effect transistor mode is one of the widely used strategies to manipulate the charge carrier density and energy band alignment in semiconductors. It has been demonstrated that the heterogeneous charge transfer kinetics at the MoS_2 monolayer[2] is strongly modulated by applying an external electric field on the working electrodes. Herein, I reevaluate the electric field effect on the interfacial electron transfer at a few layers MoS_2 using Scanning Electrochemical Cell Microscopy (SECCM). MoS_2 electrodes were fabricated in a field effect transistor (FET) configuration with a solid-state graphite bottom gate. The bottom gate voltage (V_{BG}) applied to graphite was used to alter carrier density and control the band alignment. I combined in-situ SECCM experiments with the electrostatic manipulation of the band alignment with V_{BG} to study the effect of charge carrier concentration on the interfacial electron transfer. I also obtained spatially resolved voltammetric responses to understand the role of in-plane charge transport in governing the electrochemical responses of 2D electrodes, especially at conditions of low carrier densities. The experimental approach and results presented here serve as a benchmark for future studies of the electrochemical behavior of two-dimensional materials.

2D van der Waals Inorganic Crystal for Anhydrous Proton Conductor Shingo Ohta[1,2], Hiroshi Nozaki[2], Liang Wang[1], Hongfei Jia[1], Nikhilendra Singh[1], Timothy Arthur[1], Daniel Hashemi[1] and hideo Iizuka[1,2]; [1]Toyota Research Institute of North America (TRINA), United States; [2]Toyota Central R&D Labs., Inc., Japan

We succeeded in synthesizing a novel two-dimensional (2D) van der Waals (vdW) inorganic oxychloride ion conductor which has an applicable potential for high-temperature fuel cell fuel cells (FCs).
The significant reduction of CO2 emissions is extremely important to severely address climate change mitigation. Various electrochemical devices, such as Ni-MH batteries, lithium (Li)-ion batteries (LIBs), Na-S batteries, Li-ion capacitors, FCs, solid oxide fuel cells (SOFC), and water splits, are being used to replace internal combustion engines as new power sources for energy storage and generation.
The most important key materials common to these devices with regard to electrolytes and membranes are ion conductors of hydrogen ions (proton), Li ions, sodium ions, oxygen ions, and hydroxide ions. To develop ion conductors that can be used in these devices, a wide variety of ion conductors, whether liquid, solid, organic, or inorganic, have been developed. Among these, inorganic solid ion conductors are attractive candidates as electrolytes for next-generation batteries and FCs, and they are expected to operate at high voltages and temperatures because inorganic solid materials have significant advantages: (i) high-temperature stability, (ii) wide electrochemical potential windows, and (iii) chemical stability in water and air.
Inorganic solid ion conductors are attractive candidates as electrolytes for next-generation lithium-ion batteries (LIBs) and FCs which are expected to operate at high voltage and temperature due to their high stability and oxidation resistance. However, in previously developed inorganic ion conductors derived from natural minerals, mobile ions are strongly bonded to anions, resulting in low conductivity. Thus, in this study, we present a 2D vdW inorganic proton (H+) conductor for inserting protons into halogen vdW layers. In the best case, conductivity is ~10 mS cm−1 at 120 °C, which is two orders of magnitude larger than that of inorganic conductors previously developed from natural minerals. The design of ion conductors using 2D-vdW inorganic materials can provide a route for high-performance LIBs and FCs.

Single-Atom-Catalysts of Non-Noble Metals on Carbon for Alkaline Hydrogen Evolution Reaction Juchao Yan; Eastern New Mexico Univ, United States

Alkaline water splitting for hydrogen production broadens the selection of the electrocatalysts to non-noble metal or metal oxides, but has more sluggish kinetics than acidic water splitting. To address this, the researchers have developed a number of atomically dispersed electrocatalysts based on earth abundant metals, which was coined as single-atom-catalysts (SACs). SACs exhibit high activity for hydrogen evolution reaction (HER), due to the high atom utilization, high activity, and high selectivity. In this talk, I will review various preparations of SACs on carbon, and discuss the electrocatalytic performance for alkaline HER. Emphasis will be on how to increase the metal atom loading for industrial applications.

Defective Molybdenum Sulfide for Catalysis Hong Li; Nanyang Technological University, Singapore

Electrochemical energy conversion and storage driven by renewable energy sources such as solar and wind are drawing ever-increasing interest due to their critical roles in sustainable development. Advances in these applications rely on highly active and cost-effective electrocatalysts to accelerate the sluggish kinetics of the electrochemical reactions involved. A substantial amount of such electrocatalysts have been exploited recently thanks to the advances in material science and continuous breakthroughs in engineering tools. In particular, molybdenum sulfide (MoS_x) furnishes a classic platform for study of catalysis fundamentals as well as exploration of new applications in hydrogen evolution reaction (HER), nitrogen reduction reaction (NRR), CO_2 reduction reaction (CO_2RR), polysulfide conversion reaction (metal-sulfur batteries), *etc*. Recent studies of MoS_x have focused on activating its inert part [*e.g.*, basal plan of two-dimensional (2D) molybdenum disulfide (MoS_2)] by tailoring its electronic structure through defect engineering. In this talk, I will recap recent theoretical and experimental advances in the use of defective MoS_x for various electrocatalytic applications with a highlight of our own progress. I will start with a brief description of the structure and basic electrocatalytic applications of 2D MoS_2 with 2H, 1T, and 3R crystalline phases. Then, I will discuss the employment of defective MoS_2, which is a model system thanks to its atomically isolated structure, as the electrocatalyst for the popular HER. Next, I will detail the recent development in defect-enhanced non-2D MoS_x-based (*i.e.*, amorphous and cluster structures) HER catalysts. For HER applications, I highlight the combination of theoretical and experimental tools for rational design of defects and understanding of the detailed reaction mechanisms. Lastly, I will briefly discuss the applications of defective MoS_x as catalysts for emerging application such as NRR, CO_2RR, metal-sulfur batteries, and metal-oxygen/air batteries, with a particular emphasis on the synergy built on defects for performance breakthroughs.

Painting Potential Landscapes on an Atomically Thin Canvas Archana Raja; Lawrence Berkeley National Laboratory, United States

Atomically thin van der Waals crystals like graphene and transition metal dichalcogenides allow for the creation of arbitrary, atomically precise heterostructures simply by stacking disparate monolayers without the constraints of covalent bonding or epitaxy. While these are commonly described as nanoscale LEGO blocks, many intriguing phenomena have been discovered in the recent past that go beyond this simple analogy. In this talk, I will discuss two stories from our joint experimental and theoretical work focusing on the rotationally-aligned 2D semiconductor heterostructure of monolayer WS2 and WSe2. In part one, we use electron microscopy and electron energy loss spectroscopy to directly visualize and correlate the nanoscale real space localization of excitonic states and structural reconstruction within the moiré unit cell, opening up the possibility for on-demand engineering of excitonic superlattices with nanometer precision. In part two, we use time- and spatially-resolved spectroscopies to investigate the diffusion of various interlayer exciton species as a function of temperature. We uncover the role of low energy moiré phonons or phasons in enabling exciton diffusion in the moiré potential even at low temperatures. These works are a result of fruitful collaborations with colleagues at various institutions including Berkeley Lab, UC Berkeley, Purdue University, Imperial College, Stanford Unviersity and NIMS Tsukuba.

11:00 AM NM02.10.03
Redox-Active 2D Molecular-Transition Metal Dichalcogenides Bilayer Crystals Mengyu Gao, Ce Liang, Tomojit Chowdhury and Jiwoong Park; The University of Chicago, United States

Understanding the interfacial behaviors is key to electrochemistry. Two dimensional (2D) materials, such as graphene and transition metal dichalcogenides (TMDs), are atomically flat surfaces where electrical and mass transport under electrochemical conditions could be well defined, *in situ* monitored, and precisely engineered. What's more, 2D materials can be used as a synthetic template affording atomic precision for the growth of new 2D systems that are otherwise impossible.

In this work, we present the electrochemical studies on a unique hybrid 2D system, where large-scale, crystalline redox-active 2D molecules were grown on monolayer TMDs as a *2D molecular-TMD bilayer crystal*. This system features ultrathin geometry, atomic precision, and chemical cleanness, and can be used as an ideal model system for electrochemical investigation at 2D interface. As a hybrid 2D system, the intimate interaction between the 2D molecular crystal and the underlying 2D TMD represents a unique interfacial problem, which remains less understood.

Here, toward this goal, we developed an *in situ* electrochemical setup, combining optical microscopy/spectroscopy and electrical transport measurement, to study the electrochemical behaviors of atomically thin 2D hybrid crystals with spatial, temporal and spectral resolution. Specifically, we introduced redox control of 2D molecular crystals made of ordered monolayer perylene diimide (PDI) and PDI-derivatives on monolayer MoS_2 with electrolyte gating. The uniformity, crystallinity and monolayer thickness of the 2D molecular crystals were confirmed by polarization microscopy, scanning-tunneling microscopy and cross-section transmission electron microscopy. Because of the wafer-scale crystallinity and distinct polarized optical responses, the electrochemical properties (such as redox states) of the 2D molecular crystals were accessible via far-field microscopic observations and electrical transport measurements. As the doping level was well controlled electrochemically, we optically and electrically monitored the band filling behaviors of 2D molecular crystals. Coupled with conventional electrochemical testing methods, such as electrochemical impedance spectroscopy, our integrative setup and high-quality growth of 2D molecular crystals are highly versatile, which unlocks new potentials in the electrochemical applications at 2D interface, such as electrochemical transistors, organic batteries, etc.

11:15 AM NM02.10.04
Electroactive 2D TMDC Based Polymer Hybrid and Hydrogel Matteo Crisci[1], Sara Domenici[2], Jonas Pflug[1], Felix Boll[1] and Teresa Gatti[3,1]; [1]Justus Liebig University, Germany; [2]Università di Padova, Italy; [3]Politecnico di Torino, Italy

Since the first discovery of graphene by Novoselov in 20041, graphene and in general 2D materials showed an increasing interest in the scientific community. Specifically Transition Metal Dichalcogenides (TMDC) showed a surge in interest, due to their different properties and flexibility due to the large amount of variability in the group. Not only this, but they can be easily engineered in different ways to tune their properties, examples are doping, functionalization and hybridation with other material2. In this last context, Conductive Polymers (CP)3 show complementary electrochemical properties to the 2D TMDC materials and can be exploited to further improve their performances. Here, we report on the synthesis of hybrids based polyaniline (PANI) and 2D transition metal dichalcogenides (TMDCs), employing different methodologies and formulations. In particular, we resort to liquid phase exfoliation (LPE)4 to produce 2D TMDCs in both the 2H and 1T phase and to in-situ polymerization to produce PANI chains directly on the surface of these nanomaterials to further amplify the electrochemical properties of the 2D material. Then the as obtained material can be further characterized electrochemically and can be also used in conjunction with flexible polymer scaffold in order to obtain piezo- active hydrogels. The as-obtained hydrogels are characterized through a combination of techniques and their swelling behaviour and mechanical properties are investigated.

11:30 AM NM02.10.05
Distinctively Structured WS_2 Nanotubes Embedded in SiOC Fibers for High-Rate Sodium Ion Storage Sonjoy Dey and Gurpreet Singh; Kansas State University, United States

Layered transition metal dichalcogenides (TMDs) such as tungsten disulfide (WS_2) are promising materials for a wide range of applications, including charge storage in batteries and supercapacitors. Nevertheless, TMD-based electrodes suffer from bottlenecks such as capacity fading at high current densities, voltage hysteresis during the conversion reaction, and polysulfide dissolution. To tame such adverse phenomena, we fabricate composite with WS_2 nanotubes. Herein we report on the superior electrochemical performance of ceramic composite fibers comprising WS_2 nanotubes (WS_2NTs) embedded in a chemically robust molecular polymer-derived ceramic matrix of silicon-oxycarbide (SiOC). Such hheterogeneousfiber structure was obtained via electrospinning of WS_2NT/preceramic polymer solution followed by pyrolysis at elevated temperatures. The capacity fading in WS2NT was curbed by the synergistic effect of the composite WS_2NT/SiOC electrode-high initial capacity of 454 mAh g^{-1}, and capacity retention of the composite electrode is 2-4 times higher compared to neat WS_2NT electrode.

Electroconversion Beyond the Equilibrium Limit Using Plasmons Prashant K. Jain; University of Illinois Urbana-Champaign, United States

Electroconversion is seeing a resurgence due to its utility for the manufacturing of chemicals and fuels powered by renewable energy. While catalyst design and engineering has been the key strategy for optimizing electroconversions, we have found that light excitation can instead be used to modulate the electrochemical activity in cases where the electrocatalyst is comprised of noble metal nanoparticles. The localized surface plasmon resonances of these nanoparticles allow strong absorption of light and the generation of non-equilibrium conditions at the electrode–electrolyte interface. As an outcome, the electrosynthetic activity is boosted beyond the equilibrium limit. I will describe important examples of such phenomena, including electrocatalytic ammonia oxidation, ammonia synthesis, methanol oxidation, and hydrogen evolution. I will also describe the mechanisms by which plasmonic excitations boost or modulate catalytic and electrocatalytic transformations.

11:00 AM NM03.01.02

Plasmons and Excitons in Pd-Doped Ag Nanoparticles from an *Ab Initio* GW-BSE Approach Emma Simmerman, Aaron Altman, Supavit Pokawanvit and Felipe H. da Jornada; Stanford University, United States

Combining transition-metal catalyst materials with plasmonic metals can enhance photocatalytic reaction rates, selectivity, and open non-equilibrium reaction paths. These effects are initiated by surface plasmon resonances (SPRs) in the plasmonic metal, and direct electron-hole (e-h) interactions can also significantly alter the landscape of excited states and affect SPR evolution. However, *ab initio* calculations in realistic nanoparticle systems have mostly either neglected e-h interactions or been limited to very small (<35 atom) clusters that display zero-dimensional-like excitation spectrum due to strong confinement effects and fail to describe plasmons due to use of the Tamm-Dancoff approximation (TDA). Here, we study Pd-doped Ag nanoparticles of up to 147 atoms with varying dopant levels, including e-h interactions and e-h recombination terms that are not present in the TDA, through the first-principles GW plus Bethe-Salpeter equation (BSE) approach. Applying new low-rank approximations and spectral folding techniques to accelerate these calculations, we can directly obtain excited states of nanoparticles capturing both plasmonic and excitonic effects. For small systems, we observe strong e-h interactions that redshift the spectrum by up to ~2 eV, demonstrating the importance of excitonic effects for spatially confined metallic systems. We also analyze the excitonic and plasmonic character of the excitations as a function of size and doping, and the impact of many-body interactions for reactions involving excited-state potential-energy surfaces.

11:15 AM NM03.01.03
Plasmon-Assisted *Operando* Self-Healing of Cu_2O Photocathodes Teresa Gatti; Politecnico di Torino, Italy

The ongoing problems in western countries connected to the global energy supply urgently forces the research community to strive in finding new methodologies for boosting the functional properties of earth-abundant raw materials, for example the largely available cupreous oxide. In this work, we focus on the surface sensitization of this metal oxide semiconductor with an argon plasma treatment, that promotes, during photoelectrochemical hydrogen evolution, the formation of metallic copper nanostructures. Interestingly, these copper-based hierarchical nano-branches, having inherent plasmonic properties, are at the origin of the improved shelf-life of the modified Cu_2O photocathode, as we demonstrate by advanced structural and photophysical analyses. Our proposed photophysical mechanism for an *operando* electrode stabilization suggests that a self-healing process can occur within the Cu_2O/plasmonic Cu heterostructure. These findings pave the way to the implementation of new, easy-to-make strategies to improve the properties of low-cost, low-toxicity energy materials.

11:30 AM NM03.01.04
Plasmon-Enhanced Electrochemical Oxidation of Alcohol Molecules Jingjing Qiu, Daniel Boskin and Zachary W. Ragan; San Francisco State University, United States

Plasmon-mediated electrocatalysis, i.e., the application of plasmonic nanostructures as electrodes/catalysts or both, has emerged as a promising approach to facilitate electrochemical reactions. We have investigated the electrochemical oxidation of 4-(hydroxymethyl)benzoic acid (4-HMBA) on different metallic working electrodes in alkaline electrolytes, including gold (Au), nickel (Ni), and platinum (Pt) metal. Au shows the lowest onset potential for catalyzing the electrooxidation of 4-HMBA among the three metals in base, whereas Pt does not catalyze the electrooxidation of 4-HMBA under alkaline conditions. The products of electrochemical oxidation of 4-HMBA catalyzed on Au working electrode are 4-carboxybenzaldehyde and terephthalic acid analyzed by high-performance liquid chromatography. The electrodeposited Au nanostructures on indium tin oxide (ITO)-coated glass is further utilized as the working electrode and catalyst for the 4-HMBA electrooxidation by introducing the plasmonic effects of the Au nanostructures. With the broad absorption of the Au nanostructures anchored on the ITO substrate in the visible and near-infrared range, we show that they could enhance the electrochemical oxidation of 4-HMBA under green and red LED light illuminations. The plasmonic effects of the Au nanostructures are proposed to contribute to the enhancement of the reaction and the photothermal effect is excluded based on electrolyte-temperature-dependent measurements. A possible reaction mechanism is proposed for the electrochemical oxidation of 4-HMBA on Au working electrodes in an alkaline electrolyte. Ongoing work focuses on investigating the electrochemical oxidation of electronically unique aromatic substituents of 4-HMBA and the plasmonic effects from the Au nanostructure electrodes in assisting other electrochemical reactions.

11:45 AM NM03.01.05
Utilizing Interband Transitions in Non-Noble Metal Nanoparticles for Sustainable Photocatalysis Son C. Nguyen; University of California, Merced, United States

When moving from noble to non-noble metals, the localized surface plasmon resonances of metallic nanoparticles become less distinctive, but the photo-induced interband transitions are strong and accessible in the visible region. Interband transitions in metallic nanoparticles have recently gained more attention for photocatalysis due to the unique properties of the corresponding hot carriers. It is desirable to explore interband transitions in non-noble metal nanoparticles for photocatalysis. It is also important to transition from utilizing precious (such as Au, Pd) to affordable (Co, Bi) metals for their cost effectiveness, strong light absorption, reasonable stability, and interesting electronic properties for photocatalysis. In this talk, I will share some promising photocatalytic activities of Co-B alloy and Bi nanoparticles in some model reactions and compare their peformance to Au and Pd nanoparticles.

SESSION NM03.02: Nanostructure/Ferroelectricity

1:30 PM *NM03.02.01
Manipulating Atomic Structures at the Au/TiO_2 Interface for O_2 Activation Wei David Wei; University of Florida, United States

The metal/oxide interface has been extensively studied due to its importance for heterogeneous catalysis. However, the exact role of interfacial atomic structures in governing catalytic processes still remains elusive. Herein, we demonstrate how the manipulation of atomic structures at the Au/TiO2 interface significantly alters the interfacial electron distribution and prompts O2 activation. It is discovered that at the defect-free Au/TiO2 interface electrons transfer from Ti3+ species into Au nanoparticles (NPs) and further migrate into adsorbed perimeter O2 molecules (i.e., in the form of Au-O-O-Ti), facilitating O2 activation and leading to a ca. 34 times higher CO oxidation activity than that on the oxygen vacancy (Vo)-rich Au/TiO2 interface, at which electrons from Ti3+ species are trapped by interfacial Vo on TiO2 and hardly interact with perimeter O2 molecules. We further reveal that the calcination releases those trapped electrons from interfacial Vo to facilitate O2 activation. Collectively, our results establish an atomiclevel description of the underlying mechanism regulating metal/oxide interfaces for the optimization of heterogeneous catalysis

2:00 PM NM03.02.02
One-Step Synthesis of Cu_xO_y/TiO_2 Photocatalysts by Laser Pyrolysis and Their Application for Selective Ethylene Production from Propionic Acid Degradation Juliette Karpiel[1,2], Pierre Lonchambon[1], Frédéric Dappozze[2], Chantal Guillard[2] and Nathalie Herlin-Boime[1]; [1]CEA Saclay, France; [2]Université Lyon 1, IRCELYON, France

Ethylene C_2H_4 is an essential organic molecule for chemical industries and is needed in ton quantities. However, its current synthesis pathways require high temperatures and/or pressures, leading significant energy consumption. In this context, we aim to use photocatalysis as an alternative method to produce ethylene at ambient temperature and pressure. Literature shows that photo-decarboxylation of propionic acid (PA) mainly produces CO_2, H_2 and ethane[1–4]. In addition, ethylene traces were also detected with Pt/TiO_2 or TiO_2 P25 catalysts[3,4]. In this work, we show how the use of copper-modified TiO_2 nanoparticles (NP) applied for the first time to PA degradation allows promoting high selectivity towards ethylene photo-production under UV light without noble metals.
TiO_2 and Cu_xO_y/TiO_2 photocatalysts were successfully synthetized by laser pyrolysis technique. This one-step method consists on an interaction between a CO_2 laser beam with gaseous and/or aerosolized liquid precursors. Such process offers great flexibility. Pure TiO_2 were synthesized from TTIP (Titanium Tetra Isopropoxide) precursor. Addition of Cu(acac)$_2$ in TTIP allowed obtaining copper-modified TiO_2 powders (Cu = 2 wt%). Besides the addition of Cu, only the effect of the atmosphere (He or Ar) during the synthesis was investigated in the present case. Samples were labelled TiO_2-X and Cu/TiO_2-X (X = He, Ar) depending on the atmosphere of synthesis.
The samples consist of a mix of anatase and rutile phases, with a higher rutile proportion in powders elaborated under Ar. XPS analyses reveal co-existing various Cu chemical states in both Cu/TiO_2 samples. Cu/TiO_2-He particularly favors the reduced Cu^0 and Cu^+ species at the expense of Cu^{2+}. STEM-HAADF coupled to EDX chemical analysis revealed copper species in Cu/TiO_2-He sample homogeneously dispersed on TiO_2 surface of ~10 nm diameter whereas Cu/TiO_2-Ar sample presented distinct copper species NPs of 1-3 nm on bigger TiO_2 support (~30 nm diameter). Such marked differentiation in terms of morphology between Cu/TiO_2-He and Cu/TiO_2-Ar samples are attributed to a change of flame intensity inducing different synthesis temperatures depending on the working atmosphere during laser pyrolysis.
Photocatalysts were tested for PA degradation under anaerobic conditions. Concerning pure TiO_2, the main products were CO_2 and C_2H_6. C_2H_4 (C_2H_4/CO_2 = 1%) and H_2 were found in trace amounts. Surface modifications with copper/copper oxides to TiO_2 photocatalysts lead to drastic changes in terms of levels of photo-generated products. Apart from CO_2, Cu/TiO_2-He mostly produced C_2H_6, but significantly enhanced C_2H_4 formation (C_2H_4/CO_2 = 11%) up to 200 minutes. From this time, C_2H_4 production slows down, when on the contrary H_2 production considerably takes off. This phenomenon was attributed to the reduction of highly dispersed copper species on TiO_2 surface in Cu/TiO_2-He. When Cu is reduced to Cu^0, H_2 production improves at the detriment of C_2H_4. With Cu/TiO_2-Ar, C_2H_4 was the major hydrocarbon product (C_2H_4/CO_2 = 85%), evolving linearly at the expense of C_2H_6 and H_2. In this latter case, Cu_xO_y is present as particles of 1-3 nm in diameter and is not so easily fully reduced, therefore the pathway to C_2H_4 production is enhanced. Production of ethylene at 260 ppmv/h exceeded 130 times the production rate obtained from of pure titania.
This study shows the laser pyrolysis flexibility in synthetizing Cu/TiO_2 photocatalysts with various morphologies, but also the possibility of using Cu_xO_y species to enhance the selectivity from C_2H_6 to C_2H_4 during PA decarboxylation, with a ratio C_2H_4/CO_2 as high as 85%.

Tethering Catalytic Nanoparticles to Supramolecular Nanostructures for Improved Recyclability Yukio Cho, Kiera Y. Tai and Julia Ortony; Massachusetts Institute of Technology, United States

Nano-sized catalysts are promising due to their high catalytic activity originating from ultra-large surface-to-volume ratios. However, nanoscale suspensions are also inseparable, hampering the reusability and recyclability of nano-sized catalysts. While depositing the nano-sized catalysts on supporting materials offers an approach to overcome this challenge, the surface of supporting materials often has little flexibility to harness the surface chemistry, which leads to limited loading ratios and uncontrolled nucleation growth of the catalysts on the surface. Here we show that nano-sized catalysts may be anchored to self-assembled nanostructures, offering tunable surface chemistry which can be harnessed to promote affinity with and recyclability of catalysts. In this study, we use sub-10nm gold nanoparticle (AuNP) catalysts and L-cysteine-functionalized aramid amphiphile nanotubes which exhibit a strong affinity with AuNPs, as a model system. We observe that sub-10nm AuNPs bind evenly on the surface of the nanotubes without precipitation. We confirm that the AuNP-CysAA system is capable of reducing 4-nitrophenol. Unlike only AuNPs suspension, the reacted mixture of the AuNP-CysAA system can be easily separated by filtration to reuse due to the high-aspect-ratio of the nanotubes.

Ferroelectric-Photocatalyst Nanocomposite Thin Films for Enhanced Photoelectrocatalytic Activity Joe Briscoe[1], Adriana Augurio[1], Qian Guo[1], Alberto Alvarez Fernandez[2], Vishal Panchal[3], Bede Pittenger[3], Peter Dewolf[3], Stefan Guldin[2] and Ana Jorge Sobrido[1]; [1]Queen Mary University of London, United Kingdom; [2]University College London, United Kingdom; [3]Bruker Corporation, United Kingdom

Low-cost, oxide-based photo-electrocatalysts (PEC), such as Fe_2O_3, $BiVO_4$, $CuWO_4$, are gaining increased attention to achieve unassisted water splitting to produce solar fuels. Although they possess ideal bandgaps in the range of 2-2.5 eV, they suffer from a high level of surface recombination and low carrier mobility[1]. Ferroelectric polarization has emerged as a new strategy in photocatalysis to induce opposite band bending at material surfaces facilitating increased charge separation and promoting selective redox reactions[2]. However, most ferroelectric have wide bandgaps, and therefore do not absorb visible light, and are insulating therefore cannot transport photogenerated charges. Therefore, herein, we combine ferroelectric $BaTiO_3$ with the photocatalyst Fe_2O_3 in parallel at the nanoscale to combine the benefits of ferroelectrics and photocatalysts in a nanocomposite film.

To produce this structure, porous $BaTiO_3$ (pBTO) thin films were synthesized by the soft template-assisted sol-gel method. Using different concentrations of organic template, the porosity of pBTO was controlled to obtain suitable thin films for photocatalyst integration. The overall porosity and surface area of the pBTO thin films is determined by SEM analysis and ellipsometry.

The ferroelectric phase of pBTO is confirmed by XRD analysis and Raman spectroscopy. The switching of spontaneous polarization of pBTO by an electric field is verified by Piezoresponse Force Microscopy (PFM). The alignment of polar dipoles to the ferroelectric surface (P_{up} or P_{down}) is evaluated by testing the PEC performance of pBTO after electrochemical (EC) poling at ±8V, which show that the photoanode performance is improved for P_{down}.

Lastly, the pBTO/Fe_2O_3 thin film shows an enhancement of the photocurrent density compared to either the bare Fe_2O_3 (by ~2 times) and pBTO thin films (by ~20 times), which could be correlated to the upward band bending induced by the ferroelectric polarization of pBTO. The PEC response in pBTO/Fe_2O_3 is accordingly regulated by EC poling without altering the Fe_2O_3 layer chemically (as confirmed by XPS), leading to further enhancement of the photocurrent. This research work shows a facile and low-cost approach for the development of novel ferroelectric/photocatalyst photoanodes with switchable control of their PEC performance, which possess a great potential for photoelectrochemical applications.

Assisted Enhanced Photocatalysis by the Addition of a Ferroelectric Component to Copper-Doped TiO_2 Nanotubes Gilles D. Berhault[1], Nouf Al-Aqeel[2], Wadha Alrashedi[2], Mohammad Yunas[3], Nuhad Abdullah Alomair[2], Fathi Jomni[4] and Hafedh Kochkar[2]; [1]Research Institute on Catalysis and Environment, France; [2]Imam Abdulrahman Bin Faisal University, Saudi Arabia; [3]King Fahd University of Petroleum and Minerals, Saudi Arabia; [4]University Tunis El Manar, Tunisia

Introduction

Titanium dioxide is the most used semiconductor in photocatalysis due to its good chemical stability and suitable band edge potentials for H_2 production. However, its large band gap (3.2 eV for anatase) restrains its use to photoexcitation under UV illumination. TiO_2 also presents a high recombination rate of electron-hole pairs limiting its intrinsic activity. Different strategies have been envisaged to decrease recombination including change of morphology, formation of heterojunctions, doping with cations or combination with carbon allotropes. Even if successful, these strategies rely on the consumption of part of the excitons to keep others available for reaction. In this respect, ferroelectric polarization can modify band structures and charge transport performance in adjacent semiconductors without consumption of part of the excitons. Among ferroelectrics, $SrTiO_3$ offers favourable conditions for photocatalysis with a conduction band only 200 meV more negative than TiO_2 while it is also a metastable paraelectric compound becoming ferroelectric under optical excitation. Therefore, herein, the interest of using $SrTiO_3$ with Cu-doped TiO_2 nanotubes was here considered.
.

Materials and Methods

TiO_2 nanotubes (TNT) were synthesized using a hydrothermal procedure under strong alkaline conditions. TiO_2 nanotubes were impregnated with $Cu(NO_3)_2.3H_2O$ (0.5 wt% Cu) before drying and calcination. The resulting material was then doped with strontium (0.2 to 1.0 wt %). Photocatalytic tests were performed under UV and visible irradiations for the formic acid photodegradation.

Results and Discussion

Deep structural characterization was performed. First, UV-vis DRS emphasizes the role of plasmonic properties following the Cu addition making these materials active under visible irradiation. Second, Raman shows the formation of surface Sr-O-Ti entities up to 0.8 wt% Sr.
XPS analysis also reveals a net modification of the Ti, O and Sr species with increasing addition of strontium resulting from the progressive replacement of surface oxygen vacancies by Sr-O-Ti entities. PL and EIS also show that incorporating strontium decreases the recombination rate of electron-hole pairs and stabilizes photogenerated charges increasing their lifetime by 75%.
Combined together, limited recombination and higher stabilization of photogenerated charges leads to an increase of the photocatalytic activity under UV irradiation by 50% at the optimum Sr loading for in situ $SrTiO_3$ formation (0.8 wt% Sr) and by an impressive higher activity under visible irradiation (initial rate: 0.6 $\mu mol.L^{-1}.min^{-1}$ without Sr, 109 $\mu mol.L^{-1}.min^{-1}$ at optimum Sr loading).
Extension of this study was also made to Cu-doped systems comprising graphene oxide. Once again, the Sr addition results in a strong increase of the photocatalytic response. Modelization of the kinetics of photodegradation including diffusion phenomena was performed and compared to dielectric properties. A perfect correlation was observed between the increase of activity and the propensity to charge polarization induced by Sr addition confirming the role played by the ferroelectricity induced by in situ $SrTiO_3$ entities on the enhanced photocatalytic properties.

Conclusion

Assisted photocatalysis by addition of a ferroelectric component to semiconductor systems was herein demonstrated as a promising alternative for enhancing the photocatalytic performance of commonly used semiconductors like TiO_2 through stabilization of photogenerated charges while limiting recombination processes. Application made using Sr addition to Cu-doped TiO_2 nanotubes can be extended widely to other semiconductor systems allowing better yields in pollutant abatement or in green energy production.

Tuning Surface States as Performance Parameters for Water Oxidation on Metal Oxide Photoanodes Hang Chen[1], Jingguo Li[2], Carlos A. Triana[1], Yonggui Zhao[1] and Greta Patzke[1]; [1]University of Zurich, Switzerland; [2]Uppsala University, Sweden

During the past decades, photoelectrochemical strategies have attracted increasing interest for the direct conversion of solar energy into sustainable chemical fuels. Generally, surface states generated from the water oxidation process by photogenerated holes are recognized as a key parameter for tuning the performance of photoanodes in water splitting setups, but their behavior and precise chemical nature remains to be explored for many prominent materials.

This applies specifically for hematite Fe_2O_3 photoanodes, for which we recently investigated fundamental questions associated with its two different types of surface states (referred to as S1 and S2) and their interaction.[1] While S1 has long been identified as an iron-oxo species through operando spectroscopy and related rate law investigations, the precise nature and behavior of S2 with lower oxidative energy has been controversially discussed. Photoanodes with hematite nanorods were prepared via published protocols and the dynamic interaction of their surface states was evaluated concerning the influence of oxidative potentials, illumination intensity, and electrolyte pH. We tentatively assigned S2 to an iron-peroxo intermediate of the water oxidation process via photoelectrochemical impedance spectroscopy (PEIS) measurements, which were complemented with transient photocurrent spectroscopy (TPS) results. Our assignment was based on the following key observations: Potential-dependent rate law analyses revealed a transition of 1st order reaction kinetics for surface holes with low densities to 3rd order kinetics at higher hole density for higher applied potentials (1.3 V vs. RHE). At lower potentials (0.9 V vs. RHE) a transition from zero to 3rd order kinetics was observed. Further, the lifetime of S2 was rather long with >3 min, and it was generated from the accumulation of shorter-lived S1 states. In strongly alkaline media, S1 states became more mobile to be transformed into S2 states which displayed 3rd order reaction kinetics. Near the point of zero charge, a unique three-stage transformation of the reaction mechanism was unraveled. The quick migration and reaction of oxo species under intense illumination or surface deprotonation conditions can give rise to longer-lived peroxo species and higher reaction orders. This model paves new ways to optimize photoanode performance through tuning the accumulation and migration of oxo species.

In a parallel study, we enhanced the efficiency of bismuth vanadate $BiVO_4$ photoanodes through introduction of a reduced catalytic layer on TiO_2 protected $BiVO_4$.[2] The surface of the resulting R-TiO_2@$BiVO_4$ photoanodes was enriched in oxygen vacancies and their performance was clearly superior to pristine $BiVO_4$. Our PEIS studies revealed the presence of two surface states on $BiVO_4$ photoanodes (S1 around 0.45 V and S2 near the water oxidation potential around 1.05 V), while R-TiO_2@$BiVO_4$ displayed only S2 with S1 being passivated. Moreover, the hole densities in S2 were notably increased for R-TiO_2@$BiVO_4$ as the accumulation of intermediates was promoted with rapid water oxidation kinetics, which identifies S2 as reaction centers related to oxygen vacancies. Our R-TiO_2 surface coating strategy was furthermore investigated with a wide range of analytical methods, showing that the excellent water oxidation activity of R-TiO_2@$BiVO_4$ photoanodes arises from a simultaneous enhancement of S2 reaction centers and suppression of adverse VO_2+/VO^{2+} recombination processes. Therefore, our surface engineering strategy not only stabilizes $BiVO_4$ photoanodes but also highlights the essential role of surface states in their performance optimization.

Reactor Design for Nanoparticle-Based 3-Dimensional Photocatalysts Markus Niederberger and Fabian Matter; ETH Zurich, Switzerland

Multiscale nanoparticle assembly is at the heart of efforts to integrate nanoparticles into macroscopic materials and devices [1]. The idea of arranging nanoparticles in a modular and defined way to larger entities is extremely appealing, because in such a way a nearly indefinite number of different architectures is accessible from a limited set of building blocks. Among the many geometries, 3-dimensional structures like aerogels are unique in the sense that the size-specific properties of the nanobuilding blocks are fully preserved in the macroscopic material [2]. With their extensive porosity and large surface areas aerogels are particularly attractive for applications in gas-phase photocatalysis [3]. Moreover, if they can be produced in monolithic form with sizes in the centimeter range, completely new possibilities and challenges open up, which are also associated with interesting scientific and technical questions. In particular, gas flow through and the penetration of light into the macroscopic bodies represent important parameters that must be taken into account in the development of suitable photoreactors [4-7]. Only if the macroscopic shape of the aerogel and the reactor design are perfectly matched can the full photocatalytic performance of the aerogel be exploited [7]. Based on photocatalytic methanol reforming as a model reaction, this presentation will show how all these aspects are interrelated and how they have to be optimized to increase the hydrogen production rate.

4:15 PM NM03.03.03
Photocatalytic Activity and Electron Storage Capability of TiO_2 Aerogels with Adjustable Surface Area Anja Hofmann[1], Alexandra Rose[2], Pascal Voepel[2], Barbara Milow[2] and Roland Marschall[1]; [1]University of Bayreuth, Germany; [2]German Aerospace Center, Germany

Aerogels are a group of nanostructured materials which offer the possibility for tailoring the surface area and crystallinity in a wide range. TiO_2 aerogels are suitable candidates for photocatalytic applications due to this high surface area with presumably high amount of reactive sites and improved charge separation.[1,2] Additionally, TiO_2 in general is known for the trapping of electrons close to the surface with the formation of Ti^{3+} states, showing a characteristic broad absorption at a maximum of 650 nm with dark blue coloration.[3] These stored electrons can be used for different reduction reactions, such as the reaction with different metal ions to metal nanoparticles.[4,5] The nitrogen reduction reaction to ammonia in the dark is another very promising reaction which was reported the first time by Bahnemann *et al.* in 2011 for TiO_2 colloids.[6] This reaction can pave the way to a decentralized, energy efficient production of ammonia, which is commonly produced *via* the extremely energy intensive Haber-Bosch process.

Herein, mesoporous TiO_2 aerogels with varying properties were investigated for their electron storage capability and photocatalytic activity. These aerogels were synthesized *via* a novel modified acid catalyzed sol-gel synthesis with subsequent supercritical drying.[7] The surface area could be tailored in a range of 92 up to 600 $m^2 g^{-1}$ by variation of the heat treatment conditions. Absorption measurements and quantification experiments revealed an increase in the storage of photogenerated electrons in water-methanol mixtures with decreasing calcination temperature and increasing surface area. At the same time, the sacrificial hydrogen evolution rate decreased. It could be further shown, that the electron storage capability depends on the concentration of the hole scavenger. Beside the reduction reaction of Pt ions in the dark using the photogenerated electrons in the TiO_2 aerogels, a nitrogen reduction reaction to ammonia in the dark, using these stored electrons could be performed and verified by salicylate test.

Effects of Periodic Pore Ordering on Photocatalytic Hydrogen Generation with Mesoporous Semiconductor Oxides Tobias Weller[1] and Roland Marschall[2]; [1]Justus-Liebig-Universität Giessen, Germany; [2]University of Bayreuth, Germany

Since the first reports on periodically ordered mesoporous silica materials by the Kresge group[1,2] and some earlier works, scientist all over the world have been fascinated by the crystalline (periodic) pore ordering in such materials. Since then, long-range periodically ordered mesopores with a number of geometries have been reported, including two-dimensional (2D) hexagonal, three-dimensional (3D) cubic, 3D continuous gyroidal and others, for a range of different materials including a vast number of (crystalline) oxides and hybrid materials.[3–5]
Scientists have been using such ordered mesoporous materials for a range of different applications including in catalysis, since the large surface area, e.g. of periodically ordered mesoporous oxides, can exhibit a higher number of active sites. The advantage of large surface area has been utilized in a number of other applications including sensing, proton conduction and batteries.[6] In many cases where periodically ordered mesoporous materials have been achieved, the authors were inclined to link the improved performance with the degree to which the material displayed porosity and associated increased surface area.
But since a review by Rolison[7] suggesting that periodic pore ordering in catalysis is not required, no systematic study has been reported on how periodic pore order in mesoporous materials affects hydrogen generation in photocatalysis. The most probable reason for the lack of such studies is that it is experimentally challenging to vary solely the degree of periodic pore order, e.g. of a mesoporous semiconductor, without changing other important material parameters, like the crystallite size, pore wall thickness, surface area, pore diameter or pore wall surface chemistry, the latter being easily affected by using different types of templates (e.g. using polymer or silica spheres as templates).
Motivated by this challenge, we showed that the triblock terpolymer poly(isoprene-*b*-styrene-*b*-ethylene oxide) (PI-*b*-PS-*b*-PEO; ISO) can be used for the preparation of a phase-pure and three-dimensionally (3D) co-continuous periodically ordered mesoporous quaternary $CsTaWO_6$ semiconductor for photocatalytic hydrogen generation with cubic alternating gyroid morphology.[8]
By varying the amount of templating polymer ISO relative to inorganic precursors, as well as adjusting other synthetic parameters, we are now able to control major physicochemical characteristics of the resulting mesoporous network. We show the preparation of mesoporous $CsTaWO_6$ powders that differ mainly in the degree of long-range periodic mesopore ordering, without significantly changing crystallite size in the pore walls or accessible surface area. Utilizing the resulting oxides as photocatalysts for sacrificial hydrogen evolution reaction (HER), we experimentally demonstrate that the degree of pore connectivity in mesoporous photocatalysts is the main factor controlling liquid phase photocatalytic HER when other parameters are kept non rate-limiting.[9]

Detonation Synthesis of TiO_2-TiC Photocatalyst for NO_x Oxidation under Visible Light Ahmed Al Mayyahi, Shusil Sigdel, Christopher M. Sorensen and Placidus B. Amama; Kansas State University, United States

Nucleation of TiO_2 on TiC is a promising strategy to design narrow band gap anatase-rutile junction TiO_2 supported on TiC with visible light photocatalytic activity. However, the lack of a facile and scalable approach for the synthesis of TiO_2-TiC has impeded its application in photocatalysis. This study reports a scalable, low-cost, reliable, and green approach for producing TiO_2-TiC. The approach is based on detonating a mixture of hydrocarbon (C_7H_8) and titanium precursor ($TiCl_4$) with O_2 in a multi-liter chamber to produce scalable amounts of TiO_2-TiC per day. Results show that the band gap of TiO_2-TiC is sensitive to the molar ratio of $TiCl_4$ to C_7H_8 used in the detonation. TiO_2-TiC with a band gap of 2.7 eV is produced when the molar ratio of $TiCl_4$ to C_7H_8 is 0.73. The TiO_2-TiC produced exhibits high performance in the oxidation of NO_x to nitrates with minimal release of NO_2 under blue light and shows limited activity under green light. Also, the same TiO_2-TiC ($TiCl_4/C_7H_8 = 0.73$) exhibits noticeable photocatalytic activity in NO_x oxidation under high humidity, a condition that simulates the environment in urban cities. The high photocatalytic activity is attributed to (1) the narrow band gap of TiO_2-TiC enabling visible light absorption; (2) the synergy between anatase and rutile in the hybrid structure allowing effective electron-hole separation and subsequently increasing the number of active radicals on the catalyst surface; and (3) the presence of TiC providing a non-photocatalytic domain to store NO_x photooxidation products on the catalyst surface and hindering their release to the atmosphere in the form of nocuous NO_2.

Ferroelectric $Bi_{1+x}FeO_3$ Thin Film for Enhanced Photoelectrochemical Water Splitting Performance Haozhen Yuan, Joe Briscoe, Subhajit Pal and Chloe Forrester; Queen Mary University of London, United Kingdom

$BiFeO_3$ thin films have been widely studied for photoelectrochemical water splitting application because of its narrow bandgap and good ferroelectricity which can promote the separation of photo-generated charges. Bismuth is well known as volatile and excess bismuth is usually added into the precursor to compensate the loss of bismuth during heat treatment. However, the exact quantity of excess bismuth and how excess bismuth affects its PEC performance have not been studied. Herein, self-doped $Bi_{1+x}FeO_3$ (x from 0 to 0.3) thin films are prepared via simple chemical solution deposition method. The grain size of films increases firstly and then decrease with increasing x. The loss of bismuth after annealing is confirmed by EDX and it estimates that a stoichiometric $BiFeO_3$ thin film can be achieved between x=0.05 and 0.1. Enhanced photocathodic photocurrent density is observed in slightly bismuth-rich films (x=0.15 and 0.2) which can be ascribed to the co-existence of rhombohedral and orthorhombic crystal structures. Moreover, the switching of ferroelectric domains in BFO thin films is observed using piezoresponse force microscopy, confirming the ferroelectric polarization. In addition, the PEC performance can be controlled via the ferroelectric polarization using electrochemical (EC) poling. Our work offers a simple and low-cost approach to enhance the photocathodic current density, which could help the further development of $BiFeO_3$-based thin films for PEC water splitting application.

5:00 PM NM03.04.05
Fabrication and Characterization of TiO_2 Nanotube Array for Seawater Splitting Electrode Prepared by Anodization Han-Sol Yoon[1], Kyeonghan Na[2,2], Jae-Yoon Kim[1], So-Hyeon Lee[1] and Won-Youl Choi[1,2,2]; [1]Gangnueng-Wonju National University, Korea (the Republic of); [2]Gangneung-Wonju National University, Korea (the Republic of)

Among the technologies for hydrogen production, water splitting is a technology that attracts much attention that doesn't cause carbon emissions. But there is a limitation in using highly purified fresh water for hydrogen production through water splitting. Only 2.5 vol% of the water on Earth is fresh water and the other is seawater, and freshwater has many uses, so applied research for the use of seawater is necessary for the dissemination of water-splitting technology. To splitting seawater, the oxygen evolution reaction (OER) electrode requires some unique properties such as high catalytic activity for seawater and chlorine corrosion resistance. To improve these properties, methods for the fabrication of various nanostructures have been suggested and among them, anodization is a method that can be growing aligned nanotube arrays on the surface of a TiO_2 plate. In this study, the TiO_2 OER electrode was fabricated by anodizing to improve catalytic activity and resistance to chlorine corrosion. Morphological and electrochemical properties of TiO_2 OER electrode were characterized using field emission scanning electron microscopes, X-ray diffraction, cyclic voltammetry, and Ultraviolet-visible spectroscopy. Among the anodized electrodes, the sample fabricated in electrolyte using NH_4F-H_2O-$C_3H_8O_2$ was shown the most hydrogen evolution, and the best resistance to chlorine corrosion was measured for the sample in which the H_2SO_4 electrolyte was used. The average pore diameter of the nanotubes was measured to be below 114 nm using FE-SEM image analysis, and the layer thickness was observed to be more than 10μm.

5:00 PM NM03.04.06
Ultra-stable, 1D TiO_2 Lepidocrocite for Photocatalytic Hydrogen Production in Water-Methanol Mixtures Hussein Badr and Michel Barsoum; Drexel University, United States

Water and sunlight are the cleanest, renewable, and most abundant resources on Earth. Developing inexpensive, scalable photocatalysts that are long-stable, for hydrogen, H_2, production has long been a cherished dream of humanity. Herein we report on one dimensional lepidocrocite-based nanofilaments, NFs, $\approx 5\times5$ Å^2 in cross-section - that generate H_2 from 80:20 vol.% water/methanol mixtures, when exposed to Xe-lamp radiation that simulates the solar spectrum. The NFs were stable in the mixtures for times > 4,300 h, 300 h of which were under irradiation, whilst being stirred. Apparent quantum yields as high as 12.6% were obtained. Based on deuterated water results we conclude that water is the H_2 source. No carbon dioxide nor oxygen is produced. Since our NFs do not produce CO_2, their green credentials, and their economic prospects for large scale-up suggest new lines for developing cheap and ultra-stable materials able to produce H_2 photochemically for long times.

5:00 PM NM03.04.07
Solar Energy Conversion Using Multinary Complex Oxides Prepared by Arc-Synthesis Nadia G. Macedo, Jessica C. Alvim, Leonardo C. Soares, Márcio Sangali, Rubens Caram Jr, Luelc Costa, Miguel T. Galante and Claudia Longo; University of Campinas, Brazil

Semiconductor oxides have been used as photocatalysts for conversion of solar energy in different applications of technological interest. Compared to binary oxides, the multinary oxides can exhibit improved sunlight harvesting; also, the conduction and valence band edges can be modulated, that can enhance the selectivity for some photoelectrochemical (PEC) reactions. Recently, our research group used the arc-melting of Cu_2O and WO_3 precursors for synthesizing Cu_2WO_4, a p-type semiconductor. Ongoing studies revealed that Cu_2WO_4 particles immobilized on gas diffusion electrodes produced ethanol from PEC CO_2 reduction reaction (PEC-CO_2RR). Electrodes prepared with particles of the composite containing $CuFeO_2$ and copper oxides, obtained by arc-synthesis from of Cu_2O and Fe_2O_3 precursors, also behave as p-type semiconductor electrodes and have been evaluated as photocathodes for PEC-CO_2RR and in-situ H_2O_2 production from PEC O_2 reduction reaction. On the other hand, electrodes containing ilmenite ($FeTiO_3$) particles synthesized by arc-melting of TiO_2 and Fe_2O_3 precursors behave as n-type semiconductor; ongoing studies revealed that ilmenite electrodes exhibited high efficiency and excellent long-term stability for application as photoanodes for PEC oxygen evolution reaction (PEC-OER). PEC properties of n-type semiconductor electrodes were also observed for the multiphasic α-$AgVO_3$/Fe_2O_3/Ag synthesized by arc-melting. Scanning electron microscopy and energy dispersive spectroscopy revealed that this composite consisted of Ag nanoparticles decorating micrometric Fe_2O_3 and nanostructures of the metastable α-$AgVO_3$. The performance of such photoanode for PEC OER and for removal of contaminants of emerging concern from water is under investigation. These results revealed that arc-melting can be used as a time-efficient methodology for synthesizing multinary complex oxides for application in PEC reactors for water decontamination and for solar fuels production from CO_2RR.

5:00 PM NM03.04.08
Enhanced Photocatalytic Activity of TiO_2 Brookite Phase by Sono-Reduction Method Seyyedmohammadhossein Hejazi[1,2], Mahdi Shahrezaei[1], Alberto Naldoni[1], Stepan Kment[1,2] and Hana Kmentova[3]; [1]Czech Advanced Technology and Research Institute (CATRIN), Czechia; [2]Nanotechnology Centre, Centre of Energy and Environmental Technologies, Czechia; [3]Palacky University Olomouc, Czechia

The reduction of TiO_2 has been proven to enhance its photocatalytic activity by extending its light absorbance from UV to the visible part of the light spectrum and by optimizing the amount and position of defects that can act as co-catalytic sites. Traditional reduction method at elevated temperatures in contact with a reductant gas like hydrogen, has some disadvantages like phase transformation, sintering and even introducing impurities because of the harsh reaction conditions. In this contribution, we used the sono-reduction method in mild conditions at room temperature and aqua media under Ar atmosphere, to input defects at the surface of brookite as the most photoactive TiO_2 phase and to produce so-called "black TiO_2". We have shown that this strategy, without using a noble metal co-catalyst, could increase the H_2 evolution rate up to 3 times (from 19.3 to 58.5 $\mu mol.g^{-1}.h^{-1}$) in comparison with the pristine (white) sample.

5:00 PM NM03.04.09
Multidimensional Ternary Heterostructured Self-Precipitated Ag Nanoparticles on TiO_2@$SrTiO_3$ for Photoreforming of Plastics Face Mask to Hydrogen Ting-Han Lin, Jia-Mao Chang and Ming-Chung Wu; Chang Gung University, Taiwan

Solar-to-hydrogen via the photocatalytic reaction has been considered a promising way to obtain sustainable green energy in this generation. In the past three years, the COVID-19 pandemic changed our life habits and led people produce waste of personal surgical masks daily. Photoreforming of plastics waste to hydrogen contributes to lowering the environmental load and provides another route of sustainable energy acquirement. In this study, we prepared the ternary photocatalysts with heterostructure construction of zero-dimensional $SrTiO_3$ nanocubes ($SrTiO_3$ NC) and one-dimensional TiO_2 nanofibers with self-precipitating Ag nanoparticles (AT NFs). AT NFs synthesized by hydrothermal method showed the unique Ag NPs on the surface of TiO_2 NFs, increasing the absorption. Via in-situ hydrothermal growth reaction of $SrTiO_3$ NC, we precisely manipulate the distribution of $SrTiO_3$ NC on AT NFs by tuning the proportion of strontium titanate. As a high proportion of $SrTiO_3$, the one-dimensional structure of AT@$SrTiO_3$ gradually weakened, and the self-precipitated Ag nanoparticles were covered as dopants in the AT@$SrTiO_3$. From the morphology observation and the study of XPS and XAS spectra to investigate interface bonding information, we noticed that several $SrTiO_3$ NC covered the silver particles, and partial Ag NPs were retained on AT@ $SrTiO_3$ with specific concentration, maintaining the excellent photoresponse due to surface plasma resonance of Ag NPs. The photocatalytic hydrogen production rate in a mixture of water/ethanol under xenon lamp irradiation can reach 320.8 $\mu mol \bullet g^{-1} \bullet h^{-1}$. In addition, for the photoreforming of the surgical mask to hydrogen production, we carried out the hydrolysis pretreatment in an alkaline solution and then used UV ozone to activate PP and PE molecules. Both pretreatments were beneficial to the hydrolysis and polarity that showed the hydrogen production to 316.9 $\mu mol \bullet g^{-1} \bullet h^{-1}$.

5:00 PM NM03.04.10
Cu_2O/Mo:$BiVO_4$ PN Junction Photoelectrode for Solar Water Oxidation Hervin Errol T. Mendoza, Zongkai Wu, Samutr Assavachin, Chengcan Xiao and Frank E. Osterloh; University of California, Davis, United States

Semiconductor-based solar water splitting for renewable fuel generation is one of the practical means of addressing the increasing global energy demand. Cu_2O (p-type, $E_g = 2.0$ eV) is earth-abundant and inexpensive while $BiVO_4$ (n-type, $E_g = 2.4$ eV) is preparable using scalable methods, making these two materials suitable choices for cost-efficient and sustainable energy production. A Cu_2O/$BiVO_4$ structure with a theoretical solar-to-hydrogen efficiency of 9.2% can potentially exhibit unassisted water splitting, but very few studies have been carried out to investigate this system (Wu, Z. et al., Chem. Comm., 2018, 54(65), 9023-9026). In this work, bilayer photoelectrodes were constructed from Cu_2O and Mo-doped bismuth vanadate (Mo:$BiVO_4$) and characterized. Cu_2O was electrodeposited onto a F-doped tin oxide (FTO) substrate and Mo:$BiVO_4$ nanoparticles were prepared by solution phase synthesis. The bilayer was then obtained through electrophoretic deposition of Mo:$BiVO_4$ on Cu_2O followed by argon annealing at 550^{o}C for 8 hrs. X-ray diffraction data indicated the formation of new phases in the film after annealing. Photoelectrochemical experiments in 0.1 M Na_2SO_4 solution at pH 7 showed anodic photocurrent with onset potential of ~0.6 V vs. reversible hydrogen electrode (RHE). Surface photovoltage spectroscopy suggests formation of a pn junction between Cu_2O and Mo:$BiVO_4$, likely causing the device to work only under applied bias conditions. Use of oxygen evolution cocatalysts and charge selective contacts had been explored in an attempt to mitigate the issue.

5:00 PM NM03.04.11
Transition Metals and Stainless Steel for Low Cost Direct Water Splitting Stefan L. Schweizer[1], Haojie Zhang[2] and Ralf B. Wehrspohn[1]; [1]Univ of Halle-Wittenberg, Germany; [2]Max Planck Institute of Microstructure Physics, Germany

The research on materials for the water splitting reactions is in focus for several years...
the Oxygen evolution reaction (OER) and the Hydrogen evolution reaction (HER),
We review the recent process of the global research on transition metal phosphide (TMP) based heterostructures for efficient water splitting.

To reduce the cost of electrochemical water splitting, two strategies to prepare robust and abundant 3D electrodes:
a) the design and preparation of highly active catalysts, and
b) the use of a cheaper substrate stainless steel for the preparation of 3D electrodes.

Both strategies have promising potential for the further design and preparation of abundant and robust 3D electrodes for efficient electrochemical water splitting as well as for other electrochemical areas.

For the first strategy, we prepared a heterostructure by combining two different catalysts, namely NiFe LDH (*layered double* hydroxides) nanosheets and NiCoP nanowires.
The resulting 3D NiFe LDH/NiCoP@NF (nanofoam) electrodes demonstrated a better bifunctional activity for both the HER and the OER when compared to its counterparts.
A new recipe for preparing TMP by the ALD process was also explored and optimized for the first time. The CoP ultrathin films prepared with our ALD recipe show a higher HER activity than CoP films prepared by the traditional post-phosphorization method.

The heterostructure with a strong synergistic effect is an effective approach to improve the catalytic activity of prepared catalysts and a novel strategy to design and prepare bifunctional electrocatalysts for efficient water splitting. However, the related reaction mechanisms happening on the surface of the heterostructure are still not understood.
For the second strategy, we used carbon nano tubes (CNT) as the interface material to combine a stainless steel (SS) mesh with highly active catalysts to improve the activity of SS-based 3D electrodes for efficient water splitting. The CVD process for growing CNTs on the surface of SS was optimized, and the as-prepared CNT/SS electrodes were successfully modified with the state-of-the-art catalysts Pt and RuO2. The resulting 3D Pt/OxCNT/SS and RuO2/OxCNT/SS exhibited a better HER and OER activity, respectively, than the reference of 20 wt% Pt/C/SS and RuO2/SS.

Employing CNT as an interface material can make extremely stable SS become more suitable to the decoration with highly active electrocatalysts for the preparation of SS-based 3D electrodes towards efficient water splitting. The possibility of modifying CNT/SS with abundant and efficient catalysts to further enhance the performance of 3D SS-based electrodes is still needed to be investigated further.

The TMP-based catalysts deposited by ALD show a promising application potential for designing and preparing 3D electrodes for (photo)electrochemical water splitting as well as other electrochemical areas by depositing TMP on various 3D structures. Our work explored and improved the ALD process to obtain the controllable deposition of highly pure and stable CoP, but other TMP, such as Ni-based, Fe-based and Mo-based phosphides as well as their bi-/trimestral phosphides can also be prepared by the ALD approach.

5:00 PM NM03.04.12
Photopolymerized Superwettable Coatings Enabled by Dual-purpose ZnO for Liquid/liquid Separation Chenxuan Li and Lei Fang; Texas A&M

University, United States

Low-cost and scalable superwettable coating methods provide viable approaches for energy-efficient separation of immiscible liquid/liquid mixtures. A scalable photopolymerization method is developed to functionalize porous substrates with a hybrid coating of tetrapodal ZnO (T-ZnO) and polymethacrylate, which exhibits simultaneous superhydrophobicity and superoleophilicity. Here, T-ZnO serves dual purposes by (i) initiating radical photopolymerization during the fabrication process through a hole-mediated pathway and (ii) providing a hierarchical surface roughness to amplify wettability characteristics and suspend liquid droplets in the metastable Cassie—Baxter regime. Photopolymerization provides a means to finely control the conversion and spatial distribution of the formed polymer, whilst allowing for facile large-area fabrication and potential coating on heat-sensitive substrates. Coated stainless-steel meshes and filter papers with desired superhydrophobic/superoleophilic properties exhibit excellent performance in separating stratified liquid-liquid mixtures as well as water-in-oil emulsions. The hybrid coating demonstrates desired mechanical robustness and chemical resistance for their long-term application in large-scale energy-efficient separation of immiscible liquid/liquid mixtures. The integration of photopolymerization features, superwettability, and excellent durability renders this hybrid coating approach a highly promising platform technology for various applications.

5:00 PM NM03.04.13
Selective Photocatalytic Conversion of Benzyl Alcohol to Benzaldehyde or C-C Coupling Products over Ion Exchanged CdS Hyun Sung Kim[1,2] and Hangil Lee[3]; [1]Pukyong National University, Korea (the Republic of); [2]Core Research Institute, Korea (the Republic of); [3]Sookmyung Women's University, Korea (the Republic of)

In this study, visible light absorbing CdS nanoparticles were partially modified with Au_2S and Ag_2S via a simple cation exchange process to prepare heterostructure photocatalysts (Au_2S@CdS and Ag_2S@CdS) for the conversion of aromatic alcohols to valued-added products, such as benzaldehyde and C-C coupling products. When Au_2S@CdS was used as the photocatalyst, benzaldehyde was obtained as the main product with a selectivity of 99%, and when Ag_2S@CdS was used as the photocatalyst, deoxybenzoin and hydrobenzoin were obtained as the main products with a selectivity of 95%. The critical photogenerated electron and hole transfer occurring during the photocatalytic reaction was systemically investigated by carrying out various control experiments and using in-situ high-resolution X-ray photoelectron spectroscopy. We believe that our study makes a significant contribution to the literature it provides a feasible approach for the formation of complex heterostructures via a simple ion exchange process. Further, we believe that this study provides a novel strategy for the preparation of catalyst complexes for the conversion of aromatic alcohols into value-added compounds.

5:00 PM NM03.04.15
Effect of Doping on Optical and Photocatalytic Properties of TiO_2-$Ti_3C_2T_x$ Hybrid Ahmed Al Mayyahi and Placidus B. Amama; Kansas State University, United States

The light absorption of TiO_2 can be extended from ultraviolet to visible region via structure disorder, chemical and physical doping, but with the trade-off of photocatalyst deactivation due to the short lifetime of photoexcited charge carriers. In this study, we report the simultaneous reduction and carbon doping of TiO_2 through refluxing with titanium carbide MXene ($Ti_3C_2T_x$) in the presence of a reducing agent (ethanol or hydrazine) to shift TiO_2 absorption to the visible region and allow visible light activity without compromising the lifetime of charge carriers. Carbon doping and defects (oxygen vacancies and Ti^{3+} ions) in TiO_2 enable visible light absorption by allowing sub-band transition while MXene hinders the consumption of charge carrier and promotes the formation of active radicals on TiO_2-$Ti_3C_2T_x$ by accepting the photoexcited electrons. UV-Visible spectroscopic measurement reveals absorption of TiO_2-$Ti_3C_2T_x$ in the visible region with an indirect band gap of ~2.85 eV. The effective charge carrier separation and subsequent formation of active radicals in TiO_2-$Ti_3C_2T_x$ are confirmed by photoluminescence and electron paramagnetic resonance spectroscopy. Multiple spectroscopic techniques are used to investigate the chemical interaction between TiO_2 and $Ti_3C_2T_x$ in the hybrid structure and evaluate carbon doping in TiO_2, as well as correlate the density of defects in TiO_2-$Ti_3C_2T_x$ with photocatalytic activity.

5:00 PM NM03.04.16
Heating Influence on Atomic Site Structural Changes of Mesoporous Au Supported Anatase Nanocomposite for Photocatalytic Progression Adil Alshoaibi; King Faisal University, Saudi Arabia

Semiconductor nano photocatalysis has considered a promising methodology for polluted water remediation. The electrons and holes' high recombination rate and low reaction rate have obstructed their large-scale applications. Thus, heterogeneous nano photocatalysts are needed for promoting their practical applications. Herein, anatase nanoparticles (ANPs) are synthesized and heat-treated within two-time intervals of 1 h and 2 h at 300 °C by sol-gel method and doped with gold nanoparticles (AuNPs) at room temperature (29 °C) owing to photocatalytic application. Vapor pressure scanning electron microscopy (VPSEM) shows the porous and granular localized homogeneous surface of Au-ANPs before and after heat treatment. The average nanoparticles diameter is calculated as 4.7 nm and after 2 h heat treatment it increased up to 4.9 nm. Atomic force microscopy (AFM) and Brunauer-Emmett-Teller (BET) method show that the Au-ANPs possessed low average surface roughness (Ra) ~ 3 nm, large surface area (SA) ~ 288 m2/g, and pore size distribution (PSD) 1.81 nm, respectively. Whereas Au-ANPs/2 h revealed Ra around 5 nm, SA ~ 145 m2/g, and PSD ~ 2.37 nm. All three nano photocatalysts exhibited thermal stability at ≤400 °C by thermogravimetric analysis. The Au-ANPs/2 h exhibited high photocatalytic activity with degradation of PR dye of 94% ($k = 0.01$ min−1, under ultraviolet radiation) after 280 min of reaction.

5:00 PM NM03.04.17
Controlling the Photoelectrochemical Water Oxidation Reaction Pathway via Surface Amorphous Overlayer Jaekyum Kim, Seung Hun Roh and Jung Kyu Kim; Sungkyunkwan University, Korea (the Republic of)

Hydrogen peroxide (H_2O_2), regarded as a green fuel and powerful oxidant, has represented high attention in the energy and environment field recently. Also, H_2O_2 is attracting attention in that it can be used as an energy carrier since it has an energy density of 2.1 MJ kg^{-1}, which is comparable to compressed hydrogen (3.5 MJ kg^{-1}). Over 95% of H_2O_2 is produced by Anthraquinone process, which needs high pressure of hydrogen, requires expensive catalyst, and consumes lots of energy during whole process. Therefore, it is vital to develop an alternative method for H_2O_2 production that is eco-friendly and economical. In this regard, photoelectrochemical (PEC) synthesis of H_2O_2 via 2-electron water oxidation is an alternative route. The water-oxidation process follows two pathways: oxygen evolution reaction (OER) at 1.23 V vs. reversible hydrogen electrode (RHE), and H_2O_2 production reaction at 1.76 V vs. RHE. Unfortunately, the two-electron pathway must compete with the four-electron pathway, which generates O_2. Due to these competitive pathways, the reaction kinetics become sluggish, and intense degradation of electrode occurs. To date, studies have demonstrated that the free energy change of adsorbed OH radicals is a key factor in H_2O_2 evolution. Therefore, it is challenging to design efficient, selective, and stable photoanode materials for efficient H_2O_2 production from H_2O.

For PEC water splitting photoanode materials, semi-conductive metal oxides such as Fe_2O_3, ZnO, $BiVO_4$, WO_3, SnO_2 and TiO_2 have been widely studied. Among various metal oxides for PEC water oxidation, titanium dioxide (TiO_2) is the most extensively studied and numerous efforts have been conducted to enhance the PEC activity of TiO_2. However, TiO_2 itself is OER favorable because of native defects derived surface oxygen vacancies. Moreover, TiO_2 has an unsatisfactory Faraday efficiency (FE) in water-oxidation reaction (WOR)-mediated H_2O_2 evolution, since TiO_2 has a higher OH adsorption energy compared with $BiVO_4$, WO_3, and SnO_2, which leads to the undesirable four-electron pathway and O_2 evolution. Since H_2O_2 production by WOR is a competitive reaction with the oxygen evolution reaction (OER), it is crucial and highly challenging to control the reaction pathway toward our goal, H_2O_2. In this study, we demonstrated the incorporation of amorphous titanyl phosphate (a-TP) overlayer on TiO_2 nanoparticles (TiO_2 NP) is conducive to modulate the WOR pathway and results in highly selective PEC H_2O_2 production. The ultrathin (*ca*. 2 nm) a-TP was conformally overlaid by *in-situ* surface reforming via lysozyme-molded mineralization. The a-TP overlayer manipulates the surface adsorption energies for the reaction intermediates to promote the WOR for H_2O_2 production, instead of the competing O_2 evolution reaction. Moreover, the a-TP overlayer conformally passivated the surface trap states, which eventually generated an efficient charge transfer. Consequently, a-TP/TiO_2 shows 3.7-times higher Faraday efficiency (63%) at 1.76 V vs. RHE under 1 sun illumination comparing to bare TiO_2 (17%), which is the highest performance among TiO_2 based catalyst. To sum up, the introduction of the a-TP overlayer is a promising strategy for steering the reaction pathway and achieving efficient solar-to-chemical energy conversion. We believe that introducing an overlayer on photoanodes to manipulate the reaction kinetics provides alternative and environmentally friendly PEC H_2O_2 production method, instead of the conventional anthraquinone process.

SESSION NM03.05: Semiconductors

8:30 AM *NM03.05.01
The Relationships Between Excited State Dynamics and Photocatalysis of Nanoscale Semiconductors Gordana Dukovic; University of Colorado Boulder, United States

The synthetic tunability of electronic structure and surface chemistry of semiconductor nanocrystals make them attractive light absorbers for light-driven chemistry. A variety of architectures have been constructed where nanocrystals are coupled with multielectron redox catalysts to drive reactions like H_2 generation, CO_2 reduction, N_2 reduction, and water oxidation with light. In these systems, light absorption in nanocrystals is followed by charge transfer to catalysts, which then use them for redox transformations, and/or to sacrificial carrier scavengers. Interfacial charge transfer between the nanocrystal and the catalyst and its competitiveness with other relaxation pathways in nanocrystals are of paramount importance to the overall photochemical reactivity. In this talk, I will focus on our efforts to elucidate both the kinetics of charge transfer and the kinetics and mechanisms of the competing photophysical pathways in nanocrystal-based systems for light-driven multielectron chemistry. This work entails transient absorption spectroscopy measurements, extensive kinetic modeling to extract rate constants of relevant processes in these heterogeneous systems, and, for some systems, contributions from theory.

9:00 AM NM03.05.02
Doped III-V Quantum Dots for Enhanced Light Harvesting Forrest Eagle, Samantha Harvey, Ryan Beck, Xiaosong Li, Daniel Gamelin and Brandi Cossairt; University of Washington, United States

As demand for value added chemicals ever increases with population growth, new methods must be established to perform the complex chemical reactions required to create said products. Photocatalysis is a potential avenue to perform these reactions, using photoexcited materials to serve as a source of high energy electrons involved in more complex processes. However, creating efficient photosenitizers is a non-trivial task and must be painstakingly designed for high efficiency.
Shelled semiconducting nanocrystals (also known as shelled quantum dots) have two the main characteristics required for efficient light harvesting/photosensitization. These qualities are high absorption coefficients (up to 10^5 cm^{-1} M^{-1}) and robust photostability. However, the shell that imparts the increased absorption coefficient and photostability also traps charge carriers in the core. This leads to charge carriers with high overlap, leading to short excited-state lifetimes on the scale of tens of nanoseconds. This disadvantage can be mitigated by the introduction of a dopant such as Ag^+ or Cu^+ which causes the excited state lifetime to increase to hundreds of nanoseconds. We can measure electron transfer from these quantum dots to molecular acceptors via photoluminescence and transient absorption spectroscopies. In doing so, we see that the doped quantum dots exhibit enhanced electron transfer by up to a factor of 10. Finally, we use examine the electronic structure of these materials *in silico* to determine why the charge transfer is so greatly increased upon doping.

9:15 AM NM03.05.03
Scavenger-Dependent Hole Removal Dynamics in Pt-Tipped CdSe/CdS Dot-in-Rod Nanohybrids Soenke Wengler-Rust[1], Yannic U. Staechelin[1], Holger Lange[1,2] and Horst Weller[1,3,2]; [1]Universität Hamburg, Germany; [2]The Hamburg Centre for Ultrafast Imaging, Germany; [3]Fraunhofer IAP-CAN, Germany

Combining the light-absorbing properties of semiconductors with the catalytic activity of noble metals, Pt-tipped CdSe/CdS dot-in-rods are perfectly suited for photocatalytic applications including light-driven hydrogen generation in water.[1-3]
We conducted a systematic study, investigating the influence of the choice of hole (h^+) scavenger and pH value on the quantum yield of the hydrogen evolution reaction and combined this with investigations on the charge carrier dynamics, using time-resolved transient absorption (TA) spectroscopy from the femtosecond- to the microsecond-time scale. While the fs-TA spectroscopy enabled us to investigate the charge carrier movement within the semiconductor domain and onto the metal tip, in the µs-TA measurements the h^+ transfer onto the h^+ scavengers was observable. Contrary to expectations, the charge carrier dynamics did not follow the observed trend of the scavenger-dependent performance in hydrogen production. Instead, it was possible to distinguish exclusively between “surface-active” and “diffusion-controlled” scavengers, based on the charge carrier dynamics. These results reveal that it is not the h^+ transfer onto the scavenger, that is the efficiency-limiting step of the photocatalytic process and therefore represent an important insight on the way towards optimizing this nanoscopic photocatalytic system.

Single-Nanoparticle Measurements of Charge Transport in $SrTiO_3$:Rh and $BiVO_4$ Photocatalysts for Z-Scheme Water Splitting Brian T. Zutter[1], Zejie Chen[2], Luisa Barrera[3], Aliya Lapp[1], Austin Bhandarkar[1], William Gaieck[2], Kenta Watanabe[4], Akihiko Kudo[4], Daniel Esposito[5], Rohini B. Chandran[3], Shane Ardo[2] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]University of California, Irvine, United States; [3]University of Michigan–Ann Arbor, United States; [4]Tokyo University of Science, Japan; [5]Columbia University, United States

Solar-powered water splitting using nanoparticle photocatalyst suspensions is a promising route to economical, clean hydrogen production. In the Z-scheme approach, hydrogen and oxygen-evolving photocatalysts, such as $SrTiO_3$:Rh and $BiVO_4$, are coupled with a redox mediator to improve light absorption compared to single-photocatalyst systems. A key step in the water-splitting process is the separation and transport of photo-excited electrons and holes to the photocatalyst surface. Here we characterize charge transport in individual $SrTiO_3$:Rh and $BiVO_4$ nanoparticles using a nanoprobe within a scanning electron microscope, and directly map photocarrier diffusion lengths with electron-beam induced current. Charge transport in $SrTiO_3$:Rh particles is space-charge limited by bulk Rh^{4+} defect states within the nanoparticle, in contrast to nearly Ohmic (band) conduction in $BiVO_4$ nanoparticles. Photogenerated e-h pairs diffuse less than 10 nm before recombining within $SrTiO_3$:Rh particles due to the high concentration of Rh traps (1%), whereas band conduction in $BiVO_4$ particles allows for photocarrier diffusion lengths in excess of 400 nm. Inefficient charge transport explains why the H_2-evolving $SrTiO_3$:Rh nanoparticles are the limiting component within this Z-scheme system.

9:45 AM NM03.05.05

Liquid Surface Photovoltage Spectroscopy Analysis of Quasi Fermi Level Splitting and Minority Carrier Electrochemical Potential at $BiVO_4$ /Liquid Junctions under Illumination Sahar Daemi, Chengcan Xiao, Sherdil Khan, Hervin Errol T. Mendoza and Frank E. Osterloh; UC-Davis, United States

$BiVO_4$ is an important photoanode material for water oxidation, but its photoelectrochemical properties with regard to other redox couples have not yet received much attention. Here, we use a combination of open circuit potential measurements, photoelectrochemical scans, and surface photovoltage spectroscopy (SPS) to evaluate the factors that control the oxidation of aqueous oxygen/hydrogen peroxide, sulfate/sulfite and hexacyanoferrate (III)/(II) redox couples with $BiVO_4$. Here, a vibrating Kelvin probe is used to measure the quasi Fermi Level splitting (qFLS) of each $BiVO_4$-liquid junction under illumination. For instance, the sulfate/sulfite couple yields SPV of 0.186 V under 45.9 mW/cm^{-2} (400 nm LED) illumination, comparable to the photovoltage from PEC (0.142 V) and suggests that photovoltage is limited by standard reduction potential of the SO_4^{2-}/SO_3^{2-} couple. For hexacyanoferrate (III/II), on the other hand, both photovoltage from SPV and photovoltage from PEC are zero, which suggests charge carrier recombination at $BiVO_4$/hexacyanoferrate interface. Using this information together with majority carrier potential (E_{Fn}), the electrochemical potentials of the minority carriers can be calculated. For instance, $E_{Fp} = 0.26$ V vs RHE under 45.9 mW/cm^{-2} for the $BiVO_4$ - sulfate/sulfite junction and $E_{fp} = 1.19$ V vs RHE under 51.6 mW/cm^{-2} for the oxygen/hydrogen peroxide junction. This shows that $BiVO_4$ can photoelectrochemically oxidize both redox couples, without applied bias. Generally, we find that the built-in voltage at the $BiVO_4$-liquid junctions controls the photovoltage, i.e. the maximum possible energy conversion efficiency. Lastly, the SPS measurements also provide information about the reversibility of the redox processes occurring in front of the $BiVO_4$ electrode. Overall, this work provides new insight into the factors that control the energy conversion efficiency of metal oxide photoanodes.

InterContinental, Fifth Floor, Ballroom A

10:30 AM *NM03.06.01

Widefield Infrared Photothermal Imaging and Spectroscopy Masaru Kuno; University of Notre Dame, United States

Infrared Photothermal Heterodyne Imaging (IR-PHI) is now a well-established, chemical and morphological characterization technique widely applicable to environmental and material science applications. Examples include studying micro- and nanoplastics in spectrally complex, chemical environments as well as monitoring cation migration in hybrid lead halide perovskites. These successes portend future applications of IR-PHI to studying chemically heterogeneous processes such as those involved in catalytic reactions. Traditional IR-PHI possesses a spatial resolution of ~300 nm and works in a point-by-point scanning fashion. Time-expensive, single-point data acquisition limits image collection and subsequent chemical characterization. Consequently, we introduce here a widefield modality to IR-PHI where photothermal IR images are acquired using a high-speed CMOS camera. The approach parallelizes data collection and makes possible hyperspectral imaging of chemical specimens. Widefield image resolution and detection limits are established and compared with those of traditional IR-PHI.

Inherent Photosensitization Efficiency of TiO_2-Bound RuP Chromophores in Natural Sunlight Thomas Cheshire and Frances Houle; Lawrence Berkeley National Laboratory, United States

Photoabsorbers such as those in the RuP (phosphonated and methyl-phosphonated tris(2,2-bipyridine)ruthenium(2+)) dye family enable wide band-gap nanomaterials such as TiO_2 to absorb visible light, enabling their use in porous photoanodes that can convert sunlight directly into electricity or drive reduction-oxidation reactions for generation of chemical products from water and CO_2. The core physical process is electronic excitation of the dye followed by charge injection into the nanoparticle, the efficiency of which is a key factor in the overall efficiency of these energy conversion systems. It has been estimated in the literature that the charge injection frequency from these dyes into TiO_2 nanoparticle-based electrodes under continuous solar excitation is about 1 s^{-1}, however by performing quantitative simulations of photoexcitation and charge injection kinetics we have determined that the charge injection frequency is actually in the range of 50-60 s^{-1}. In this presentation the computational mechanistic framework for the dye-nanoparticle photophysics, validated using ultrafast transient absorption spectroscopic techniques, will be described. The framework includes the influence of light scattering in the nanoparticle film on dye excitations, and is adapted to simulate photosensitized water oxidation by dye-catalyst diads. The prediction that these dyes are capable of far higher photoconversion efficiency than estimated previously points to unrecognized sources of inefficiencies in these systems. The calculations show that the inefficiencies do not involve simple recombination losses, revealing that there may be opportunities for improvements of dye sensitized solar cells and photoelectrochemical systems through improved optical and materials designs. The computational framework has been developed for the Ru dyes but is readily extendable to other metal-centered dyes whose metal-to-ligand charge transfer excitations result in charge injection.

Quantum Effects in Nanoparticles of TiO_2, WO_3, and Y_2O_3 Sergey Mamedov; HORIBA Scientific, United States

Metal oxide nanoparticles are attractive for many applications but have recently become an essential part of highly efficient catalysis materials. The material's efficiency depends on size, shape, and surface chemistry, which critically determine their properties and interaction.
Raman spectroscopy is a powerful method to investigate nanoparticles' vibrational properties, as the Raman band's peak and width are very sensitive to the local structure. Besides, phonons' behavior at the nanoparticle boundary strongly depends on the particle size and is a critical factor in creating a highly efficient material. It was shown that the Raman peak of TiO_2 at 142.9 cm^{-1} shifted with a decrease in the nanoparticles' size due to the quantum confinement. However, nanopowders of WO_3 and Y_2O_3 were not investigated yet. The samples of TiO_2, WO_3, and Y_2O_3 with a mean size ranging from 5 to 40 nm were investigated by Raman spectroscopy in the broad spectral range. The model of phonon confinement was used to describe the experimental data. The correlation length of the phonons calculated from the spectra of nanoparticles shows a good correlation between grain sizes obtained from Raman spectra and XRD. Raman spectra are more sensitive to nanoparticles' structural motive compared to XRD. The Raman spectra may differ even if X-ray diffraction shows the same particle size. It reflects the differences in the surface structure of nanoparticles.

Visualizing Ultrafast Structural Deformations in Photoexcited Nanocrystals Burak Guzelturk; Argonne National Laboratory, United States

In the last decades colloidal nanocrystals have become ubiquitous materials in optoelectronic and solar energy applications ranging from light-emitting diodes to artificial photosynthesis. Pushing performance limits in these applications beyond the state of the art requires understanding and controlling microscopic electronic and structural responses in the ensembles of photoexcited nanocrystals. Particularly, understanding the origins of nonradiative losses such as carrier trapping and hot carrier relaxation is critical to increase the utilization of excited electronic states for efficient energy transport and conversion. In this talk, I will highlight the use of pump-probe electron diffraction and X-ray scattering approaches to unravel electron – phonon couplings in colloidal nanocrystals to investigate the atomistic origins of nonradiative relaxation and associated transient lattice deformations. I will present our recent work resolving dynamic lattice responses in photoexcited II-VI, IV-VI and metallic nanocrystals which reveales dynamic structure - property relationships key to manipulating photocatalytic functionalities in these nanomaterials.

11:45 AM NM03.06.05
Photocatalytic Activity Enhancement of Iron Oxide in Structural Engineered Anodic Aluminum Oxide Photonics Crystals Carina Hedrich[1], Anna R. Burson[1], Silvia González-García[2], Víctor Vega[3], Victor M. Prida[2], Abel Santos[4], Robert H. Blick[1] and Robert Zierold[1]; [1]Center for Hybrid Nanostructures, Universität Hamburg, Germany; [2]Physics Department, School of Sciences, University of Oviedo, Spain; [3]Laboratory of Nanoporous Membranes (STSs), University of Oviedo, Spain; [4]School of Chemical Engineering and Advanced Materials, The University of Adelaide, Australia

Over the last decade, iron (III) oxide (Fe_2O_3) has increasingly come into focus as a promising photocatalyst since it is abundant on earth and its' electronic band gap is located in the visible region of the electromagnetic spectrum. Thus, solar light can be used to excite iron oxide and thereby induce photocatalytic reactions such as oxidative water purification. However, Fe_2O_3 photocatalysts often suffer from inefficient charge carrier generation or fast recombination of them. One well-studied approach to overcome this limitation is to combine Fe_2O_3 with other semiconductors, generating heterojunctions which facilitate the charge separation. Alternatively, the charge carrier generation can be enhanced by tuning the light-matter interaction, for instance, by utilizing the so-called slow photon effect which appears in photonic crystals (PhCs).
PhCs are periodical arrangements of materials with different dielectric constants and possess photonic stopbands (PSBs), also known as photonic band gaps, wherein photons of the respective wavelengths cannot exist in the structure – similar to electrons in a semiconductor band gap. At the PSB edges, the group velocity of incoming photons is strongly reduced and thereby the interaction probability between photons and the PhC material increases. This slow photon effect can improve the charge carrier generation in semiconductor-based PhCs when the PSB edge is aligned with the electronic band gap of the semiconductor.
Realization of two-dimensional PhCs is possible by tailoring the anodization of aluminum. In general, anodic aluminum oxide (AAO) membranes feature self-organized, highly ordered pores with distinct geometrical characteristics. Modifying the electrochemical anodization parameters and applying pulse-like anodization profiles allow to adjust the pore morphology from straight towards modulated structures, e.g., distributed Bragg reflectors or gradient index filters.
Herein, such AAO-PhCs are conformally coated with Fe_2O_3 thin films by atomic layer deposition (ALD) which is based on sequential, self-limiting gas-solid surface reactions allowing for conformal material deposition in high aspect ratio nanostructures. The PSB position of the AAO template can be precisely tuned across the whole visible region and will be aligned with the semiconductor band gap to take advantage of the slow-photon effect. The influence of the Fe_2O_3 thickness (1-6 nm) on the photocatalysts' performance is systematically investigated by studying the photodegradation of methylene blue as a model pollutant of water.
Optimizing and combining AAO-PhC templates with ALD functionalization of cheap and abundant semiconductors, i.e., iron oxide, might pave the way to wavelength-selective, effective photocatalytic nanostructures.

SESSION NM03.07: Water Splitting

1:30 PM *NM03.07.01
Development of Particulate Photocatalysts for Water Splitting Kazunari Domen[1,2]; [1]Shinshu University, Japan; [2]The University of Tokyo, Japan

Sunlight-driven water splitting has been studied as a means of producing renewable solar hydrogen. Overall water splitting using particulate photocatalysts has been attracting growing interest, because such systems can be spread over wide areas by potentially inexpensive processes [1]. In fact, a solar hydrogen production system based on 100-m^2 arrayed photocatalytic water splitting panels and an oxyhydrogen gas-separation module was built, and its performance and system characteristics including safety issues were reported recently [2]. Nevertheless, it is essential to radically improve the solar-to-hydrogen energy conversion efficiency (STH) of particulate photocatalysts and develop suitable reaction systems. In my talk, recent progress in photocatalytic materials and reaction systems will be presented.

The author's group has studied various semiconductor oxides, (oxy)nitrides, and (oxy)chalcogenides as photocatalysts for water splitting [3]. $SrTiO_3$ is an oxide photocatalyst that has been known to be active in overall water splitting under ultraviolet irradiation since 1980. Recently, the apparent quantum yield (AQY) of this photocatalyst in overall water splitting has been improved to more than 90% at 365 nm, equivalent to an internal quantum efficiency of almost unity, by refining the preparation conditions of the photocatalyst and the loading conditions of cocatalysts [4]. This quantum efficiency is the highest yet reported and indicates that a particulate photocatalyst can drive the endergonic overall water splitting reaction at a quantum efficiency comparable to values obtained in photon-to-chemical and photon-to-current conversion processes by photosynthesis and photovoltaic systems, respectively.

For practical solar energy harvesting, it is essential to develop photocatalysts that are active under visible light irradiation. Recently, Ta_3N_5 [5], $Y_2Ti_2O_5S_2$ [6], TaON [7], and $BaTaO_2N$ [8] were reported to be active in photocatalytic overall water splitting via one-step excitation under visible light irradiation. In these achievements, the synthesis of well-crystallized semiconductor particles and the loading of composite cocatalysts were important for improving the photocatalytic activity. Nevertheless, further improvements in the preparation of cocatalyst/photocatalyst composites are still required to achieve a sufficient STH value.

It is possible to combine hydrogen evolution photocatalysts (HEPs) and oxygen evolution photocatlaysts (OEPs) and decompose water into hydrogen and oxygen via two-step excitation. Such a process is recognized as Z-scheme widely. Particulate photocatalyst sheets consisting of La- and Rh-codoped $SrTiO_3$ as the HEP and Mo-doped $BiVO_4$ as the HEP immobilized onto Au and C layers split water into hydrogen and oxygen with STH values exceeding 1.0% [9,10]. Some other (oxy)chalcogenides and (oxy)nitrides with long absorption edge wavelengths are also applicable to Z-schematic photocatalyst sheets and hold the promise of realizing greater STH values.

Immobilization of Cobalt-Based Polyoxometalate on Titanium Dioxide Nanorods for Photoelectrochemical Water Oxidation Boon Chong Ong, Teik Thye Lim and Zhili Dong; Nanyang Technological University, Singapore

The production of hydrogen from water as a source of renewable energy is a crucial technology to overcome the energy crisis and world pollution issues. However, there are challenges due to its non-thermodynamically favorable reaction and the complex electron transfer process. Titanium dioxide (TiO_2) has been widely used as a photocatalyst due to its high stability and activity towards light radiation. It is considered one of the promising types of catalysts that can catalyze the water oxidation reaction under light radiation, but its performance is often hampered by the fast recombination of photogenerated electron-holes pairs. Polyoxometalates (POMs), a class of transition metal oxides, with good redox properties, tunable structure and high durability could act as an effective hole scavenger layer to enhance the activity of TiO_2 towards water oxidation. In this study, a nanocomposite film, consisting of TiO_2 and cobalt-based POMs, was synthesized by the growth of TiO_2 on a conductive fluorine-doped tin oxide (FTO) substrate *via* the hydrothermal technique. This step was followed by layer-by-layer deposition of POMs. The photoelectrochemical water oxidation test showed that the onset potential of POMs coated TiO_2 photoanode was lower. The induced photocurrent at the applied potential of 1.23 V *vs.* reversible hydrogen electrode (RHE) was approximately two times that of pristine TiO_2. POMs layers would reduce the recombination rate of electron-hole pairs by extracting and transporting the generated holes, thus improving the overall PEC performance. The photoelectrochemical response was further enhanced with increasing POMs layers, but there was an optimal number beyond which the produced current density began to decline owing to light penetration limitation. In term of durability, the generated photocurrent density remained relatively stable throughout the test period with minor fluctuations that could be caused by the formation and evolution of oxygen bubbles. This work provides a facile layer-by-layer deposition method to immobilize layers of POMs on TiO_2 to promote PEC water oxidation under neutral conditions, which is attractive for long-term applications.

2:15 PM NM03.07.03
Photocatalytic Water Oxidation of WO3 Nanoparticles with Regenerative Redox Couple Noyoung Yoon[1,2], Sang Youn Chae[3], Oh-Shim Joo[1] and Eun Duck Park[3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Ajou University, Korea (the Republic of)

Photocatalytic water splitting is one of the promising ways to produce green hydrogen with zero CO_2 emission. However, current stage, solar to hydrogen conversion efficiency (~1%) is much lower than industrial meets. for visible light utilization, the band gap of semiconductor photocatalyst is limited to less than ~3 eV, however, water splitting reaction requires a large driving force due to its high overpotential for each hydrogen evolution and oxygen evolution reaction and also due to fast electron-hole recombination at the semiconductor photocatalyst surface. Therefore, sacrificial agents such as Ag+, persulfate, and O_2 were used to facilitate the photoelectrochemical reaction and fast carrier extraction from the semiconductor. However, only a half-reaction of water splitting occurs in presence of the sacrificial agent. Moreover, the sacrificial agent is also an energy-contained chemical resource, therefore consuming the sacrificial agent is not the regenerative pathway for water splitting or green hydrogen production. Lastly, some sacrificial agents can lead to the poisoning of photocatalysts. Therefore it is better to use regenerative redox couple as electron or hole donner for photocatalytic reaction. with redox coupled in a water medium, the photocatalysts successfully store solar energy via half-reaction, then the redox couple can be regenerated by the counterpart reaction. In this study water oxidation of WO_3 was carried out with an electron-accepting sacrificial agent, Ag^+, and redox couples such as Io_3^-/I^-, $Co(phen)_3^{2+/3+}$, $Fe^{2+}/^{3+}$. To improve the kinetics of both the electron acceptor reduction reaction and water oxidation reaction, the PtRu alloying nanoparticle co-catalyst was introduced. The ratio of Pt and Ru was controlled for the best activity, and also confirmed the PtRu co-catalyst is active for both redox couple reduction and water oxidation reaction. This study shows that the PtRu cocatalyst is useful for tandem photocatalyst systems with a redox mediator or other tandem system for photocatalytic full water splitting systems.

Mechanisms Governing Solar-to-Hydrogen Conversion Efficiency in Multijunction Silicon Nanowire Photocatalysts Samantha R. Litvin, Taylor Teitsworth, Samuel Bottum and James Cahoon; University of North Carolina-Chapel Hill, United States

In the nearly 50 years since the first demonstration of photoelectrochemical water-splitting, solar fuels such as hydrogen have yet to become a practical source of alternative energy in large part due to the high cost and low efficiency of solar fuel systems. Si-based particle suspension reactors (PSRs), which consist of light-absorbing photocatalytic particles in solution that can individually split water, are a simple and potentially low-cost paradigm to generate hydrogen and enable solar fuel generation on a large scale. Multijunction silicon nanowires (MJ SiNWs) can absorb light across the visible spectrum, have p-n junctions that facilitate charge separation, and have recently demonstrated the ability to split water. Here, we present the bottom-up vapor-liquid-solid synthesis of single nanowires with multiple p-i-n junctions consisting of degenerately-doped segments and abrupt dopant transitions <10 nm. MJ SiNWs are functionalized for water-splitting with oxygen and hydrogen evolution co-catalysts via a spatioselective photoelectrodeposition process. Photovoltaic and electrochemical characterization of single-nanowire devices show tunable photovoltages exceeding 10 V under 1-sun illumination and water splitting activity at infrared wavelengths up to ~1050 nm. Experimental techniques and finite-element modeling have allowed us to systematically isolate and investigate aspects of STH including light absorption and charge carrier activity. Our studies indicate that photocatalyst performance and efficiency is dictated by nanowire dopant profile and surface composition, as well as the photonic characteristics of the sub-wavelength nanowire diameter. Unlike wider bandgap oxide and chalcogenide particles previously studied for PSRs, MJ SiNWs bring the photonic advantages of a tunable, mesoscale geometry and the cost and environmental advantages of Si to the PSR design, providing a new approach for water-splitting reactors.

2:45 PM NM03.07.05
Growth of $MoSe_2$ Nanosheets Around ZnO-SnO_2-$ZnSnO_3$ Hollow Nanofibers (h-ZTO) for Effective CO_2 Photoreduction Hazina M. Charles and Caroline Sunyong Lee; Hanyang University, Korea (the Republic of)

Hazina Charles, Rajendra C. Pawar, Haritham Khan, Jin-Goo Park, Caroline Sunyong Lee*
Department of Materials and Chemical Engineering,
Hanyang University, Ansan, Republic of Korea

Solar-driven semiconductor photocatalysts, especially photocatalysts with multi-heterojunctions, have gained a lot of interest as a potential solution to the world energy crisis and environmental pollution. In this study, simple electrospinning followed by solvothermal technique were used to synthesize h-ZTO/$MoSe_2$ hybrid photocatalysts with multiple heterojunctions. Hybrid photocatalysts were fabricated by adjusting the h-ZTO/$MoSe_2$ ratio, which demonstrated outstanding photocatalytic activity than that of pure h-ZTO, due to its double growth of $MoSe_2$ nanosheets on h-ZTO hollow nanofibers. To understand morphology, microstructure, phase composition, and functional characteristics of the synthesized photocatalysts, different techniques were employed including FE-SEM, TEM, XRD, XPS, PL, TR-PL, and PEC. Optimal h-ZTO/$MoSe_2$ hybrid photocatalyst exhibited efficient photocatalytic transformation of CO_2 into CO, $H_{2,}$ and CH_4, with yielding rates of 140, 64, and 33 $\mu molg^{-1}h^{-1}$, respectively. Moreover, the optimal hybrid photocatalyst showed the highest CO_2 photoreduction selectivity of 93%. This remarkable activity could be driven by the homogeneous growth of $MoSe_2$ in/on the hollow nanofibers walls, which improved their capacity for light scattering and offered a significant number of active sites to activate and desorb CO_2 throughout the reaction. This study indicated that hollow nanofibers well coated with MoSe2 nanosheets can provide bright insights on how to design a catalyst with high product selectivity.

Time-resolved Optical Spectroscopy to Accelerate the Development of Particulate Carbon Nitride (CN_x) Photocatalysts Robert Godin; The University of British Columbia, Canada

Polymeric photocatalysts made of Earth-abundant elements have been extensively developed over the past decade to take advantage of their synthetic tunability.[1] Within this family, carbon nitrides (CN_x) are emerging as exciting photocatalysts because of their high photocatalytic performance combined with good stability and facile synthesis. However, significant gaps remain in our knowledge of the photophysical properties of these organic polymeric materials. Determining the pathways and mechanism of photoinduced processes will greatly aid our efforts to engineer better CN_x photocatalysts for solar fuel production.[2]
Time-resolved spectroscopies, particularly transient absorption spectroscopy (TAS), enable us to determine the nature of short lived photoexcited states and determine the kinetics of competing processes. We utilize TAS to shed light on leading strategies followed in the pursuit of improved photocatalytic activities: 1) morphological modifications, 2) heterojunction formation, and 3) CN_x precursor blends.
CN_x possesses a 3D morphology resulting from π–π stacking of 2D sheets composed of condensed heptazine units, which gives insoluble particles with low surface area. Nanostructured CN_x can show improved efficiency by allowing for fine-tuning of properties such as length, diameter, and polymer backbone conformation. However, there are contradictory reports in the literature the on the relationship between surface area and photocatalytic efficiency. To address this question, we devised a method to tune the morphology of CN_x after polymerization occurred, thus limiting the potential for uncontrolled chemical changes during the high temperature polymerization step. Using water-soluble CN_x nanosheets as the building block, we observed unique CN_x morphologies using mesoporous silica as the template.[3] Our spectroscopic investigations identified that residual CN_x nanosheets caused charge trapping and the loss of photocatalytic activity, possibly counteracting any gains from reducing the size of features.
Forming a heterojunction is a common strategy to promote charge separation and charge carrier lifetime to improve the efficiency of CN_x photocatalysts, though the distinct molecular interface formed are not well-understood.[4] A highlighted example is the case if organic-organic CN_x heterojunctions with carbon nanodots (CDs). Despite the similarity in material compositions, different CN_x/CD heterojunctions show that the flow of charges is dependant on the type of CDs incorporated.[5] Segregation of opposite charges across the two different materials leads to impressive chemical selectivity methanol formation from CO_2.

Incorporation of other small molecules into the framework of CN_x in a copolymerization process provides a handle to regulate the intrinsic framework of CN_x and optimize electronic band structures, optical absorption, and the overall photocatalytic performance of CN_x.[6] We carried out the systematic synthesis of CN_x prepared through copolymerization at various precursor ratios. Our optical spectroscopy and material characterization investigations highlight the complex interconnections between chemical structure, electronic structure, physical properties, photophysics, and photoactivity.

Light-Driven *sp*^{3}-*sp*^{3} Cross-Coupling of Carboxylic Acids and Alkyl Halides over a Ni Single-Atom Catalyst Mark A. Bajada[1], Giovanni Di Liberto[2], Vincenzo Ruta[1], Sergio Tosoni[2], Alessandra Sivo[1], Gianfranco Pacchioni[2] and Gianvito Vile[1]; [1]Politecnico di Milano, Italy; [2]University di Milano Bicocca, Italy

The coupling of two *sp*^{3} hybridized fragments remains a challenging protocol for organic synthesis. Although visible light-driven metallaphotoredox catalysis, a method that combines photoabsorbers and transition metals, has become a powerful tool to conduct such transformations, resource economical and scalability issues persist, due to the use of catalysts and light absorbers which exploit critical raw materials (e.g., iridium complexes) and are homogeneous in nature. Here we report the first synergistic merger of metallic single-atom and photoredox catalysis, in the form of a Ni atom-supported carbon nitride material, for decarboxylative *sp*^{3}-*sp*^{3} cross-coupling between carboxylic acids and alkyl halides. This operationally straightforward system, comprised of only earth abundant components, works with chloro-, bromo-, and iodoalkanes, and exhibits a wide functional group tolerance in terms of both the coupling partners, *i.e.* the alkyl halide and carboxylic acid. Further still, since the metal and photoredox catalytic cycles were essentially combined within one single-atom material, we were able to easily recover and re-use the heterogeneous system for several times, preserving its activity between individual trials. With the help of computational studies, we have elucidated the active site of the Ni single-atom material, analyzing both the metal coordination with the carbon nitride support and binding of the substrates to the active site, thus proposing a plausible reaction mechanism. The reaction time is 83% shorter than the reported homogeneous procedure, making the method highly attractive for industrial applications. We thus further exemplify the versatility of our system through the synthesis of an API precursor, and the adaptation of our single-atom catalytic system within a continuous flow photoreactor device.

4:15 PM NM03.08.03
Nitrogen-deficient Carbon Nitride Photocatalyst for Selective Oxidation of HMF Coupled with Hydrogen Evolution Dai-Ling Tsai, Hsing-Ting Liu and Jih-Jen Wu; National Cheng Kung University, Taiwan

Two-dimensional polymeric carbon nitrides composed of earth-abundant elements have been known to be the potential visible-light-driven photocatalysts for solar energy conversion and environmental remediation. Intrinsic defect engineering in carbon nitrides has drawn substantial attention because it provides a promising approach to boost the photocatalytic performance of carbon nitrides without introducing heteroatom in the basic unit. In this work, melon-based carbon nitrides are prepared by thermal polycondensation of supramolecular complexes of various nitrogen-rich organic compounds. Solid-state nuclear magnetic resonance characterizations reveal that defect-modified carbon nitride can be obtained by varying the composition of supramolecular complexes. Nitrogen-deficient carbon nitride is produced by thermal polycondensation of the supramolecular complex of melamine, cyanuric acid, and triaminopyrimidine. The nitrogen-deficient carbon nitride with the exceptional photocatalytic performance for simultaneous biomass valorization and H_2 evolution compared to the pristine melon carbon nitride is demonstrated in this work. The simultaneous H_2 evolution from water splitting coupled with selective oxidation of 5-(hydroxymethyl) furfural (HMF) to 2,5-diformylfuran (DFF) is achieved over the nitrogen-deficient carbon nitride photocatalyst with activities of 70 mmol g^{-1} h^{-1} and 94 mmol g^{-1} h^{-1} under AM 1.5G (100 $mWcm^{-2}$) illumination with a UV filter. The photophysical properties of carbon nitrides are tunable by modifying the microstructure towards efficient photocatalytic activities. The influences of chemical and electronic structures on the photocatalytic activity of nitrogen-deficient carbon nitride will be discussed in this presentation.

SESSION NM03.09: Poster Session II

Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM NM03.09.01
Graphitic Carbon Nitride Films with Biomimetic Structure for Photocatalytic Conversion of Carbon Dioxide I-Hsiang Tseng[1], Yu-Hsuan Liu[1], Yu-Cheng Tsai[1] and Ta-I Yang[2]; [1]Feng Chia University, Taiwan; [2]Chung Yuan Christian University, Taiwan

A hydrothermal method was developed to synthesize carbon-modified graphitic carbon nitride (gCN). Meanwhile, natural leaves with hierarchical surface structure were introduced to homogeneously graft gCN and to improve light absorption. The modification resulted in the exfoliation of graphitic stacking and formation of defects for better charge transfer. The addition of glucose and the presence of hierarchical structure improved the photocatalytic activity. Carbon monoxide and methanol were main products from the photoreduction of gaseous carbon dioxide and water vapor under visible light illumination. By tuning the type and concentration of hole scavengers, the photocatalytic activity and product selectivity could be further enhanced.

5:00 PM NM03.09.02
Z-Schematic Artificial Leaf-like Structure for Biosolar Oxyfunctionalization of C-H Bonds Lee Chung Hyun; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The natural Z-schematic photosynthesis is a promising catalytic system for biocatalytic solar-to-chemical production. Here, we construct a Z-schematic, wireless photoelectrocatalytic (PEC) system (i.e., artificial leaf) for biocatalytic oxyfunctionalization reactions. The monolithic leaf structure consists of a tandem photoanode-photocathode configuration that uses sunlight as the sole energy source to drive redox reactions. Under solar light, inorganic oxide photoanode extracts electrons from H_2O electron feedstock and transfers the electrons to the organic photocathode. Meanwhile, the conjugated thiophene based organic photocathode absorbs photoanode-filtered light for O_2 reduction to H_2O_2 with a high faradaic efficiency (76 %) even in neutral pH environments. The *in situ* generated H_2O_2 activates biocatalytic enzyme to drive C-H oxyfunctionalization (e.g., ethylbenzene oxyfunctionalization) with an excellent enantioselectivity (enantiomeric excess > 99%). Furthermore, we solve hydroxyl radical mediated inactivation of biocatalyst using a membrane, which increases enzymatic productivity with a benchmark total turnover number of about 100,000 among PEC and photocatalytic platforms that trigger biocatalyst mediated synthesis. This work presents the first artificial leaf architecture for enzymatic oxyfunctionalization of C-H bonds.

5:00 PM NM03.09.03
Photocatalytic Gold Deposition on Titanium Dioxide Templates Mimicking Axonal Growth Fatemeh Abshari, Moritz Paulsen, Jan Schardt, Blessing Adejube, Salih Veziroglu, Alexander Vahl and Martina Gerken; Christian-Albrechts-Universität zu Kiel (CAU), Germany

Nanoionic memristive devices that are based on the field driven migration of metal cations and oxygen vacancies have gathered high interest in the scientific community for their capability to technically mimic synaptic connections. Less attention has been given to long-range global plasticity in artificial neuronal networks. The aim of our research is to use light-stimulated growth of gold metal lines to technically mimic the growth of long-range axonal connections for neuromorphic computing architectures. To mimic the growth of axons we investigate the formation of metal lines by UV-light-stimulus-driven photocatalytic deposition of gold on titanium dioxide layers. The growth process is conducted in a beaker by reduction from aqueous gold chloride precursor ($HAuCl_4$) and is observed by transmission optical measurements in an inverted-microscope setup. Surface properties are analyzed by 3D laser interference microscopy and scanning electron microscopy (SEM) and electrical conduction measurements are taken.
We fabricated the photoactive titanium dioxide layers with the thickness of 40-100 nm on quartz glass by DC sputtering. The substrates were then heat treated for 1h at 300°C and subsequently cooled on a metal plate to achieve the photocatalytically active anatase phase of titanium dioxide. In the growth process the substrates are placed in a beaker containing 15 ml of the precursor. The solution is obtained by dissolving 15 mg of $HAuCl_4$ crystalline powder in 60 ml of deionized water. We utilize a UV LED with the wavelength peak of 365 nm to illuminate the sample in the beaker. The illumination time and UV-intensity are crucial for this dynamic process. Here we illuminated for 3h and replaced the solution every hour. Furthermore, we repeated this experiment by adding a surfactant to the solution to achieve faster growth and better surface coverage as proposed by literature.
In-situ characterization of the growth process is possible by placing the beaker in an optical microscope with transmission configuration. While the sputtered titanium dioxide and the quartz glass substrate show high transparency, the grown gold will absorb and reflect the transmitted light and thus yield an observable change in transmission. We also analyzed the morphology of the grown gold layers by 3D laser interference microscopy and scanning electron microscopy (SEM) after the growth procedure. The measurements show the formation of gold clusters on the surface of the titanium dioxide layers. Sufficient growth time is needed to reach the percolation threshold and attain a conductive gold layer which is crucial for our aim of mimicking axonal connections. We recorded electrical current-voltage characteristics to investigate the electrical conductivity of the grown gold. Our measurements revealed a value of electrical conductivity ��=0.015 S for areas with high surface coverage. It is obvious from 3D laser interference microscopy that the thickness of gold clusters is not uniform throughout the surface of titanium dioxide. Therefore, the conductivity across the 2D surface of the TiO_2/Au composite varies. With its potential capability to locally control the growth of long-range metallic connections, photocatalysis is a promising approach towards mimicking the dynamic formation of long-range axonal connections in neural networks.

Photocatalytic Degradation of Perfluoroalkyl Substances in Water by Using a Duo-Functional Tri-Metallic-Oxide Hybrid Catalyst Junjie Niu; University of Wisconsin--Milwaukee, United States

Abstract
Perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) are the most typical poly- and perfluoroalkyl substances (PFASs) compounds. PFOA is detected in surface water, groundwater, sediment, sludge, and municipal wastewater. In recent years, various adsorbents such as activated carbon, polymer-supported carbon, anion exchange metal-organic framework, and beta-cyclodextrin have been used for the removal of PFASs. The recalcitrant nature of PFASs urges scientists to discover solutions to permanently remove PFAS contaminations from water with less energy in contrast to incineration. Here we present a duo-functional tri-metallic-oxide (*f*-TMO) hybrid photocatalyst, which displayed both high adsorption capacity and high defluorination rate of a series of PFASs including PFOA, PFOS, PFHpA, PFHxA and PFBA due to the generated holes/electrons (h^+/e^-) and multi-radicals (Samuel, Shang, Niu. ***Chemosphere***, 293 (2022) 133568). Particularly the Langmuir adsorption capacities up to 827.8 and 714.5 mg g^{-1} along with the adsorption efficiency of 99.8% and 99.4% for PFOS and PFOA were respectively achieved, which are more than two times higher than the most used activated carbons. A defluorination ratio of as high as 74.8% with PFOA and a ratio up to 67.6% with PFOS were respectively achieved. Over 98% PFOA molecules were degraded within as fast as 15 min, which demonstrates an excellent degradation kinetics. After degradation, the PFOA residuals were as low as 10 ng L^{-1} in industrial wastewater with an initial concentration of 1 ppb. As for the more recalcitrant sulfonic acid of PFOS, an as high as 95.5% degradation efficiency was obtained within 300 min. It was found the most high-F molecules such as $C_7F_{15}COOH$ were gradually degraded into low-F molecules such as CF_3COOH within 60 min before they were completely decomposed into non-toxic F^-. In parallel, the *f*-TMO photocatalyst still exhibited a >96.2% degradation efficiency after eight regeneration cycles. The high physical adsorption capacity and high defluorination rate make this *f*-TMO catalyst a promising candidate in removing various PFASs from a broad range of residential and industrial water systems.

Heterostructured Photocatalysts of Ni^{2+} Doped CdS Quantum Dots and β-$Pb_{0.33}V_2O_5$ Nanowires: Towards Selective CO_2 Reduction Karoline E. García-Pedraza and David Watson; University at Buffalo, The State University of New York, United States

Solar photocatalytic reduction of carbon dioxide (CO_2) to valuable products such as carbon monoxide, methane, and ethanol has become an appealing approach to mitigate the deleterious impact of the combustion of fossil fuels. Quantum dots (QDs), visible light-sensitive nanomaterials, have been widely studied for converting solar energy into chemical energy due to their light-harvesting properties, compositional tunability, and size-dependent energetics. However, bare QDs suffer from low selectivity toward the reduction of CO_2. To improve their catalytic activity, we have doped QDs with nickel(II) cations and interfaced them with ternary metal-intercalated vanadium oxide nanowires (NWs). Within the resulting heterostructures, QDs act as a charge donor, and the NWs exhibit intercalative mid-gap states functioning as a charge acceptor. Although our collaborative team has previously studied this type of heterostructure for hydrogen evolution and water splitting, they remain unexplored for CO_2 photoreduction. This presentation will cover the preparation and characterization of heterostructures consisting of cysteine-capped nickel(II)-doped CdS QDs (cys-NiCdS QDs) interfaced with β-$Pb_{0.33}V_2O_5$ NWs. The heterostructures are envisioned as a system to selectively reduce CO_2 under white-light illumination. This presentation will highlight recent results from materials synthesis and characterization, photophysical and photoelectrochemical assessment of excited-state charge transfer, and photocatalysis using gas chromatography (GC) for product characterization.

Perovskite-Type Oxynitride Nanofibers Performing Photocatalytic Oxygen and Hydrogen Generation Anja Hofmann and Roland Marschall;

University of Bayreuth, Germany

In times of ever-growing energy demand, the finiteness of fossil carbon reserves, and the rise in CO_2 emissions, solar-light induced photocatalytic water splitting for the generation of clean and renewable hydrogen as an alternative energy carrier becomes increasingly important. For this, photocatalysts with suitable band positions for solar water splitting and with high absorption of light in the visible light range are crucial. One promising candidate for this is $BaNbO_2N$ with an absorption edge up to 740 nm and suitable band positions.[1-4] Nanostructuring can be used to further enhance the photocatalytic activity by an increase of the surface area and presumably the number of reaction sites in the photocatalysis.
Herein, we are presenting a novel approach for complex nanostructured oxynitrides.[5] (111)-layered perovskite $Ba_5Nb_4O_{15}$ nanofibers with tailored fiber diameter were prepared *via* electrospinning and subsequent calcination, [6-8] and were then converted to cubic perovskite oxynitride nanofibers by ammonolysis.[5] Most importantly, the nanofiber morphology retains during the ammonolysis, and the nanofiber diameter can be tailored as well. A thorough characterization including Rietveld refinement revealed the formation of a novel $BaNbO_2N$-Ba_2NbO_3N oxynitride composite. The conversion resulted in visible-light absorption with a decrease of the band gap from 3.9 eV for the $Ba_5Nb_4O_{15}$ layered perovskite nanofibers to 1.9 eV for the converted oxynitride nanofibers. Diameter-dependent hydrogen and oxygen evolution activities of the converted oxynitride nanofibers decorated with Pt or $CoNbO_4$, respectively, with an optimum nanofiber diameter will be presented.

Surface Structural Change Investigations of Modified Fe_3O_4 Nanoparticles Concerning Efficient Reusability and Enhanced Photocatalytic Activity Hangil Lee[1] and Hyun Sung Kim[2]; [1]Sookmyung Women's University, Korea (the Republic of); [2]Pukyong National University, Korea (the Republic of)

As interest in energy efficiency increases, research on various types of catalyst materials is being actively conducted. However, the indiscriminate use of photocatalyst nanoparticles (NPs) can cause environmental pollution. Therefore, the recovery rate of photocatalyst NPs used to efficiently decompose organic pollutants is as important as photocatalytic efficiency. In this study, we focused on improving the recovery rate of MO NPs with improved photocatalytic properties via the modifications. For this purpose, we achieve our objective by modulating the pH after doping the Fe_3O_4 NPs with Co ions as we focus on verifying the change of surface structure of the modified Fe3O4 NPs. Interestingly, the predominant species on the surface of the Co@Fe_3O_4 NPs fabricated under basic conditions was similar to $CoFe_2O_4$ structure with an enhanced magnetic property and photocatalytic activity. In order to confirm the changes in the oxygen vacancy according to the modulation of Fe_3O_4 NPs, we tried to identify them through various surface analysis methods such as scanning transmission electron microscopy in conjunction with electron energy-loss spectroscopy and X-ray absorption spectroscopy. We further investigated the photocatalytic oxidation of 2,5-hydroxymethylfurfural (HMF) and the magnetic properties using VSM for the modified Fe_3O_4 NPs to maximize the reuse for minimizing the water pollution. As a result, we found that the base treated Co@Fe_3O_4 NPs can be enhanced by improving their photocatalytic and by increasing the recovery rate owing to enhanced magnetic property. In addition, it was confirmed that the doped Co ion showed a Co^{2+} state from XAS result. The structure of Co@Fe_3O_4-B NPs that can be predicted from these experimental results is $Co^{2+}Fe_2{}^{3+}O_4$. Therefore, we can reasonably predict that the surface structure of Co@Fe_3O_4-B NPs can be similar to that of $CoFe_2O_4$ because it is well known that the magnetic properties of $CoFe_2O_4$ are better than that of Fe_3O_4. Furthermore, the abundant defect structures formed during Co doping under alkaline conditions improved the photocatalytic properties of the Co@Fe_3O_4-B NPs. Therefore, biomass were effectively decomposed using modified Co@Fe_3O_4-B NPs, which exhibited remarkable reusability.

5:00 PM NM03.09.09
Effect of Material and Shape of Nanoparticles on Hot Carrier Generation Ly Thi Minh Huynh, Seokheon Kim and Sangwoon Yoon; Chung-Ang University, Korea (the Republic of)

Nonradiative decay of photoexcited plasmons generates energetic nonthermal charge carriers. These hot charge carriers play a major role in plasmonic photocatalysis and photovoltaics. Therefore, establishing the relationship between the hot carrier generation efficiency and the structural and chemical parameters of nanoparticles is crucial for developing highly efficient plasmonic catalysts and photovoltaic materials. In this study, we compare the quantum efficiency of hot carrier generation between gold (AuNPs) and silver nanoparticles (AgNPs), and spherical (AuNSs) and cubic gold nanoparticles (AuNCs). We construct nanoparticle-on-mirror (NPoM) systems where reactant molecules are positioned in the nanogaps between the nanoparticles and gold films. Excitation of the NPoM at 785 nm, followed by the detection of products using surface-enhanced Raman spectroscopy allows us to measure the plasmon-driven reaction yields. Dividing the reaction yield by the calculated absorption cross section at the excitation laser wavelength provides the efficiency of hot carrier generation per absorbed photon. We reveal that AgNPs are more effective at generating hot carriers than AuNPs, which is consistent with the higher electron-surface scattering rate of AgNPs. The hot carrier generation of AuNCs is marginally better than that of AuNSs, which can be attributed to the enhanced electric fields inside the AuNCs in the nanogap region. This study contributes to a rational design of plasmonic catalysts or photovoltaic materials of higher efficiencies.

5:00 PM NM03.09.10
Plasmon-Assisted Photocatalytic Conversion of Carbon Dioxide – A Demonstration by Two Case Studies Ken Elen[1,2,3], Daria Burova[1,2,3], Jordi Volders[1,2,3], Pascal Buskens[4,1], An Hardy[1,2,3] and Marlies Van Bael[1,2,3]; [1]Hasselt University, Belgium; [2]Imec - Imomec, Belgium; [3]EnergyVille, Belgium; [4]TNO, Netherlands

Emissions of carbon dioxide are widely viewed as the leading cause of climate change. To achieve the necessary emission reductions, measures must be taken in various areas by concentrating on sustainable energy sources, energy efficiency, and materials recycling. Carbon dioxide utilization can be realized by multiple complementary technologies, such as thermocatalytic, (photo-)electrochemical, and biochemical methods. Here we report on two plasmon-assisted photocatalytic processes that allow the conversion of carbon dioxide to methane or carbon monoxide.

Methanation of carbon dioxide, also known as the Sabatier reaction, involves the reduction of carbon dioxide with hydrogen gas to produce methane and water. Conventionally this is achieved using a heterogeneous catalyst at elevated temperatures (400-500°C) and pressures up to 100 bar. Conventional catalysts typically comprise metal oxide supported transition metals. In industrial plants, Ni usually serves as the preferred catalyst due to an optimal balance between low cost and high activity and selectivity towards methane. In analogy to catalysts used for the conventional thermal Sabatier reaction, plasmonic catalysts for the light-assisted methanation of CO_2 comprise metal oxide supports decorated with metal nanoparticles, primarily elements of group VIIIb, that act as the catalytic sites. Here, we present the preparation of silica- and alumina-supported Ru catalysts by deposition precipitation and subsequent chemical reduction. Our work demonstrates that these Ru-decorated catalysts can be used successfully for the light-assisted Sabatier reaction at near-to-ambient pressures ($p < 3{,}5$ bar) and at a catalyst bed temperature of approximately 220°C, realized via combined heating and illumination of the reactor. [1]

The catalytic conversion of carbon dioxide to CO can be achieved by the Reverse Water Gas Shift (RWGS) reaction. As carbon monoxide is the main reaction product, the RWGS reaction is considered a potential route for the renewable production of syngas, a mixture of CO and H_2, which can be used as a feedstock for the subsequent production of higher hydrocarbons. The RWGS reaction is endothermic and has a low equilibrium constant, even at high temperatures. In a conventional process, the RWGS reaction requires temperatures between 500°C and 800°C. The use of plasmonic metals is one of the most promising approaches to decreasing the reaction temperature. Here, we describe titania-supported Au catalysts that are suitable for the light-assisted production of CO under mild conditions ($T < 200°C$ and $p < 3{,}5$ bar). Additionally, we demonstrate that the selectivity towards CO can be improved by decreasing the size of the gold nanoparticles. We propose that illuminated plasmonic Au nanoparticles enhance the desorption of CO from the catalyst through photogenerated charge carriers, which ensures a highly selective production of CO. [2]

These two case studies demonstrate that nanoplasmonics can offer a convenient approach for activating chemical reactions by light. Furthermore, these examples illustrate that plasmon catalysis can be utilized to convert carbon dioxide to value-added chemicals with sunlight as a sustainable energy source.

Real Structure and Thermal Stability of Ag and Ag@X Core-shell Nanoparticles Prepared by Gas Aggregation Cluster Sources Tereza Kosutova, Lukas Horak, Jan Hanus, Ondrej Kylian, Hana Libenska, Zdenek Krtous, Amir M. Ahadi, Jaroslav Kousal, Miroslav Cieslar, Artem Shelemin, Pavel Pleskunov, Mykhailo Vaidulych, Pavel Solar, Andrei Choukourov, Hynek Biederman and Milan Dopita; Charles University, Czechia

In the presented work, we investigated homogeneous silver nanoparticles and silver nanoparticles wrapped in titanium oxide or plasma polymeric shell, so called core-shell nanoparticles.
Silver nanoparticles belong to plasmonic nanoparticles, in which it is possible to couple electromagnetic field with the collective oscillations of conduction electrons - plasmons. These nanoparticles have great application potential because, for Ag nanoparticles, the localized surface plasmon resonance is in the region of visible light. In combination with the titanium oxide shell, the silver cores could extend the active region to visible light for the photocatalytic properties of titanium dioxide. The conjunction of the Ag core and the plasma polymeric shell brings the possibility to tune the optical absorption by varying sizes of the cores just by changing the amount of the polymeric precursor added to the aggregation chamber.
All studied nanoparticles were prepared by gas aggregation cluster sources combined with magnetron sputtering of single metallic targets in different configurations. This physical preparation method is environmentally friendly, scalable to industry demands, provides high cleanness of the process and tunability of nanoparticles structure. The core-shell nanoparticles with varied thicknesses of TiO_x shell were prepared by the in-flight coating of primarily formed silver cores, whereas the Ag@ppHMDSO nanoparticles were created by plasma-enhanced chemical vapor deposition of hexamethyldisiloxane (HMDSO) simultaneous to the aggregation of silver cores.
This study focuses on the thermal stability of described nanoparticles as it is the critical property for applications where heat transfer occurs. The evolution of morphology, chemical and phase composition, size distribution and microstructure of Ag and both types of core-shell nanoparticles during the annealing was determined by the combination of in-situ/ex-situ x-ray scattering methods (XRD, SAXS), ex-situ transmission and scanning electron microscopies, and x-ray photoelectron spectroscopy. Optical properties were investigated by UV-Vis spectroscopy.
The measurements showed that Ag nanoparticles are not very thermally stable in the air atmosphere. Their coalescence starts around 100 °C. Contrary, both types of shells formed around nanoparticles act as protection against sintering up to 300 °C. After annealing, the size of crystallites increases and the density of structural defects is reduced for all types of nanoparticles. The evolution is the fastest for pure silver nanoparticles. On the heated samples of both types of core-shell nanoparticles, pure crystalline silver particles were observed.
The addition of secondary Ti magnetrons to the deposition chamber caused a narrowing of the size distribution of Ag cores and the formation of the covering shell [1]. The series of samples with different shell thicknesses was simply prepared by varying the magnetron current on the titanium targets.
For the second type of studied core-shell nanoparticles, the presence of HMDSO in the chamber leads to changes in the size distribution and the architecture of prepared nanoparticles [2]. The increasing amount of HMDSO induces the formation of individual core-shell nanoparticles, chains of core-shell nanoparticles and, for the highest concentration of HMDSO, the synthesis of multicore-shell nanoparticles. The size of crystallites in the silver cores of nanoparticles decreases with the addition of HMDSO, which prevents further aggregation.

Functionalized Anodic Aluminum Oxide Photonic Crystals as Tailor-Made Photocatalysts Carina Hedrich[1], Anna R. Burson[1], Siew Yee Lim[2], Abel Santos[2], Robert H. Blick[1] and Robert Zierold[1]; [1]Center for Hybrid Nanostructures, Universität Hamburg, Germany; [2]School of Chemical Engineering and Advanced Materials, The University of Adelaide, Australia

Reusable, cheap, non-selective and decentralized water purification systems for chemicals are urgently needed to provide drinking water to everyone, especially with respect to the challenges humanity is facing these days, such as climate change, growing population, or overfertilization of the soil, just to name a few. Photocatalysts are promising materials for providing purified water by using sunlight to induce various chemical reactions, e.g., the decomposition of pollutants.
Electrochemical oxidation of aluminum results in the formation of anodic aluminum oxide (AAO) membranes which consist of aluminum oxide matrices that contain ordered cylindrical pores perpendicular to the surface. Pulse-like anodization profiles periodically modulate the pore diameter whereby photonic crystals (PhCs) – periodic arrangements of materials with different dielectric constants – are created featuring a photonic stopband (PSB) in which

the transmission of light within the structure is forbidden. The PSB position is defined by the PhC composition, namely the utilized materials, their thicknesses, and the sequence. Note, the group velocity of incoming photons is significantly decreased at the PSB edges enhancing the interaction probability of photons with the PhC material. This slow-photon effect can increase the degradation of chemicals whose absorption maximum is aligned with the PSB edge. However, to ensure the PSB position matching, this approach requires a specific PhC for each compound that should be decomposed. In contrast, we report a more general strategy by utilizing semiconductor-based PhCs to increase the charge carrier generation when the PSB edge is aligned with the semiconductor bandgap. As a consequence, the photocatalytic degradation performance is improved regardless of the pollutants' absorption properties and the same PhC structure can be applied for decomposition of various compounds at the same time.

Herein, we present the fabrication and characterization of tailor-made titanium dioxide (TiO_2) coated AAO-PhCs. First, AAO-PhC structures are prepared by pulse-like anodization with precise adjustment of the PSB position to match the semiconductor bandgap. Second, tailor-made AAO-PhCs are conformally coated with TiO_2 of different thicknesses (0.5-6 nm) by atomic layer deposition (ALD). ALD is a gas phase deposition technique based on sequential, self-limiting gas solid-surface reactions which enable conformal coating of high aspect ratio structures such as AAO. Finally, optical characterization of TiO_2-functionalized AAO-PhCs is correlated with their photocatalytic properties which are studied by degradation of organic dyes, specifically methylene blue, methyl orange, and rhodamine B.

We believe that tailor-made AAO-PhCs combined with semiconductors deposited by ALD can further improve the photocatalytic efficiency regarding the decomposition of several chemicals. Therefore, such structures might be utilized for water purification by filtration in combination with *in situ* photocleaning.

Facile Fabrication of Hierarchical Graded Structure to Maximize Photocatalytic Surface Area via Additive Manufacturing Heungseok Oh, Haritham Khan, Taehyeob Im, Jin-Goo Park and Caroline Sunyong Lee; Hanyang University, Korea (the Republic of)

TiO_2 hierarchical structure which has high surface area was demonstrated via additive manufacturing to maximize its exposed area from sunlight. Conventionally, structures are fabricated by electrospinning, hydrothermal and nanoparticle synthesis. Using these processes, complex shapes are not possible to make. In this study, we have adopted extrusion based additive manufacturing method which is one of the various additive manufacturing technologies to overcome existing problems to have no limitation in making complex shapes with great variety of materials. The hierarchical graded structure was fabricated by extrusion-based additive manufacturing machine using TiO_2 feedstock which is composed of Anatase-TiO_2 powder and polymeric binder system. Then, Hierarchical structure was debound and sintered to obtain porous ceramic structure. During sintering temperature ranging from 400 to 900 °C, anatase to rutile phase transformation occurs. Sintering conditions should be optimized to increase the weight percentage of anatase phase which shows much better photocatalytic efficiency than that of rutile phase. The amount of anatase phase tends to increase with deceasing sintering temperature. In order to find the optimized sintering temperature condition, the CO_2 selectivity based on CO_2 photoreduction result using each structure was measured and compared. Finally, it was confirmed that the extrusion-based additive manufacturing could be a potential fabrication route for photocatalytic application by making hierarchical structure with high surface area.

5:00 PM NM03.09.14
Hybrid Nanoparticles of Conjugated Polymers and Gold Nanocrystals for controllable energy and charge transfer Dabin Lee and Juhyun Park; Chung-Ang University, Korea (the Republic of)

We demonstrate how to make hybrid nanoparticles of conjugated polymers and gold nanocrystals using a film dispersion approach, and how to manipulate the paths for energy and charge transfer by varying the conjugated polymers used as the donor and acceptor. The conjugated polymers could be assembled with a phospholipid having a hydrophobically modified polar head to create conjugated polymer nanoparticles (CPNs) with an average diameter of about 60 nm and inner voids with a diameter of about 10 nm. It was discovered that when conjugated polymers and phospholipid were assembled in a film by solvent drying, nanowires with inside voids of 10 nm diameter were first formed. Upon ultrasonication in water dispersion, the nanowires were fragmented by Ralyleigh instability, resulting in a uniform conjugated polymer nanoparticle with an average diameter of 60 nm. By embedding gold nanocrystals inside the void regions of CPNs, the resulting hybrid nanoparticles had gold nanocrystals that were 3 nm apart, greatly improving the localized surface plasmon resonance and light-harvesting properties. We showed that charge transfer from hybrid nanoparticles to species in water medium was the main route when energy levels of conjugated polymers were well-matched with gold, whereas photothermal effect became a major energy dissipation route when hybrid nanoparticles comprised of a conjugated polymer with a mismatched energy level with gold. These findings point to the potential for hybrid nanoparticles based on conjugated polymer and gold to be used in photothermal or photocatalytic processes, depending on the alignment of energy levels.

5:00 PM NM03.09.15
Formation of TiO_2 Thin-Films Through Laser-Induced Oxidation of a TiS_2 Precursor Drake R. Austin[1,2], Brian M. Everhart[3], Morgen Smith[3], Susanna Post[4], Christopher Muratore[4], Placidus B. Amama[3] and Nicholas Glavin[1]; [1]Air Force Research Laboratory, United States; [2]UES Inc., United States; [3]Kansas State University, United States; [4]University of Dayton, United States

In this work, crystalline thin-films of anatase and rutile TiO_2 are formed within an amorphous TiS_2 precursor (400 nm thick) through laser-induced oxidation. This was achieved by scanning a continuous wave, 514 nm laser beam across the precursor film surface in the presence of oxygen (ambient air and pure O_2). The 20 μm ($1/e^2$ diameter) focal spot allowed for the oxidation of many localized regions at varying intensities and scan speeds. These regions were characterized under Raman and ultraviolet-visible spectroscopy to determine the crystalline phase and band gaps of the laser-oxidized regions. After identifying the conditions needed to produce varying anatase/rutile mixtures in the intensity/scan speed phase space, large regions of crystalline TiO_2 were then produced by raster-scanning the laser repeatedly. Raman mapping was used to determine the spatial variation in the crystallinity of these larger regions, while X-ray diffraction analysis was used to estimate the anatase/rutile mass fraction present. Multiple whole-sample (2 in^2 area) thin-films of varying antase/rutile mixtures were subsequently created in the same manner, with each sample produced using different laser-processing conditions. Finally, the photocatalytic activity of each sample was determined by measuring the relative change in concentration of various NO_x species in a flow reactor during exposure of the film to simulated sunlight. Mechanisms driving the reaction kinetics of the TiS_2 oxidation/crystallization as well as the photocatalytic activity of the films are discussed.

5:00 PM NM03.09.16
Photocatalytic Denitrification by Sensitized Electrospun Filters Jessica M. Andriolo[1], Erik M. Grumstrup[2], A. A. Talin[3] and Jack L. Skinner[1]; [1]Montana Technological University, United States; [2]Montana State University, United States; [3]Sandia National Laboratories, United States

Nitrogen-based fertilizers are critical to the production of successful crops for farmers, yet use of these supplements has led to nitrate contamination of surface and ground waters. Nitrate is a frequently occurring ground water pollutant that has significantly increased in concentration over the last century due to use of fertilizers. Nitrates in aquatic environments promotes biological growth and algal blooms, resulting in eutrophication and depleted oxygen. Lack of oxygen results in damage to aquatic ecosystems, causing death of aquatic animals and infiltration of nitrogen oxyanions that severely affect human health by reducing nitrate to nitrite in the human gut.

Several water treatment technologies have been examined to address nitrate pollution. While nitrate removal has been predominantly approached by traditional physicochemical and biological treatment processes, these methods have presented drawbacks including high operational and labor costs, large energy requirements, and residual waste production. Recently, more sustainable processes for denitrification of natural waters have been explored. Such technological approaches include use of nanomaterials that serve as catalysts to promote photocatalytic denitrification at a reduced fingerprint.

In this work, a catalytic electrospun filter was designed to use photons from natural sunlight to promote reduction of aqueous nitrate. The filter was designed to have a high surface area, presenting many photocatalytic sites for nitrate reduction and to improve catalytic efficiencies. Polymer fibers in the filter consisted of a coaxial structure with a polycaprolactone-poly(3-hexylthiophene-2,5-diyl) (PCL-P3HT) blend core (sensitizer layer to promote absorption and electron injection) and a PCL - polyethylene glycol (PEG) block copolymer shell. In the design used, PEG blocks would be dissolved from the shell structure and filled with zirconium oxide nanoparticles (ZrONPs) that exhibit an adequate reduction potential and provide stability. The ZrONPs would then be accessible by aqueous solution at the fiber surface while still making contact with the semi-conducting fiber core.

In past work, thin film versions of the photocatalytic fibers were fabricated to determine feasibility of the design. In the thin film version, a glass cover slip was spin coated with a PCL-P3HT blend. PCL-PEG block copolymer was then spin coated onto the PCL-P3HT layer. PEG blocks were subsequently dissolved and filled in with ZrONPs by sonication in an ethanol-ZrONP solution for 10 min. The resulting structure provided protection of the P3HT from water by the glass cover slip and PCL, and the edges of the material were sealed with glue. Using a Hepatochem PhotoRedOx Box system and a 540 nm LED source, nitrate reduction was monitored over 8 hr. Results showed a 22 % reduction of aqueous nitrate. The solution used also contained methanol as the electron shuttle during the reaction. In a simpler version of the thin film, excited state lifetimes of P3HT thin films were compared to P3HT thin films coated in ZrONPs using ultrafast pump-probe spectroscopy. Results showed that at 2 ns, the P3HT thin film had returned back to ground state, whereas the P3HT thin film coated in ZrONPs maintained excitation, possibly indicating a long-lived charge separated state. Conductivity characterization of PCL-P3HT thin films was also performed and showed typical semiconductor characteristics of the material on an I-V curve.

In this work, we will begin fabrication of the electrospun, sensitized photocatalytic denitrification filter. Our preliminary results showed a 60 % PCL / 40 % P3HT blend provided preferrable viscosities for electrospinning. The final filter will be tested for nitrate reduction efficiency in the Hepatochem PhotoRedOx system and characterized by electron microscopy.

Mesoporous Zinc Oxide Supported Silica-Titania Nanocomposite—Structural, Optical and Photocatalytic Activity Adil Alshoaibi; King Faisal University, Saudi Arabia

Sol-gel-based titania nanoparticles (TNPs), Silica-titania nanocomposite (STNC), and zinc supported silica-titania nanocomposites (Z/STNC) are synthesized at low temperature. FESEM/EDX shows that ZNPs are homogeneously distributed in the STNC. The STNC has average roughness (Ra) ~6 nm, surface area ~340 m2/g, pore volume ~0.24 cm3/g, and particle size 4 nm ± 0.3 nm, which decrease down to Ra ~5 nm, large surface area 351 m2/g, pore volume 0.4 cm3/g, and particle size 3 nm ± 0.4 nm due to filling of STNC pores by Zn species. STNC is revealed 94% transmission, refractive index 1.34 at 633 nm, and bandgap 2.7 eV, which decreased down to 80% transmission, large refractive index 1.38, and low bandgap 2.25 eV after ZNPs doping. The Z/STNC observed high photocatalytic activity 92%, R2 ~98%, and rate constant 0.011 min−1 in the photodegradation of phenol red under UV-light irradiation.

Effect of $BaTiO_3$ Polarisation on Photocurrent Generation and Charge Carrier Dynamics in Ferroelectric Photoanodes for Photoelectrochemical Water Splitting Chloe Forrester[1,2], Adriana Augurio[3], Joe Briscoe[1], James Durrant[2], Ji-seon Kim[2] and Charlie Henderson[2]; [1]Queen Mary University of London, United Kingdom; [2]Imperial College London, United Kingdom; [3]AO Research Institute Davos, Switzerland

Solar-driven photoelectrochemical water splitting can provide a sustainable source of hydrogen as a clean and renewable form of energy. Semiconductors employed in water-splitting photoanodes can have large rates of recombination which ultimately reduces the amount of oxygen evolved and limits the solar-to-hydrogen conversion efficiency. Ferroelectric materials possess a permanent internal electric field which has been shown to increase the lifetime of charge carriers by an order of magnitude and has the potential to reduce recombination in ferroelectric semiconductors[1].

Here, $BaTiO_3$ is studied as a wide-bandgap ferroelectric semiconductor and the effect of enhancing the ferroelectric properties by a method of poling is explored. The impact of the ferroelectric field on photocurrent generation and charge carrier dynamics is examined using steady state and transient spectroscopic techniques.

Comparing as-grown films with little ferroelectric alignment to poled films, an increase of photocurrent from 30 to 145 $uAcm^{-2}$ at 1.23 V vs RHE and an increase in IPCE from 3.5 to 34% at excitation wavelengths (325 nm) was observed after poling. Heating above the Curie temperature for $BaTiO_3$ to remove the polarisation was also shown to decrease the photocurrent in a reversible process. Transient absorption spectroscopy measurements demonstrate that the lifetime of probed electrons increases from $t_{50\%}$ from 0.1 ms to 4 ms after poling. Simultaneous transient photocurrent measurements show a corresponding increase in charge density extracted from 0.2 to 2 $uCcm^{-2}$, showing a link between electrons living longer and less recombination and more charge extraction. A model is suggested to explain how the orientation of ferroelectric dipoles and subsequent internal screening can influence surface band bending in a direction which favours the extraction of holes from the photoanode to the electrolyte. This study highlights the benefits of using ferroelectric fields to reduce recombination in photoanodes.

Harvesting *C*lean Fogwater by Using Nanoengineered Photocatalytically Reactive Fog Harvesters Ritwick Ghosh[1,2], Adrien Baut[2], Giorgio Belleri[2], Michael Kappl[1], Hans-Jürgen Butt[1] and Thomas Schutzius[2]; [1]Max-Planck-Institute for Polymer Research, Germany; [2]ETH Zürich, Switzerland

The increasing mismatch in location of population density to the distribution of freshwater availability has aggravated the global freshwater stress. To handle this stress, researchers have looked into possibilities of tapping water from alternative resources like fog, dew, rain and desalination. Fog being a passive resource and is estimated to have a huge potential for supplying water, happens to be the most promising one. However, in many places the utility of fog as potable water becomes limited as air-borne contaminants (a major concern near urban areas) present in the surroundings get attached to the fog droplets and get collected. A possible passive way to mitigate the contaminants from being collected with fog will provide a sustainable solution for the different fog harvesting communities. The present study was focused to find such passive solution to this identified problem by leveraging the existing knowledge of both photocatalysis and fog harvesting. Photocatalysis is a process where metal oxides with semiconductor properties like titanium dioxide or zinc oxide get energized due to exposure to light in the ultraviolet wavelength and are capable of reducing organic molecules on their surface. We spray the fog harvester mesh fibers with the titanium dioxide nanoparticle coating and graft PDMS brush onto the nanoparticles after that. The coating thickness is optimized and is of the order of microns, thus not having any significant effect on the aerodynamic efficiency of the fog harvester. On the other hand, the PDMS brush helps in modulating the surface wettability of the coated fiber, besides imparting robustness to the surface coating. Later using inductively coupled plasma - optical emission spectrometry we confirmed that no additional concentration of titania or silica is found in the collected water, confirming the coating is safe for fog harvesting applications.
Two types of coated surfaces (varied by wettability i.e. superhydrophilic and hydrophobic) were prepared and tested against contaminated artificial fog, methyl orange dye was used as a contaminant surrogate. The concentration of organic contaminants were also varied and it was seen that for concentration at maximum allowable limit (referring to US EPA guidelines), the decontamination of the organic molecules leads to an impressive removal of 91% of the contaminants while dripping along the hydrophilic reactive surface. The best case for the hydrophobic reactive surface was at 76%, meaning the process takes longer timescale to decay on a hydrophobic surface than hydrophilic. To investigate this, a fundamental study was done using epifluorescence microscopy at micro-droplet scale to find the deciding factors driving the photocatalytic reduction reaction. It was found that the interplay between surface reactivity and the diffusivity of the molecules drive the photocatalytic decay reactions. Following the trends by finding lines of best fit and considering the operating conditions, a theoretical framework could be developed. The theoretical framework can predict the extent of decay expected at the given time depending on the concentration and the size of water droplets intercepted at the surface. It also predicts whether the reaction falls in the reactivity limited or the diffusion limited regime. Additionally, with the epifluorescence microscopy we developed a new process based on imaging the intensity to determine the rate of decay of contaminants in water droplets, an easy and scalable way to quantify the extent of cleaning of the water. The collection efficiency for the fog incidents were measured and the rate of collection was comparable to outdoor fog harvesting. These coated meshes were also tested outdoors, interestingly the decontamination was seen to even get enhanced on continuous UV exposure from the sun. Overall, the study may be considered as the first step towards understanding how to obtain drinkable water from contaminated fog.

Photosensitized Thermoplastic Nano-Photocatalyst for Potential Applications in Extraterrestrial Facilities Lidia Mezzina, Angelo Nicosia and Placido G. Mineo; University of Catania, Italy

Nowadays space colonization is one of the most popular topics, leading many space agencies to launch several space missions. However, considering that future space missions (such as NASA's Artemis Program) have the goal of settling humans on the Moon (and later on Mars) the presence of xenobiotic pollutants in closed environments could represent a health risk for organisms exposed to long-time exposure in a close environment. Indeed, the scarceness of primary resources such as air and water and the importance of their purification and recycling have determined the need to seek new low-energy depollution methods. Photocatalysis activated by solar light is a promising depollution method that uses reactive oxygen species (ROS) to mineralize organic pollutants. One of the most used photocatalysts is titanium dioxide in form of nanoparticles (TiO_2 NPs) [1]. However, the photocatalytic approach is unsuitable to be used in underground facilities and/or space environments (e.g., extraterrestrial facilities), because the photocatalytic mechanism of TiO_2 cannot be promoted by photons generated from the indoor lighting system, since they don't have enough energy to activate the photocatalysts [2]. Finally, recovery of the photocatalytic slurry from the depolluted solution is not easily feasible, particularly in low-gravity conditions.
To overcome the above issues, we produced different filmable nanocomposites using the *in-situ* radical copolymerization of an ad-hoc synthesized porphyrinic macromonomer (the photosensitizer) and methylmethacrylate directly into TiO_2 NPs. This approach aims to improve the photocatalytic performance of TiO_2 by ensuring intimate contact between the photocatalyst and the photosensitizer, also exploiting the PMMA waveguide effect [3].
The photocatalytic activity of the so-obtained nanocomposites was verified against both common dye probes and recalcitrant xenobiotic pollutants, employing light sources falling in the visible light range (λ>390 nm). The experimental data showed that the sensitized nanocomposites' photocatalytic performance is about double that of the unsensitized nanocomposite. This improved effect is due to the photosensitizer which could act both as an electron transfer and/or a dopant agent, boosting the TiO_2 photocatalytic efficiency. Thanks to their intrinsic properties (good filmability, thermal stability, wettability, etc), this new kind of thermoplastic nano-photocatalyst is suitable to be used in the form of thin films as an auxiliary system to the already employed depolluting systems in unconventional sceneries: underground or Low Earth Orbit laboratories, or (potentially) in future lunar shelters [4].

Photocatalytic NO_x Mitigation Under Relevant Conditions Using Carbon Nanotube-Modified Titania Brian M. Everhart, Ahmed Al Mayyahi, Bade Tonyali, Umut Yucel and Placidus B. Amama; Kansas State University, United States

Although a majority of photocatalysts exhibit improved NO conversion to NO_2, the performance in the oxidation of NO_2, the more toxic form of NO_x, to nitrate remains a challenge; in addition, the performance of hybrid photocatalysts under practical conditions is unclear. This study demonstrates the use of carbon nanotube-TiO_2 (CNT-TiO_2) photocatalyst films for the effective transformation of NO_x into nitrates. Using the objective figure of merit for NO_x abatement, $DeNO_x$ index, the catalyst performance in a laminar-flow reactor was evaluated under simulated conditions that are relevant in abating NO_x. The conditions probed include relative humidity (RH), initial NO_x concentration, reactor geometry (headspace distance), and state of the catalyst (fresh vs. recycled). Our results reveal CNT-TiO_2 significantly outperforms P25 despite exhibiting comparable NO conversion at low RH. P25 experiences a 66% reduction in DeNOx at high RH compared to low RH while CNT-TiO_2 only incurs a 27% reduction. For recycled photocatalysts, this disparity becomes even more pronounced; CNT-TiO_2 experiences a 49% reduction in DeNOx at high RH, whereas P25 experiences a 134% reduction. In addition, mass transfer from the bulk airflow was found to limit NO conversion when the reactor headspace is too large (> 3 mm), due to limited diffusion of NO_x to the photocatalyst surface. Our findings highlight the importance of headspace distance, a parameter that has mostly been overlooked in reactor design for photocatalytic oxidation of NO_x, but is expected to dictate the optimal catalyst configuration for flue gas treatment. The remarkable $DeNO_x$ activity observed in CNT-TiO_2 over a wide range of RH levels is rationalized based on the ratio of physisorbed-to-chemisorbed water on the photocatalyst surface.

In Situ Liquid Cell Transmission Electron Microscopy Study of Nanoparticle Catalytic Reactions Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Liquid cell transmission electron microscopy (TEM) has become a powerful tool for the real-time study of chemical reactions and dynamic phenomena at solid-liquid interfaces. Various advancements have been made. For example, UV light was introduced into a liquid cell which enabled the study of photocatalytic water splitting by TiO_2 nanoparticles. Interestingly, it was found that electron beam may serve as a “light” source for the investigation of pseudo-photocatalytic water splitting with rutile TiO_2 nanorods. The observation revealed the catalyst facet dependent water splitting behavior, for instance, the catalytic reactions generated hydrogen gas bubbles were found preferentially residing at the {110} facet of the rutile TiO_2 nanorod under a low electron dose rate. The electron beam effects were suppressed under the low dose imaging. Development has also been made for the study of other complex catalytic reactions, and catalytic nanoparticle restructuring has been found. Direct observation of catalytic nanoparticle structural evolution at the atomic level opens many opportunities to uncover the catalytic reactions mechanisms, and future design of novel catalysts.

11:00 AM NM03.11.02
Prediction of Excited-State Reaction Barriers in Heterogeneous Catalytic Systems with Many-Body Perturbation Theory Aaron Altman and Felipe H. da Jornada; Stanford University, United States

Excited-state catalysis encompasses a class of catalytic chemical reactions where the system of reactants adsorbed on a catalyst surface is in an excited electronic state, usually reached through light absorption or injection of a hot electron. Studies over the past decade have demonstrated the ability of illuminated nanoparticle catalysts to dramatically speed up reaction rates, selectivity amongst multiple products, and open new reaction pathways, leading to products that are otherwise not attainable in thermodynamic equilibrium. However, even with the large experimental effort, the theoretical understanding of these phenomena is still lagging. Despite substantial advances coupling non-adiabatic dynamics with excited-states, there are still few demonstrated formalisms that are able to map the rich phase space of excited-state energies in chemically complex and heterogeneous systems. Here, we present one of the first rigorously-computed excited-state potential energy surfaces (PESs) for an extended heterogeneous catalytic system, computed with the GW plus Bethe-Salpeter equation approach. In particular, using a mixed stochastic-deterministic method recently developed in our group to enable such large calculations, we compute the excited state PESs for the hydrogen adsorption/desorption reaction on a rutile TiO2 (110) surface including many-electron interactions. We find that the hydrogen desorption energy barrier in the first excited state is about half of the ground-state barrier, confirming the general expectation that lower barriers may be obtained when a catalytic system is in the electronic excited state. Additionally, we see that the primary cause of the decrease in excitation energy as a function of the reaction coordinate is the effective shift in bandgap of the system due to changing hybridization of the valence bands of TiO2 with the unoccupied H orbitals. These results confirm that barriers in the excited state PES can be significantly smaller than in the ground state and reveal that the excited state activation barriers are tunable via the hybridization of the catalyst’s surface states with the adsorbate.

11:15 AM NM03.11.03
Mediating Photoredox Cycloaddition Reactions of Enones Using Surface-Modified Metal Halide Perovskite Nanocrystal Catalyst Chen Wang and Jingheng Yuan; City University of New York, Queens College, United States

Cycloaddition reactions are employed to construct essential chemical motifs in multiple types of bioactive compounds. We utilize the excellent optical property of perovskite nanocrystals to efficiently sensitize these important reactions and explore surface chemistry approaches to control the chemo- and diastereoselectivity of reaction products. By modifying the surface ligand shell of cesium lead bromide perovskite nanocrystals ($CsPbBr_3$ PNCs), we obtained a stable photocatalyst that can effectively activate different cycloaddition reactions of enones. Time-resolved optical spectroscopic investigation reveals the reactions undergo a photoredox mechanism. The PNC sensitizes [2+2] cycloaddition resulting in a cyclobutyl motif by generating the triplet excited state of enones through photoinduced electron transfer followed by a charge recombination process. The kinetic information collected by transient absorption indicates that it is possible to preserve the anion radicals of enones by introducing appropriate sacrificial electron donors to compete with charge recombination from the PNC. Unlike the triplet excited state, these anion radicals serve as the intermediates for [1+4] cycloaddition and lead to products with cyclopentyl rings. In this specific scenario of photoredox reactions, the stability of our surface-modified PNCs surpasses conventional metal chalcogenide nanocrystals, such as CdSe, due to the fast hole removal ability. Our work demonstrates that metal halide PNCs are versatile photocatalysts for synthetic chemistry, and mediating photoredox processes can realize the selection of reaction pathways to yield different products.

Scanning (Electrochemical) Probe Microscopy—Morphological and Activity Studies ofHeterogenized Photocatalytic Systems Eva Oswald, Andreas Hellmann, Giada Caniglia and Christine Kranz; Ulm University, Germany

Efforts towards carbon-neutral energy conversion and storage such as light-driven water splitting (*i.e.,* artificial photosynthesis), fuel cells, etc. require

understanding of processes that occur at interfaces. Usually, catalytic studies to determine the light-driven catalytic activity in homogenuous and heterogenous catalysis are performed at the bulk-level, *e.g.,* using head-space gas chromatography. Hence, insight into heterogeneities of molecule-in-matrix systems like active component distributions and with that information on variety in activity require spatially resolved measurements. Scanning electrochemical probe microcopy such as scanning electrochemical microscopy (SECM) and scanning electrochemical cell microscopy (SECCM) and hybrid SPM techniques are attractive not only in studying electrocatalysts [1,2] but also for activity screening of heterogenized molecular catalysts in light-driven water splitting [3]. Moreover, morphological changes associated with degradation processes can be studied.
In this contribution, an overview of the potential of SEPM techniques in light driven catalysis will be given ranging from nanoscale surface modifications like deposition of photocatalysts using SECCM to spatially resolved *in situ*determination of light-driven reaction intermediates and products such as hydrogen (H_2), oxygen (O_2) and hydrogen peroxide (H_2O_2) using miniaturized electrodes modified with electrocatalytic layers like as Prussian blue or Pd. Selected examples of heterogenized hydrogen evolution reaction (HER) and water oxidation catalysts (WOC) will be presented and challenges in these SEPM studies will be discussed.

Probing Surface Defects in Photocatalytic Materials Under Operando Conditions Raul Quesada-Cabrera[1,2]; [1]Universidad de Las Palmas de Gran Canaria, Spain; [2]UCL (University College London), United Kingdom

Vacancy engineering is widely explored as an efficient approach to drastically change the chemical and physical properties of functional materials. Oxygen vacancies (V_0) are perceived as some of the most reactive sites on a semiconductor surface, playing an important role in charge transport and charge trapping properties. Unfortunately, due to the inherent low concentrations and high reactivity of V_0, probing vacancy sites under *relevant* experimental conditions is challenging, with standard techniques requiring ultra-high vacuum conditions, cryogenic temperatures and/or ideal single-crystal surfaces. Such techniques are usually highly specialised and operate at the atomic scale, making it challenging to extrapolate any observation to microstructured materials for practical applications. It is thus critical to be able to gain information on the potential role and kinetics of V_0 in polycrystalline materials under *operando* conditions; particularly in areas where the formation of V_0 sites can greatly influence the material performance, such as photocatalysis and energy storage applications.

A few years ago, we developed a sensing technique based on surface-enhanced Raman spectroscopy, where the chemical contribution of semiconductor substrates was greatly enhanced upon formation of photon-induced surface V_0 sites (*photo-induced enhanced Raman spectroscopy* or PIERS). As a sensing tool, this effect relied on the interaction of plasmonic nanoparticles with V_0 sites at the semiconductor surface (**Nature Commun** 2016, 7, 12189). This discovery further allowed for the application of PIERS as a probing technique to evaluate atomic V_0 dynamics in metal oxide surfaces (**Adv. Sci.** 2019, 6, 1901841). In this case, we studied the formation and healing rates of surface-active V_0 in archetypical semiconductor photocatalysts, namely, TiO_2, WO_3, and ZnO. Contrary to conventional analytical tools, PIERS can provide intuitive and valuable information on the surface stability of atomic defects at ambient pressure and under operando conditions. Further insight into the charge transport properties on photon-induced defected metal-oxide surfaces has been recently sought using advanced time-resolved atomic force microscopy (AFM) techniques (**Nano Letters** 2021, 21, 19, 8348).

The implications of these results will be challenged and proposed as a lab-based approach to investigate the impact of defect sites in the photocatalytic performance of advanced materials with potential application in emerging (*solar*) technologies.

2:15 PM NM03.12.03
Real-Time Study of Surface-Guided Nanowire Growth by *In Situ* Scanning Electron Microscopy Amnon Rothman[1], Kristýna Bukvišová[2,2], Noya R. Itzhak[1], Ifat Kaplan-Ashiri[1], Anna E. Kossoy[1], Xiaomeng Su[1], Libor Novák[3], Tomáš Šikola[2,2], Miroslav Kolíbal[2,2] and Ernesto Joselevich[1]; [1]Weizmann Institute of Science, Israel; [2]Brno University of Technology, Czechia; [3]Thermo Fisher Scientific, Czechia

Surface-guided growth has proven an efficient approach for the production of nanowire arrays with controlled orientations and their large-scale integration into electronic and optoelectronic devices. Much has been learned about the different mechanisms of guided nanowire growth by epitaxy, graphoepitaxy and artificial epitaxy. A model describing the kinetics of surface-guided nanowire growth has been recently reported. Yet, many aspects of the surface-guided growth process remain unclear due to a lack of its observation in real-time. In this study we observe how surface-guided nanowires grow in real-time by *in situ* scanning electron microscopy (SEM). Movies of ZnSe surface-guided nanowires growing on periodically faceted substrates of annealed M-plane sapphire clearly show how the nanowires elongate along the substrate nanogrooves while pushing the catalytic Au nanodroplet forward at the tip of the nanowire. The movies reveal the timing between competing processes, such as planar vs nonplanar growth, catalyst-selective vapor-liquid-solid elongation vs nonselective vapor-solid thickening, and the effect of topographic discontinuities of the substrate on the growth direction, leading to formation of kinks and loops. Contrary to some observations for nonplanar nanowire growth, planar nanowires are shown to elongate at a constant rate and not by jumps. Decrease in precursor concentration as it is consumed after long reaction time, causes the nanowires to shrink back instead of growing, thus indicating that the process is reversible and takes place near equilibrium. This real-time study of surface-guided growth, enabled by *in situ* SEM, enables a better understanding of the formation of nanostructures on surfaces.

8:00 AM *NM03.13.01
Modifying the Bi-Based Photocatalysts with Nanosized Metal Particles for Improved Catalytic Performances Ziyi Zhong[1], Yibing Song[2] and

Chenchen Zhang[1]; [1]Guangdong Technion Israel Institute of Technology, China; [2]Shantou University, China

Semiconductor photocatalysts have great potential applications in solar energy conversion and environmental purification [1-3]. However, most of them mainly work in the ultraviolet region due to their wide band gap. Bismuth oxyhalides, BiOX (X = Cl, Br and I), an important class of V–VI–VII ternary oxide semiconductors, show the improved property in separating photoinduced electron-hole pairs due to their layered structures [2]. However, their response is still limited to only ultraviolet (UV) in the solar spectrum, leading to low light utilization efficiency and, finally, low photocatalytic activity [4-5]. To address these issues, we modified the Bi-based catalysts with nanosized metal particles to improve their photocatalytic properties.
In the BiOI/TiO_2 system, we first generated metallic Bi nanoparticles in situ between the supported BiOI and TiO_2 support using the oxygen vacancies in the TiO_2 nanosheets. The theoretical and experimental results confirmed the reaction of the electron-rich oxygen vacancies in the 2D-TiO_2 nanosheets (TiO_2-NS) with the adsorbed BiO+ species, which broke the Bi-O bonds to form Bi0 nanoparticles in situ at the interface but still maintained the p-n heterojunction well. The existence of the Bi^0 nanoparticles allows electron transfer like that in the Z-scheme mechanism, enabling the effective separation and higher redox ability of photogenerated charge carriers. The formed BiOI/Bi/TiO_2 catalyst was used for Rhodamin B (RhB) photodegradation and achieved a much improved catalytic performance, i.e., duplicated apparent quantum yield (AQY) and triplicated reaction rate constant in the oxidation of Rhodamin B (RhB), was obtained [6].
For the 3D-BiOCl catalyst system, we modified the 3D-BiOCl hierarchical structure with Au particles (Au NPs) to obtain the Au/3D-BOC photocatalyst. The catalyst was used for CO_2 reduction, which was coupled with the selective benzyl alcohol (BA) oxidation to enhance the former reduction. After this modification, the reactive sites for photocatalytic CO_2 reduction changed from 3D-BOC to Au NPs, and the interaction between Au NPs and 3D-BOC could accelerate the electron transfer and the separation of carriers to prolong their lifetime further and adjust the band structure, which is beneficial to improve the redox ability of photogenerated carriers. Also, an enhanced light absorption efficiency was observed. As a result, the 1.0%Au/3D-BOC catalyst produced 94.2 µmol g^{-1} h^{-1} CO from CO_2 and converted 46.8% BA with a 99% selectivity to the high-value benzaldehyde (BAD) product.
These results provide new insights into the photocatalysis of Bi-based photocatalysts and feasible ways to improve their catalytic performances.

8:30 AM NM03.13.02

Hot Electron Driven Photocatalysis on Plasmon-Resonant Grating Nanostructures Steve Cronin; Univ of Southern California, United States

Understanding the relaxation and injection dynamics of hot electrons is crucial to utilizing them in photocatalytic applications. While most of the studies focused on hot carrier dynamics at various metal/semiconductor interfaces, we study the *in situ* dynamics of direct hot electron injection from metal to chemical adsorbates during photoelectrochemical reactions. Here, we report hot electron driven photocatalysis and ultrafast dynamics by exciting the localized surface plasmon resonance (LSPR) in Au grating photoelectrodes. *In situ* ultrafast pump-probe transient absorption (TA) measurements are used to study the dynamics of hot electrons when driving the hydrogen evolution reaction (HER). Here, a positive modulation of the absorption in the TA spectra corresponds to the interband transitions and a depletion peak results from LSPR-induced hot electrons. The extracted electron-phonon interaction time from LSPR bleaching decreases from 0.94 ps to 0.67 ps when the sample is immerged in 0.5 M Na_2SO_4 solution under -1 V applied potential due to extra energy dissipation channels. In aqueous electrolyte, the LSPR signal is red-shifted with delay time due to charge transfer between the metal surface and adsorbates' lowest unoccupied molecular orbital (LUMO) states and subsequent change of dielectric constant of nearby water environment. In contrast, when the grating is optically excited in air, the LSPR signal is blue-shifted with time, as the pump-induced hot electrons cool through electron-phonon scattering. Plasmon resonant enhancement of the photoelectrochemical current (up to 15.6X) was also observed on these gratings when irradiated on resonance, as produced by hot electrons generated from LSPR dephasing (i.e., damping). Here, hot electrons are transferred from metal surface states to adsorbates' LUMO states by chemical interface damping or chemical interface scattering, and no peak is observed when light is s-polarized (electric field parallel to grating lines), in which there is no coherent oscillation of electrons. By changing the polarization of the incident light, we can distinguish processes driven by hot electrons from those driven by interband transitions. Plateau-like peaks appear when exciting a 266nm-linewidth grating with monochromatic light between 3.6° and 9.0° incident angles, and a similar profile is observed in the measured absorptance. In addition, double peaks (6.7° and 8.4°) in the photocurrent measurement are observed when irradiating a 300nm-linewidth grating. The enhancement factor (i.e., reaction rate) is 15.6X between p-polarized (resonant) and s-polarized (non-resonant) light for 300nm-linewidth grating and 4.4X for 266nm-linewidth grating. Finite difference time domain (FDTD) simulations show two resonant modes for both grating structures, one corresponding to a dipolar LSPR mode at the Au/fused silica interface and the other on the metal surfaces away from the fused silica substrate.

NIR-Responsive Metal-Free Multifunctional GQDs/Phosphorus-Doped g-C3N4 Composite for Starving Strategized Photodynamic Chain Therapy
Xichu Wang; University of New South Wales, Australia

NIR-responsive carbon nanocatalyst which combines glucose consumption and reactive oxygen species (ROS) generation is engineered to develop a chain reaction strategy for cancer starvation and photodynamic synergistic therapy. Graphene quantum dots and carbon nitride composite can cut off the energy supply by catalyzing glucose decomposition and producing H_2O_2 in response to NIR light at the targeted tumor area. Upon irradiation, visible light emitted by upconversion-functional GQDs part to carbon nitride, photolyzed glucose into H_2O_2, bursting the hydroxyl radical generation from the decomposition of hydrogen peroxide. The generated ROS serves as the cancer-killing weapon, resulting in excellent anticancer effects, as evidenced by in vitro and in vivo studies. For the first time constructed for cancer starving/photodynamic chain therapy, which yields a remarkable anticancer effect with minimum side effects at ultralow NIR light intensity.

9:00 AM *NM03.13.05

Nano-, Micro- and Macrostructuring of Multicomponent Aerogels from Nanocrystals Nadja C. Bigall[1,2]; [1]Leibniz Universität Hannover, Germany; [2]Cluster of Excellence PhoenixD (Photonics, Optics, and Engineering – Innovation Across Disciplines), Germany

Nanocrystal aerogels and solvogels are macroscopic assemblies which which exhibit extremely low densities and good accessibility of their large specific surfaces. When employing colloidally synthesized nanocrystals as building blocks, a high degree of control over size, shape and facets, as well as over the surface chemistry, composition, and hence, over the nanoscopic properties, can be exploited for such macroscopic gel materials. Additionally, depending on the nanoscopic and microscopic architecture of these networks, macroscopic gel monoliths with either the properties of the nanoparticles, or with even new collective properties can be yielded. Therefore, finding routes for nano- micro- and macrostructuring in especially multicomponent nanocrystal-based gels paves the way to distinct material properties.
As an example, gels from metal and semiconductors or from various semiconductors etc. benefit from controlling their network architecture which strongly influences the physicochemical properties with possible future applications in electrocatalysis and photocatalysis as well as in sensing, amongst others.
Here, we present our recent advances in structure-property-correlation as well as on synthetic approaches regarding nano, micro- and macrostructuring of nanocrystal-based gels.[1]

Harnessing Ultrafast Hot Carrier Dynamics in Perovskite Nanocrystals Peng Zeng[1], Xiaochun Liu[1], Xinjian Ren[1], Klaus Boldt[2], Trevor Smith[3] and Mingzhen Liu[1]; [1]University of Electronic Science and Technology of China, China; [2]Universität Konstanz, Germany; [3]The University of Melbourne, Australia

Rapid cooling of photoinduced carriers with excess energy above the bandgap, or hot carriers (HCs), is one of the major energy loss channels in current photovoltaics/photocatalysis applications. These processes are receiving intense interest following the triumph of the perovskite-based photoelectronic and photonic devices. The emergence of all inorganic $CsPbX_3$ (X=I, Br, Cl) perovskite nanocrystals (PeNCs) have again revived the hot-carrier-based applications for their relatively long hot carrier relaxation process. However there still remains demand for the longer hot-carrier relaxation process that is more favorable for maintaining a long time window for harvesting the excess energy from the hot electronc prior to being scattered by phonons. Concurrently it has been revealed that the relaxation is mostly mediated by the carrier-phonon coupling (CPC) interaction, in which hot carriers relax to band states mainly via emission of phonons. One straightforward approach is to suppress CPC in order to reduce longitudinal optical (LO) phonon emission that will slow the HC cooling accordingly. So far the PeNC community is still lacks an insightful investigation of a method for the direct control of the CPC and subsequently the HC cooling process. One may expect sizeor component-dependent CPC strengths, and indeed some works so far have revealed such a dependence in $CsPbX_3$ NCs. However, size- and/or component-control is not feasible for applications that require specified optical properties of NCs and usually either size or component need to be maintained. By thinking outside the (particle-in-a-)box, surface ligands in the NC system may provide a way by which the CPC can be tuned.
In this talk, we raise the question in what ways ligands affect the CPC interaction and subsequently the hot carrier relaxation. We model the ligand as a damper in an oscillation model that describes the electron-LO phonon coupling. The model predicts a mechanical damping effect on the CPC strength by the resistance of surface ligands against the lattice vibrations. Different capping ligands may possess different stiffness or rigidity that results in a varied damping effect. We accordingly applied (3-aminopropyl)triethoxysilane (APTES) ligands which form a thin polysiloxane layer wrapping $CsPbBr_3$ PeNCs. We find a significantly slowed HC cooling process (more than 3-fold slower) in the polysiloxane-capped $CsPbBr_3$ NCs in comparison to conventional long alkyl chain oleylamine (OAm) ligands (OAm-$CsPbBr_3$), using ultrafast transient absorption spectroscopy. We attribute the retarded HC cooling process to the suppressed CPC process caused by the cross-linked APTES, and provide evidence for the weak CPC strength in the APTES-$CsPbBr_3$ through cryogenic PL spectroscopy measurements. Our model also successfully rationalizes the linear temperature dependence and the difference of CPC strength in two samples.
Our work confirms the crucial role of the surface ligands in the CPC of perovskite NCs, and provides a way of controlling the HC cooling process. From a wider perspective, our fundamental understanding of the CPC will lead to both theoretical interest and practical inspiration to the perovskite community of future optoelectronic and photonic applications of the PeNCs.
This talk also summarizes our recent works on interfacial charge separation processes occuring for $CsPbBr_3$ PeNCs. We will also present an interesting finding of instaneous plasmonic-induced charge carrier transfer in bulk gold-$CsPbBr_3$-layered-heterostructures. This leads to efficient charge separation at metal/perovkite interface even using low photon energy excitation, which we believe is of great potentials in future hot-carrier applications.

8:30 AM NM03.14.02
Porous TiO_2 Fibres Loaded with Plasmonic Au Nanoparticles for Water Treatment Shiling Dong[1], George Tebbutt[1], Barbara Maciejewska[1] and Nicole Grobert[1,2]; [1]University of Oxford, United Kingdom; [2]Williams Advanced Engineering Limited, United Kingdom

Facing the global shortage of clean water, photocatalytic degradation is one of the greenest technologies to decompose the organic pollutants in wastewater. Over the past decades, TiO_2 has been the most popular photocatalytic material. Upon light irradiation, it generates highly reactive free radicals that can inactivate the microorganisms and mineralize the organic matter. However, there are factors limiting overall photocatalytic efficiency, mainly, the narrow visible-light photoresponse due to wide band gap, and the limited quantum yield due to the rapid recombination of charge carriers. More importantly, although TiO_2 nanopowder demonstrates high photocatalytic reactivity, it is difficult to be removed and recycled from water suspension, therefore, not suitable for applying in large-scale water treatment.
To address the identified issues, we developed highly porous TiO2 fibers coupled with plasmonic Au nanoparticles (NPs). We synthesized TiO_2 fibers by electrospinning from solution containing TiO_2 precursor and calcining the precursor fibres at high temperature. Cu ions were doped into TiO_2 lattice to reduce the bandgap from 3.22 eV to 2.89 eV, thus extending the photosensitive light wavelength from 385 to 430 nm. We are the first to engineer the porous structure by combining the previously reported strategies for producing mesoporous TiO2 fibers, e.g., use surfactant and control the crystallization, with a sacrificial polymer template method, in which the thermal decomposition of polymer particles creates homogenously distributed macropores. New science has been overserved in the synergetic effects of these two strategies in manipulating the porous structure of ceramic fibres.

The porous TiO_2 fiber is an ideal host for anchoring noble metal NPs to form Schottky heterojunctions. In our study, we create plasmonic Au NPs/TiO_2 fibres that show doubled photocatalytic efficiency in the photodegradation of two types of organic dyes, methyl blue and methyl orange, compared to bare TiO_2 fiber. We focus on understanding the localized surface plasmon resonance of Au NPs in enhancing the photocatalytic activities of TiO_2 fiber in terms of the overlapping of absorption band and the enhanced localized light intensity. Furthermore, our Au NPs/TiO_2 fibres could also be easily filtered out from water and reused for at least six times without losing the efficiency, therefore, showing great potential for degradation of organic pollutants in large-scale water treatment.

8:45 AM NM03.14.03
Hydrogenated Tantalum Nitride a Novel Photocatalyst for Enhanced Hydrogen Evolving Performance Mrinalini Mishra[1] and Tsong-Pyng Perng[2]; [1]Sustainability Science and Engineering Program International College, Tunghai University, Taiwan; [2]National Tsing Hua University, Taiwan

Solar-driven water splitting via semiconductor photocatalysts is a promising alternative in energy carriers in terms of clean, sustainable, and abundant energy sources. In recent times, tantalum-based (oxy-)nitride materials are being extensively explored due to their small bandgaps and favorable band edge positions for overall water splitting. The theoretical solar to hydrogen (STH) conversion rate for tantalum nitride (Ta_3N_5) is 16%. However, practically such high activity has not yet been reported. Previously, we investigated the photocatalytic efficiency of hydrogenated oxides like TiO_2 and ZnO. Hydrogenation induces surface and/or bulk defects depending on the condition of H_2 treatment. The surface defects act synergistically in improving the electrons and hole transport in oxide photocatalysts. However, the repercussions of hydrogenation on nitride semiconductors have seldom been studied.
In this work, Ta_3N_5 thin films were fabricated on Si wafer by 400 cycles of atomic layer deposition and were crystallized at 800 °C in NH_3. The crystalline films were hydrogenated at 300-500 °C under 20 bar H_2 for 30-120 min. Water splitting efficiencies of the treated and untreated Ta_3N_5 films were then evaluated under 300 W Xe lamp. Hydrogenation at 300 °C for 30 min resulted in a shift of X-ray diffraction (XRD) peaks towards higher angles, suggesting a contraction of the lattice and enhanced H_2 generation as compared to untreated Ta_3N_5. Whereas hydrogenation at 500 °C for 30 min exhibited XRD peak shift towards lower angles and the H_2 generation deteriorated severely. To further elucidate the effect of hydrogenation, the samples were also characterized by photoluminescence spectroscopy, ultraviolet photoelectron spectroscopy, valence band X-ray spectroscopy, atomic force microscopy, and Raman analysis

9:00 AM NM03.14.04
Synthesis and Characterization of a Carbon Nanodot-Cobalt Oxide Nanohybrid Anuoluwapo Anele[1], Sherine Obare[1,2] and Jianjun Wei[1]; [1]University of North Carolina, Greensboro, United States; [2]North Carolina A and T State University, United States

Carbon nanodots are a novel class of nanocarbons with fluorescent capabilities which conform to a size less than 10 nm. They have desirable properties such as their photoluminescence, solubility, electronic, photocatalytic, optical properties, and ease of functionalization. Cobalt oxide nanoparticles are metal oxides that have unique structural, chemical, physical, magnetic and optical properties making them useful for several applications such as energy storage, and catalysis. Synthesis of cobalt oxide and carbon nanodots include methods such as the arc-discharge method, laser ablation method, electrochemical method, thermal pyrolysis, hydrothermal method, casting, chemical reduction, co-precipitation, ionic liquid-assisted approach, irradiation, microemulsion, sol-gel approach, solvothermal approach, template method, and vapor deposition approach. Some of these methods of synthesis of carbon nanodots and cobalt oxide employ harsh temperatures and/or require longer reaction time for synthesis. The low toxicity of carbon nanodots coupled with its high solubility could also help improve on the same properties of cobalt oxide. In this research, we present a two-step microwave assisted synthesis of a novel cobalt oxide-carbon nanodot hybrid synthesized in reduced time and a cleaner way. This nanohybrid possesses enhanced optical properties compared to carbon nanodots alone. Structural properties of this nanohybrid are also presented. This nanohybrid could be applicable for several environmental and biological applications such as remediation, catalysis, bioimaging, sensor detection and drug delivery.

9:05 AM *NM03.14.06
Charge Transport Calculations Through Nanomaterial Interfaces Maytal Caspary Toroker; Technion-Israel Institute of Technology, Israel

Interfaces have long been studied for their fundamental importance in material microstructure as well as their broad applicability in electronic devices. However, the challenge involved in characterizing the relation between structure and electron transport of a large number of interface combinations inhibits the search for interfaces with improved functionality. Therefore, we develop a novel high-throughput screening approach that combines computational and theoretical techniques. We use a Density Functional Theory + U (DFT+U) quantum mechanical formalism to produce effective Schroedinger equations, which are solved by wave packet propagation to simulate charge transport across the metal/oxide interface. We demonstrate this method on nanomaterials, including molybdenum disulfide with vacancies interfacing with metals and dielectric materials.

This research is relevant for the activities in COST Action CA18234 titled “Computational Materials Sciences for efficient water splitting with nanocrystals from earther abundant elements”. This COST Action intends to focus on bridging the knowledge gaps between different theoretical methods and computer codes in order to facilitate the discovery of novel materials for energy conversion. The objectives of this challenge include building an organized network of European scientists working on achieving greater scientific understanding of water splitting and developing approaches for reliable and realistic multi-scale modelling of nano-oxides material architectures. I will display the networking activities and opportunities that are available by joining our COST Action.

SESSION NM04.01: Advanced Manufacturing of 2D Materials at the Atomic Scale I

Session Chairs: Wenpei Gao and Chenglin Wu
Tuesday Morning, April 11, 2023
InterContinental, Fifth Floor, Ballroom B

10:30 AM *NM04.01.01
Towards Controlled Synthesis and Scalable Manufacturing of 2D Crystals Jun Lou; Rice University, United States

The emergence of two-dimensional (2D) materials has captured the imagination of researchers since graphene was first exfoliated from graphite in 2004. Their exotic properties give rise to many exciting potential applications in advanced electronic, optoelectronic, energy and biomedical technologies. Scalable growth of high quality 2D materials is crucial for their adoption in technological applications the same way the arrival of high-quality silicon single crystals was to the semiconductor industry. A huge amount of effort has been devoted to grow large-area, highly crystalline 2D crystals such as graphene and transition metal dichalcogenides (TMDs) through various methods.
While CVD growth of wafer-scale monolayer graphene and TMDs has been demonstrated, considerable challenges still remain. In this talk, we first advocate for the focus on the crystal growth morphology as an underpinning for understanding, diagnosing and controlling the CVD process and environment for 2D material growth. Like snowflakes in nature, 2D crystals exhibit a rich variety of morphologies under different growth conditions. The mapping of crystal shapes in the growth parameter space “encodes” a wealth of information, the deciphering of which will lead to better understanding of the fundamental growth mechanism and materials properties. However, the morphology pattern evolution of 2D crystals such as MoS_2 monolayers under a practical CVD growth condition is highly complicated due to the entanglement of multiple growth factors. The ability to directly monitor it in real-time would be substantial to provide first-hand data to lay the groundwork for most advanced tools such as machine-learning to unravel those threads. A customized system with the function of observing and recording the CVD growth of MoS_2 in a miniature furnace is developed in this work. Image processing techniques are utilized to convert the real-time growth footage into frame-wise digital numbers and machine-learning is deployed to uncover the importance of multiple controlling factors in the growth. The model successfully guides the discovery of experimental control parameters to grow ultra-large size MoS_2monolayers. The model also demonstrates the possibility to trace back experimental condition by analyzing the crystal morphology parameters. In a parallel effort, we also demonstrate that the widely used powder-processing technique of dry ball-mill, can be improved to produce high-quality 2D flakes in large scale and with low cost. Seventeen types of commonly seen polymers, including both artificial and natural ones, have been examined as additive to dry ball-mill of hexagonal boron nitride. The potential of polymer-assisted ball-mill exfoliation as a universal way to produce ultra-thin 2D nanosheets is also demonstrated.

11:00 AM NM04.01.02
Effect of Substitutional Oxygen on Properties of $Ti_3C_2T_x$ MXene synthesized from TiO_2 Precursor Aamir Iqbal[1], Hyerim Kim[2], Jung-Min Oh[3], Yury Gogotsi[4], Hanjung Kwon[5] and Chong Min Koo[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Innomxene, Korea (the Republic of); [4]Drexel University, United States; [5]Jeonbuk National University, Korea (the Republic of)

MXenes are an emerging class of 2D materials with unique properties including excellent metallic conductivity, mechanical flexibility, hydrophilicity, and tunable surface functionality, which ensure their utility for diverse applications. However, the synthesis of stoichiometric MXenes with high quality in a low-cost process is still challenging because of the difficulty in controlling the oxygen substitution in the precursors and final products of MXenes. Here, we report a novel cost-effective method to synthesize $Ti_3C_2T_x$ MXene with controlled contents of substitutional oxygen by optimizing the amount of excess carbon in carbothermal reduction of TiO_2 precursor. The highest used content (2 wt.%) of excess-carbon yields TiC with minimal oxygen substitutes, which leads to Ti_3AlC_2 MAX phase with improved crystallinity and stoichiometry, and, finally, $Ti_3C_2T_x$ MXene with a high electrical conductivity (>11700 S cm^{-1}) and superior electromagnetic shielding effectiveness. Additionally, the effects of substitutional oxygen on the physical properties of TiC, and Ti_3AlC_2 are elucidated by density-functional theory calculations. This TiO_2-based method of synthesizing high-quality $Ti_3C_2T_x$ MXene substantially lowers the material cost and can facilitate large-scale manufacturing, thus accelerating global research on MXenes and their introduction into industrial products.

11:15 AM NM04.01.03
Synthesis of Quantum-Confined Borophene Nanoribbons Qiucheng Li[1], Luqing Wang[1], Hui Li[1], Maria K. Chan[2] and Mark C. Hersam[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Borophene refers to synthetic two-dimensional (2D) boron, which has attracted significant attention due to its anisotropic metallicity, correlated electron phenomena, and diverse superlattice structures.[1] Reducing the dimensionality of nanomaterials imposes additional quantum confinement effects that unlock new physical phenomena, such as one-dimensional (1D) confined plasmons, spin-polarized edge states, and Luttinger liquid behavior. However, the realization of quantum-confined borophene nanoribbons (BNRs) is hampered by limited boron precursor options for bottom-up synthesis. In this work, we present a substrate mediation strategy to synthesize quantum-confined BNRs on vicinal Ag(977) substrates. The resulting BNRs inherit the high degree of polymorphism present in borophene, resulting in $v_{1/5}$ and $v_{1/6}$-BNR lattice configurations in addition to phase intermixing.[2] Through atomic-scale imaging, spectroscopy, and first principles calculations, the edge structures of BNR polymorphs are shown to possess reconstructed armchair edges for $v_{1/6}$-BNRs and sawtooth zigzag edges for $v_{1/5}$-BNRs. The confined electron wave functions in 1D BNRs lead to the observation of energy level quantization and spatial nodes characteristic of quantum-well states.

11:30 AM NM04.01.04
Interlayer Coupling and Strain Localization in Twisted Bilayer 2D Materials Rui Huang[1], Ganbin Chen[1], Vahid Morovati[2] and Kenneth M. Liechti[1]; [1]The University of Texas at Austin, United States; [2]University of Connecticut, United States

Twisted bilayer 2D materials exhibit a wide range of intriguing physical properties, such as superconductivity, ferromagnetism, and superlubricity. Depending on the twist angle, periodic moire superlattices form in twisted bilayer graphene, with inhomogeneous interlayer coupling and lattice deformation. For a small twist angle, each moire supercell contains a large number of atoms (>10,000), making it computationally expensive for first-principles and atomistic modeling. In this work, a finite element method based on a continuum model is used to simulate the inhomogeneous interlayer and intralayer deformations of twisted bilayer graphene and MoS2. The van der Waals interactions between the 2D layers are described by a periodic potential energy function, whereas each 2D layer is treated as a continuum membrane with effective elastic properties. Our simulations show that structural relaxation and the induced strain localization are most significant at small twist angles, where the strain distribution is highly localized as shear strain solitons along the boundaries between neighboring domains of commensurate AB stacking. Moreover, it is found that there exist many metastable equilibrium configurations at particular twist angles, depending on the specimen size. The nonlinear mechanics of twisted bilayer 2D material is thus expected to be essential for understanding the strain distributions in the moire superlattices and the strain effects on other physical properties.

SESSION NM04.02: Advanced Manufacturing of 2D Materials at the Atomic Scale II

1:30 PM *NM04.02.01
Direct Atomic Assembly and Physics Studies of Defects and Artificial Molecules in 2D Materials via Electron Beam Sergei Kalinin and Kevin Roccapriore; The University of Tennessee, Knoxville, United States

Direct fabrication of matter on atomic level is the North Star goal for areas spannign quantum computing, quantum communications, biological sensing, and fundamental physical research. Over the last decade, it has been shown that electron beams in Scanning Transmission Electron Microscopy can be used not only to probe structure and electronic properties of materials on atomic level, but also to modify materials on the atomic level. Harnessing electron beam changes for direct atomic farication however requires synergy between machine learning methods and microscope control. In this presentation, I will illustarte the progression of automated electron microscopy from real-time data analysis to physics discovery to atomic manipulations. Here, the applications of classical deep learning methods in streaming image analysis are strongly affected by the out of distribution drift effects, and the approaches to minimize though are discussed. The robust approach for real-time analysis of the scanning transmission electron microscopy (STEM) data streams, based on the ensemble learning and iterative training (ELIT) of deep convolutional neural networks, is implemented on an operational microscope, enabling the exploration of the dynamics of specific atomic configurations under electron beam irradiation via an automated experiment in STEM. Combined with beam control, this approach allows studying beam effects on selected atomic groups and chemical bonds in a fully automated mode. We demonstrate atomically precise engineering of single vacancy lines in transition metal dichalcogenides and the creation and identification of topological defects graphene. The ELIT-based approach opens the pathway toward the direct on-the-fly analysis of the STEM data and engendering real-time feedback schemes for probing electron beam chemistry, atomic manipulation, and atom by atom assembly. We further illustarte how deep kernel learning (DKL) methods allow to realize both the exploration of complex systems towards the discovery of structure-property relationship, and enable automated experiment targeting physics (rather than simple spatial feature) discovery. The latter is illustrated via experimental discovery of the edge plasmons in STEM/EELS. Jointly, these developments open the pathway for creation and characterization of designed defect configurations and artificial molecules in 2D materials.

2:00 PM NM04.02.02
A General Fruit Acid Chelation Route for Eco-Friendly and Ambient 3D Printing of Metals Soo Young Cho[1], Dong Hae Ho[2], Yoon Young Choi[3], Dong Gue Roe[1], Yonghyun A. Kwon[1], InCheol Kwak[1], Seonkwon Kim[1], Jung Woo Moon[1], Seonmi Eom[1], Sae Byeok Jo[4] and Jeong Ho Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Virginia Tech, United States; [3]University of Illinois at Urbana-Champaign, United States; [4]Sungkyunkwan University, Korea (the Republic of)

Recent advances in metal additive manufacturing (AM) have provided new opportunities for prompt designs of prototypes and facile personalization of products befitting the fourth industrial revolution. In this regard, its feasibility of becoming a green technology, which is not an inherent aspect of AM, is gaining more interests. A particular interest in adapting and understanding of eco-friendly ingredients can set its important groundworks. Here, we demonstrate a water-based solid-phase binding agent suitable for binder jetting 3D printing of metals. Sodium salts of common fruit acid chelators form stable metal-chelate bridges between metal particles, enabling elaborate 3D printing of metals with improved strengths. Even further reductions in the porosity between the metal particles are possible through post-treatments. A compatibility of this chelation chemistry with variety of metals is also demonstrated. The proposed mechanism for metal 3D printing can open up new avenues for consumer-level personalized 3D printing of metals.

2:15 PM NM04.02.03
Emergent Moiré Phonons Due to Zone Folding in WSe_2-WS_2 van der Waals Heterostructures Hsun Jen J. Chuang[1], Madeleine Phillips[1], Kathleen M. McCreary[1], Darshana Wickramaratne[1], Matthew R. Rosenberger[2], Vladimir P. Oleshko[3], Nicholas Proscia[1,4], Mark Lohmann[1,5], Dante J. O'Hara[1], Paul D. Cunningham[1], C. Stephen Hellberg[1] and Berend Jonker[1]; [1]Naval Research Lab, United States; [2]University of Notre Dame, United States; [3]National Institute of Standard and Technology, United States; [4]NRC, United States; [5]American Society for Engineering Education, United States

Bilayers of 2D materials offer unique opportunities for creating devices with tunable electronic, optical, and mechanical properties. In van der Waals heterostructures (vdWHs), where the constituent monolayers have different lattice constants, aligned bilayers foster a superlattice moiré length scale that is larger than the lattice constant of either constituent material. Here, we report new Raman modes in WSe_2-WS_2 vdWHs in the range of 240-260 cm^{-1}, which are absent in both monolayers and homobilayers of WS_2 and WSe_2. Using first-principles calculations and geometric arguments we show that these new modes are a consequence of the large moiré length scale, which results in zone-folded phonon modes that are Raman active. These modes are sensitive to changes in twist angle, but notably, they occur at identical frequencies for a given small twist away from either the 0-degree or 60-degree aligned heterostructure. Our measurements also show that the Raman intensity in the frequency range of interest, which includes both the new Raman modes and the WSe_2 A_{1g} peak, exhibits a markedly different dependence on excitation energy in near-0 vs. near-60 degree vdWHs. Temperature-dependent reflectivity measurements demonstrate the significant Raman intensity modulation arises from resonant Raman effects

2:30 PM NM04.02.04
Adhesive Matrix Transfer for Direct van der Waals Integration of Two-Dimensional Materials into Functional Devices Peter Satterthwaite[1], Weikun Zhu[1], Patricia Jastrzebska-Perfect[1], Melbourne Tang[1], Hongze Gao[2], Hikari Kitadai[2], Ang-Yu Lu[1], Qishuo Tan[2], Jing Kong[1], Xi Ling[2] and Farnaz Niroui[1]; [1]Massachusetts Institute of Technology, United States; [2]Boston University, United States

Pristine van der Waals (vdW) interfaces between two-dimensional (2D) and other materials are essential for emerging optical and electronic devices. Their fabrication is, however, challenged by weak vdW forces that are constrained by the intrinsic material properties and hence not readily tunable to accommodate formation of arbitrary heterostructures. Conventional techniques overcome this limitation by facilitating transfer using sacrificial layers, solvents and high temperatures, steps which could introduce damage and contaminants. In addition, often, post-transfer fabrication steps are required for device integration, which could further introduce damage. An ideal fabrication approach would accommodate a single-step 2D material-to-device integration.

To realize such a platform, here, we present the adhesive matrix transfer approach. This approach enables sacrificial layer-free, dry, and pristine fabrication of arbitrary vdW interfaces, and their integration into functional devices. Core to this approach is decoupling the vdW forces defining the interface of interest from the forces responsible for 2D material transfer. This is achieved by embedding the substrate of interest in a matrix whose surface adhesive forces can be independently tuned to allow for the transfer of arbitrary layers. With this approach we have demonstrated conventionally forbidden, direct vdW integration of diverse 2D materials, including MoS_2, WSe_2 and GaS, with bulk dielectrics (SiO_2, Al_2O_3), core building blocks of functional devices. We use this technique to then demonstrate single-step integration of 2D materials into devices, using an example of arrays of monolayer-MoS_2 transistors. With no exposure to polymers and solvents, our approach enables clean interfaces and pristine surfaces with reduced fermi-level pinning, which can be further engineered to demonstrate high-quality n- and p-type behavior. Beyond serving a platform to probe intrinsic properties of 2D and other sensitive nanomaterials without the influence of processing steps, our fabrication technique further allows efficient formation of devices with unconventional form-factors, here we discuss its application in 2D flexible electronics.

2:45 PM NM04.02.05
Spectroscopic Characterization of Buried 2D-3D Interfaces Enabled by Novel Polymer-Free Transfer Technique Christopher M. Smyth, John M. Cain, Alex M. Boehm, Stanley Chou, Taisuke Ohta and Tzu-Ming Lu; Sandia National Laboratories, United States

Two-dimensional (2D) materials have been studied for use in a variety of emerging electronic, optoelectronic, and photonic applications. Device fabrication often involves depositing various three-dimensional (3D) materials, such as metals or dielectrics, onto the 2D material, which creates a buried interface. Interfacing materials significantly affect the nature and homogeneity of the electronic and phononic structure in 2D materials. To date, spectroscopic studies of the doping and strain in supported 2D materials have mostly been limited to unrealistic cases where the 2D material is transferred or exfoliated onto a substrate of interest [1,2], with a few exceptions [3]. A polymer-free transfer technique capable of exposing any buried 2D-3D material interface would enable direct physical characterization of realistic heterojunction properties.

In this presentation, we present a new polymer-free transfer technique that allows direct characterization of the buried interface in almost any 2D-3D heterostructure. The method is enabled by employing a water soluble GeO_2 substrate and wafer bonding process. We demonstrate the diversity of the technique by fabricating various heterostructures on monolayer MoS_2, including inert and reactive metals and oxide dielectrics, and expose the initially buried interfaces for direct characterization. We also fabricate the same heterostructures by exfoliating MoS_2 onto metals and oxides to directly compare strain, doping, and chemistry in MoS_2 across fabrication techniques. We employ Raman spectroscopy to measure the strain and doping profile in MoS_2 heterostructures. The surface chemistry and band alignment (where applicable) are measured using X-ray photoelectron spectroscopy (XPS).

Reactively sputtered GeO_2 films exhibit a 2:1 O:Ge ratio according to XPS. After heterostructure fabrication and wafer bonding, the GeO_2 layer is completely dissolved in deionized H_2O within a few hours, exposing the buried interface. In general, peak shifts in MoS_2 Raman spectra indicate the degree of strain and doping imparted on MoS_2 significantly depends on the interfacing material and the fabrication method. When the interfacing material is directly deposited on MoS_2, the strain imparted on the MoS_2 is more significant than the degree of doping. Reactions between MoS_2 and reactive metals (Ti, Ni) are significant when the heterostructure is fabricated by direct deposition according to XPS and Raman spectroscopy. In contrast, when heterostructures are fabricated by exfoliating MoS_2 onto a substrate of interest, doping dominates over strain. Our novel method enables direct characterization of buried 2D-3D interfaces and expanded control over the strain profile in 2D materials, which could lead to new discoveries and functionalities.

This work was supported by a Laboratory Directed Research & Development program at Sandia National Laboratories. From *h*-BN to Graphene: Understanding Electrical Conductivity of Single-Crystal Carbon-Doped *h*-BN through Its Structure Supawan Ngamprapawat[1], Tomonori Nishimura[1], Kenji Watanabe[2], Takashi Taniguchi[2] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]National Institute for Materials Science (NIMS), Japan

Hexagonal boron nitride (h-BN) is a promising ultrawide-bandgap semiconductor for emerging optoelectronic and high-power electronic devices. Nevertheless, ohmic current injection into h-BN remains a significant challenge in developing these current-driven devices. Interestingly, the hybridized two-dimensional structure containing boron, carbon, and nitrogen, which was reported to have modifiable electrical properties by controlling C concentration [1], is a potential material to overcome this challenge. It is thus possible that a small C concentration introduced to hybridize with h-BN could improve the electrical conductivity of h-BN.

In this study, the effect of C on the electrical conductivity of h-BN was investigated. To minimize the influences from other C-unrelated defects, the single-crystal h-BN synthesized under high pressure and high temperature (HPHT) was selected. C was introduced by post-growth diffusion with two different conditions: at 2.5 GPa and 3100°C for 30 minutes and at 1 atm and 2000°C for 4 hours. The former condition results in gray-colored h-BN and the latter one gives yellow-colored h-BN. According to SIMS profiles, the gray C-doped h-BN (h-BN:C) shows ~10 at.% C, which is ~100 times higher in C concentration than the yellow h-BN:C. The transverse dielectric breakdown of both h-BN:C is comparable to that of undoped h-BN. Raman spectra show the apparent differences between these two types of h-BN:C. At 3 K, the E_{2g} vibrational mode of h-BN is observed at ~1368 cm^{-1} for both h-BN:C, while the peaks corresponding to G and 2D modes in graphene are detected only in the gray h-BN:C, indicating the existence of C–C bonds. It can be expected that C and h-BN domains coexist in the gray h-BN:C. The electrical conductivity was investigated by forming metal contact following the method described in Ref. 2. The I-V characteristic of the gray h-BN:C initially exhibited nonohmic conduction within an applied voltage of ±100 V at 298 K and transformed to ohmic conduction after the breakdown-like behavior at 598 K. The surface topology change of the h-BN channel can be seen in most of the devices with ohmic conduction after the high-T measurements. On the other hand, the yellow h-BN:C requires at least ±50 V to inject current with nonohmic conduction for all T, and no breakdown-like behavior nor topology change in the channel is observed. After the T-dependent I-V measurements, the devices were characterized by electron-beam-induced current (EBIC) mapping, cross-sectional TEM, and EELS. The EBIC results indicate the formation of a conductive path in the gray h-BN:C channel. The EELS mapping and its energy loss spectra reveal the existence of discrete graphite/graphene layers and randomly distributed C domains in the gray h-BN:C, which is consistent with the Raman spectra. These results suggest the possibility that C structures existing in h-BN induced the local breakdown of h-BN, which functions as a conductive path. Therefore, to enable the development of h-BN:C-based high-power electronics, the formation of randomly distributed C domains and graphite/graphene layers must be controlled.

High-Performance Monolithic Tellurene CMOS Through Polarity Engineering Mingyi Wang and Wenzhuo Wu; Purdue University, United States

Tellurene is an emerging 2D p-type semiconductor. By contact engineering and post-metallization annealing process, the ambipolar Te-FETs were fabricated in this study. Interestingly, thinner Te flakes tend to have a p-type characteristic while thick Te possesses n-FET property. Here, based on experiments and simulations, we propose a new transport model for 2D Te FETs. This model helps us understand the thickness-polarity dependence. Such phenomena in other 2D semiconductors were previously interpreted using the theory of band structure in different thicknesses. However, the subtle change in the band structure of Te is not capable of tuning the polarity from p-type to n-type. In other similar p-type 2D materials like BP, the role of surface native oxide was often ignored in FET transport. We further demonstrated for the first time a monolithic CMOS inverter based on tellurene, leveraging the symmetric operation of p- and n-type tellurene FETs. Our results not only demonstrate robust and high-performance tellurene CMOS inverters, but also provide a new transport model to similar 2D semiconductors, shedding light on high-performance 2D electronics and CMOS design.

Autonomous Beam Fabrication of 1D-2D Nano Hetero-structures within 2D Materials Matthew G. Boebinger[1], Kevin Roccapriore[1], Ayana Ghosh[1], Panchapakesan Ganesh[1], Maxim Ziatdinov[1], Sergei Kalinin[2] and Raymond R. Unocic[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

One of the central goals of nanotechnology is to directly fabricate nanoscale architectures with atomic-scale precision. With recent advancements in aberration corrected scanning transmission electron microscopy (STEM), the sub-Å sized electron beam can be used to manipulate the atomic structure of materials. Previous work has shown the electron beam is capable of locally and controllably creating defect structures within 2D materials such as nanopores and atomic edge configurations that have enhanced electronic, magnetic, optical and catalytic properties. In the model MoS_2 materials system, several such defect structures can be fabricated through the localized irradiation of sulfur sites within the lattice through the knock-on process. In this work, an emphasis was placed on the controlled fabrication and characterization of two distinct defect structures. First, the sulfur vacancy line (SVL) defect structure, composed of a line of single sulfur vacancy sites, that has previously been shown to conglomerate together to form a local metallic MoS area within the MoS_2 monolayer. Second, the metallic Mo_6S_6 (MoS-NW) nanowire-type defect structure that forms along the edge of nanopores within the MoS_2 monolayer. Initial work has demonstrated that these MoS-NW form preferentially along the zig-zag sulfur terminated direction within the lattice. Through precise control over the electron beam irradiation of S sites along this direction, edge decorated nanopores can be fabricated. To increase the reliability of this fabrication method, Python-based codes have been developed that allow for *in situ* data acquisition, decoding and automated beam control in-line with the electron microscope workflow following the ensemble learning iterative training (ELIT) approach for deep convolutional neural networks (DCNNs). Using ELIT DCNNs, during fabrication, the image is decoded in real time into the atomic coordinates and identities allowing for precise targeting of atomic species and locations. In this regard, automated electron beam manipulation experiments have been developed that can form these beneficial defect structures that can lead to direct bandgap engineering.

Microscopy research was performed at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory, which is a US Department of Energy (DOE), Office of Science User Facility.

High Throughput 2D Materials Fabrication with a Fully Mechanized Platform Suji Park, Houk Jang, Kevin Yager, Gregory S. Doerk, Aaron Stein, Jerzy Sadowski and Charles Black; Brookhaven National Laboratory, United States

Quantum Information Science (QIS) is an emerging research area that promises to revolutionize computing, communication, and sensing. Two-dimensional (2D) materials are one of the most versatile motifs for generating new QIS materials since one layer in arbitrary stacks forms heterostructures unconstrained by epitaxy. Since manual mechanical exfoliation, or "tape exfoliation," produced mono and few-layered graphene in 2004, researchers have made tremendous progress in 2D material research. However, it has been challenging to study and utilize 2D materials because of a time- and labor-consuming fabrication process that highly depends on the hands-on experience of researchers. Here, I present the ongoing development of a high throughput 2D material fabrication platform, Quantum Material Press (QPress), an integrated cluster tool including three custom machines: an exfoliator, cataloger, and stacker. The exfoliator is a fully automated machine for tape exfoliation using commercial pressure-sensitive adhesive (PSA) tape and a roller assembly. The mechanism of the exfoliator is the same as that of the manual tape exfoliation. However, the PSA tape is compressed onto a substrate by a press roller and peeled off by a tape rewinder instead of human hands. After the exfoliation, the cataloger detects and classifies the exfoliated flakes, and makes a data library for users. Finally, we use the fully motorized stacker to stack selected flakes into heterostructure, with 3-axis and 6-axis manipulation stages for a substrate and a stamp, respectively. These machines allow us to investigate underlying mechanisms of 2D material fabrication. We believe that QPress will help us to provide a more reliable method of 2D material fabrication by developing optimum conditions for higher yield and reproducibility.

Layer-number Dependency of Phase Transitions in 2D Layered Materials Revealed by Cryogenic Scanning Transmission Electron Microscopy Miaofang Chi; Oak Ridge National Laboratory, United States

Two-dimensional (2D) van der Waals (vdW) materials and their heterostructures provide excellent platforms for exploring fascinating physical phenomena and implementing intriguing applications. One of the most attractive features of this family of materials is the tunability of their quantum behavior depending on the layer number. Different exotic physical properties, such as magnetic, electronic, and optoelectronic properties, were observed in samples with different thicknesses, especially in a thickness range from monolayer through several nanometers. It is recognized that lattice structural transformations often accompany electronic and spin structural changes that provoke exotic quantum phenomena. It is however unclear whether the same structural transformation as bulk material occurs in thin flake samples. Indeed, a consistent result is often missing regarding the structure-property relationship in several-layer thick 2D vdW materials. In this talk, we reveal the thickness dependency of low-temperature phase transformation and exciton state change in several model 2D vdW materials by utilizing cryogenic atomic resolution scanning transmission electron microscopy (STEM) and monochromated electron energy loss spectroscopy (EELS). Our results allow a precise understanding of relevant layer-number-dependent properties, information critical to harnessing unique quantum characteristics in thin layer 2D vdW materials for device applications.

9:00 AM *NM04.03.02
***In Situ* Imaging of Phase and Twist Boundaries in 2D Materials** Yichao Zhang[1], Chia-Hao Lee[1], Ji-Hwan Baek[2], Huije Ryu[2], Gillian Nolan[1], Gwan-Hyong Lee[2] and Pinshane Y. Huang[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Seoul National University, Korea (the Republic of)

Scanning transmission electron microscopy (STEM) provides uniquely powerful tools to study the interfacial structure and transformations of 2D materials up to atomic resolution. Here, we utilize 2D multilayer stacks to create nanoscale laboratories for studying the atomic structure, structural transformations, and properties of 2D interfaces inside the STEM. We utilize graphene encapsulation in combination with a MEMS-based heating holder to conduct in-situ studies of solid-solid phase transformations and interfacial restructuring in 2D transition metal dichalcogenides. The graphene encapsulation protects the 2D materials from the vacuum environment of the STEM, enabling high temperature studies up to 1000°C. We use these structures to directly visualize the layer-by-layer phase transformation of $MoTe_2$ and the lattice reconstruction of 2D moirés.

First, we study the interfacial reconstruction mechanisms of twisted bilayer transition metal dichalcogenides ($MoSe_2$ and WSe_2) using *in situ* aberration-corrected STEM and dark-field transmission electron microscopy (DFTEM). We discover a new mechanism of local reconstruction from moiré patterns to parallel (3R) and/or antiparallel (2H) domains in twisted bilayer 2D transition metal dichalcogenides (TMDCs). Unlike previous reports, where the twist angle is altered by the rotation of a whole flake, we observe the nucleation and growth of commensurate domains through the formation and migration of grain boundaries. We capture the dynamic nucleation and growth of the aligned structure through a series of atomic resolution STEM images combined with atom-tracking analysis. These results provide new insights into the mechanisms of interlayer rotation at the atomic scale and potential method into engineering the structure of moiré superlattices.

Second, we examine the atomic mechanisms of phase transitions of $MoTe_2$. $MoTe_2$ exhibits multiple structural and electronic phases at room temperature (2H, 1T', and T_d) that can be easily manipulated with different stimuli, making it a promising candidate for phase-change memories, high-performance transistors, and broadband photodetectors. In order to capture the dynamics of the T_d-to-2H phase transition, we apply heat pulses as short as 0.5s to "freeze" the growth front of the 2H phase at different temperatures. Next, we combine dark-field TEM and aberration-corrected STEM to image the phase transitions of few-layer $MoTe_2$ *in situ* from the micro- to atomic scales. We find that T_d-to-2H phase transitions initiate at the phase boundary at temperatures as low as 200-225 C, much lower than previously thought. We individually measure the phase front of each layer and find that the linear growth rate of the 2H phase at 275^{o}C varies from 5 to 14 nm/sec between different layers, which suggests that factors such as strain and local defect densities affect the energy barrier of the phase transition. In addition, the 2H-T_d interfaces propagate primarily along the b-axis of the T_d grain, producing an anisotropic, layer-by-layer phase transformation. These results should lead to new methods to manipulate the quantum and electronic properties within individual atomic layers.

MOCVD Grown MoS_2 and WS_2 Characterized With Tip-Enhanced Raman Spectroscopy and Kelvin Probe Force Microscopy Michael Curtis[1], Patrick El Khoury[2], Chen Chen[3,4], Joan M. Redwing[2,4] and David Estrada[1,5]; [1]Boise State University, United States; [2]Pacific Northwest National Laboratory, United States; [3]The Pennsylvania State University, United States; [4]2D Crystal Consortium, United States; [5]Center for Advanced Energy Studies, United States

For decades Silicon based field-effect transistors (FETs) have been the foundation of modern semiconductor technology. Advancements in device fabrication have reduced the size of FETs down the nanoscale while improving performance and efficiency. Silicon however has reached its scaling limit and is no longer suitable for next generation devices due to inadequate carrier mobility, heat generation, and atomic scale thickness limitations. Transition metal dichalcogenides (TMDs) are intrinsic semiconductors that transition from indirect to direct band gaps in the near infrared to visible spectrum, making them excellent candidates for optoelectronic applications. However, the synthesis of these materials is not a trivial exercise, and the method of mechanical exfoliation, that jumpstarted the field, is not well suited for deeper research into the properties of these materials. Additionally, mechanical exfoliation has the potential to degrade the crystalline structure of the layers and is the source of significant defects. Interface quality and layer integrity are of vital importance when producing heterostructures, which is a key step in the functionalization of next-generation devices. To this end, direct epitaxial growth techniques such as metal oxide chemical vapor deposition (MOCVD) facilitates improved control of growth conditions by precise delivery of precursor gases at consistent reactor temperature and pressure, which enables the modulation of material properties. In this study, we demonstrate wafer scale growth of MoS_2 and WS_2 in a horizontal MOCVD reactor as part of the National Science Foundation's 2-dimensional Crystal Consortium. We use molybdenum hexacarbonyl, tungsten hexacarbonyl, and hydrogen sulfide precursors and grew MoS_2 at 9, 10, and 11 minutes at 50 torr reactor pressure. We also reduced the metal flow rate by 20% while increasing growth time. For WS_2 we grew for 12 and 15 minutes at 200 torr without varying the metal flow rate. Samples were characterized via Raman Spectroscopy and Atomic Force Microscopy to analyze the quality of the growth and bilayer coverages. Using imaging processing techniques in MatLab, we found that the percent of bilayer coverage of MoS_2 varied between 57% and 24%. For WS_2, the 15 minute growth yielded a fully coalesced monolayer with approximately 16% bilayer coverage while the 12 minute growth did not fully coalesce. Raman spectroscopy of the MoS_2 samples also revealed an average 21.4 cm^{-1} difference between the A1g and E2g phonon modes, confirming monolayer growth with varying percentages of bilayer coverage. These same layers were further characterized through tip-enhanced Raman spectroscopy (TERS) and kelvin probe force microscopy (KPFM). These techniques provided insight on chemical composition at the nanometer scale and the variation of the TMD material's work function across the layer surface respectively. Our results provide fundamental insights into the conditions for nucleation and growth kinetics of wafer scale 2-dimensional TMDs and explore the chemical and electrical consistency across samples grown via the MOCVD technique.

10:30 AM NM04.03.05

Autonomous Atomic Manipulation and Characterization in the STEM Kevin Roccapriore[1], Maxim Ziatdinov[1], Matthew G. Boebinger[1], Ondrej Dyck[1], Ayana Ghosh[1], Raymond R. Unocic[1] and Sergei Kalinin[2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Control over matter has allowed physics, condensed matter, and materials science communities to realize a wide range of properties useful in many fields and applications. Accessing control of nanometer and smaller scales allows to shape materials properties in fundamentally new and exciting ways. The scanning transmission electron microscope (STEM), like scanning probe microscopy (SPM), routinely enables direct visualization of matter at the atomic scale. The atom-sized electron probe in the STEM, however, also contains enough energy and momentum to structurally and chemically alter matter at the same atomic scale, where this electron-matter interaction is typically considered "beam damage." It is argued that understanding and harnessing this interaction to manipulate matter at atomic scales will allow a more complete design and control of materials.

While manipulation of matter at the level of single atoms has been demonstrated in both STEM and SPM, this has primarily been performed manually without reproducibility or useful precision. Beam-induced effects in the STEM have been notoriously difficult to control, and the ordinarily stochastic changes have also been challenging to characterize analytically via electron energy loss spectroscopy (EELS) or 4D-STEM methods.

Artificial intelligence is leveraged to guide the microscope towards both atomic fabrication and autonomous characterization. The first step towards accurate atomic manipulation is to obtain knowledge of the atomic landscape in as close to real time as possible, while the second step is instructing the electron beam where to go relative to these positions. The atomic coordinate extraction – from image data - must be performed both quickly and reliably. Several methods exist that can detect atoms, but here we use deep convolutional neural networks. However even though a trained neural network is fast, it, like other methods, usually requires fine tuning of several parameters to ensure a reliable extraction. The extra time this incurs cannot be exhausted during a live experiment; further, each new image might require different parameter tuning. To overcome this and ensure robust predictability, deep ensembles are used, which handle the issues - also encountered in self-driving vehicles - of so-called "out of distribution" shifts.

Given atomic coordinates, one can classify different atomic or defect classes based on mixture models, intensities, or graph analysis, which allows to experiment with beam-induced effects precisely at the single-defect level. Different strategies of beam control are demonstrated in both graphene and MoS_2 and are shown to produce structures that cannot be fabricated by any other means.
Meanwhile, characterization of atomic and mesoscale features in the STEM is largely carried out by operator intuition and expertise such that a small region of interest is selected for detailed analyses, e.g., EELS or 4D-STEM, by inspection of the structural image, i.e., the annular dark field (ADF) signal. For several reasons, including handling beam sensitive materials, autonomous exploration of a larger sample space via EELS or 4D-STEM is useful. Deep kernel learning is utilized here to develop and learn a relationship between image data (structure) and a physical response by either EELS or 4D-STEM (property). These structure-property relationships are constructed from scratch and on-the-fly, with no prior information being supplied to the model. In this way, a material system can be explored in a completely autonomous fashion, without operator bias and without imparting too much unnecessary dose to the specimen.

Therefore, in leveraging AI and deep learning routines, atomic fabrication and autonomous characterization are made possible in the STEM. In the former, beam-matter interaction is exploited, while in the latter, it is minimized to only what is necessary. Both schemes are explored, and the challenges and practical limitations are discussed.

10:45 AM NM04.03.06

Atomic-Scale Observation of Few-Layers MoSSe Devices for Biasing *via In Situ* Transmission Electron Microscope Hsin-Ya Sung[1], Yu-Lun Chueh[2] and Wen Wei Wu[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Tsing Hua University, Taiwan

Recently, two dimensional transition metal dichalcogenides (TMDs) have been widely applied in electronic devices because of their excellent electronic, optical and mechanical properties. Nowadays, due to the scaling demand of electronic devices, it is necessary to better investigate the performance of materials in electronic and optoelectronic devices. In this regard, electrical breakdown associated with material damage is a critical issue in device failure. In this research, the device behaviors of MoSSe samples prepared under different selenization temperatures are revealed *via* in-situ biasing experiments and recorded by transmission electron microscope (TEM) at the atomic scale. The crystalline atomic-layer MoSSe was synthesized through chemical vapor deposition (CVD) system and plasma-assisted chemical vapor reaction (PACVR) process, followed by transferring the as-grown samples onto specialized TEM electrical chips. The TEM characterization of initial sample was conducted for the basic understanding of as-grown MoSSe. The advanced *in situ* technique was employed to record the structural evolution during biasing. Furthermore, we utilized atomic resolution scanning transmission electron microscope (STEM) images to identify the propagation of cracks and voids. It is noted that the selenization temperature is the key factor of defect concentration on the surface, which further affect the mechanical property of MoSSe.

11:00 AM NM04.03.07
High-performance Ambipolar Dual-gate Transistors Based on Transition Metal Dichalcogenides for Logic Applications Xintong Li[1], Peng Zhou[2], Joseph Friedman[2], Deji Akinwande[1] and Jean A. Incorvia[1]; [1]The University of Texas at Austin, United States; [2]The University of Texas at Dallas, United States

Two-dimensional materials possess distinctive electrical and physical properties, providing great opportunities towards the next-generation semiconductor devices. Compared with unipolar transistors, ambipolar devices that allows both the electron and hole transport provide more flexibility in circuit applications. The potential of the ambipolar device can be maximized in a dual-gate structure, where one of the gates can tune the ambipolar transistor from p-type to n-type, or vise versa. The major benefit of these transistors is that due to the two independent gate inputs, the number of transistors needed in a circuit can be reduced. Previously, ambipolar dual-gate transistors based on low-dimensional materials such as graphene, carbon nanotube and transition metal dichalcogenides (TMD), and their application in logic gates, are demonstrated [1][2]. But the problem exists, for example, in the unsymmetric n- and p-branch transport, lack of ability to form logic gates that can be cascaded, inequivalent gate control and so on. Till now, a well-designed ambipolar transistor that can be used in cascadable, standard, non-pass-transistor logic circuits is never developed.
In this work we designed and fabricated high-performance ambipolar dual-gate transistors based on TMDs and demonstrated their applications in logic circuits. Through the hBN sandwiched structure, the well-engineered contacts for both electron and hole injection, and the control of threshold voltages, for the first time, the transistors have achieved simultaneously the correct logic input and output, low contact resistance, high on-off ratio, well-balanced p- and n-branch transport, and low hysteresis. We then connected the devices and formed logic gates such as XOR, NAND, etc. All gate stages are connected between a Vdd and Vss, to prevent the problems brought by other pass transistor logics. We found that the logic input and output of these gates are stable, and they can work in the same operation voltages ranges, which means these logic gates can be cascaded. The total number of transistors are reduced, comparing with the traditional CMOS technology. Then the ability of forming more complicated logic circuits is demonstrated through a full adder. This work shows the potential of 2D material based transistors, and paves the way of using 2D based ambipolar transistors in practical application of logic circuits.

11:15 AM NM04.03.08
Using Suspended Graphene to Limit Beam Induced Damage in Nanometer-Sized Samples Antoine Lainé[1], Matteo Amati[2], Luca Gregoratti[2] and Miquel B. Salmeron[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Elettra Synchrotron, Italy

Thin films and nanoparticles are ubiquitous components of many devices such as membranes for filtration or electrodes in electrochemical energy storage and reaction centers for catalysis. As the use of techniques based on high energy electron or x-ray probes for microscopy and spectroscopy is particularly relevant to study such materials operando, issues arise from material degradation by the probe radiation. Here, by using an x-ray and electron transparent graphene film as the sample support, we observe a remarkable reduction of the radiation damage in thin films. In such geometry, the amount of secondary electrons originating from the substrate vanishes, and thus the main source of damage disappears. Demonstration using highly focused x-ray beams evidences the capabilities of the technique, paving the way for the development of experimental setups with crucial damage control/reduction.

11:30 AM NM04.03.09
Self-Crosslinking of Graphene Oxide Sheets by Dehydration Haiyue Huang[1], Hun Park[2] and Jiaxing Huang[2]; [1]University of California, Los Angeles, United States; [2]Westlake University, China

Graphene oxide (GO) sheets have attracted increasingly high interest due to their relative ease of synthesis and water processability for a wide range of applications. Understanding how the sheets interact with each other is a crucial and foundational piece of knowledge guiding the production, processing, and use of GO in many applications. Here, we report that dehydration, such as by vacuum drying, triggers irreversible self-crosslinking of GO sheets and drastically alters their solution processability. Dehydrated GO films maintain structural integrity in water, and they can no longer redisperse as single layers even after agitation. At the bilayer level, dehydration fixes the stacked GO sheets together and prevents them from dissociation after sonication. Spectroscopical studies support the formation of new ester bonds, suggesting a condensation-esterification reaction between GO sheets. This new insight about a fundamental property of GO sheets should have broad implications in how the material should be processed and used.

Laser Shock Nano-Straining in 2D Materials Gary J. Cheng; Purdue University, United States

Straining nanomaterials to break their lattice symmetry is perhaps the most efficient approach toward realizing bandgap tunability. Graphene has a great potential to replace silicon in prospective semiconductor industries due to its outstanding electronic and transport properties; nonetheless, its lack of energy bandgap is a substantial limitation for practical applications. In this talk, a large-scale strain engineering technique to control the local strains in 2D materials and their heterostructures will be discussed. First, laser shock nanostraining will be introduced to generate three-dimensional (3D) nanostructures and thus induce local strains in the graphene sheet. The size dependent straining limit of the graphene and the critical breaking pressure will be discussed. Moreover, laser shock nanostraining induces modulated inhomogeneous local asymmetric elastic–plastic strains as results of 1-100 GPa-level shock loading at a high strain rate of 10^6–10^8 s^{-1}. Currently, due to the weak lattice deformation induced by uniaxial or in-plane shear strain, most strained graphene studies have yielded bandgaps <0.5 eV, laser shock nanostraining can induce tunable bandgaps in graphene of up to 2.1 eV. Finally, laser shock nanostraining will be discussed to controllably tune the interlayer distance between VdW heterostructures and generate strain coupling between layers. The strains in the 2D heterolayers, providing a simple and effective way to modify their optic and electronic properties.

2:00 PM NM04.04.02
Proton Beam Modifications on 2D TMDs—Optically Active Chalcogen Vacancies and Robust N-type Doping Haidong Liang, Yuan Chen and Andrew A. Bettiol; National University of Singapore, Singapore

Defect engineering of atomically thin semiconducting crystals is an attractive route to developing single photon sources and valleytronic devices. For these applications, defects with well-defined optical characteristics need to be generated in a precisely controlled manner. However, defect-induced optical features are often complicated by the presence of multiple defect species, hindering identification of their structural origin. Here, we report systematic generation of optically active atomic defects in monolayer MoS$_2$, WS$_2$, MoSe$_2$, and WSe$_2$ *via* proton beam irradiation. Defect-induced emissions are found to occur 100~200 meV below the neutral exciton peak, showing typical characteristics of localized excitons such as saturation at high excitation rate and long lifetime. Using scanning transmission electron microscopy, we show that freshly created chalcogen vacancies are responsible for the localized exciton emission. Density functional theory and GW-BSE calculations reveal that the observed emission can be attributed to transitions involving defect levels of chalcogen vacancy and the valence band edge state.
Besides the optically active property, the defects generated by proton irradiation also induce a robust n-type doping effect in 2D TMDs. For example, we demonstrated a reliable and long-time air stable n-type doping scheme with WSe$_2$ by proton irradiation. The irradiated WSe$_2$ remains an n-type semiconductor even after it is exposed to ambient conditions for a year. Localized ion irradiation with a focused beam can directly pattern on the sample to make high performance homogenous p-n junction diodes.
Controllable proton irradiation provides both optically active and N-type doping effects, which is also compatible with current CMOS processes, thus would be an ideal platform for future complementary high-performance electronics and optoelectronics applications.

2:15 PM NM04.04.03
Enhanced Robustness of Atomic Precision Devices under Accelerated Lifetime Testing Jeffrey A. Ivie[1], Connor Halsey[1], Jessica Depoy[1], DeAnna M. Campbell[1], Evan M. Anderson[1], Scott W. Schmucker[1], Daniel R. Ward[2,1], David Scrymgeour[1], Xujiao Gao[1] and Shashank Misra[1]; [1]Sandia National Laboratories, United States; [2]HRL Laboratories, LLC, United States

As transistor features move towards the atomic scale, the ability to study and design for atomic scale effects become critical for next-generation microelectronics. Atomic precision advanced manufacturing (APAM) of electrical devices, fabricated using hydrogen depassivation lithography in a scanning tunneling microscope (STM), offers a way to explore atomic scale physics with the ultimate degree of control. While almost all previous APAM work has focused on exploring applications in quantum physics, particularly with a focus on qubits, we have recently demonstrated successful integration of microelectronic-focused APAM devices within Sandia's 0.35-micron CMOS node [1]. However, demonstration of the compatibility of APAM material with CMOS at relevant operational temperatures and device drive current conditions is lacking.

To establish APAM + CMOS operational compatibility, we performed accelerated lifetime testing of both standard photolithographically patterned APAM delta layer devices (>5 µm width) as well as STM patterned APAM devices (<1 µm width). Variable width devices allow for testing at higher current densities along with connecting robustness results to a wide range of different application spaces (transistor channel, interconnect material, etc.). Analysis of the APAM devices shows that all but one device survived for several weeks at 300 °C at high current densities (minimum of 2.5 MA/cm^2) while all three implanted phosphorus samples failed under the same conditions [2]. Further characterization demonstrated that the failure mechanism was a result of the metal bond-wire interconnects used to package the devices, and not the APAM devices themselves. Modeling using Sandia's open-source TCAD code Charon validates that the current flow is tightly confined around the delta layer, resulting in an estimate of current density of >8 MA/cm^2, almost 10x higher than copper (~1 MA/cm^2 at 300 °C). Demonstration of the robustness of APAM devices relative to wire-bonds used to make device contacts coupled with the previous demonstration of APAM's integrability [1] with a CMOS process opens the door for utilizing APAM to enhance CMOS transistors along with providing wider manufacturing interest.

Wafer-Scale 2D Molecular Crystals with Highly Anisotropic Optical Response Tomojit Chowdhury[1], Fauzia S. Mujid[1], Ce Liang[1], Ariana Ray[2], Aurelie Champagne[3], Jeffrey B. Neaton[3], David A. Muller[2], Nathan Guisinger[4] and Jiwoong Park[1]; [1]Univeristy of Chicago, United States; [2]Cornell University, United States; [3]University of California Berkeley, United States; [4]Argonne National Laboratory, United States

Two-dimensional (2D) materials are poised for the atom-precise engineering of materials morphology, composition, and phase that has established them as platforms to investigate new physical, chemical, and quantum phenomena. Given the range of exciting physics and chemistries that these materials offer, realizing diverse 2D platforms is critical to push the frontiers of next generation materials and devices. Here, we introduce 2D molecular crystal (2DMC) composed of single organic molecules in an atomically flat geometry. We develop a gas phase synthetic technique to generate high quality, high fidelity molecular crystals with wafer-scale homogeneity. Room temperature scanning tunneling microscopy (STM) together with cross-polarized microscopy reveal "superatomic" unit cells within single crystalline domains as large as a few hundred microns. Optical imaging and spectroscopic characterization reveal significant optical anisotropy in terms of polarization and birefringence in the 2DMCs, which is attributed to the diverse superatomic unit cell geometries and compositions. Further optoelectronic and time-resolved photoemission studies will be discussed to substantiate the unique excitonic properties of the 2DMCs and their heterostructures. This work expands the state-of-the-art in 2D materials through the realization of atomically thin, wafer-scale molecular films for new molecule-based nanostructures and device fabrication.

Large-Scale Spontaneous Wrinkling of Polycrystalline Atomically Thin Films Jaehyung Yu, Colin Scheibner, Ce Liang, Vincenzo Vitelli and Jiwoong Park; The University of Chicago, United States

Wafer-scale atomically thin films are inherently polycrystalline, and therefore criss-crossed by defect laden grain boundaries. It is well understood that a single, isolated crystalline defect creates long range deformations in a thin film, much like an electron that sources an electric field. Yet, unlike Maxwell's equations, the elasticity governing a buckled sheet is nonlinear. Thus, when multiple defects are present, superimposing their undulations will not give the sheet's final shape. This poses a challenge for understanding the shape of atomically thin films when they are not confined to a substrate. Here we perform spatially resolved measurements of the wrinkling of monolayer MoS_2 in a relatively force free environement. In doing so, we directly investigate the relationship between grain size and emergent corrugations of single layer polycrystalline MoS_2. We show that polycrystallinity, even with free boundaries, gives rise to micron scale wrinkles. Using universal scaling properties of thin sheets, we rationalize the large-scale features of the topography, including wrinkle wavelength and amplitude. Though the wrinkles we observe originate from a network of topological defects, our continuum arguments depend only on average strain and grain size, and not on atomistic details. The scaling relations we obtain suggest guidelines for tailoring grain size for specific application requirements.

3:30 PM NM04.04.06
Defect Networks and Site Selective Deposition of 2D/3D Heterostructures Kate Reidy[1], Joachim Dahl Thomsen[1,2], Andrzej Zak[3], Vera Zarubin[1], Aubrey Penn[1] and Frances Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Los Angeles, United States; [3]Wroclaw University, Poland

Site selective deposition (SSD), in which substrate and deposition parameters are adjusted to allow growth in one region of a surface while avoiding growth in adjacent regions, is a promising strategy for circumventing the limitations of top-down fabrication processes and enabling etch free pattering of nanoscale features. Layered two-dimensional (2D) materials provide an excellent platform for SSD integration: their van der Waals surfaces are generally unreactive but exhibit strongly tuneable properties if heterogeneities are present. In particular, deliberate introduction of defects or other heterogeneous nucleation sites can control the diffusion and nucleation of materials grown on the surface. SSD of metals on 2D materials has been demonstrated at micrometer scales, but not at the length scales required in future devices. *Nano- and atomic- scale* guided deposition on 2D materials would meet three needs: etch-free selective deposition to form 2D/metal, 2D/dielectric, and 2D/semiconductor interfaces at specific locations; pushing the resolution limits of conventional lithography; and fabrication of structures that that require ultra-precise (<1 nm) alignment between structures, such as nanoscale interconnects, on-chip optical systems, and emerging quantum information sources.

Here, we explore the local structural properties and routes towards SSD for device-relevant 2D/3D Au/Ti interfaces using a combination of atomic resolution scanning transmission electron microscopy (STEM), *in situ* ultra-high vacuum (UHV) TEM, and monochromated high-energy resolution electron energy-loss spectroscopy (EELS). First, we demonstrate ultra-low nucleation density, single crystal, epitaxial Ti nanoislands using slow metal evaporation rates onto clean suspended 2D materials in UHV. We characterize the nucleation, epitaxy, island morphology and formation mechanism. We find that the island morphologies depend on the substrate compliance, such that thinner 2D substrates result in Ti islands that curve to accommodate strain, while thicker 2D substrates are less compliant and result in Ti islands with ordered arrays of dislocation networks. We then utilize these Ti islands as selective nucleation sites for Au metal deposition. We find 100% selectivity for Au nucleation under conditions where the substrate remains free of heterogeneous nucleation sites. We discuss the alignment and defect structures in Au grown on Ti and the stability of Au on the Ti surface on *in situ* heating. The importance of UHV conditions in the fabrication of these heterostructures is discussed. Lastly, we explore further routes towards SSD of tailored metallic nanostructures on 2D materials, such as ion beam patterning and utilizing printed nanoparticle seeds for UHV growth.

3:45 PM NM04.04.07
Isotropic Atomic Layer Etching of TiN by Oxidation to TiO_2 and Selective Etching of TiO_2 by SF_6 and H_2 Plasma Azmain A. Hossain[1], Haozhe Wang[1], David Catherall[1], Russ Renzas[2], Harm Knoops[2,3] and Austin J. Minnich[1]; [1]California Institute of Technology, United States; [2]Oxford Instruments, United Kingdom; [3]Technische Universiteit Eindhoven, Netherlands

We report isotropic plasma atomic layer etching (ALE) of titanium nitride (TiN) using sequential and self-limiting oxidation and etching steps. TiN is oxidized to TiO_2 via exposure to O_2 gas which is subsequently spontaneously etched by exposure to a H_2 and SF_6 plasma. The process exploits the selectivity of spontaneous etching of TiO_2 over TiN with the plasma. A 4:1 ratio of H_2:SF_6 is shown to be highly selective, etching TiO_2 but exhibiting negligible etching of TiN over 50 cycles. TiN ALE was observed at temperatures between 200°C and 300°C, with a maximum etch rate of 0.8 Å/cycle observed at 300°C, measured using ex-situ ellipsometry. After ALE, the etched surface was characterized using X-ray photoelectron spectroscopy and atomic force microscopy. These findings have relevance for applications of TiN in microwave kinetic inductance detectors and superconducting qubits.

Atomic Reconstruction in Trilayer Graphene Moiré Superlatices Isaac Craig[1,2], Madeline Van Winkle[1], Catherine Groschner[1], Kaidi Zhang[1], Nikita Dowlatshahi[1], Sinead Griffin[2] and Kwabena Bediako[1,2]; [1]Universiy of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Moiré superlattices formed from independently twisting trilayers of graphene have been proposed as an ideal model for studying electronic correlation. Multilayered moiré systems offer several advantages over their twisted bilayer analogs, including more robust and tunable superconductivity, a wide range of twist angles associated with flat band formation, and larger scale moiré patterns. Atomic reconstruction, which strongly impacts the electronic structure of twisted graphene structures, has been suggested to play a major role in the relative versatility of super-conductivity in trilayers. Despite this, reconstruction in graphene trilayers has been only probed using indirect measurements or those only applicable to exposed samples. Herein, we exploit an inteferometric 4D-STEM approach to obtain displacement and strain maps in a representative range of twisted trilayer graphene structures. This methodology correlates local intensity modulations to stacking order and allows us to selectively probe bilayer interfaces within the material. The resulting mechanism we present informs a more complete understanding of how atomic reconstruction scales with layer number in graphene moirés and modulates symmetries crucial for establishing superconductivity.

SESSION NM04.05: Poster Session: Advanced Manufacturing of 2D Materials at the Atomic Scale V

Nanofluidics: Transport In Chirality-Controlled Carbon Nanotube Porins (CNTPs) Sidi Zhao[1,2]; [1]University of California, Merced, United States; [2]Lawrence Livermore National Laboratory, United States

Carbon nanotubes (CNTs) with different chirality are great models to study electronic properties that influence ion transport through single-channel nanotubes. Based on band gap theory, CNTs in different chirality with different curvatures of tube surface may have different conductivity. Herein we report ion transport through chirality-separated pure (6,5), (7,4), and (7,5)/(8,4) CNT porins (CNTPs). Single channel conductance from chirality-pure, yet almost identical in diameter CNTPs indicates that electronic properties have a weak effect on ion transport. Furthermore, we measured ion transport through fluorescence ultrashort nanotubes (FUNs) – functionalized channels with defective walls. These channels have significantly lower conductance compared to the pure (6, 5) CNTPs. Besides, ions can successfully transport through CNTP dispersed by surfactants such as CHAPS and SDOC, the ion conductance of CNTPs is independent of the surfactant used to cut the CNTs.

Proximity Growth of Monolayer MoS$_2$ Films via Concurrent O$_2$ Etching and Sulfurization Benjamin Tan, Martha Serna, Sivasakthya Mohan, Yuqian Gu, Kenneth M. Liechti and Deji Akinwande; The University of Texas at Austin, United States

The synthesis of homogeneous monolayer molybdenum disulfide (MoS$_2$) thin films has been an important benchmark for enabling its usage in industrial scale electronic and optoelectronic devices. Recently, molecular O$_2$ has emerged as a reagent for scalable production of MoS$_2$ films through either gradual etching of an Mo source or evolution from MoO$_3$ preceding sulfurization. However, oxidation of MoS$_2$ and its precursors is not well understood and is a frequent subject of study. Here, we invert the order of traditional MoS$_2$ sulfurization to demonstrate that balancing the etch rate of partially formed MoS$_2$ films as opposed to an unreacted Mo source is an alternative pathway towards producing homogeneous monolayer MoS$_2$ films. Further, this growth enables adjacent regions of either multilayer or monolayer MoS$_2$ to be patterned dependent on whether the respective region was deposited with a Mo metal film or was left as exposed substrate. We study growth effects at 550 °C and 650 °C as well as different O$_2$ flow rates of 1 sccm and 5 sccm. This study suggests that MoS$_2$ formation through O$_2$ etching traverses two separate mechanisms based on the pristine quality of the partially formed MoS$_2$ source film. As suggested in theoretical studies, defect-filled MoS$_2$ lowers the activation energy of O$_2$ adsorption to 0.8 eV and leads to growth of monolayer-bilayer MoS$_2$ flakes. Alternatively, O$_2$ adsorption onto pristine MoS$_2$ raises the activation energy to 1.59 eV and generates monolayer MoS$_2$ films that spread homogeneously across a 1x5 cm area. The films were characterized as MoS$_2$ using Raman spectroscopy. XPS analysis also confirms peaks for MoS$_2$ that are shifted to higher energies due to the presence of trace MoO$_3$. This demonstrates that the joint adsorption of oxygen and sulfur species onto Mo is advantageous to the creation of the observed homogeneous monolayer MoS$_2$. Beyond this, Mo-O bonds present in the film could be a significant factor in increasing its photoluminescence compared to traditional MoS$_2$ syntheses.

5:00 PM NM04.05.04
Quasi-van der Waals Epitaxial Recrystallization of Gold Thin Film into Crystallographically Aligned Single Crystals Yunah Lee[1], Yunyeong Chang[1], Huije Ryu[1], Jong Hun Kim[1], Kenji Watanabe[2], Takashi Taniguchi[2], Miyoung Kim[1] and Gwan-Hyoung Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]National Institute for Materials Science, Japan

Heterointerfaces between two-dimensional (2D) materials and bulk metals determine the electrical and optical properties of their heterostructures. Although deposition of various metals on 2D materials were studied, there is still lack of studies on the interaction at the van der Waals (vdW) heterointerface between 2D materials and metals. Here, we quasi-van der Waals (qvdW) epitaxial recrystallization of a gold thin film into crystallographically aligned single crystals by encapsulation annealing of gold thin film with hexagonal boron nitride (hBN). When a polycrystalline gold thin film passivated with hBN was annealed, it was recrystallized into single gold crystals with planar shape and crystallographic alignment with hBN due to a strong interaction between the gold film and hBN at the heterointerface. This reflects that a weak vdW force at the heterointerface is sufficiently strong to induce epitaxial recrystallization. Using this method, we fabricated a gold nanocrystal array with the same crystalline orientation and smooth top surface. Our work demonstrates a new method for epitaxial recrystallization of bulk crystals and provides a deep understanding of the interaction at the vdW heterointerface of 2D materials and metals.

5:00 PM NM04.05.05
Multi-Printed MoS$_2$ Semiconductor and Source and Drain Electrodes Using Jet-Printing for TFT Application Thi Thu Thuy Can and Woon-Seop Choi; Hoseo University, Korea (the Republic of)

Recently, transition-metal dichalcogenides (TMDs) have attracted much attention as new materials for electronics devices, electrocatalysts, photocatalysts, sensors, batteries, and bio-applications. Most TMDs are two-dimensional (2D) materials with a single layer. Bonds between each layer are made up of Van der Waals bonds, while intra-layer atoms bind together as covalent bonds.

Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS$_2$ can be obtained from this method using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process. Even though there is sulfur in the precursors of the solution-process synthesis methods, supplementing the sulfur that is lost in the high-temperature CVD process is unavoidable.

Electrohydrodynamic (EHD) jet printing is a technique that uses electric fields to yield fluid flows for delivering solution/paste materials to a target substrate. EHD printing can create smooth areas or patterns with a large range of material viscosity, even with low-viscosity solutions or high-viscosity pastes, which are better by far than inkjet printing for this concern. Moreover, the merit of EHD jet printing is that MoS$_2$ TFTs can be patterned simply without using any shadow masks compared to other methods such as E-beam or thermal evaporation.

Directly printed transistors have been in the limelight due to low cost and an environmentally friendly technique. An electrohydrodynamic (EHD) jet printing technique was employed to pattern both MoS$_2$ active layer and Ag source/drain electrodes. Printed MoS$_2$ lines were patterned on a silicon wafer using a precursor solution and simple annealing, and the patterns were transferred on other SiO$_2$ substrates for TFT fabrication. On top of the patterned MoS$_2$, Ag paste was also patterned for source and drain electrodes using EHD jet printing. The printed TFTs had a high on-off current ratio exceeding 10^5, low subthreshold slope, and better hysteresis behavior after transferring MoS$_2$ patterns. This result could be important for practical TFT applications and could be extended to other 2D materials.

5:00 PM NM04.05.07
Realization of the Ideal vdW Contact Between Metals and Two-Dimensional Semiconductors Through Schottky Diode Gihyeon Kwon[1], Hyeon-Sik Kim[1], Kwangsik Jeong[2,1] and Mann-Ho Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Dong-Guk University, Korea (the Republic of)

Ideal van der Waals (vdW) metal contact with weak interaction can achieve high performance of the two-dimensional (2D) electrical and optical devices and stable interface states since it is possible to prevent Fermi level pinning (FLP) and interface defects occurring between 2D semiconductors and metals. Recently, there have been many reports to demonstrate ideal vdW metal contact by avoiding damage from metal deposition such as representative method of transferred metal contact. However, the transferred contact method through handwork technology is vulnerable from forming uniform and stable vdW interface. To overcome this limitation, we choose the vdW contact method using a selenium (Se) buffer layer that consisting of conventional fabrication processes. In this study, in order to explore the ideal vdW metal contact, we compare vdW metal contact, transferred metal contact and conventional metal contact (direct metal contact) in Schottky diode structure with graphite as 2D vdW bottom contact that can analyze difference of Schottky barrier height through rectification and photovoltaic effect. As a result, we derived that Se buffer layer method is the most suitable way to form stable and ideal vdW contact between 2D semiconductors and metal, which can prevent FLP. Using vdW Au and graphite contact, we fabricate tungsten diselenide (WSe_2) Schottky diode that exhibit excellent operation with ideality factor about 1, on/off ratio over 10^7 and coherent properties.

5:00 PM NM04.05.08
Measuring Seebeck Coefficient of High Resistance 2D $PtSe_2$ Thin Film by Annealing Process Minjeong Kim, No-Won Park, Gil-Sung Kim, Min-Sung Kang, Chanho Park and Sang Kwon Lee; Chung-Ang University, Korea (the Republic of)

Seebeck coefficient serves as an important indicator for understanding the thermoelectric (TE) properties. In order to derive thermoelectric properties, it is inevitable to measure the exact Seebeck coefficient. However, in certain cases, it is very difficult to evaluate Seebeck coefficient of a 2D film with a large area when the electrical resistance is extremely large. Here, we report a simple way to measure the in-plane Seebeck coefficient of the 2D transition metal dichalcogenide (TMDC) film, whose electrical resistance is over 2 MW, through two-step thermal annealing process. By the two-step annealing at 573 K in $PtSe_2$ film on sapphire substrate, it is possible to obtain the effect in two ways, first, between the 2D TMDC layers, and second, interface of metal and film. As a result, we observe the electrical resistance is lowered to ~400 kW and the Seebeck coefficient is also measurable, and its value is exceeding ~160 mV/K, which is a 400% improvement compared to the single-crystalline bulk of $PtSe_2$. In addition, it is confirmed that the Seebeck coefficient of the annealed samples are independent of the top electrode materials. We discuss the necessity of annealing process in measuring Seebeck coefficient of having high resistance 2D $PtSe_2$ films by atomic crystallographic characteristics and contact resistance between metal and $PtSe_2$ film. Our finding is an important accomplishment in measuring and understanding the Seebeck effect and provide a promising guideline with a high TE property in 2D TMDC material.

5:00 PM NM04.05.10
Thermoelectric Properties of the Thickness-Modulated $PtTe_2$ Thin Films Hyeok-Jun Kwon, Si-Hoo Kim, Min-Sung Kang, Jae Won Choi, Yun-Ho Kim, Jung-Min Cho, Minjeong Kim, Chanho Park, No-Won Park, Gil-Sung Kim and Sang Kwon Lee; Chung-Ang University, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) -based homo- and hetero-structures result in unusual route to drastically increase the Seebeck coefficient through the interface-induced Seebeck effect. Such intriguing properties have led to us to study the in-plane Seebeck coefficient and electrical conductivity of thickness-controlled a relatively new class of metallic 2D TMDCs, 2D platinum ditelluride ($PtTe_2$) thin films. We followed a series of processes, including a simple tellurization of the Pt thin films with ~5, ~10, ~20, and ~30 nm-thick and a wet chemical transfer on sapphire substrates, to measure in-plane thermoelectric properties of the 2D $PtTe_2$ thin films. We observe the higher in-plane Seebeck coefficient and power factor of ≥ 3.0 μV/K and ≥ 16.0 μW/mK^2 in the thicker 2D $PtTe_2$ (≥ 20 nm) films, which is related to the more semimetallic transition as increasing $PtTe_2$ film thickness. These in-plane TE properties of the thickness-modulated 2D $PtTe_2$ thin films that are anticipated to offer an alternative approach for fabricating high-efficiency TE devices comprising vertically stacked 2D/2D hetero-structures (i.e., $PtTe_2/MoS_2$ and $PtTe_2/PtSe_2$)

5:00 PM NM04.05.11
Crystal Structure Identification and Application of Type-II Red Phosphorus Donggyu Kim[1], Jun-Yeong Yoon[1,2], Yangjin Lee[1], Dong Gun Oh[3], JinKyun Kim[4], Chae Un Kim[4,2], Young Jai Choi[1], Yanhang Ma[5] and Kwanpyo Kim[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]Samsung Electronics, Korea (the Republic of); [4]UNIST, Korea (the Republic of); [5]ShanghaiTech UniversityiTech University, China

Red phosphorus (RP) is one of the allotropes of phosphorus and has many structural phases. Type-I RP is amorphous, and other types (type II, III, IV, and V) are known to be crystalline phases. The structures of Type-IV (fibrous RP) and Type-V (Hittorf's phosphorus) have been identified through previous experiments, but the structures of Type-II and Type-III have yet to be reported. Here we unravel the crystal structure of type-II RP by complementary structure characterization techniques via powder X-ray diffraction, 3D electron diffraction, and atomic-resolution scanning transmission electron microscopy (STEM) imaging. The type-II RP crystals were synthesized by the chemical vapor transport method and identified through powder XRD and Raman spectroscopy in comparison with previous literature. From our study, we successfully identify that type-II RP has approximately 250 phosphorus atoms in a triclinic unit cell. Moreover, STEM imaging clearly confirms the helical tubular structure is the building block of type-II RP. The electrical properties of type II RP toward optoelectric device applications are also experimentally verified.

5:00 PM NM04.05.12
Surface Modification of Molten Salt Etched Ti3C2Tz MXene by Annealing and their Tribological Evaluation Kailash Arole, Stefano Micci-Barreca, Swarnima Athavale, Jodie Lutkenhaus, Miladin Radovic, Hong Liang and Micah Green; Texas A&M University, United States

The new class of two-dimensional (2D) material, "MXene," has displayed state of the art of performance in energy storage, membranes, electromagnetic shielding, and chemical sensors. To further improve the performance of MXenes for diverse applications, there is a need to develop a method for the alteration of surface properties of MXene. Theoretical studies suggested that manipulation of the MXene surface termination (such as =O, -Cl, -F, -OH) strongly alter their functional properties; however, experimental control of the MXene surface termination is still in the developmental stage. Here, we demonstrated that the terminal groups of salt-etched $Ti_3C_2T_z$ MXene surface can be removed by annealing under an inert atmosphere. The removal of terminal groups of MXene was confirmed by XRD, EDS, and XPS measurements. The free active sites available after the annealing can be re-functionalized by a varied species. In this work, the annealed $Ti_3C_2T_z$ were re-functionalized by -OH groups and (3-Aminopropyl) triethoxysilane (APTES), which FTIR confirmed. The surface-modified $Ti_3C_2T_z$ were utilized as a solid lubricant showing about a 50 % reduction in friction. This paper discusses an effective approach to alter the surface functionalization of MXene, thus providing a way to utilize surface-dependent properties.

5:00 PM NM04.05.14
High Quality 2D α-MoO3 Microcrystals Produced by Laser Processing María Eva Nieto Piñero[1], Christian Lanza[2], Javier Martín Sánchez[2], Fernando Chacón[1], Beatriz Galiana[3], Isabel Muñoz Ochando[4], María del Sol López de Andrés[5] and Rosalia Serna[1]; [1]Instituto de Óptica Daza de Valdés, Spain; [2]Universidad de Oviedo, Spain; [3]Universidad Carlos III, Spain; [4]Instituto de Ciencia y Tecnología de Polímeros, Spain; [5]Universidad Complutense de Madrid, Spain

2D-Transition Metal oxides (TMOs), although less studied than the well-known 2D transition metal dichalcogenides(2D-TMCs) are appealing due to some specific advantages. Like the TMCs they are semiconductors, however they are less contaminant and offer a large potential for tuning their electro-optical properties by varying their stoichiometry. In particular, MoO_3 is transparent and shows a wide bandgap (>3 eV) and a high dielectric constant k ~ 500. Additionally, orthorhombic α-MoO_3 possesses the well-known layered crystal structure of MoO_3 which offers the possibility to create two dimensional (2D) morphologies.[1] In this context, 2D MoO_3 has shown extraordinary properties such as anisotropic polariton propagation,[2] and is an ideal material for electronic applications for high power electronics and short wavelength optoelectronics.

Currently most of the work in 2D-semiconductors is still made using small flakes obtained from mechanically exfoliated single crystals, however there is no doubt that it will be advantageous to deposit large 2D-strucutres as this will have tremendous impact both for the manipulation an integration of these materials.[3] In context we show the successful preparation of nanometer thick thin films formed by 2D MoO_3 crystals by a pulsed laser deposition-based process that starts with the deposition in vacuum from a MoO_3 target of dense, amorphous and continuous substoichimetric MoO_{3-X} layers. Subsequently, the films are annealed in air up to 300 C while following the evolution of their optical properties in-situ in the UV-VIS wavelength region by spectroscopic ellipsometry. When the temperature reaches 250 C a clear change in the optical properties starts that is related to the films crystallization. Analysis of the optical properties shows how the initially absorbing films with a metallic-like behavior after the annealing become transparent in the NIR and VIS regions, and shows a band gap >3 eV. This optical change is related to the formation of large rectangular micron size α-MoO_3 single crystals with a thickness of the order 10 nm easily observable by optical microscopy. A full characterization of the morphology, structure and stoichiometry has been confirmed by X-ray diffraction analysis, Raman spectroscopy, AFM and transmission electron microscopy. We will show the distinct fetures of the measured dielectric constant of the 2D MoO_3 microcrystals and compare them to that of the bulk in terms of defects and lattice stress. Finally, we analyze the implications for different optoelectronic applications.

Improved In-plane Seebeck Coefficient in $PtTe_2/MoS_2$ Hetero-junction Structure Jung-Min Cho, Si-Hoo Kim, Minjeong Kim, Hyeok-Jun Kwon, Chanho Park, Jae Won Choi, Yun-Ho Kim and Sang Kwon Lee; Chung-Ang University, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDc) is rapidly emerging as a material for thermoelectric (TE) devices. The energy conversion efficiency of the thermoelectric materials is figure of merit, $ZT=PF\times T/\kappa$ (where $PF=S^2\times\sigma$, PF is power factor, T is absolute temperature, κ is thermal conductivity, S is Seebeck coefficient, σ is electrical conductivity). In order to achieve a high ZT, it is important to obtain a high PF, and a low κ. Except for T and κ, it is important to improve $PF=S^2\times\sigma$. Unfortunately, Seebeck coefficient and electrical conductivity are through trade-off relations. In this report, we develop a $PtTe_2/MoS_2$ hetero-junction structure to break this trade-off relationship. The 2D $PtTe_2$ and MoS_2 films are synthesized by using low-pressure chemical vapor deposition (LP-CVD) method. The 2D $PtTe_2$ film exhibits a semi-metallic property with low resistance (≤ 2 kΩ), whereas the MoS_2 is considered as an insulator with high resistance (≥ 10 MΩ). We prepared five sets of samples, including $PtTe_2$ (5-nm), $PtTe_2$ (5-nm)/MoS_2 (7-nm), $PtTe_2$ (5-nm)/MoS_2 (7-nm)/MoS_2 (7-nm), $PtTe_2$ (5-nm)/MoS_2 (21-nm), and $PtTe_2$ (5-nm)/MoS_2 (21-nm)/MoS_2 (21-nm). As a result, we observe that the in-plane Seebeck coefficient for $PtTe_2$ (5-nm)/MoS_2 (7-nm)/MoS_2 (7-nm) hetero-junction structure is -19 μV/K at 300K. It indicates an increase of ~200% compared to that of the $PtTe_2$ (5-nm) thin film. Also, the electrical conductivity (5.3 kS×cm) is improved by ~170%. Consequently, the power factor (190 $\mu W/K^2m$) is improved by ~720%. These findings represent that the 2D TMDc hetero-junction structures have good advantages in improving the power factor in future TE applications.

Two-Dimensional Titanium Nitride ($Ti_4N_3T_x$) MXene—Synthesis, Characterization and EMI Shielding Effectiveness Tufail Hassan, Aamir Iqbal and Chong Min Koo; Sungkyunkwan University, Korea (the Republic of)

Two-dimensional transition metal carbides/carbonitrides/nitrides also known as MXenes are promising candidates for many applications due to their high electrical conductivity, mechanical flexibility, surface tunability, and easy processability. Carbide and carbonitride MXenes have been explored for multiple applications, however, a few reports are available on nitride MXenes due to higher formation energy and poor stability against etchant, typically HF. In this work, we optimize synthesis conditions of $Ti_4N_3T_x$ MXene by using molten salt etching method in air environment. Successful synthesis of $Ti_4N_3T_x$ MXene was verified by XRD, XPS, SEM, TEM, and AFM techniques. Moreover, freestanding $Ti_4N_3T_x$ films were obtained by vacuum-assisted filtration which exhibit 99.99% shielding efficiency at 150 μm thickness. Electrical and electronic properties of $Ti_4N_3T_x$ can be tailored to expand areas of applications of nitride MXenes.

Study of a Facile Cerium Oxide Nanoparticles Hydrothermal Synthesis by Ceric Ammonium Nitrate Yifei Fu, Craig J. Neal, Elayaraja Kolanthai, Udit Kumar and Sudipta Seal; University of Central Florida, United States

Cerium oxide nanoparticles (CNPs) are a well-known functional material with broad applications in catalysis, gas sensor, and nanomedicine due to their unique shape-dependent properties. In recent years, solutions-based, sol-gel, and template-assisted synthesis routes have been explored for CNPs synthesis. Among these methods, hydrothermal synthesis has been considered one of the most effective and scalable routes thanks to its merit of single-step, one-pot synthesis. Regarding hydrothermal synthesis, cerium (III) nitrate/chloride/sulfate, sodium hydroxide, and ammonium hydroxide are the most commonly used precursor and oxidizers in CeO_2 hydrothermal synthesis. However, the application of the nanoparticles synthesized from a harsh high-pH alkaline synthetic environment usually suffers from vigorous nanoparticle aggregation, which could severely affect their performance.
In this study, we report a facile hydrothermal synthesis method to fabricate cerium oxide nanoparticles with different shapes. The ceric ammonium nitrate (CAN) was used as a cerium precursor to synthesize a highly dispersed CNPs in a low-pH acidic environment to obtain a cubic fluorite structure with narrow size distribution. The octahedron shape of CNP was synthesized by introducing only CAN into the aqueous precursor. The strong shape transformation of CNPs from octahedron to truncated octahedron to cubical is achieved by controlling the introduction of acetic ion which is done by varying the concentration between sodium acetate and acetate acid in precursor. CNP synthesized in pH >10 environments was considered a control in this study to compare the physiochemical properties difference between CNPs synthesized in acidic or alkaline precursor environments. One of the key properties of CNPs is its cyclic change of redox potential Ce^{3+}/ Ce^{4+} on its surface. Hence the variation in the morphology of CNPs changed its redox potential, which was measured and analyzed using X-Ray photoelectron spectroscopy. CNP's change in size and shape affects its superoxide dismutase activity (SOD). The result, which showed better SOD activity, will be studied for their application in biomedical therapy.

5:00 PM NM04.05.18
Patterned Growth of Vertical van der Waals Heterostructure by Strain Modulation Jaewoong Joo, Yeonjoon Jung, Seong Chul Hong, Jin Woo Kim and Gwan-Hyong Lee; Seoul National University, Korea (the Republic of)

Van der Waals (vdW) heterostructures of transition metal dichalcogenides (TMDs) have attracted great interests because a variety of combinations in vdW heterostructures provide a platform to explore novel physics and fabricate electronic devices with superior performance. In this regard, effective methods for large-scale growth and patterning of vdW heterostructure are required. Here, we report a patterned growth method of vertical MoS_2/WS_2 heterostructure by controlling nucleation sites by strain. We generated a large strain in the local region of growth substrate, WS_2, by transferring it on a patterned SiO_2 substrate with etched steps. When MoS_2 was grown by chemical vapor deposition (CVD) on the WS_2, the strain-concentrated regions of WS_2 serve as favorable nucleation sites for MoS_2. Therefore, the vertical vdW heterostructure of MoS_2/WS_2 was successfully grown at desired positions. Our work shows a novel way to control nucleation of 2D materials by strain and to selectively produce the vertical vdW heterostructure at the patterned areas.

5:00 PM NM04.05.19
Oxygen Species Role in the Nitrogen Doping of N-rGO from GO José M. Ruiz-Marizcal[1,2], David Dominguez[2], Uriel Caudillo-Flores[2], Gabriel Alonso-Nuñez[2] and Jose M. Romo-Herrera[2]; [1]Centro de Investigación Científica y de Educación Superior de Ensenada, Mexico; [2]Universidad Autónoma de Baja California - Centro de Nanociencias y Nanotecnología, Mexico

Graphene is a nanostructure of great interest due to its extraordinary properties such as high surface area, high thermal conductivity, high mobility of charge carriers and excellent mechanical properties. However, the chemical stability of Graphene causes it to be a very inert material in chemical interactions with its environment and therefore of little catalytic activity. However, Nitrogen-doped Graphene has emerged as a great alternative to metal catalysts due to its catalytic properties. The charge distribution of the Carbon atoms is influenced by the neighboring-Nitrogen atoms doping the material, which induces active regions on the Nitrogen-doped Graphene (N-rGO) surface. These regions or active sites, together with its property as a good electrical conductor, allow it to participate in electrocatalytic reactions of great interest such as: the oxygen reduction reaction (ORR) **[1]**, the iodide reduction reaction (IRR) **[2]** or charge storage; which are essential for fuel cells, dye-sensitized solar cells (DSSC), supercapacitors or Metal-Air batteries.
These types of applications require considerable amounts of material, so it is vital to implement and understand the mechanisms involved in scalable treatments to achieve N-doping. In this sense, thermal treatments as a post-synthesis method correspond to a simple and easily scalable technique. Furthermore, it is well known that Nitrogen atoms can be incorporated into the sp^2 Carbon lattice in different configurations: pyridine nitrogen, graphitic nitrogen, pyrrolic nitrogen or even as oxidized nitrogen species **[1-2]**. However, each of these configurations or Nitrogen species may have different roles in the reactions of interest **[1]**; therefore, being able to modify or modulate the proportion between the Nitrogen species present in the N-rGO would be very useful.
The present work analyzes in detail the doping of Graphene with Nitrogen through post-synthesis thermal treatments in an inert atmosphere, using Graphene Oxide (GO) as a precursor, seeking to understand at atomic level and propose a reaction mechanism. Special emphasis has been placed on the role of oxygen species present in GO as precursor and its importance in the incorporation of Nitrogen atoms into the N-rGO network. This analysis has been carried out using different sets of samples with a systematic monitoring of their physico-chemical and structural properties using X-ray photoelectron spectroscopy (XPS), thermogravimetric analysis (TGA), Raman spectroscopy, X-ray diffraction (XRD), optical microscopy and atomic force microscopy (AFM). Even more, it is shown how the temperature in a second thermal treatment on the N-rGO obtained, plays a key role to modify or modulate the proportion of the different Nitrogen species present in the final N-rGO.

5:00 PM NM04.05.20
Ultra-High Vacuum Molecular Beam Synthesis of 2D Molybdenum Telluride ($MoTe_x$) Grown on Epitaxial and Non-Epitaxial Substrates Ossie Douglas, Quang Ho, Elis Daniela Zamora Alviarez, Md Rubayat-E Tanjil, Zhewen Yin, Daiyue Wei, Muhammad Shahbaz Rafique and Mike C. Wang; University of South Florida, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDCs), such as molybdenum tellurides ($MoTe_x$), exhibit optoelectronic and physicochemical properties strongly dependent on the material crystalline structure and polymorphic phase. Although the phase-dependent properties of 2D $MoTe_x$ are conducive for additional degrees of freedom of control at the device level, synthesis of large-area, phase-pure crystals is challenging due to the small ground-state energy differences between the different polymorphs. While established methods in synthesizing and/or isolating 2D $MoTe_x$ have enabled fundamental studies of their unique properties, they are limited in their control over crystallinity, stoichiometry, and manufacturing scalability. This work focuses on the deterministic synthesis of 2D $MoTe_x$ on epitaxial, van der Waals epitaxial, and non-epitaxial substrates via ultra-high vacuum (UHV) molecular beam "epitaxy" (MBE) and combines *in situ/in operando* and *ex situ* characterization techniques.

5:00 PM NM04.05.21
Developing High-Pressure Techniques for Controlling Twisted Trilayer Graphene Alexander Sanchez[1], Manish Kumar[1], Kenji Watanabe[2], Takashi Taniguchi[2] and Matthew Yankowitz[1,1]; [1]University of Washington, United States; [2]National Institute for Materials Science, Japan

Research into two-dimensional van der Waals (vdW) materials continues to flourish due to the large selection of crystals available. In stacks of vdW materials, the interlayer interactions prove to be a crucial variable in determining the electronic properties of a given structure. It has been shown that using hydrostatic pressure, the interlayer coupling can be finely tuned in magic angle twisted bilayer graphene (MATBG) to induce superconductivity, which is strong evidence of an induced electronic flat band, effectively simulating changing the twist angle in the heterostructure after it has been fabricated. Magic angle twisted trilayer graphene (MATTG) could prove to be an interesting platform to further study the effects of tuning interlayer coupling via hydrostatic pressure, owing to the fact that it has been shown to have a similar flat band to MATBG. Using MATTG devices inside a pressure cell loaded with hydrostatic pressure on the order of a few GPa, superconductivity could potentially be induced in an MATTG device which otherwise did not exhibit correlated phases owing to a relative twist angle that deviates too far from MATTG's magic angle of ~1.6°. Such a result could further confirm both the utility of hydrostatic pressure as a method of changing interlayer coupling, and TTG as a tunable heterostructure.

5:00 PM NM04.05.22
Oxycarbide MAX and MXenes Identification Using Ultra-Low Energy Secondary Ion Mass Spectrometry Mark Anayee[1], Pawel P. Michilowski[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Institute of Microelectronics and Photonics, Poland

The MXene family of two-dimensional transition metal carbides and nitrides already includes ~50 members with distinct numbers of atomic layers, stoichiometric compositions and solid solutions, in-plane or out-of-plane ordering of atoms, and a variety of surface terminations. MXenes have shown properties that make them attractive for applications ranging from energy storage to electronics and medicine. Although this compositional variability allows fine-tuning of the MXene properties, it also creates challenges during the analysis of MXenes because of the presence of multiple light elements (for example, H, C, N, O, and F) in close proximity. Here, we show depth profiling of single particles of MXenes and their parent MAX phases with atomic resolution using ultralow-energy secondary-ion mass spectrometry. We directly detect oxygen in the carbon sublattice, thereby demonstrating the existence of oxycarbide MXenes. We also determine the composition of adjacent surface termination layers and show their interaction with each other. Analysis of the metal sublattice shows that Mo_2TiAlC_2 MAX exhibits perfect out-of-plane ordering, whereas Cr_2TiAlC_2 MAX exhibits some intermixing between Cr and Ti in the inner transition metal layer. Our results showcase the capabilities of the developed secondary-ion mass spectrometry technique to probe the composition of layered and two-dimensional materials with monoatomic-layer precision.

***In Situ* High Resolution Liquid Cell Transmission Electron Microscopy Study of 2D Nanomaterials Formation** Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Two-dimensional (2D) materials have attracted significant interests due to the large surface-to-volume ratio, electron confinement, and various surface-enhanced applications. Although significant advances have been made in the synthesis of 2D nanomaterials, an understanding of the formation mechanisms is crucial for the future success in design, synthesis, and applications of novel 2D materials. We use liquid cell Transmission Electron Microscopy (TEM) to study model 2D systems at the atomic resolution. Our direct observations allow to uncover the nucleation, formation of intermediates, and dynamic structural evolution leading to 2D nanostructures. Assisted with theoretical calculation, the underlying mechanisms have been revealed. In this talk, progress made in our recent in situ studies of 2D nanomaterials formation at the atomic level will be presented, including the growth of 2D nanosheet with nanoclusters as the building blocks, and the dynamic formation of 2D molecular crystals.

Epitaxial Growth of Single Crystalline Hexagonal Boron Nitride on Vicinal Germanium (110) for Atomically Clean Assembly of Twisted Multilayers Ju-Hyun Jung[1,2], Seong-Jun Yang[1,2] and Cheoljoo Kim[1,2]; [1]Institute for Basic Science (IBS), Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Atomically-thin hexagonal boron nitride (hBN) has gained attentions as a material platform for broad applications in nano-photonics and electronics, including near-infrared waveguide, deep-ultraviolet emitter and dielectric film. Recent studies show that the dielectric and electronic properties of multilayers (ML) can be tuned with control of the interlayer rotational angle, θ. While layer by-layer assembly of singly crystalline hBN can enable fabrications of uniform, polytypical structures, large-scale films for atomically clean assembly is still missing. Here, we report the epitaxial growth of single-layer (SL) hBN fims on wafer-scale, which can be exfoliated and assembled by van der Waals interactions. Chemical vapor deposition on a vicinal (110) surface of germanium with miscut toward the <001> direction results in SL films with a single crystallographic orientation. Density functional theory calculations show that it is energetically favorable for the nitrogen-terminated zig-zag edges of hBN to be aligned to the step edges along the <110>, guiding the unidirectional growth. The SL hBN can be repeatedly grown on a same substrate after mechanical exfoliations, and assembled into twisted MLs with controlled θ. Optical absorption spectra show a clear θ-dependency, suggesting effective modulations of the band structures of hBN. Furthermore, the ML films can be integrated with a semiconducting MoS2 channel with tunable dielectric properties by θ.

Scalable, One-Pot, Facile Synthesis of Carbon-Doped TiO_2-Based 1D Nanofilaments and 2D Flakes, Their Properties and Potential Applications Hussein Badr and Michel Barsoum; Drexel University, United States

Two-dimensional (2D) materials, which possess atomic or nanometer thickness and infinite planner dimensions, thrive on the rich variety of features and properties that are vastly distinctive from their bulk counterparts. Conventionally, bulk synthesis of 2D materials has predominantly been through selective etching of layered solids. Herein and for the first time, we convert – near ambient conditions – a dozen of cheap, earth-abundant, water-insoulble precursors into one-dimensional (1D) nanofilaments than self-assemble into 2D flakes. In that, the precursor is simply heated in tetramethylammonium hydroxide aqueous solution at 50 -80 ° C for tens of hours. The structure, composition, oxidation state, and morphology of the resulting sheets are resolved by density functional theory, X-ray diffraction, X-ray photoelectron, electron energy loss, Raman, X-ray absorption near edge structure spectroscopies, atomic force microscope, scanning, transmission and high-resolution transmission electron microscopies and selected area diffraction. The resulting flakes showed enhanced electrochemical performance as cathodes in both Li-ion battery and Li-S battery. They also found to be biocompatible to human cells but fatal to come types of cancer cells, thus showing potential in biomedical applications. The developed synthesis protocol of 1D and 2D materials in bulk-scale at near ambient conditions is paradigm shifting and will undoubtedly open new and exciting avenues of research and applications.

10:15 AM NM04.06.06
Synthesis and Chemistry of Two-Dimensional Transition Metal Carbides (MXenes) Mark Anayee, Christopher E. Shuck, Mikhail Shekhirev, Ruocun (John) Wang and Yury Gogotsi; Drexel University, United States

The family of two-dimensional (2D) transition metal carbides and nitrides (MXenes) has grown to encompass numerous structures and compositions. MXenes have shown properties that make them attractive for applications ranging from energy storage to electronics and medicine, including high electrical conductivity, redox-active surfaces, and plasmonic behavior. MXenes are typically produced through topochemical etching of atomically thick layers from precursor layered MAX phases using corrosive aqueous etchants. However, the harsh synthesis conditions lead to various defects in the MXene lattice that make them susceptible to degradation and limit their practical storage, distribution, and application. Herein, we investigate the chemistry of the precursor MAX phases and demonstrate the existence of oxycarbides; and explore the influence of MAX stoichiometry on the chemical and thermal stability of the resulting MXenes. We also probe the mechanism and kinetics of the MAX etching reaction for MXene synthesis using in situ analytical and microscopic techniques and demonstrate the influence of critical etching parameters on the structure, chemistry, and properties of the resulting MXenes. We further develop kinetic models that allow prediction of the optimal synthesis conditions, and which make the synthesis more scalable, environmentally friendly, and efficient.

Probing Aluminum-Oxo 2D Cluster Assembly Pathways to Gibbsite Nanoplates Xin Zhang, Ying Chen, Sebastian T. Mergelsberg, James J. De Yoreo, Carolyn Pearce and Kevin Rosso; Pacific Northwest National Laboratory, United States

Aluminum is the third-most abundant element in Earth's crust. As a result, aluminum hydroxide polymorphs such as gibbsite and bayerite are abundant minerals in soils and dominate aluminum ores. They have also been widely used as adsorbents, fire retardants, coatings, catalysts, and luminescence powders, as well as comprising important precursors to various alumina products. Understanding the crystallization pathways of the aluminum hydroxide polymorphs is thus important to geochemistry, environmental science, energy storage, catalysis, biomedicine, industrial processing, and even nuclear waste treatment. Here we use *in situ* magic angle spinning nuclear magnetic resonance (MAS-NMR), scanning electron microscopy (SEM), scanning/transmission electron microscopy (S/TEM), atomic force microscopy (AFM), small angle X-ray scattering (SAXS), X-ray absorption spectroscopy (XAS), electrospray ionization (ESI)-mass spectrometry, X-ray diffraction (XRD), and X-ray pair distribution function (PDF) techniques to probe the nucleation and crystal growth mechanisms of gibbsite nanoplates in detail. By focusing on understanding the role of aluminum coordination change dynamics from tetrahedral in solution to octahedral in solids and vice versa, and by quantifying intermediate polyoxoaluminate cluster formation, some unifying principles governing these transformations emerge. Furthermore, various advanced techniques reveal the transformation and assembly of aluminum-oxo 2D clusters during the hydrothermal process, which indicate cluster assembly pathways to gibbsite nucleation and crystal growth. These findings are important for developing new methods for morphology and size-controlled synthesis of 2D aluminum hydroxide materials and may aid in the design of novel metal oxide 2D materials.

2:00 PM NM04.07.02
Spin Defects and Blue Quantum Emitters Generated by High Energy Ion Irradiations in hBN Haidong Liang, Yuan Chen, Chengyuan Yang, Goki Eda and Andrew A. Bettiol; National University of Singapore, Singapore

Recently the negatively charged boron vacancies (V_B^-) in hexagonal boron nitride (hBN) have been shown as spin defects that have great potential in quantum sensing. However, so far the sensitivity is limited by either photoluminescence (PL) brightness or the optically detected magnetic resonance (ODMR) contrast, and linewidth. In this work, we demonstrate the generation of these spin defects using high energy helium ion beams and perform ODMR measurements with different laser and microwave powers. The spin defects generated by high energy helium ions exhibit a high PL brightness and ODMR contrast while keeping a small linewidth, hence a good sensitivity. By comparing different fluences of helium irradiations, we determine an optimal fluence which is sufficient in creating spin defects without damaging the overall crystal lattice structure. With this optimal fluence, we can obtain a high signal-to-noise ratio ODMR spectrum with an accurate measurement of zero field splitting frequency, and a best sensitivity as ~2.55μT/sqrt (Hz). Moreover, with a focused beam, we can deterministically create such spin defects with nanometer precision.
Hexagonal boron nitride (hBN) has been a centre of interest due to its ability to host several bright quantum emitters at room temperature. However, the identification of the observed emitters remains challenging due to spectral variability as well as the lack of atomic defect structure information. In this work, we report two new blue quantum emitters with zero phonon line (ZPL) centred around 460 nm and 490 nm in hBN powders. We further demonstrate that the new emissions can be created by high temperature annealing or high energy ion irradiation in exfoliated hBN flakes. Scanning transmission electron microscopy (STEM) reveals that the dominant defect structures present in ion irradiated sample are vacancy type and adatom (intercalant) type. Through first principle GW-BSE (Bethe-Salpeter equation) calculation, we attribute the observed emissions at 460nm and 490nm to originate from boron intercalant and nitrogen intercalant respectively. Our results not only discover a new group of blue quantum emissions in hBN, but also provide an insight on the physical origin of the emissions by correlating the emission wavelength with local atomic structures in hBN.

2:15 PM NM04.07.03
Molybdenum Blues with Tunable Light Absorption Synthesized by Femtosecond Laser Irradiation of Molybdenum Trioxide in Water/Ethanol Mixtures Fan Ye[1,1,2], Ahsan Ayub[1], Darren Chang[1,2], Roman Chernikov[3], Qiaoyun Chen[1], Reza Karimi[1], Shawn Wettig[1], Joseph Sanderson[1] and Kevin Musselman[1,2]; [1]University of Waterloo, Canada; [2]Waterloo Institute for Nanotechnology, Canada; [3]Canadian Light Source, Canada

A novel strategy to synthesize molybdenum blue (MB) nanorings by irradiating MoO_3 suspended in water/ethanol mixtures with intense femtosecond laser pulses is demonstrated. It is found that the MoO_3 can be dissolved in the water during laser irradiation to form molybdic acid, which provides an acidic environment for the formation of MB. Concentrations of ethanol as low as 1% result in the formation of MB and by adjusting the concentration of ethanol in the solvent, the absorption band can be tuned due to the modification of Mo^{V}-O-Mo^{VI} entities. The MB synthesized in 30% ethanol appears the darkest blue and assembly of vesicles 115 nm in size is observed. At high concentrations of ethanol (>70%), H_XMoO_3 and MoO_{3-X} are preferentially formed instead of MB. The photothermal conversion efficiency of the MBs synthesized in 1% and 30% ethanol is above 40%.

2:30 PM BREAK

3:30 PM NM04.07.04
One-Dimensional Bose Gase within Mirror Twin Boundary Formations in WS_2 John C. Thomas[1], Antonio Rossi[1], Johannes T. Küchle[1,2], Elyse Barré[1], Zhouhang Yu[3], Shalini Kumari[3], Hsin-Zon Tsai[4], Joshua Robinson[3], Mauricio Terrones[3], Archana Raja[1], Ed Wong[1], Chris Jozwiak[1], Aaron Bostwick[1], David F. Ogletree[1], Jeffrey B. Neaton[1,4], Michael F. Crommie[4], Francesco Allegretti[2], Willi Auwärter[2], Eli Rotenberg[1] and Alexander Weber-Bargioni[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Technical University of Munich, Germany; [3]The Pennsylvania State University, United States; [4]University of California, Berkeley, United States

Cross-correlation studies using nano angle-resolved photoelectron spectroscopy (nARPES) coupled with scanning tunneling microscopy and scanning tunneling spectroscopy (STM/STS) measure a band gap renormalization on purposefully induced defects in monolayer tungsten disulfide (WS$_2$). Mirror twin boundary (MTB) defects are identified with non-contact atomic force microscopy, which enables structural comparison to local studies performed with nARPES and STM. Both nARPES and STS studies a formation of Tomonaga–Luttinger Liquids within mirror twin boundary (MTB) defects, which are created through the growth of one-dimensional (1D) MTBs from point defects tht are induced into WS$_2$ with Ar$^+$ bombardment. Chalcogen defect creation also provides a path to study novel substitutional defects. 1D MTBs are substantially charged at the nanoscale.

3:45 PM NM04.07.05
Wafer-Scale Layer-by-layer Assembly of One-atom-thick Crystals with Atomically Clean Interfaces Seong-Jun Yang[1,2], Ju-Hyun Jung[1,2], Eunsook Lee[3], Edmund Han[4], Min-Yeong Choi[1,2], Daesung Jung[5], Shinyoung Choi[1,2], Jun-Ho Park[1,2], Dongseok Oh[3], Siwoo Noh[3], Ki-Jeong Kim[3], Pinshane Y. Huang[4], Chan-Cuk Hwang[3] and Cheoljoo Kim[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science (IBS), Korea (the Republic of); [3]ohang Accelerator Laboratory, Korea (the Republic of); [4]University of Illinois at Urbana-Champaign, United States; [5]Sungkyunkwan University, Korea (the Republic of)

Modulation of thicknesses and atomic structures can broadly program the physical properties of crystalline films. The layer-by-layer assembly of atomically thin crystals provides a powerful means to arbitrarily design films at the atomic level, which are unattainable with existing growth technologies. However, atomically clean assembly of the materials with high scalability and reproducibility remains challenging. Here, we report programmed crystal assembly of graphene and monolayer hexagonal boron nitride, assisted by van der Waals interactions, to form wafer-scale films of pristine interfaces with near-unity yield. The atomic configurations of the films are tailored with layer-resolved compositions and in-plane crystalline orientations. We demonstrate batch-fabricated tunnel device arrays with modulation of the resistance over orders of magnitude by thickness control of the hexagonal boron nitride barrier with single-atom thick precision and large-scale, twisted multilayer graphene with programmable electronic band structures and crystal symmetries. Our results constitute an important development in the artificial design of large-scale films.

4:00 PM NM04.07.06
Growth of Embedded Transition Metal Dichalcogenides for Ultraclean Interface with Metal Minseok Yoo, Minsu Seol, Kyung_Eun Byun, Junyoung Kwon and Sang Won Kim; Samsung Advanced Institute of Technology, Korea (the Republic of)

Transition metal dichalcogenides (TMD) is a promising candidates as a channel material for next-generation electrical and optoelectrical applications. The atomic thin body and outstanding properties of it, however, are highly affected by integration processes such as transfer, photolithography and metallization. Here, we proposed novel synthesis method for utilizing TMD having ultraclean heterojunctions by employing confined interfacial chalcogenization (CIC). We synthesized TMD at the junction of two metal, Au and transition metal (TM) and the embedded TMD exhibit high crystallinity and atomically clean interfaces with adjacent metals. Chalcogenization at confined space suppressed defect generation and guided lateral growth of TMD. In addition, top Au acts as an epitaxial template for growing underling TMD and enables the chalcogenization at low temperature. We proved that CIC is a general synthesis method for TMD including vertical heterostructure. We elucidated that TM dissolved in Au accelerated the diffusion of chalcogen inside of Au and enables the fast and controlled CIC. Moreover, we achieved the site-selective CIC and demonstrated vertical memristor with excellent device uniformity. This method, therefore, offers preparation platform for the electrical devices utilizing TMD as a vertical channel with ensuring ideal contact of metal and TMD.

4:15 PM NM04.07.07
Formation of Chiral Helices by Self-Assembling Molecules on Semiconductor Nanosubstrates Jiunn Hong Po and Sandrine Ithurria; ESPCI Paris, France

Among semiconductor colloidal nanocrystals, 2D nanoplatelets (NPLs) are geometrically seen as well-defined flexible substrates for the self-assembly of molecules. In the presence of mechanical stress brought by surface stabilizers, helical structures are formed according to the parameters of the initial material after internal energy relaxation.
Here, we demonstrate the tuning of the NPLs helices radii through the organic ligands, described as an anchoring group and an aliphatic chain of a given length. A perfect control in surface chemistry allows the switch between different morphological features of these nanohelices. Nonetheless, their optical properties in the visible region are well-preserved upon such modifications. Numerical simulations and as well as structural X-ray diffraction studies done on these anisotropic nanoparticles, unveil a strong preferential orientation effect on their resulting scattered patterns.
A mechanical model accounting for the misfit strain between the inorganic core and the organic ligands, enables to predict the nanohelices radii. The model treats these different layers of substrate, anchoring group and aliphatic chain contributions individually and demonstrates good agreement for all studied homo- and hetero-structure cadmium-based NPLs. It reveals ultimately that the self-assembly of surface molecules is equivalent to a layer, whose Young modulus in lateral compression can be estimated close to 0.9 GPa.
Furthermore, the chirality of the semiconductor nanohelices shown in this work is dictated by the ligands anchoring group and can be inverted from one population to another. Chiroptical properties exhibited in circular dichroism measurements show a special interest in investigating this type of mirror-symmetry-breaking particles and could undoubtedly, lead to the emission of circularly polarized light in the visible spectrum.

4:30 PM NM04.07.08
Thermodynamically Driven Tilt Grain Boundaries of Monolayer Crystals Using Catalytic Liquid Alloys Min-Yeong Choi[1,2], Chang-Won Choi[1,2], Dong-Yeong Kim[1,2], Si-Young Choi[1,2] and Cheoljoo Kim[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Grain boundaries (GBs) of two-dimensional (2D) materials host unique atomic defects that reveal novel properties, but deterministic control of the defect structures has not been achieved. Here, we report selective formations of dislocation cores at GBs of monolayer (ML) MoS$_2$ by vapor-liquid-solid (VLS) growth with Na-Mo-O eutectic alloys. The alloys function as a growth catalyst and provide Mo-rich chemical environments during the growth, which guide the formation of pentagon-heptagon defects with Mo-Mo homo-elemental bond (Mo 5|7) by yield > 95 %. In particular, we found that GBs with high tilt angle ($\theta_t > 34°$) relieve strains by deformation-twining, instead of forming a dense arrays of defects including derivatives of S 5|7 defects. Polycrystalline MoS$_2$ films grown by VLS mode present about 8 times higher photoluminescence (PL) intensity than the films grown by vapor-solid-solid (VSS) mode. Density-functional theory (DFT) calculations suggest that the enhancement of PL intensity is associated with suppression of S 5|7 donor-type derivatives and electron doping. Using eutectic alloys will be useful to precisely determine atomic defects of various polycrystalline 2D films for engineering the material properties.

Two-dimensional Stacked Composites of Self-Assembled Alkane Layers and Graphene for Transparent Gas Barrier Films with Low Permeability Yoonjeong Kim and Seokhoon Ahn; Korea Institute of Science and Technology, Korea (the Republic of)

Recently, demanding for OLEDs (organic light-emitting diode) has increased rapidly, many researchers are researching to develop better OLED products. Currently, it is possible to manufacture a device that can fold and bend the display, but it is still very difficult to realize flexible and stretchable displays. One of these difficulties is absence of gas barrier films. Graphene has been considered as one of the best candidates for gas barrier films, because it is theoretically ideal for flexible and transparent gas barriers. However, large-scale graphene synthesized using chemical vapor deposition (CVD) contains numerous defects, and therefore has poor gas barrier properties (water vapor transmission rate WVTR = 1.57 g/(m^2-d) for 3-layer graphene). In order to solve this problem, we introduced two-dimensional (2D) self-assembled alkane layers on graphene. The scanning tunneling microscopy (STM) study revealed that a self-assembled hexatriacontane (HTC) monolayer on graphene covers nanometer-size defects due to the flexible nature and strong intermolecular van der Waals interactions of alkane. In addition, HTC multilayers between graphene layers greatly improve their adhesion, indicating that HTC multilayers between graphene layers can effectively block the lateral pathway between graphene layers by filling open space with close-packed self-assembled alkanes. By these mechanisms, alternately-stacked composites of graphene and self-assembled alkane layers greatly increase gas-barrier property to WVTR as low as 1.2 x 10^{-3} g/(m^2-d), whereas stacked graphene layers generally show WVTR > 0.5 g/(m^2-d). Furthermore, the self-assembled alkane layers have superior crystallinity and wide band gap, so they have little effect on the transmittance. However, the limitation of this method is that defects in graphene which are larger than the length of the alkane molecule might not be covered, because absent molecule-graphene interaction impedes alkane self-assembly.

SESSION NM04.08: Advanced Manufacturing of 2D Materials at the Atomic Scale VIII

Operando Experiments and Modeling on the Dynamics and Heterogeneity of Composite Electrodes in Batteries Kejie Zhao; Purdue University, United States

The composition dynamics regulate the accessible capacity and rate performance of rechargeable batteries. Heterogeneous Li reactions can lead to non-uniform electrochemical activity and amplify mechanical damage in the cell. We develop operando optical microscopy as a laboratory tool to map the spatial composition heterogeneity in a solid-solution cathode for Li-ion batteries. We observe that the active particles charge asynchronously with reaction fronts propagating on the particle surfaces during the 1st charging, while the subsequent (dis)charge cycles transition to a synchronous behavior for the same group of particles. Such transition is understood by computational modeling which incorporates the dependence of Li diffusivity and interfacial reaction on the state of charge. Furthermore, we use synchrotron experiments to visualize the morphological defects at multi-scales ranging from the macroscopic composite, particle ensembles, to individual single particles. We find that the interfacial failure reconstructs the conductive network and redistribute the electrochemical activities that render a dynamic nature of electrochemistry and mechanics evolving over time in the composite electrodes.

9:00 AM NM04.08.02
Deterministic Monolayer Manipulation of Single-Crystalline Ruddlesden-Popper Halide Perovskite for Opto-Electronic Device Array Fabrication Ki-Tae Park; Seoul National University, Korea (the Republic of)

Ruddlesden-Popper perovskite (RPP), a quasi two-dimensional phase of organic-inorganic hybrid halide perovskites have been considered as promising candidates for next generation opto-electronic applications. In addition to their broad controllability of bandgap between 2 and 3 eV, their inert surface nature can realize high-performance optoelectronic devices even at nanometer scale. Moreover, phase-pure monocrystalline RPPs can be synthesized by using solution processes, which exhibit significantly enhanced optoelectronic characteristics. However, the multi-layer structure of fabricated RPP crystals and the high solubility in typical solvents have been major challenges to obtain monolayer RPP for device fabrication. Conventional layer splitting and photolithography-based patterning processes which involves solvents are incompatible with RPPs. Therefore, a dry process for monolayer manipulation of RPP must to be established to realize nanoscale device array.
In this contribution, we develop a novel all-dry layer manipulation process through adhesion control of RPP. We first synthesize inch-scale phase-pure monocrystalline RPP crystals. Using the RPP crystals, we characterize the adhesion between RPP and various inorganic materials for adhesion layer by using atomic force microscopy. We find out that adhesion between RPP and inorganic materials surface can be tailored depending on the surface roughness as well as the material of adhesion layer. We investigate the fracture mechanics of RPP monolayers by measuring the out-of-plane adhesion to in-plane toughness ratio. Simultaneous processes of deterministic monolayer spitting and lateral patterning with micrometer-scale resolution are demonstrated. Furthermore, we demonstrate RPP monolayer photodetector array fabricated by the developed monolayer manipulation process.

9:15 AM NM04.08.03
Studying the Behavior of Potential Electronic Nanodevices on Individual CNTs Hugo Borbon-Nunez[1,2], David Dominguez[2], Eduardo Murillo[2], José M. Ruiz-Marizcal[3,2], Luis A. Rios[4] and Jose M. Romo-Herrera[2]; [1]CONACyT - Centro de Nanociencias y Nanotecnología de la UNAM, Mexico; [2]Centro de Nanociencias y Nanotecnología de la UNAM (CNyN-UNAM), Mexico; [3]Programa de Posgrado en Nanociencias CICESE / CNyN-UNAM, Centro de Investigación Científica y de Educación Superior de Ensenada (CICESE), Mexico; [4]División de Física Aplicada, Centro de Investigación Científica y de Educación Superior de Ensenada (CICESE), Mexico

Electronics miniaturization has been a driving force for the development of new electronic devices. Nanotechnology can be able to contribute not only to the synthesis of new nanostructures but to the analysis of their physical properties, including the appearance and understanding of new phenomena due to the dimensions in the nano regime.
Since several decades ago, carbon nanotubes (CNTs) have shown excellent electrical conduction properties, which has allowed them to be used as efficient interconnects decreasing the required space. Following the pioneering proposes of assembling 1D nanostructures into ordered arrays as a potential alternative for developing electronic nanocircuits, Ordered Networks based on Carbon Nanotubes (ON-CNTs) were designed **[1]** and their electronic transport properties studied **[1-2]** theoretically by computational calculations. This type of CNTs arrays can be seen as electronic nanocircuits, where the CNTs junctions (network nodes) could behave as the electronic nanodevices with different functions, which are interconnected by the CNTs with good electrical conduction properties behaving as the conducting wires.
In such type of nanocircuits, the electronic nanodevices functions would be directly dictated by the physical properties of the junctions between the pair of individual CNTs. In this sense, as the first stages towards developing this type of nanocircuits based on CNTs experimentally, it is of great importance to start studying the electrical conduction properties of a single cross-junction between a pair of individual CNTs and even the electrical conduction properties of an individual CNT under the presence of spots of different materials (*e.g.* Platinum, amorphous Carbon or even holes), whose disturbance should be

different on the electronic transport properties along the CNT, therefore dictating different functions for the potential nanodevices.
Here, we will show some of our recent results on the analysis of the electrical conduction properties of individual CNTs influenced by the presence of spots of different sizes of holes, amorphous Carbon or Platinum. These spots are generated on individual CNTs either by ion milling (holes) or by controlled deposition (amorphous Carbon or Platinum) with a gas injection system (of an organometallic molecule as precursor) and a focused ion beam (FIB) in a dual-beam scanning electron microscope (FIB-SEM).

10:00 AM NM04.08.04
Defect Engineering of 2D Hexagonal Boron Nitride Using Electron and Ion Beam Methods Dana O. Byrne[1,2], Archana Raja[2], Aleksandr Noy[3,4], Jim Ciston[2], Alex Smolyanitsky[5] and Frances I. Allen[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States; [4]University of California, Merced, United States; [5]National Institute of Standards and Technology, United States

Vacancy defect engineering of 2D membranes is essential for advancing fundamental understanding of ion and molecule transport through subnanometer pores for applications in filtration and molecular sensing. Nanopores in 2D materials are thermally and mechanically stable, and are tunable in terms of their shape, chemistry, distribution, and size. Therefore, nanopores in solid state 2D membranes can have fine control over ion selectivity and molecule permeability and have become primary candidates for selective transport membranes. For example, recent theory and simulation has shown that ion transport behavior in graphene-embedded crown ethers and in sub-nanometer pores in MoS2 can be strain-modulated [1,2]. This behavior mimics that of mechanosensitive ion channels in biological membranes. In pursuit of a solid-state analog for biological mechanosensitivity, heteroatomic 2D materials such as MoS2 and hexagonal boron nitride (hBN) present the advantage of pre-"functionalized" nanopores by default, eliminating the need for additional chemical functionalization of the pore edges, as would be the case for graphene.

In our work we use electron beam and ion beam methods to fabricate nanopores in 2D hBN. We use hBN exfoliated from bulk and monolayer CVD-grown hBN, mechanically transferring the samples to holey substrates to produce suspended hBN. Following the electron beam method in a transmission electron microscope (TEM), we modulate the electron dose to nucleate vacancy defects and grow nanopores of desired size and shape [3]. This method enables in-situ nanopore fabrication and imaging at atomic resolution but lacks the high throughput necessary for large scale fabrication. In contrast, the ion beam method uses ion bombardment in a focused ion beam (FIB) microscope to nucleate defects and produce a large distribution of nanopores [4], offering higher throughput albeit with less control over the exact nature and size of the resulting pores. We investigate nanopores generated by irradiation with gallium, neon, and helium ions using a multibeam FIB microscope and also explore a combined ion and electron beam approach in which we seed vacancy defects using the the light helium ions and controllably grow those defects with the electron beam of the TEM. Nanopores are imaged at atomic resolution using a double-aberration-corrected (scanning)TEM (STEM).

Nanopore structure is also sensitive to environmental effects, which can alter the nanopore's functional properties. We survey the local chemistry of the electron beam and ion beam fabricated nanopores using electron energy loss spectroscopy (EELS) in the TEM, probing the local bonding and chemical composition of the nanoporous regions based on variations in the core loss signals. We find that local chemistry of the nanopores is susceptible to change both inside the vacuum environment of the various microscopes as well as upon exposure to air. Hence, we argue that the investigation of the effect of the environment on the pore edge chemistry is essential for designing nanoporous 2D membranes for real life applications.

Vertical $Ti_3C_2T_x$ MXene Nanosheets under an Alternating Current Electric Field Changjae Lee[1], Soon Mo Park[1], Dong Ki Yoon[1] and Seon Joon Kim[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Aligning atomically thin two-dimensional materials vertically to the bottom has received much attention to utilize its structural anisotropy. In particular, various strategies have been reported to achieve vertical MXene, early transition metal carbide and nitride, for high capacitive performance. However, controlling the azimuthal orientation of the vertical MXene nanosheets cannot be achived with the previous methods, so its application was limited predominantly to capacitors. Here, vertical alignment induced by applying an alternating electric field to MXene colloid is presented. The reversible alignment switching of the colloid depending on the ON and OFF states of the electric field is observed through a polarized optical microscope. The immobilized nanosheets maintaining the colloidal orientation under the electric field can be obtained through in-situ freeze-drying. The oriented vertical MXene nanosheets exhibit an anisotropic electrical conductivity with a difference of nearly 9 times depending on the direction. In addition, various patterns composed of vertical MXenes are devoloped using diversified electrode designs. Based on these results, a new paradigm is suggested for various applications of vertical MXene such as sensors, optical polarizers, and heat-dissipating films, not limited to high-performance storage batteries.

TMDs Functionalized-SWCNTs Based Nanosensors for the Detection and Early Warning of Gas Leakage in Li-Ion Batteries Haifa Taoum, Ileana Florea, Mariam Ezzedine, Fatima Jardali and Costel-sorin Cojocaru; Ecole Polytechnique de Paris, France

Lithium-ion battery technology has seen immense success in consumer electronics and is becoming a leading technology for the mobility electrification with increasingly more attention being paid to battery safety problems[1]. Detecting gas molecules (including hydrogen, carbon monoxide, carbon dioxide, ethylene, and methane) released from battery thermal runaway using gas sensors is one of the effective strategies to achieve early safety warnings for Lithium-ion batteries. Benefiting from the superiorities of small size/compactness, high sensitivity, and stable performance, resistive gas sensors are considered promising candidates in this field.

Two-dimensional (2D) materials have demonstrated great potential in the field of gas sensing due to their layered structures. Particularly, 2D Transition Metal Dichalcogenides (TMDs) possess high surface areas and exhibit semiconducting properties with tunable band gaps making them excellent candidates for sensing applications[2]. Among the different TMDs materials, MoS_2 has gas sensing ability comparable to graphene and WS_2 can sense both toxic and non-toxic gases. In combination with the general benefits of 2D nanomaterials, the incorporation of one-dimensional (1D) nanomaterials with 2D TMDs is a recent approach for improving the gas sensing performance of these materials by the synergistic effects of hybridization. Indeed, hybrid (2D/1D) nanostructured materials provide the opportunity to fabricate and test the synergy between two or more different materials to achieve new functions. The use of single-wall carbon nanotubes (SWCNTs) as a skeleton for the TMDs enables the tuning of the electrical properties as the d orbitals from the transition metal M may partially overlap with the Π orbitals in the SWCNTs.

The purpose of this work is to fabricate a gas nanosensor based on TMDs@SWCNTs resistive channel and to further couple it to a Lithium-ion battery with the aim of detecting toxic byproducts released due to battery thermal runaway.

In this work, high-quality WS_2@SWCNTs and MoS_2@SWCNTs are fabricated using a bottom-up approach. First, the SWCNTs are synthesized via a chemical vapor deposition (CVD) method on a quartz substrate where the characteristics of the SWCNTs, i.e., diameter, density, and length are controlled by controlling the catalyst and CNT growth conditions. Next, mono and bilayer WS_2 and MoS_2 nanoflakes with diameters ranging between 10-20 nm are directly synthesized on the walls of the CNTs using homemade molecular beam evaporation/epitaxy (MBE) system.

To test the sensing abilities of WS_2@SWCNTs and MoS_2@SWCNTs, the electrical measurements are first performed under tunable relative humidity environments. An opposite electrical response towards humidity is obtained for the two types of heterostructures. The WS2@SWCNTs have shown a positive response followed by a negative response which highlights the change in the intrinsic properties of the material depending on the injected percentage of relative humidity. Whereas, the MoS_2@SWCNTs have shown only a positive response with the change in the percentage of relative humidity. This opposite response can be explained by the fact that intrinsically WS_2 behaves as an n-type semiconductor while MoS_2 behaves as a p-type semiconductor.

Further measurements will be performed to evaluate the selectivity, sensibility, and the ability to perform monitoring functioning of TMDs@SWCNTs nanosensors in the presence of different byproduct gas molecules. Finally, the TMDs@SWCNTs nanosensors will be coupled to a homemade Li-ion pouch cell battery and will be tested under harsh environments.

In Situ Self-Healing of Beam Damaged MXenes under TEM Congjie Wei[1], Yanxiao Li[2] and Chenglin Wu[1]; [1]Missouri University of Science and Technology, United States; [2]New York University, United States

With the significant improvements and developments in transmission electron microscopes (TEM) techniques, accurate observation and identification is now more commonly adopted in angstrom-level precision, which reveals as sequential images about the real-space information. However, it still has difficulties to analyze the spatial defect distribution, phase transformation and dynamic phenomena since the TEM images can only record the appearances of the surface atoms while the out-of-plane information is severely missing. In this work, the healing process, characterized by the regeneration of crystalline structures within the e-beam burned holes, has been experimentally observed using TEM images. Modeling based on density functional theory and molecular dynamics was conducted to study the energy path as well as the stabilized phases of all stages before and after the healing of MXene. Furthermore, a first principle based deep learning algorithm is proposed and adopted to reconstruct the 3D transition states of a MXene healing process experimentally observed. Starting from the TEM image. Around hole atoms are assumed to have crystalline structure and set as the input along with the in-plane information of atoms that can be observed directly within the hole. Out-of-plane information of the latter group of atoms are then treated as the output of the algorithm along with the spatial distribution of all underlying atoms. The input and output information are reformed into graphical representations and treated as a graph reference problem. The trunk of this algorithm is set as a deep convolutional neural network incorporated with attention-based and non-attention-based components. To conform to the distance prediction, smooth potentials are constructed for Ti-Ti, Ti-C and C-C interactions based on first principle calculation. The minimum potential energy accumulation of all atoms within the hole is set as one of the convergence conditions of the algorithm along with the fitting of the training data sets. Our models are trained on defected MXene structures optimized with DFT, where different sizes and number of atoms are considered. The predictions of this algorithm fit well with the TEM images and help with the understanding of the healing processes observed in MXene materials.

Stability of Carbon Cluster on Candidate Substrates Evaluated by Molecular Dynamics Satoru Kaneko[1,2,3], Takashi Tokumasu[4], Manabu Yasui[1], Masahito Kurouchi[1], Masahiko Mitsuhashi[1], Ruei Yu[5], Shigeo Yasuhara[6], Tamio Endo[6], Musa Can[7], Kripasindhu Sardar[3], Sumanta K. Sahoo[3], Masahiro Yoshimura[3], Akifumi Matsuda[2] and Mamoru Yoshimoto[2]; [1]KISTEC, Japan; [2]Tokyo Institute of Technology, Japan; [3]National Cheng Kung University, Taiwan; [4]Tohoku University, Japan; [5]Asian University, Taiwan; [6]Japan Advanced Chemicals, Japan; [7]Istanbul University, Turkey

Choice of substrate is one of important factors for synthesis of thin films. For oxide materials, Schlom et.al. comprehensively investigate the thermodynamic stability of more than 80 binary oxides for epitaxial growth on silicon substrates , however thermodynamics stability literary evaluates the thermal stability between oxide and silicon, and does not include any crystallographic factors such as lattice mismatch and crystal orientation. The thermal stability is literally potential use for epitaxial growth as Schlom mentioned in his report[1].

In previous report, we employed an absorption energy between oxide and silicon (Si) substrate to predict the direction of crystal growth of oxide films, and experimentally deposited oxide films on Si substrates[2]. In this study, molecular dynamics was applied on carbon clusters placed on variety of substrates with vacuum slab (supercell), and the absorption energy was estimated on the supercell. Carbon films were experimentally deposited on the target substrates by pulsed laser deposition (PLD) in carbon dioxide atmosphere[3].

For evaluation of absorption energy, supercell was consisted of carbon clusters placed on variety of substrates with vacuum slab. As carbon clusters, (1) carbon atom, (2) six-membered ring (6-ring) and (3) seven six-membered rings (nanographene) were placed on SrTiO, silicon and sapphire substrates. On the surface of SrTiO(001), for an example, carbon clusters were placed on either Sr, Ti or O atom. And the absorption energy was estimated by using the density functional theory (DFT) with a semi-core pseudopotential. The generalized gradient approximation (GGA) method was used to obtain the electron density. The energy difference for self-consistent field was set at 1.0x10-6 Ha. Crystal structure of each substrates was optimized with periodic condition, and supercell consisting of slab and vacuum layer was used to optimize the top layer of substrate. After optimal surface was prepared on each substrates, supercell with graphitic cluster and slab was optimized, and total energy was estimated on supercell combined cluster and substrate (Etot_combined). Absorption energy was evaluated to be

Etot_sub + Etot_cluster - Etot_supercell,

where Etot_sub and Etot_cluster) were total energy of subs and graphitic cluster, respectively.

Among target substrates, the absorption energy were in range from 500 to 1000 J/mol. On the surface of Si(001), nanographene was stable with the absorption energy of ~940 J/mol, however 6-ring did not flatly cover the surface. The 6-ring vertically stood up on the Si(001), which impeded flat growth of graphene. Carbon clusters flatly covered only on SrTiO(001)[4].

For demonstration deposition, PLD method was employed with carbon dioxide atmosphere and the surface morphology was observed by atomic force microscopy (AFM). As expected, the surface morphology of SrTiO(001) shows flat surface with Ra ~ 63 pm, which is comparable with superflat CVD graphene annealed in carbon dioxide atmosphere (Ra~76 pm)[5]. In general, the deposited clusters migrate on the target surface, and the clusters are captured by a kink. Interestingly, graphene showed layer by layer growth and grew not from kink but the terrace edge. We will show optimized structure of supercell with candidate substrates, and compared with experimental results.

Mechanics of Biosurfactant Aided Liquid Phase Exfoliation of 2D Materials Xuliang Qian[1], Matteo Andrea Lucherelli[2], Céline Corcelle[2], Alberto Bianco[2] and Huajian Gao[1,3]; [1]Nanyang Technological University, Singapore; [2]CNRS, Immunology, Immunopathology and Therapeutic Chemistry, France; [3]A*STAR, Singapore

Biosurfactant-aided liquid-phase exfoliation (LPE) is emerging as a biocompatible, green, economical, safe, and efficient approach to prepare two-dimensional (2D) materials for biomedical applications. However, relatively little is known about the molecular mechanisms of this process. Herein, we present the first study of how flavin mononucleotide (FMN) interacts with hexagonal boron nitride (hBN) nanosheets in the context of LPE. We demonstrate that FMN molecules can self-assemble on hBN via π-π interactions, as well as intermolecular hydrogen bonds (H-bonds) between the isoalloxazine moieties. Binding free energy analysis has shown FMN to be an efficient surfactant for LPE of hBN in water. According to the theoretical simulations, stable water suspension of hBN were experimentally obtained by LPE using FMN. With this work, we aim to exemplify how molecular dynamics (MD) simulation can predict and guide empirical LPE experiments, direct the surfactant screening and improve scalable production of 2D materials for biomedical applications.

Two-Dimensional Sheets Derived from Non-Van der Waals Crystals: Mechanism of the Mechanochemical Synthesis Jing-Yang Chung, Yanwen Yuan, Tara P. Mishra, Silvija Gradečak and Slaven Garaj; National University of Singapore, Singapore

Recent studies of mechanically-synthesised two-dimensional (2D) sheets from otherwise three-dimensional non-van der Waals (vdW) crystals are harbingers of a new approach for materials engineering. Yet, the nature in which 2D sheets can be derived from a non-layered, isotropic crystal remains unknown. In the case of boron, the complex crystal structure of the bulk material and its abundance of phases, as well as the influence of crystal orientation and thickness on structure interpretation, make it challenging to determine the nature of the exfoliated 2D sheets. Here we demonstrate, using aberration-corrected scanning transmission electron microscopy (STEM) and extensive structural modelling, that liquid phase exfoliated boron sheets consist of a planar arrangement of icosahedral subunits, formed from the cleaving of the {001} planes of β-rhombohedral boron. Our experimental results supported by density functional theory (DFT) calculations show that planar defects in the form of stacking faults — which form parallel layers of faulted planes in the same orientation — play a significant role in the exfoliation of 2D sheets from bulk boron, reducing the energy required to cleave the bulk {001} surface by ~ 36%. We demonstrate that planar defects are key to an engineerable pathway for the exfoliation of 2D sheets from boron, and more broadly of other covalently-bonded materials. This provides opportunities for the design of new 2D materials from non-vdW crystals.

3:15 PM NM04.09.05
Domain-Dependent Surface Adhesion in Twisted Few-Layer Graphene Valerie Hsieh[1], Dorri Halbertal[1], Nathan R. Schleder[2], Mattia Angeli[2], Kenji Watanabe[6], Takashi Taniguchi[6], Eun-Ah Kim[4], Efthimios Kaxiras[2], James Hone[1], Cory Dean[1] and Dmitri N. Basov[1]; [1]Columbia University, United States; [2]Harvard University, United States; [3]Stanford University, United States; [4]Cornell University, United States; [5]Boston University, United States; [6]National Institute for Materials Science, Japan

Twisted van der Waals heterostructures are a highly tunable platform due to the many degrees of freedom available for controlling their electronic and chemical properties. Here, we focus on the local stacking order of low-degree twisted graphene heterostructures as a platform for manipulating the surface chemistry of this class of materials. We report the emergence and engineering of stacking domain-dependent surface adhesion in twisted few-layer graphene. Minimally twisted double bi- and tri-layer graphene heterostructures were fabricated and imaged using mid-infrared near-field optical microscopy and atomic force microscopy to identify rhombohedral and Bernal stacking domains. We then observed that metallic nanoparticles and liquid water exhibit a domain-selective adhesion on these heterostructures, with preference for the rhombohedral stacking configurations. Finally, we used an atomic force microscope to manipulate nanoparticles located at certain stacking domains, resulting in a local reconfiguration of the moiré superlattice near the nanoparticles at the μm-scale. Our findings establish a new approach to controlling moiré chemistry and nanoengineering.

3:30 PM NM04.09.06
Orientation Dependent Large Plasticity of Single Crystalline Gallium Selenide Song Xu[1], Heyi Wang[2] and Yang Lu[2]; [1]The Chinese University of Hong Kong, Hong Kong; [2]City University of Hong Kong, Hong Kong

Unlike metals and alloys with high ductility, inorganic semiconductors are mostly ceramics with brittle nature due to covalent/ionic bonding. Recent studies showed that some layered/van der Waals semiconductors could exhibit substantial room-temperature ductility, despite that the underlying mechanisms remain to be understood. Here we report that van der Waals semiconductor GaSe can have crystal orientation-dependent large plasticity at room temperature. Through in situ tensile and compressive experiments inside electron microscopes, we demonstrate that microfabricated GaSe can have substantial ductility loaded along and slanted with the intralayer direction, while showing predominantly elastic deformation perpendicular to the intralayer direction until brittle fracture. We further reveal that, despite the interlayer gliding as the main mechanism, cross-layer slips induced by buckling associated with stacking faults also contribute to the plasticity. This study offers insights to understand the ductility and plasticity of van der Waals semiconductors and shows promising flexible/deformable electronics and energy device applications.

Computational Perspectives on Chalcogen-Terminated MXene Pernilla Helmer, Jonas Bjork and Johanna Rosen; Linköping University, Sweden

The MXenes are a family of 2D materials which have since their discovery in 2011 received ever increasing attention. MXenes consists of alternating monoatomic layers of carbon or nitrogen and transition metals, with the metal always as the outermost layers. These structural and compositional degrees of freedom of the MXenes let them display a wealth of properties and characteristics. Many different MXenes are investigated for a variety of applications, ranging from energy storage to catalysis and water desalination. The outermost transition metal layers of MXenes are in general decorated with additional atoms and molecules, so called terminations. These also influence the MXene properties, and thus increase even further the potential for materials design and property tailoring of MXenes.

At the beginning of 2022, a new way of synthesizing S-terminated MXene through delamination of van der Waals multilayer parent phases was reported, along with two novel 2D structures synthesized in this way. These 2D structures can be viewed either as MXenes with chalcogen terminations, or – as suggested by the authors – as transition metal carbo-chalcogenides (TMCCs), to emphasize their similarity to another large family of 2D materials: the transition metal dichalcogenides (TMDCs). This structural duality of the new sub-family of chalcogen-terminated MXenes further emphasizes their relevance and calls for more in-depth investigations. Thus, we consider the possibility to expand this sub-family, by computationally evaluating the stability of the corresponding van der Waals parent phases, as well as other related potential parent phases. We confirm the results reported in the original publication, discuss computational results for prediction of further members of the chalcogen-terminated MXenes, and present materials properties of identified stable phases.

Large Area Synthesis of Transition Metal Chalcogenides as Semiconducting Channels in Transistors and Photodetectors Jinbo Pang[1], Chongyang Hou[1] and Hong Liu[1,2]; [1]University of Jinan, China; [2]Shandong University, China

The electronic and optoelectronic properties[1-3] of 2D materials and their stacking heterostructures[4-6] have inspired enormous interests. WSe_2, as a p-type semiconductor,[7,8] represents a foremost building block in the p-n junctions. WSe_2 shall possesses the features of large area, homogeneity, and precise layer control. To date, there is yet an ideal synthesis method ever reported. First, we present a facile approach to prepare high-quality wafer-scale homogenous WSe_2 full films. In brief, we first deposit a thin layer of metal and then do the selenization. We can control the film thickness of WSe_2 in a chemical equilibrium environment. Second, we present a facile approach to prepare high-quality large-area homogenous WSe_2 full films. In brief, we developed a pre-seeding strategy for depositing W-containing precursors over dielectric substrates, which form well-distributed particles as seeding center. Upon the salt-assisted sublimation of tungsten oxides, the WSe_2 forms over the seeded substrates (at high temperature) in the Se-rich atmosphere. Eventually the high quality of the synthetic film has been reflected on the high performances of photodetectors and field-effect transistors. Our finding may pave the way of wafer scale integration of transition metal dichalcogenides in the integrated flexible electronics.
Keywords: WSe_2; optoelectronics; photodetectors; transistors; transition metal dichalcogenides; $PdSe_2$; layered noble metal dichalcogenides

Gas-Phase "Prehistory "of CVD Grown MoS_2 —Atomistic Reaction Mechanism of MoO_3 and S_2 Precursors Zhengzheng Dang and Yanming Wang; Shanghai Jiaotong University, China

Two-dimensional MoS_2 is one of the most promising materials for next-generation electric and optoelectronic devices due to its semi-conducting nature and plenty of other suitable properties. The primary approach to synthesizing large-scale and high-quality MoS_2 monolayers is chemical vapor deposition (CVD), where the gas phase process is a crucial step in CVD. However, few experiments have given a detailed explanation of the gas-phase reaction mechanism, which is essential for researching the reactive pathways to precursors and controllable growth of MoS_2. This motivates the development of atomic and molecular dynamic simulation to give micro-scale insights. Here we used reactive molecular dynamics (RMD) simulations to investigate the reaction mechanism of MoO_3 and S_2 precursors in the gas phase. Firstly, the bond-order-based algorithm was developed to automatically analyze products' real-time distribution and we used cluster analysis to screen the main intermediate product ($Mo_xO_yS_z$) statistically. Then we developed path-tracking tools based on target atoms to obtain the trajectory distribution of all Mo clusters in the entire reaction stage, and determine the most critical reaction pathway in statistics. Finally, we mapped the energy barrier pathways and did ReaxFF-NEB calculations to verify the feasibility of distributed reaction pathways, also explored their sensitivity to temperature and Mo/S ratio in the gas phase. These results provide valuable insight into guiding rational synthesis of MoS_2 and other transition metal dichalcogenides by the CVD process.

Bendable Xenes-Based Membranes Chiara Massetti[1,2], Christian Martella[1], Daya Dhungana[1], Carlo Grazianetti[1] and Alessandro Molle[1]; [1]CNR-IMM Agrate Brianza, Italy; [2]University of Milano-Bicocca, Italy

Xenes, the monoelemental family of two-dimensional (2D) materials, exhibit a variety of interesting physical properties with potential exploitation in nanotechnology [1]. In the framework of flexible electronics, photonics and related applications including wearable and strain-responsive devices, 2D bendable membranes are highly desired. We report here on the realization of Xenes-based membranes by taking benefit from the recently developed scheme of the Xene heterostructure, namely silicene-stanene grown by molecular beam epitaxy [2], where silicene is sandwiched in between an alumina encapsulation layer on the top surface and stanene on thin Ag(111) crystal at the bottom face. When the so-grown Xenes-base membrane is transferred onto a flexible substrate [3], the application of macroscopic mechanical deformations induces a strain-responsive behavior in the Raman spectrum of silicene. Under tensile strain, the bendable membrane shows Raman frequency shift comparable to other promising flexible systems, like those based on transition metal dichalcogenides, and high stability up to one thousand bending cycles. We also show that the membranes under elastic tension relaxation are prone to form microscale wrinkles displaying a local generation of strain in the silicene layer consistent with that observed under macroscopic mechanical deformation. Moreover, similarly to the unstrained case [4], optothermal Raman spectroscopy measurements reveal a curvature-dependent heat dispersion in silicene. Finally, as compelling evidence of the technological potential of the membranes, we demonstrate that they can be readily introduced into a lithographic process flow resulting in the definition of flexible device-ready architectures. Bendable Xenes-based memebranes may thus hold high potential for flexible and silicon-compatible applications [5]. The work is within the ERC-COG 2017 Grant N0. 772261 "XFab" and ERC-PoC 2022 Grant N. 101069262 “XMem”.

Controlling Few-Donor Quantum Dots Coupled to SETs Using Surface Gates Pradeep Namboodiri[1], Fan Fei[1], Jonathan Wyrick[1], Xiqiao Wang[2], Joseph Fox[1], Utsav Utsav[1] and Richard Silver[1]; [1]National Institute of Standards and Technology, United States; [2]Rigetti Computing, United States

Monolayer phosphorous dopant devices with high dopant confinement are an emerging methodology that allows the measurement and manipulation of single or few-dopant atom quantum dots for quantum computation and arrayed devices for analogue quantum simulation. STM fabrication of these devices provides a unique ability to create near perfect atomic structures on clean atomically ordered silicon in ultrahigh vacuum conditions. The devices are encapsulated in situ with a UHV grown ~30 nm epitaxial silicon layer followed by metallization for contact to the buried device components and top gates. In this talk we will present a single electron transistor (charge sensor) coupled to a few donor cluster where the chemical potential of the central island and the charge occupation on the few atom cluster are controlled via two capacitively coupled in-plane gates while current through the source/drain-leads and the SET island are used to determine the charge state. An external aligned metal gate on the surface is integrated ex situ using HfO2 as a dielectric. We confirm the functionality of the surface gates and measure a near zero-leakage current over a large gate range. Based on charge stability measurements, the surface gates have a similar lever arm as compared to the in-plane gates and therefore greatly expand the effective device gating range. We demonstrate the tuning of a few-donor cluster coupled to an SET charge sensor using surface gates while we use in-plane gates to load/unload individual electrons from the donor-cluster as well as demonstrate spin sensitive readout in a magnetic field. We will discuss the design, fabrication, and use of surface top gates to individually or globally address individual components in few-donor/quantum dot devices as well as a 2x2 arrayed device.

Broken Symmetry in van der Waals Layers Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany

Van der waal's structures provide for many opportunities for breaking symmetry. We show that the presence of topological chiral spin textures in both Fe_3GeTe_2[1] and and $Cr_{1+\delta}Te_2$ ($\delta \approx 0.3$)[2], namely Néel skyrmions, is the result of a lowering of their nominally centrosymmetric structures. High resolution x-ray diffraction from thin lamellae of these compounds shows an asymmetric distribution of Fe vacancies in the former and in the latter a superstructure formed by Te atoms within the vdw gaps. On the other hand we show non-reciprocal superconducting properties in Josephson junctions formed by proximitizing the van der Waals compound $NiTe_2$ using superconducting electrodes formed from niobium electrodes[3]. We discuss proximity induced superconductivity in several other van der Waals materials that show evidence for intrinsic time reversal symmetry breaking.

Asymmetric Magnetic Proximity Interactions in Ferromagnet/Semiconductor van der Waals Heterostructures Scott Crooker[1], Junho Choi[1], Christopher Lane[2] and Jian-Xin Zhu[2]; [1]National High Magnetic Field Lab, United States; [2]Los Alamos National Laboratory, United States

The ability of short-range proximity interactions to imbue magnetic functionality into otherwise nonmagnetic materials has exciting prospects for devices that combine the optical and electrical properties of monolayer semiconductors with additional magnetic tuning parameters that couple directly to spin and valley pseudospin. The atomically-smooth surfaces that are nowadays routinely achieved with van der Waals (vdW) materials allow for nearly ideal interfaces between monolayer transition-metal dichalcogenide semiconductors (such as WSe_2 or MoS_2) and magnetic substrates (such as EuO or CrI_3). Magnetic proximity interactions (MPIs) between atomically-thin semiconductors and two-dimensional magnets therefore provide a means to manipulate spin and valley degrees of freedom in nonmagnetic monolayers, without the use of applied magnetic fields.

In such vdW heterostructures, MPIs originate in the nanometer-scale coupling between the spin-dependent electronic wavefunctions in the two materials, and historically their overall effect is regarded as an effective magnetic field acting on the semiconductor monolayer. Here we demonstrate that this picture, while appealing, is incomplete: The effects of MPIs in vdW heterostructures can be markedly *asymmetric*, in contrast to that from an applied magnetic field [1]. Valley-resolved optical reflection spectroscopy of $MoSe_2/CrBr_3$ vdW structures reveals strikingly different energy shifts in the K and K' valleys of the $MoSe_2$, due to ferromagnetism in the $CrBr_3$ layer. Strong asymmetry is observed at both the A- and B-exciton resonances. Density-functional calculations indicate that valley-asymmetric MPIs depend sensitively on the spin-dependent hybridization of overlapping bands, and as such are likely a general feature of such hybrid vdW structures. These studies suggest routes to selectively control *specific* spin and valley states in monolayer semiconductors. [1] J. Choi, C. Lane, J.-X. Zhu, S. A. Crooker, Asymmetric magnetic proximity interactions in $MoSe_2/CrBr_3$ van der Waals heterostructures, *in press (Nature Materials); arXiv:2206.09958*

11:15 AM *QM01.01.03
Floquet Engineering of Quantum Materials on Demand Junyi Shan[1], Mengxing Ye[2], Hao Chu[1], Sungmin Lee[3], Je-Geun Park[3], Leon Balents[2] and David Hsieh[1]; [1]California Institute of Technology, United States; [2]University of California, Santa Barbara, United States; [3]Seoul National University, Korea (the Republic of)

Tuning properties of quantum materials with light has a long history - from simple heating to driving selective excitations inside the materials. While many novel optical engineering mechanisms have been proposed, there has been a gap regarding the experimental realizations of light modulating material properties without being absorbed, i.e., the Floquet engineering strategy. In this talk, I will discuss our recent experiments on using light to Floquet engineer van der Waals materials in a heating-free manner. We achieved reversible control of the nonlinear optical properties and the bandgap size of the antiferromagnetic insulator MnPS$_3$ on a timescale of 100 femtoseconds. I will also discuss how we can combine this Floquet principle and the versatile material platforms in order to create new phases of matter out of equilibrium.

11:45 AM *QM01.01.04
Spin Dynamics in Electron-Doped Cr2Ge2Te6 and Other van der Waals Magnets Hidekazu Kurebayashi; University College London, United Kingdom

Charge carrier injection into materials are a powerful way to enhance targeted material properties as well as to discover novel, hidden quantum phases. For van der Waals (vdW) materials, it is possible to inject charge carriers into nano-meter thick exfoliated flakes by solid-state and electrolyte gating, and into bulk flakes by chemical doping within vdW gaps, so-called intercalation. This approach is very effective in controlling magnetism, e.g. a dramatic change of Curie temperature of vdW magnet such as Fe3GeTe2 and Cr2Ge2Te6 been observed by electrostatic carrier injection [1, 2] and intercalation [3]. Here, we present our work on spin dynamics characterisation of Na-intercalated, electron-doped Cr2Ge2Te6. We have successfully intercalated Na atoms into the vdW gap of pristine Cr2Ge2Te6 and observed clear enhancement of its conductivity due to electron doping and an increase of Curie temperature from 65 K (undoped case) to 240 K (doped-system).
We characterised the spin dynamics properties by ferromagnetic resonance techniques and extrapolate the Gilbert damping to be in the order of 10^{-4} at higher temperatures, which is at least an order of magnitude smaller compared to spin dynamics response in other vdWs magnetic systems [4]. We also find the doped system to host exotic magnetic state at low temperature, where we pick up signatures of canonical spin glassiness in the DC magnetometry and AC magnetic susceptibility measurements. Hence, a bulk Na-Cr2Ge2Te6 system seems to have intriguing magnetic properties which are not realised by the on-chip electrostatic doping in 2D-flakes [1,2].
If time permits, we will show relevant spin dynamics properties for other materials to compare their results with those of Na-CGT.

Tuesday Afternoon, April 11, 2023
Marriott Marquis, Fourth Level, Pacific A

1:30 PM *QM01.02.01
Skyrmionics and Meronics Based on Inversion Symmetric Layered Ferromagnets Luis Balicas[1,2]; [1]Florida State Univ, United States; [2]National High Magnetic Field Lab, United States

Here, we will discuss the role of topological spin textures on the electrical and thermal transport properties of layered ferromagnets like Fe$_{3-x}$GeTe$_2$ and Fe$_{5-x}$GeTe$_2$. In Fe$_{3-x}$GeTe$_2$, a layered ferromagnetic displaying a Curie temperature $T_c \approx 220$ K, we observe[1] anomalous transport variables for magnetic fields m_0H applied along the gradient of the chemical potential generated by thermal gradients or electrical currents, a configuration that should not lead to their observation due to the absence of Lorentz force. These anomalous planar quantities are found to not scale with the component of the planar magnetization ($M_{\|}$), showing instead a sharp decrease beyond $m_0H_{\|} = 4$ T which is the field required to align the magnetic moments along $m_0H\|$. We argue that locally chiral spin structures, such as skyrmions, and probably hybrid domain walls, lead to a field dependent spin-chirality. This in turn generates a novel type of topological transport in the absence of interaction between the magnetic field and electrical or thermal currents. For Fe$_{5-x}$GeTe$_2$ ($T_c \approx 310$-330 K) this unconventional topological transport is observed at, and beyond room temperature, correlating with the observation of merons through Lorentz transmission electron microscopy (LTEM)[2]. LTEM in Fe$_{5-x}$GeTe$_2$ also reveals the coexistence of merons with skyrmions upon approaching its magnetostructural transition at $T_s \approx 110$ K, due to a progressive rotation of the magneto-crystalline axial anisotropy towards the c-axis. The presence of these spin textures and their coexistence is exposed by thermal transport measurements as a function of the temperature, which unveils, for example, an anomalously large Nernst effect. Therefore, in Fe$_{5-x}$GeTe$_2$ the formation and stabilization of distinct thermally driven topological spin textures can be chosen on demand by just adjusting the temperature. Given that Fe$_{5-x}$GeTe$_2$ can be grown in large area substrates and its Ni and Co doped crystals display T_cs well above room temperature, we suggest that this compound along with its doped variants, can, not only open a new era in skyrmionics, but also open a new field of research, that of meronics.

2:00 PM *QM01.02.02
Tailored Heterointerfaces in 2D Atomic Crystals and 2D Molecular Frameworks Thomas Kempa; Johns Hopkins University, United States

The tuning of lateral and vertical interfaces between 2D materials offers a powerful means of eliciting new phenomena. Vertical stacking of 2D atomic crystals or synthesis of 2D crystals with embedded lateral junctions furnishes materials with heterointerfaces that support unique excitonic, electronic, and magnetic properties. Here we present our progress towards the investigation of two new interfaces in and between 2D materials. First, we perform directed growth of heterostructured transition metal dichalcogenide nanoribbons with the goal of achieving precise control over the type, location, and extent of lateral heterointerfaces in these crystals. Precise spatial control over the placement of these heterointerfaces provides new avenues for tuning the optoelectronic properties of these crystals and permits realization of candidate single-photon emitters. Second, we explore the design of heterointerfaces between 2D atomic crystals and 2D molecular assemblies. The intersection of these atomic lattices with synthetic molecular lattices adds new degrees of freedom for tuning and instantiating electronic states through control of spin-orbit coupling gap, charge transfer, and dielectric environment. We demonstrate how such architectures offer fertile ground to explore new photonic devices.

3:00 PM *QM01.03.01
Spin-Charge-Lattice Coupling in 2D Magnetic Semiconductor CrSBr John W. Cenker[1], Kaichen Xie[1], Shivesh Sivakumar[1], Geoff Diederich[1], Harvey Yang[1], Zhaoyu Liu[1], Avalon Dismukes[2], Daniel Chica[2], Xiaoyang Zhu[2], Xavier Roy[2], Jiun-Haw Chu[1], Di Xiao[1,1], Ting Cao[1] and Xiaodong Xu[1,1]; [1]University of Washington, United States; [2]Columbia University, United States

The interplay of spin and charge in magnetic semiconductors lies at the heart of the field of spintronics and has attracted significant interest for new computing technologies. In this talk, I report our recent progress in studying and controlling spin-charge coupling in the layered antiferromagnetic semiconductor CrSBr. Such coupling enables the anisotropic Wannier-type excitons to serve as a powerful sensor of the interlayer magnetic order, and the generation of giant tunneling magnetoresistance (TMR) in magnetic tunnel junction (MTJ) heterostructures. Using these probes, we found that the magnetic order is extremely tunable by the application of tensile strain, with a reversible antiferromagnetic to ferromagnetic phase transition occurring at large but experimentally feasible strains. We utilize this phase transition to realize a straintronic MTJ, with zero-field TMR switching approaching 10,000% at 30 K and remaining above 100% until ~ 140 K. Moreover, the fine and continuous control of interlayer magnetic exchange coupling enables us to create metastable domains which switch stochastically with a strain-tunable sigmoidal response curve akin to the stochastic binary neuron or probabilistic bit. Our results establish CrSBr as an exciting platform for harnessing spin-charge-lattice coupling towards new, highly tunable 2D devices for spintronic applications, such as magnetic memory, random number generation, and probabilistic and neuromorphic computing.

3:30 PM QM01.03.02
Magnetic Order Change and Proximity Coupling of Single Photon Generation in van der Waals Heterostructures Xiangzhi Li[1], Andrew Jones[1], Junho Choi[1], Huan Zhao[1], Vignesh Chandrasekaran[1], Michael T. Pettes[1], Andrei Piryatinski[1], David Aaron Broadway[2], Maerta Tschudin[2], Patrick Reiser[2], Patrick Maletinsky[2], Nikolai Sinitsyn[1], Scott Crooker[1] and Han Htoon[1]; [1]Los Alamos National Laboratory, United States; [2]University of Basel, Switzerland

Quantum light emitters (QEs) that are stable and can be positioned deterministically are of the utmost importance for the evolution of solid-state photonic quantum technologies. Highly chiral QEs are necessary for the construction of advanced quantum networks. Local strain-induced proximity effects can be employed in concert with strain engineering to generate chiral quantum effects (QEs) in WSe2/NiPS3 heterostructures.[1] One of the numerous advantages of these on-chip QEs is that they may be easily coupled to other photonic and/or plasmonic devices. In addition, magnetic two-dimensional materials provide unparalleled opportunities for studying magnetic material responses at the two-dimensional limit. These magnetic two-dimensional materials provide the optimal platform for controlling spin and photon degrees of freedom (DOF), facilitating the regulation of spin degeneracy, and enhancing light-matter interactions of quantum effects in atomically thin semiconductor nanostructures. Nonetheless, the origin of this finding is not completely understood. Here, we present the most recent experimental research discoveries that address the underlying puzzles. Using scanning NV microscopy, we are able to offer direct evidence of a change in magnetic order following the nano-indentation of NiPS3. Our findings are consistent with temperature-dependent magneto-PL studies. In addition, we have used the nano-indentation technique with other members of the TMPX3 family, the same proximity effect is in action here as well. Our recent findings establish TMD/TMPX3 heterostructures as viable material platforms for the continuing investigation of novel emergent phenomena and the advancement of solid-state quantum transduction and sensing technologies.

Topology for Energy Efficient Spintronics and Energy Conversion Claudia Felser; Max Planck Institute, Germany

Topology, a mathematical concept, recently became a hot and truly transdisciplinary topic in condensed matter physics, solid state chemistry and materials science. All 200 000 inorganic materials were recently classified into trivial and topological materials, such as topological insulators, Dirac, Weyl and nodal-line semimetals, and topological metals [1]. More than 25% of all materials host topological bands around the Fermi energy. Beyond the single particle picture, we have identified first antiferromagnetic topological materials [2]. Experimentally, we have realized ferromagnetic materials, examples are Co_2MnGa and $Co_3Sn_2S_2$. Surprisingly all crossings in the band structure of ferromagnets are Weyl nodes or nodal lines [3]. Mn_3Sn and $YbMnBi_2$ are examples of non collinear antiferromagnetic Weyl semimetals, which show giant values for the anomalous Hall and Nernst effect [4]. It is expected that many more ferromagnetic materials with Weyl Fermions are out there, also in 2D materials. In the context of real space topology, skyrmions and antiskyrmions are a possible new direction for new data storage [5]. Our goal is to identify new quantum-materials for highly efficient spintronics, quantum computing and energy conversion.

4:15 PM QM01.03.05
A Systematic DFT+U and Quantum Monte Carlo Benchmark of Magnetic Two-dimensional (2D) CrX_3 (X = I, Br, Cl, F) Daniel Wines, Kamal Choudhary and Francesca Tavazza; National Institute of Standards and Technology, United States

The search for two-dimensional (2D) magnetic materials has attracted a great deal of attention because of the experimental synthesis of 2D CrI_3, which has a measured Curie temperature of 45 K. Often times, these monolayers have a higher degree of electron correlation and require more sophisticated methods beyond density functional theory (DFT). Diffusion Monte Carlo (DMC) is a correlated electronic structure method that has been demonstrated successful for calculating the electronic and magnetic properties of a wide variety of 2D and bulk systems, since it has a weaker dependence on the Hubbard parameter (U) and density functional. In this study we designed a workflow that combines DFT+U and DMC in order to treat 2D correlated magnetic systems. We chose monolayer CrX_3 (X = I, Br, Cl, F), with a stronger focus on CrI_3 and $CrBr_3$, as a case study due to the fact that they have been experimentally realized and have a finite critical temperature. With this DFT+U and DMC workflow and the analytical method of Torelli and Olsen, we estimated an upper bound of 43.56 K for the T_c of CrI_3 and 20.78 K for the T_c of $CrBr_3$, in addition to analyzing the spin densities and magnetic properties with DMC and DFT+U. We expect that running this workflow for a well-known material class will aid in the future discovery and characterization of lesser known and more complex correlated 2D magnetic materials.

8:30 AM *QM01.04.01
Magneto-Optical Properties of Perovskite Thin Films and Crystals Angela R. Hight Walker; National Institute of Standards and Technology, United States

Hybrid lead halide perovskites have opened a new era for photovoltaics research over the last decade due to their high energy conversion energy. These materials are promising for future electronics and optoelectronics and applications in spin-electronic devices due to their unique properties, such as high coherent emission, spin-orbit coupling, and strong light-matter interaction [1]. Recent experimental and theoretical studies have shown that the polar organic cations affect the lattice polarization, giving rise to a ferroelectric behavior and enhancing their photovoltaic performance [2]. Furthermore, magnetism in halide perovskite at room temperature has been confirmed, suggesting a route toward spintronics applications based on magneto-optical perovskites [3-4]. However, the hybrid perovskites' magnetic properties are not well understood. Our work reports magneto-photoluminescence (MPL) and magneto-Raman (MR) measurements of methylammonium lead iodide $CH_3NH_3PbI_3$ ($MAPbI_3$) ~ 280 nm thin film materials at low temperatures (<60 K), where the crystalline structure is in the orthorhombic domain. We obtained different MPL spectra from random spots on the sample surface and fitted them with gaussian curves at 55 K and 1.6 K. The MPL spectra confirm the existence of a dual emission peak at a low temperature, consistent with previous works [5]. For each spot, we applied a magnetic field up to 9T in the perpendicular direction of the surface and analyzed the MPL plots as a function of the external magnetic field. Changes in the intensity, the central position, and the FWHM of the gaussian components were observed in the MPL spectra. We also compare the response of the thin film at room temperature (tetragonal domain) under the external magnetic field to the low temperature data.

Probing Collective Magnetic Excitations in Magic-Angle Twisted Bilayer Graphene Correlated Insulating States with Electron Spin Resonance Spectroscopy Rupini Kamat[1], Sandesh Kalantre[1], Aaron Sharpe[2], Takashi Taniguchi[3], Kenji Watanabe[3], Marc Kastner[1] and David Goldhaber-Gordon[1]; [1]Stanford University, United States; [2]Sandia National Laboratories, United States; [3]National Institute for Materials Science, Japan

In MATBG, correlated insulating (CI) states emerge at an integer number of electrons per moiré unit cell. These states are suspected to emerge from successive filling of the fourfold degenerate spin and valley states of the nearly-flat miniband [1][2]. This would imply that different CI states in MATBG have different associated spin/valley flavor polarizations. Indeed evidence of an anomalous hall effect in MATBG, stemming from polarized orbital magnetic moments, has been observed at CI states associated with specific integer filling factors [3][4][5], albeit in only a handful of samples. However, the order in which the spin/valley flavor states are populated remains unknown, as does the nature of how electrons in these states couple to one another and to external magnetic fields. One potential technique for learning the flavor polarization properties of these CI states is to probe their excitations using resistively-detected electron spin resonance (ESR). We implement this by measuring near-DC transport through an encapsulated MATBG device, noting the change in resistivity when we couple in microwave magnetic fields from a microfabricated superconducting coplanar waveguide.

In general, ESR is a form of microwave spectroscopy: Microwaves are shone on the material, and when the energy of the microwaves exactly matches the energy cost to generate an excitation of a magnetic state, the material will absorb the microwaves. In resistively-detected ESR, this resonant microwave absorption is observed via a corresponding change in resistance, through heating of the electron system or some other mechanism. This measurement has been performed on several CVD graphene samples [6][7][8][9] as well as on MATBG with spin-orbit coupling induced by a proximal TMDC layer [10], but has yet to be seen in more canonical MATBG with clear CI states. Given the suspected spin/valley polarization of CI states and the ability of ESR to probe collective magnetic excitations, ESR offers the prospect of unambiguously establishing the flavor polarization of the CI states. Understanding the magnetic ground state of these CI states may also offer clues to the nature of superconducting pairing that occurs upon doping these flavor-polarized states.

Magnetic Properties of CrX_3 in Excited States Prakash Mishra and Tunna Baruah; The University of Texas at El Paso, United States

The CrX_3 (X=Cl,Br,I) are a new class of 2D magnetic semiconductor that show interesting properties such as ferromagnetism in monolayers, magneto-optical Kerr and Faraday effects, large tunnel magnetoresistance etc. The magnetism in these materials can be tuned through chemical doping or external field. In this talk we present our theoretical studies on the magnetic properties of the excited states of CrX_3 monolayer. Our calculations are carried out using density functional theory for different types of excitations on a cluster model of chromium trihalides. The cluster model of the monolayer is built with six Cr centers whereas a bilayer has two six-center Cr-halide clusters. These clusters are cut-outs of the bulk but are further passivated and optimized.

We performed the three types of excited state calculations namely a) photo-induced excited state, b) excited states with different symmetry, and c) spin-flip excitons. The photo-induced single particle-hole excited states are being calculated with the perturbative delta-SCF method. The dipole and spin allowed transitions are selected to determine the possible set of excited states within the range of 1.5-3.5 eV. The calculated magnetic properties such as spin moments, exchange coupling constants, and magnetic anisotropy energies of these systems will be presented and discussed.
This work is supported by the National Science foundation through grant no. DMR-2105109.

Imaging Domain Switching and Revealing Emergent Orders in 2D Antiferromagnets Liang Wu; University of Pennsylvania, United States

The family of monolayer two-dimensional (2D) materials hosts a wide range of interesting phenomena, including superconductivity, charge density waves, topological states and ferromagnetism, but direct evidence for antiferromagnetism in the monolayer has been lacking. Antiferromagnets have attracted enormous interest recently in spintronics due to the absence of stray fields and their terahertz resonant frequency. Despite the great advantages of antiferromagnetic spintronics, controlling and directly detecting Neel vectors in 2D materials have been challenging. In my talk, I will show that we have developed a sensitive second harmonic generation (SHG) microscope and detected long-range Neel antiferromagnetic (AFM) order down to the monolayer in MnPSe3[1]. In MnPSe3, we observed the switching of an Ising-type Neel vector reversed by the time-reversal operation. We rotated them by an arbitrary angle irrespective of the lattice by applying uniaxial strain. The phase transition in the presence of strain in MnPSe3 falls into the Ising universality class instead of the XY type, and the Ising Neel vector is locked to the strain. I will also talk about using the newly developed optical confocal microscopy to image other emergent orders in 2D antiferromagnets[2, 3,4].

Coherent Spin-Phonon Coupling in the Layered Ferrimagnetic Crystal $Mn_3Si_2Te_6$ Luis M. Martinez[1,2], Yu Liu[2], Cedomir Petrovic[3], Marshall Campbell[2], Michael T. Pettes[2], Rohit Prasankumar[2], Srinivasa Rao Singamaneni[1] and Prashant Padmanabhan[2]; [1]The University of Texas at El Paso, United States; [2]Los Alamos National Laboratory, United States; [3]Brookhaven National Laboratory, United States

Layered magnetic materials have enormous potential in enabling the next generation of high-speed nanoscale information storage and spintronic technologies. In order to realize their promise, it is of critical importance that we understand how lattice structure and magnetic order are coupled, particularly on their intrinsic ultrafast time scales. Here, we use ultrafast optical microscopy to study the coherent lattice dynamics of the pseudo-van der Waals ferrimagnet $Mn_3Si_2Te_6$. Our results reveal strong coherent phonon oscillations under near-infrared pumping that persist from room temperature down to below the magnetic ordering temperature of ~75 K. An analysis of the frequency of these modes as a function of temperature highlights a significant stiffening of the oscillatory frequency across the critical temperature that cannot be explained using a thermal expansion model. Instead, we suggest that this is due to an exchange-mediated contraction of the lattice, highlighting a strong magneto-structural coupling in this material. This is mirrored in the temperature dependence of incoherent dynamics, measured across the magnetic phase transition. Our findings showcase the ultrafast dynamics in this semiconducting layered ferrimagnet and suggest a new route for their optical control through their intertwined electronic, lattice, and spin degrees of freedom.

10:45 AM *QM01.05.02
Imaging of Magnetic Domain Behavior in van der Waals Ferromagnets Charudatta Phatak[1], Arthur McCray[1,2], Yue Li[1], Eric Qian[2], Jianguo Wen[1], Wei Wang[1], Xuedan Ma[1], Duck Young Chung[1], Mercouri G. Kanatzidis[2] and Amanda Petford-Long[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

Magnetic van der Waals (vdW) materials are increasingly studied due to the discovery of ordered ferromagnetism down to monolayer thickness as well as them hosting chiral and topologically protected magnetic domains. The realization of such states in van der Waals ferromagnets opens further opportunities to explore and control their behavior using interfacial interactions such as strain or interfacing with dissimilar materials to create novel functionality in heterostructures. In this work, we will present the magnetic domain behavior of two iso-structural compounds – Cr2Si2Te6 (CST) and Cr2Ge2Te6 (CGT). They both belong to the R–3 space group, with Cr forming honeycomb network and octahedrally coordinated with Te atoms. CST shows a Curie temperature of 30 K while CGT has a Curie temperature of 70 K. We have performed an in-situ study and directly imaged the magnetic domain structure under varied temperature and external magnetic fields using cryo-Lorentz transmission electron microscopy (LTEM). They both show easy-axis of magnetization along the c-axis of the crystal. In CGT, we observe the formation of Bloch-type domains and bubble lattices with mixed chirality. Despite a lack of chiral energy terms in CGT, we have also observed topologically protected lattices containing homochiral bubbles. By contrast, in CST, we observe formation of Néel-type stripe domains and skyrmions. Both these materials also possess a strong magneto-elastic coupling. We will discuss the implications of strain and magnetostriction on the alignment of magnetic domains and skyrmion/bubble lattices in these materials.

11:15 AM QM01.05.03
Coherent Exciton-Magnon-Photon Interaction in van der Waals Magnets Florian Dirnberger[1], Rezlind Bushati[1,2], Biswajit Datta[1] and Vinod Menon[1,2]; [1]The City College of New York, United States; [2]The City University of New York, United States

Strong light-matter interaction results in the formation of half-light half-matter quasiparticles (polaritons) that take on the advantages of both. The advent of van der Waals magnets that host electronic excitations (excitons) correlated to the magnetic order presents a unique opportunity to implement strong light-matter coupling and thereby manipulate electronic and spin degrees of freedom via light. Here we report our recent works on such strongly coupled exciton

polaritons that are correlated with the underlying magnetic order. Specifically, we will discuss the formation of polaritons in antiferromagnetic insulator NiPS3 and the use of polariton nonlinear spectroscopy to shed light on the nature of excitons in this system [1]. Following this, we will discuss our work on magnetic semiconductors and the potential to modify magneto-optical response via strong exciton-photon coupling.

11:30 AM *QM01.05.04
Scanning Probe Microscopy of Stray Magnetic Fields Produced by 2D Magnets Martino Poggio; University of Basel, Switzerland

The ability to map magnetic field sensitively and on the nanometer-scale – unlike global magnetization or transport measurements – overcomes ensemble or spatial inhomogeneity in systems ranging from arrays of nanometer-scale magnets, to superconducting thin films, to strongly correlated states in van der Waals heterostructures. Local imaging of nanometer-scale magnetization, Meissner currents, or current in edge-states is the key to unraveling the microscopic mechanisms behind a wealth of new and poorly understood condensed matter phenomena.
I will discuss efforts in our group aimed at developing and applying high-sensitivity, high-resolution, non-invasive magnetic scanning probes. In particular, we have been pushing two types of sensors to their limits: mechanical sensors, based on NW cantilevers, and superconducting sensors, based on nanometer-scale superconducting quantum interference devices. I will also discuss recent imaging experiments with these tools on 2D magnets, including EuGe$_2$ and Cr$_2$Ge$_2$Te$_6$.

SESSION QM01.06: Sensing/Imaging/Probing/Magneto-Optical Properties III

1:30 PM QM01.06.01
Sensing the Local Magnetic Environment Through Optically Active Defects in a Layered Magnetic Semiconductor Julian Klein[1], Zhigang Song[2], Benjamin Pingault[2], Florian Dirnberger[3], Hang Chi[1], Jonathan Curtis[2], Rami Dana[1], Rezlind Bushati[3], Jiamin Quan[3], Lukas Dekanovsky[4], Zdeněk Sofer[4], Andrea Alu[3], Vinod Menon[3], Jagadeesh Moodera[1], Marko Loncar[2], Prineha Narang[2] and Frances Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States; [3]The City College of New York, United States; [4]Department of Inorganic Chemistry, University of Chemistry and Technology Prague, Czechia

Van der Waals layered magnets have triggered strong interest for studying low-dimensional magnetism. [1] A particularly attractive material is the magnetic semiconductor CrSBr. [2] The combination of air stability, energy band gap of approximately 1.6eV and high Néel temperature (132 K) provide several exciting avenues for scientific exploration. [3, 4, 5] CrSBr shows strong-light matter interaction with excitonic emission embedded in a rich magnetic phase diagram. Defects have been shown to be important for the magneto-transport in this material [5] and are generally attractive candidates for engineering artificial magnetic textures. [6]

Here, we show magnetically correlated optically active defects in CrSBr. [7] Optical emission properties in multilayer samples are excellent with 1 meV linewidth. We identify these properties as originating from a quasi-1D electronic behavior due to an anisotropic band dispersion and weak interlayer hybridization, allowing us to probe low-dimensional properties in a multilayered sample with high structural quality. [8] From scanning probe microscopy we observe different types of defects, with the Br vacancy as the most abundant defect (~ 10^{13} cm^{-2}). In low-temperature (T = 4K) photoluminescence and photoluminescence excitation spectroscopy we characterize the defect emission. The emission is polarized, shows power saturation, and can be efficiently populated by resonant excitation of excitonic resonances. We also probe the exciton and defect emission in magneto-PL. Both excitonic and defect emission energies are directly affected by changes in the magnetic order, but the shifts of the defect emission are up to 100 times weaker (depending on the orientation of the external magnetic field), highlighting the layer-localized nature of the defect wave function. Most strikingly, a recently discussed defect-related magnetic phase at low temperature (30 - 40K) [5] directly correlates with a strong narrowing of the defect emission, suggesting a direct change in the spin of the involved bands of the defect transition. We will finally discuss the coupling mechanisms of the defects and their interactions in the context of the quasi-1D electronic structure. We conclude that CrSBr is an exciting platform for investigating optically active defects that are correlated with the magnetic phase diagram, properties that open new avenues for tailor-made complex magnetic phases with easy direct optical access.

Inversion Symmetry Breaking Revealed in Fe$_{3-x}$GeTe$_2$ by Second Harmonic Generation Kaixuan Zhang and Je-Geun Park; Seoul National University, Korea (the Republic of)

Symmetry establishes the cornerstone of modern condensed matter physics since symmetry breaking would trigger exotic phase transitions and produce emergent quantum phenomena. Therefore, tailoring symmetry by symmetry engineering provides a promising and powerful method to control matter's quantum characteristics and functionalities. As a new-and-rare case of van-der-Waals topological ferromagnetic metal, Fe$_3$GeTe$_2$ (FGT) receives intensive attention recently and exhibits a spectrum of intriguing properties. Thanks to the large Berry curvatures of its topological Noda-line bands, FGT displays large anomalous Hall conductivity[1] and anomalous Nernst effect[2]. More importantly, gigantic intrinsic spin-orbit torque[3-6] by current has been revealed both theoretically and experimentally in single FGT without additional heavy-metal layer, rendering it to be an ideal and unique model system for the new conceptual spin-orbit torque and spintronics. Pristine FGT hosts a hexagonal structure with the centrosymmetric space group P6$_3$/mmc. If inversion symmetry is broken by reducing the space group to a non-centrosymmetric one, more novel phenomena and rich physical properties might present in such a system with both time-reversal and inversion symmetry breaking.

In this work, we investigated the symmetry of $Fe_{3-x}GeTe_2$ by second harmonic generation (SHG) and convergent beam electron diffraction (CBED) techniques. We discovered the inversion symmetry breaking of $Fe_{3-x}GeTe_2$, with space group reduced from the centrosymmetrical $P6_3/mmc$ to a noncentrosymmetrical polar space group P3m1. This new symmetry was co-evidenced by SHG and CBED. Such symmetry reduction and inversion symmetry breaking give rise to non-linear optical response, i.e., three-fold SHG pattern. It also backs up the gigantic spin-orbit torque in FGT in our previous report[3][5]. Our work enriches the scope of symmetry engineering for exotic quantum properties and spintronics.

Wednesday Afternoon, April 12, 2023
Marriott Marquis, Fourth Level, Pacific A

3:00 PM *QM01.07.01
Studies of Topological Magnets Under High Pressure Wenli Bi; The University of Alabama at Birmingham, United States

Eu-based magnetic materials with strong local magnetic moments have attracted much attention as intrinsic magnetic topological semimetal candidates, providing a platform to control topological states by manipulating magnetism. Here in this work, we apply pressure as an effective way to tune magnetic exchange interaction and the electronic states. Due to the small sample size in high-pressure studies using diamond anvil cells, it is technically challenging to characterize material physical properties. With the development of synchrotron X-ray techniques (diffraction, scattering, and spectroscopy) combined with extreme sample environment (pressure, temperature), information on magnetic and electronic states can be obtained under pressure on a microscopic scale. In this talk, I will discuss our recent interesting results on controlling magnetism, valence, and crystal structure in selected Eu-based topological magnetic materials using high pressure and synchrotron X-ray tools.

3:30 PM QM01.07.02
Probing the Two-Dimensional Materials with Momentum and Spin Resolved Photoelectron Microscope Der Hsin Wei[1], Tzu-Hung Chuang[1], Chuan-Che Hsu[1], Jyun-Syong Jhuan[1], I-Chun Yeh[2,1], Wei-Sheng Chiu[3,1], Wei-Ting Hsu[2], Shangjr Gwo[2,1] and Chih-Kang Shih[4,2]; [1]National Synchrotron Radiation Research Center, Taiwan; [2]National Tsing Hua University, Taiwan; [3]National Taiwan University of Science and Technology, Taiwan; [4]University of Texas at Austin, United States

Two-dimensional (2D) materials are under intensive study for their unconventional properties and potential applications. During the course of study, gaining knowledge of a material's electronic structures is often the critical step. However, this is not an easy task for the conventional photoelectron/photoemission spectroscopy (PES) setup considering there is a large mismatch between the lateral dimensions of a single flake of 2D van der Waals materials (~ µm) and the detection area defined by the spectrometer (~ mm). For 2D materials, the proper PES detection scheme needs to include additional position sensitivity. At Taiwan Photon Source beamline 27A2 (TPS 27A2), we have set up a photoelectron-based momentum microscope whose position sensitivity is given by the imaging lens sitting in front of the hemispherical analyzer (HSA) [1]. In addition, the microscope can record spin-resolved images via inserting an iridium-based spin mirror. In this presentation, I will describe our microscope's performance through selected commissioning studies conducted on the single crystal surface and monolayer/multilayer transition metal dichalcogenides (TMDs). In brief, our studies indicate that the real-space images taken with work function contrast may serve as an alternative means to identify the number of layers in a vdW thin film, and the momentum-space images offer a graphical means to measure the twisted angle between stacked 2D layers directly.

[1] Chuang, Jhuang, Hsu, Chiu, Yeh, and Wei (in preparation).

3:45 PM *QM01.07.04
Direct Visualization of Electronic Transport in a Quantum Anomalous Hall Insulator Katja C. Nowack; Cornell University, United States

A quantum anomalous Hall (QAH) insulator is characterized by quantized Hall and vanishing longitudinal resistances at zero magnetic field that are protected against local perturbations and independent of sample details. This insensitivity makes the microscopic details of the local current distribution inaccessible to global transport measurements. Accordingly, the current distributions that give rise to the transport quantization are unknown. In this talk, I will discuss how we use magnetic imaging to directly visualize the transport current in the QAH regime. As we tune through the QAH plateau by electrostatic gating, we clearly identify a regime in which the sample transports current primarily in the bulk rather than along the edges. We observe the current entering the device through a hot-spot located in the corner of the contact with its location switching, when we switch the sample's magnetization. Furthermore, we image the local response of the equilibrium magnetization to electrostatic gating. Combined, these measurements suggest that the current flows through incompressible regions whose spatial structure changes throughout the QAH regime. Identifying the appropriate microscopic picture of electronic transport in QAH insulators and other topologically non-trivial states of matter is a crucial step towards realizing their potential in next-generation quantum devices.

4:15 PM QM01.07.05
Evolution of the Magnetic Properties via Pressure in Ternary Transition Metal Chalcogenides Rubyann Olmos[1,2], Po-Hao Chang[2], Prakash Mishra[2], Tunna Baruah[2], Rajendra Zope[2] and Srinivasa Rao Singamaneni[2]; [1]Rice University, United States; [2]University of Texas at El Paso, United States

Pressure has been used as a mechanism to induce structural and magnetic phase transitions in many materials whose layers are linked via vdW forces. Such materials with weakly held layers allow relatively easy manipulation of the superexchange mechanism. Using hydrostatic pressure as a disorderless means to manipulate the interlayer coupling, we apply pressure to $Mn_3Si_2Te_6$, and $CrSiTe_3$ up to ~1 GPa. Magnetic property measurements with the application of pressure on $Mn_3Si_2Te_6$ revealed that the ferrimagnetic transition temperature increases while the opposite occurs for $CrSiTe_3$. It is also observed that pressure effects the saturation magnetization for both materials by decreasing up to pressures of 0.9 GPa. However, for $Mn_3Si_2Te_6$ the magnetization changes from below pristine magnetization to being larger than pristine magnetization once reaching 1.06 GPa of pressure. The magnetization as a function of pressure reveals no clear trend, whereas the magnetic ordering temperature steadily increases or decreases for $Mn_3Si_2Te_6$ and $CrSiTe_3$, respectively, as a function of increasing pressure. Theoretical calculations show that the overall pressure effect on layer separation, bond angle, and exchange coupling are found to strongly influence the change in subsequent magnetic characteristics in $Mn_3Si_2Te_6$. We confirm that the exchange coupling in $Mn_3Si_2Te_6$ is strongly frustrated, and we find that the first nearest neighbor interaction is the most dominant component that shows a dependence with pressure. In $CrSiTe_3$, the exchange coupling parameters exhibit very little dependence on the pressure.

SESSION QM01.08: Growth Intercalculation, Magnetic and Magneto-Optical Properties

Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM QM01.08.01
Investigating Structural and Magnetic Properties of Low-Dimensional Fe_xNbSe_2 Guanming Li, Matthew Erodici and Kwabena Bediako; University of California, Berkeley, United States

Magnetically intercalated 2D transition metal dichalcogenides (TMDs) represent a promising class of low-dimensional magnetic materials for ultralow-power applications based on the manipulation of electron spin. The ability to tune the magnetic properties based on the choice of intercalant and host lattice offers a versatile platform for designing novel 2D magnets that would be difficult to access from their bulk counterparts, yet the phase space afforded by this approach remains largely unexplored. Here, we study the chemical intercalation of Fe^{2+} ions into few-layer 2*H*-$NbSe_2$ to engineer long-range antiferromagnetic order approaching the 2D limit. Utilizing Raman spectroscopy, we investigate the structural changes between $NbSe_2$ and Fe_xNbSe_2 and track the phonon modes accompanied by Fe^{2+} intercalation to gauge the extent and homogeneity of intercalant ordering. Additionally, we monitor the effects of thermal annealing at various temperatures on the intercalation amount and degree of ordering in the material to potentially find an onset temperature for leveraging the intercalation process. Furthermore, we characterize the magnetic behavior of the system via variable-temperature magnetotransport measurements. We anticipate our results to be relevant in understanding the intercalation of related transition metal intercalated TMD systems and aid in the scalability and development of 2D heterostructures for use in next generation low-power electronic and spintronic devices.

5:00 PM QM01.08.02
Phase-Controlled Growth of Two-Dimensional Magnetic Chromium Tellurides Jiefu Yang, Bijun Tang, Naizhou Wang, Yao Wu and Chao Zhu; Nanyang Technological University, Singapore

The discovery of ferromagnetic ordering in two-dimensional (2D) materials has sparked significant interest in both academic and industrial communities for its great potential in fundamental research and novel application such as spintronics. Recently, chromium tellurides (Cr_xTe_y) with various phases and compositions, are emerging as a promising class of novel 2D ferromagnets, attributed to their tunable magnetic ordering, high Curie temperature (T_C), and desirable stability. It is believed that the rich structural and magnetic variations of Cr_xTe_y should arise from the position and content of the intercalated Cr atoms between adjacent layers. However, the synthesis of ultrathin and high-quality Cr_xTe_y with controlled phases and compositions is challenging, not to mention the in-depth investigation of the effect of intercalated Cr atoms on magnetic ordering. In this work, by carefully tuning the reaction temperature and carrier gas flow rate, controllable growth of various Cr_xTe_y, including CrTe, Cr_2Te_3, Cr_5Te_8, and $CrTe_2$, is achieved with the facile one-step chemical vapor deposition (CVD) method. Atomic-resolution scanning transmission electron microscopy-annular dark field imaging is adopted to unravel the phases of as-synthesized Cr_xTe_y. Magnetic properties of prepared Cr_xTe_y are probed using both reflective magnetic circular dichroism and magnetotransport measurements. Near-rectangular hysteresis loops not only indicate ferromagnetism with strong magnetic anisotropy in all Cr_xTe_y flakes but also suggest the high quality of the CVD-grown samples. Remarkably, the strong correlation between phase and magnetic ordering of Cr_xTe_y is comprehensively studied and reported for the first time. Density functional theory calculations further reveal the difference in ferromagnetic ordering between various phases, which can be well interpreted by the magnetic anisotropy and Stoner criterion. This work sheds light on the scalable and controllable synthesis of 2D magnetic materials and highlights the great potential of Cr_xTe_y for future spintronic applications.

5:00 PM QM01.08.04
Terahertz Time-Domain Spectroscopy of the van der Waals Ferromagnet CrI_3 Jonghyeon Kim[1], Minseong Lee[2], Junghyun Kim[3], Je-Geun Park[3] and Jae Hoon Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Los Alamos National Laboratory, United States; [3]Seoul National University, Korea (the Republic of)

CrI_3 is a ferromagnetic van der Waals insulator with Ising-type long-range ordering below the Curie temperature of 61 K. We have studied the low-frequency electrodynamics of bulk CrI_3 single crystals by using terahertz time-domain spectroscopy at various magnetic fields and temperatures. We identified a zero-field magnon mode at 2.5 cm^{-1} at 1.5 K and modeled the magnetic Hamiltonian based on the behavior of the magnon under the external magnetic field along each crystal axis. Also, the evidence of coupling between the crystal structure and magnetism was discovered from the temperature and magnetic field dependence of certain E_u in-plane optical phonon modes. Our results suggest a strong the Kitaev-type interaction and present the correct structure-field phase diagram of bulk CrI_3.

5:00 PM QM01.08.06
Correlated and Almost-Flat Hund's Metallic Phase in Kagome Nodal Surface Metal $Sc_3Mn_3Al_7Si_5$ Subhasis Samanta[1], Jungseek Hwang[2], Kwang-Yong Choi[2] and Heung-Sik Kim[1]; [1]Kangwon National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Kagome lattice has been actively studied for possible realization of frustration-induced two-dimensional flat bands and a number of correlation-induced phases. The commonality of all realistic Kagome systems proposed, however, is that flat bands are quite dispersive and a charge doping is necessary to shift flat bands close to the Fermi level. Search for Kagome systems with nearly dispersionless flat band close to the Fermi level is an ongoing study. Here, by combining theoretical and experimental tools, we present $Sc_3Mn_3Al_7Si_5$ as a novel realization of correlation-induced almost-flat bands in the Kagome lattice in the vicinity of the Fermi level. Our measurements of magnetic susceptibility, nuclear magnetic resonance, and optical conductivity hint signatures of ferromagnetic fluctuation at very low temperature below 2 K. Below 30 K, temperature dependence of resistivity alludes to development of electronic correlation. Intriguingly, our dynamical mean-field calculations reveal existence of nearly flat band in proximity of Fermi level at k_z=0 plane, induced by electron correlations. Additionally, renormalized nodal surface bands, protected by a product of two-fold screw rotation and time reversal symmetry, exist at k_z=π plane in the Brillouin zone. We observe a transition from a coherent to an incoherent metallic phase, driven by strong Hund's coupling and temperature. With spin-orbit coupling, flat band becomes almost-flat and may potentially host significant spin Hall signatures. These findings broaden a new prospect to harness correlated topological phases in 3*d*-based Kagome systems.

All-Optical Control of Spin in a 2D van der Waals Magnet Maciej Dabrowski[1], Shi Guo[1], Mara Strungaru[2], Paul Keatley[1], Withers Freddie[1], Elton J. Santos[2,2,3] and Robert J. Hicken[1]; [1]University of Exeter, United Kingdom; [2]University of Edinburgh, United Kingdom; [3]Donostia International Physics Center (DIPC), Spain

Two-dimensional (2D) van der Waals magnets provide new opportunities for control of magnetism at the nanometre scale via mechanisms such as strain, voltage and the photovoltaic effect. While ultrafast laser pulses promise the fastest and most energy efficient means of manipulating electron spin, little is known so far about how laser pulses influence the spins in 2D magnets. Stacking of 2D magnetic layers promises to deliver heterostructures with new and tuneable magnetic and magneto-optical properties. Optical control of their magnetic state would provide new opportunities in both data storage and photonics, where the non-volatility of magnetism could deliver improved energy efficiency.

The search for all optical switching (AOS) of magnetic order was ignited by the observation of ultrafast demagnetization in Ni on timescales of ~100fs [1]. AOS of the magnetization was observed in ferrimagnetic GdFeCo [2] but was found to be a thermally driven toggle switching, dependent upon the exchange coupling and different demagnetization times of Gd and FeCo [3]. Helicity dependent AOS has been observed in a number of materials including [Co/Pt] multilayers [4] but usually requires multiple fs optical pulses in a process that is believed to involve full demagnetization followed by the growth of domains driven by thermally generated spin currents. More recently, toggle switching was observed in rare-earth-free synthetic ferrimagnet structures, with switching driven by the flow of optically induced spin current between the constituent ferromagnetic layers [5].

The selective optical excitation of spin-polarised electrons by circularly polarized light in direct band gap semiconductors is well established. Optical orientation of spin within magnetic semiconductors such as GaMnAs has been found to induce coherent precessional dynamics of the Mn moments [6]. However, AOS was not observed and interest waned due to the stubbornly low Curie temperature (~200K). The electronic structure of transition metal dichalcogenides (TMDCs) also permits selective optical excitation of spin-polarised electrons. By tuning to the band gap, circularly polarized light can excite spin-polarised electrons within just one of the K(K') valleys [7]. Transfer of optically excited carriers across the interface within a WSe_2/CrI_3 bilayer leads to the presence of an interfacial exchange field that influences the photoluminescence polarization dependence and intensity [8].

Here we demonstrate laser-induced magnetic domain formation and all-optical switching in ferromagnetic CrI_3 [9]. While the magnetism of bare CrI_3 layers can be manipulated with single laser pulses through thermal demagnetization processes, all-optical switching is achieved in CrI_3/WSe_2 bilayers. The out-of-plane magnetization is switched with multiple femtosecond pulses of either circular or linear polarization, while single pulses result in less reproducible and partial switching. Our results suggest that the switching is driven by spin-dependent interfacial charge transfer between the WSe_2 and the CrI_3.

Resonant X-ray Photon Correlation Spectroscopy Experiments on the van der Waals Antiferromagnet $NiPS_3$ Rajan Plumley[1,2] and Joshua J. Turner[1]; [1]SLAC National Accelerator Laboratory, United States; [2]Carnegie Mellon University, United States

In magnetic Van der Waal (vdW) materials such as the Transition Metal Chalchogenophosphates (TMCPs), magnetic interactions between the transition metal cations are confined to the planes of the vdW layers, and thus present the opportunity to study physical 2D magnetic systems in the laboratory. One such TMCP is the antiferromagnetic Mott-insulator $NiPS_3$, which has recently established itself as a "magnetic analog to graphene" due to its two-dimensionality, hexagonal arrangement of cations, and tuneable transport properties. We employ resonant X-ray diffraction to directly probe the in-plane magnetic order in $NiPS_3$, and with the combination of X-ray Photon Correlation Spectroscopy (XPCS) and X-ray Photon Fluctuation Spectroscopy (XPFS), analyze its dynamics at time-scales ranging from seconds to the ultra-fast regime. We will share and discuss our first X-ray results and future outlooks for experiments using this approach.

9:15 AM QM01.09.03
Tunable Magnetic Ordering at the Interface of all-van der Waals Layered Heterostructures via Spin-Orbit Coupling Eun-Mi Choi[1,2], Taesoo Kim[1,2], Byeong Wook Cho[1,2] and Young Hee Lee[1,2,2]; [1]Institute for Basic Science (IBS), Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Spin-orbit coupling (SOC) possesses versatile functionalities including magneto-crystalline anisotropy, Dzyaloshinskii–Moriya interaction, and effective conversion from charge to spin current. Engineering the strength of SOC is a core to control the conversion efficiency, complex magnetic spin structures, and spin torque. Layered van der Waals (vdW)-transition metal dichalcogenides (TMDs) with intrinsic large SOC and associated spin textures have attracted immense interest. In this work, we use all-van der Waals-layered heterostructure, Fe_3GeTe_2 (FGT)/monolayer W1-xVxSe$_2$, (x = 0, 0.05, 0.1 and 0.15), for SOC strength effect on magnetic ordering of FGT. We found that various magnetic ordering such as spin-flop, spin-flip and inverted magnetization is induced as varying V-doping concentration (i.e. modulating SOC strength). The large SOC enhances magneto-crystalline anisotropy at the proximitized FGT and subsequently stabilizes the long-range magnetic order in FGT. It results in elevating ferromagnetic Curie temperature. We further demonstrate a sharp magnetic switching from antiferromagnetic to ferromagnetic in FGT/$W_{0.95}V_{0.05}Se_2$, which is characteristic of the synthetic antiferromagnetic structure. Our proof-of-concept result offers the possibility of interface-tailoring spintronics including two-dimensional magnetoresistive random access memory toggle switching.

9:30 AM *QM01.09.04
Topology in van der Waals Antiferromagnets Je-Geun Park; Seoul National University, Korea (the Republic of)

Two-dimensional (2d) magnetism has been at the center of many decades-long researches as it offers the cleanest test bed for new ideas and physics. The prime example is the Berezinskii–Kosterlitz–Thouless transition of the XY model, which was discovered in the early 1970s. Simply, it heralds the beginning of topological physics, a new chapter in condensed matter physics. Despite the immense interest from the theoretical side, there has been relatively slow progress on an experimental side: most of which has depended on either a quai-2d materials or thin films grown by a pulsed laser deposition technique.

However, the discovery of van der Waals magnets in 2016 has completely transformed the field of 2d magnetism by providing real 2d magnets that can be experimentally studied using many tools. Despite their short lifetime, van der have magnets have been used for excitingly interesting reports and ideas. With so many successes, the eyes now turn to new directions: one of which is the exploration of possible topological physics in 2d van der Waals magnets.

Among several candidates, noncollinear metallic van der Waals antiferromagnets can reveal particularly rich topological physics due to their diverse magnetic ground states. We are particularly interested in triangular lattice antiferromagnets. By using metallic triangular antiferromagnet $Co_{1/3}TaS_2$, we show that it exhibits a substantial anomalous Hall effect (AHE) related to its noncollinear magnetic order. We show that AHE in $Co_{1/3}TaS_2$ is characterised by the toroidal moment, a vortexlike multipole component that arises from a combination of chiral lattice and geometrical frustration. We will further examine this discovery from the viewpoint of neutron scattering data.

The rare earth neodymium exhibits exceedingly complex magnetic order and series of phase transitions. In this talk, we present results from small-angle neutron scattering (SANS) measurements as a function of temperature and applied magnetic field to study magnetic correlations on nanometer length scales in Nd. The SANS measurements reveal a set of new modulation vectors that characterize the ordered spin configuration. These spin textures exhibit changes in magnitude and direction that are phase dependent. Between 5.9 and 7.6 K, the additional modulation vector has a magnitude Q = 0.12 \AA^{-1} and is primarily due to order of the Nd layers which contain a center of inversion. In this region of the phase diagram, the SANS measurements also identify a phase boundary at $\approx$1 T which was not previously seen in thinner samples. An important feature of these modulation vectors is that they indicate the presence of nanometer length scale spin textures which are likely stabilized by frustrated Ruderman-Kittel-Kasuya-Yosida (RKKY) interactions.

Proliferation of Topological Magnetic Defects in a 2D Square Lattice Erxi Feng[1], Anjana Samarakoon[1], Xianghan Xu[2], Xiaojian Bai[1], Chaowei Hu[3], Lei Ding[1], Yaohua Liu[1], Ni Ni[3], Christian Batista[4], David A. Tennant[1], Sang-wook Cheong[2] and Huibo Cao[1]; [1]Oak Ridge National Laboratory, United States; [2]Rutgers University, United States; [3]University of California, United States; [4]University of Tennessee, United States

Magnetic domain walls and their crossings as magnetic vortices are typical magnetic topological defects existing in many magnetic materials. While visualizing them and their evolution under field at the atomic level are rarely reported except for magnetic skyrmions. Here I will present the proliferation of topological magnetic defects in a 2D square lattice under field, seen by neutrons.
By introducing Ising spins in a 2-dimensional (2D) bi-layer square lattice $Tb_2SrAl_2O_7$, we realized a frustrated magnet where no long-range magnetic order was found upon cooling to 100 mK. Using the local magnetic susceptibility method with polarized neutrons, we revealed canted Ising spins. With this information, we were able to simulate the neutron diffuse scattering patterns observed under selected magnetic fields through machine learning assisted spin Hamiltonian optimization. Our studies revealed a short-range ordered 2D stripe magnetic phase wrapped by domain-wall phases. By applying

magnetic field perpendicular to the square-lattice plane, the stripe magnetic phase melts and the condensed domain wall phases form a short-range ordered vortex lattice, so-called magnetic vortex liquid state, at a critical field of 2 T. Further application of the magnetic field to 4 T, makes all of the spins canted to the field direction, i.e., a polarized paramagnetic phase. Here the evolution of stripe phase and domain wall phase can be precisely controlled by a magnetic field and tracked by neutron scattering. A Z4 vortex was found to be originated from two crossed domain walls. While the density of the domain wall and vortices increase with the field and reach their maximum before entering the fully polarized paramagnetic phase.

The research was supported by the U.S. Department of Energy (DOE), Early Career Research Program Award KC0402020 and used resources at the HFIR and SNS, DOE Office of Science User Facilities operated by ORNL.

11:00 AM QM01.10.04
Structural and Magnetic Properties of EuIr$_3$Si$_7$ Single Crystals Binod K. Rai[1], Alex Bretana[1], Boris Maiorov[2], Christopher Mizzi[2], Joseph Paddison[3], Stuart Calder[3] and Matthias Frontzek[3]; [1]Savannah River National Laboratory, United States; [2]Los Alamos National Laboratory, United States; [3]Oak Ridge National Laboratory, United States

Recently, Eu-based intermetallic compounds have been reported to exhibit complex magnetic textures. In this talk, I will present the physical properties of a new member, the EuIr$_3$Si$_7$ single crystal, of the RT_3M_7 family. This family of compounds has already shown interesting magnetic properties such as anomalous metamagnetism in YbRh$_3$Si$_7$, ferromagnetic ordering along the hard axis in YbIr$_3$Ge$_7$, and charge-neutral fermions in YbIr$_3$Si$_7$. EuIr$_3$Si$_7$ crystallizes in the ScRh$_3$Si$_7$ structure type with space group R-3c, which is confirmed by single crystal XRD data. Furthermore, it exhibits two magnetic phases below T_{N1} = 5 K and T_{N2} = 15 K, with easy-axis anisotropy. The presentation discusses two magnetic phases assessed using magnetization, specific heat, ac susceptibility, and neutron diffraction data.

11:15 AM QM01.10.05
Topological Current Divider in a Chern Insulator Junction Dmitry Ovchinnikov[1,2], Jiaqi Cai[1], Zhong Lin[1], Zaiyao Fei[1], Zhaoyu Liu[1], Yongtao Cui[3], David Cobden[1], Jiun-Haw Chu[1], Cui-Zu Chang[4], Di Xiao[1], Jiaqiang Yan[5] and Xiaodong Xu[1]; [1]University of Washington, United States; [2]University of Kansas, United States; [3]University of California, Riverside, United States; [4]The Pennsylvania State University, United States; [5]Oak Ridge National Laboratory, United States

A Chern insulator is a two-dimensional material that hosts chiral edge states produced by the combination of topology with time-reversal symmetry breaking. Such edge states are perfect one-dimensional conductors, which may exist not only on sample edges but on any boundary between two materials with distinct topological invariants (or Chern numbers). MnBi$_2$Te$_4$, a recently discovered van der Waals topological magnet, offers rich opportunities for Chern number engineering. Non-trivial band structures can be engineered by means of control of the magnetic state [1], while the Chern number itself can be tuned by combining the Chern insulator and quantum Hall physics [2]. In this talk, I will report a chiral edge-current divider based on Chern insulator junctions formed within the layered topological magnet MnBi$_2$Te$_4$. In a device containing a boundary between regions of different thicknesses, topological domains with different Chern numbers can coexist [2,3]. At the domain boundary, a Chern insulator junction forms, where we identify a chiral edge mode along the junction interface. I will further demonstrate how this mode can be used to construct topological circuits in which the chiral edge current can be split, rerouted, or switched off by controlling the Chern numbers of the individual domains. Our results demonstrate MnBi$_2$Te$_4$ as an emerging platform for topological circuit design [3].

1:30 PM QM01.11.01
Negligible Hall Resistance in Dirac Semimetal EuCu$_2$Sb$_2$ Souvik Sasmal[1], Bikash Patra[1], Kritika Vijay[2], Gourav Dwari[1], Bishal Maity[1], Soma Banik[2], Bahadur Singh[1] and Arumugam Thamizhavel[1]; [1]Tata Institute of Fundamental Research, India; [2]Raja Ramanna Centre for Advanced Technology, India

Magnetic Dirac semimetal is of great interest among researchers these days. Many of these Dirac semimetals are protected by the combination of crystal symmetries and a special antiferromagnetic time-reversal symmetry [1]. There are limited systems that show magnetic Dirac state. Recently, the EuCd$_2$As$_2$ compound has been identified as magnetic Weyl semimetal [2]. A single crystal of EuCu$_2$Sb$_2$ was synthesized by flux growth method using Cu-Sb flux. The crystal structure of EuCu$_2$Sb$_2$ contains a subsequent magnetic Eu^{2+} and non-magnetic [Cu$_2$Sb$_2$]$^{2-}$ layers perpendicular to *c*- axis, and Eu moments align in antiferromagnetically between two adjacent layers. Electrical resistivity and specific heat data show antiferromagnetic transition at 5.1 K. Interestingly, it shows negligible Hall resistance with the applied magnetic field 0 – 14 T. In Angle-resolved photoemission spectroscopy measurement, the linear band crossing near the Fermi level suggests Dirac like band dispersion which results in unconventional Hall resistance.

1:45 PM QM01.11.02
Partial Disorder Phase in a Shastry-Sutherland Lattice Madalynn Marshall[1], Brianna Billingsley[2], Xiaojian Bai[1], Qianli Ma[1], Tai Kong[2] and Huibo Cao[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Arizona, United States

Geometrical frustration in two-dimensional magnetic systems can drive the stabilization of exotic phases such as spin-liquids and topological states. The Shastry-Sutherland lattice is one such geometrically frustrated lattice that consists of a two-dimensional orthogonal arrangement of spin dimers and results in rich phase diagrams when manipulated by magnetic field and temperature. In this talk I will present the discovery of the possible field-induced spin liquid state of S=1 spin dimers in the Shastry-Sutherland lattice material BaNd$_2$ZnS$_5$ from utilizing neutron diffraction techniques. A metamagnetic transition in the bulk magnetization measurement was observed under field along the *ab* plane below T$_\mathrm{N}$ = 2.9K. We established the Ising behavior in the

Nd spins by the local magnetic susceptibility method with polarized neutrons at the paramagnetic state. The zero-field 2-**Q** antiferromagnetic order of ferromagnetic dimers was determined by neutrons at 1.4 K. The constituting propagation vectors $\mathbf{q_1} = (\frac{1}{2}\ \frac{1}{2}\ 0)$ and $\mathbf{q_2} = (-\frac{1}{2}\ \frac{1}{2}\ 0)$ each exhibit a "stripe" order when viewing multiple layers and a Néel-type arrangement in a single layer. By applying field along [1 -1 0] the two sublattices respond differently. The $\mathbf{q_1}$ magnetic sublattice remains relatively intact up to 6 T while the stripe phase of the $\mathbf{q_2}$ magnetic sublattice order is suppressed at the critical field H_c = 1.7 T, indicating an emerging partial disorder, liquid state of ferromagnetic dimers, corresponding to the metamagnetic transition in the bulk measurement. With this information we constructed an *H-T* phase diagram from the bulk magnetization measurements that clearly defines the "stripe" state at lower field and a field polarized state at upper fields with a critical region emerging in between represented as a spin dimer liquid phase. To further understand the evolution of the partial disorder phase we performed ultra-low temperature specific heat measurements and discovered the emergence of novel field-induced states.
The research was supported by the U.S. Department of Energy (DOE), Early Career Research Program Award KC0402020 and used resources at the High Flux Isotope Reactor, a DOE Office of Science User Facility operated by ORNL.

2:00 PM QM01.11.03
Circuit QED Characterization for the Detection of Persistent Currents on 2D Dichalcogenide Platelets Timothy W. Carlson; Wake Forest University, United States

Qubit synthesis and measurement are lingering challenges for the quantum computing community. Traditional qubit architectures have been established in ion-trapping with lasers, nitrogen vacancies in host crystals such as crystalline silicon, and Josephson junctions in superconducting circuits, but an emerging direction is to harness the topologically-protected edge states on exotic materials such as topological insulators (TI). In ordinary metallic platelets there are counter-propagating currents through the bulk and the edges which inevitably cancel each other out. On TIs, the bulk bandgap is inverted due to strong spin-orbit coupling which allows gapless, helical edge states. These edge states follow Kramer's theorem which says that the edge currents must be separated into left and right-handed components and that these states are energetically two-fold degenerate. Additionally, these edge currents are ballistic which allow for dissipationless transport. When subjected to an external magnetic field, the edge states are shifted in momentum space which causes a net angular momentum in one direction (clockwise) versus the other (counter-clockwise.)
The topological insulator Antimony Telluride is synthesized by SLS (Solution Liquid Solid) colloidal chemistry with the addition of catalysis-hydrazine cycles. The hydrazine activates a unique spiral growth on two habit planes connected by a dislocation resulting in left and right handed chiral structures. Using optical I-line lithography we fabricate and characterize microwave circuits and then selectively place the crystals in the measurement area. The measurement area is sandwiched between two parallel plates which are coupled to a transmission line cavity (TLC.) The TLC is capacitively coupled to a sensitive input-output circuit. The phase shift of the output signal determines the perimeter direction of the persistent currents. These edge states are topologically protected and conserve charge parity allowing for room-temperature measurement which otherwise would have been strongly coupled to the environment and unmeasurable.

Pettes[1], Matthew Schneider[1], John Watt[1], David Dunlap[2], Andrei Piryatinski[1], Sergei Ivanov[1] and Han Htoon[1]; [1]Los Alamos National Laboratory, United States; [2]The University of New Mexico, United States

Transition metal phosphorus trichalcogenides, $TMPX_3$, are emerging as an exceptional van der Waals antiferromagnet material for exploring magnetic correlations, long range order and emergence of composite quasiparticles. They are reported to have a tunable bandgap from 1 eV to 3.5 eV, correlated electron physics with classification as Mott or Charge transfer insulator and different magnetic order such as Ising, XY or Heisenberg types. Here we investigate excitons in bulk and nanoflakes of different $TMPS_3$ (TM: Ni, Mn, Fe) using photoluminescence (PL) spectroscopy. By reducing the lateral dimension of flakes to tens of nanometers, we find that we could switch-off the bulk exciton emission and activate different excitonic transitions in visible range (1.8 – 2.2 eV emission peaks vary from one nanoflake to another) with much narrower linewidth of only few hundred μeV at 4.2 K. Despite the difference in energy, the excitons in nanoflakes exhibit features such as a spin correlated PL evidenced by a near-unity linear polarization and formation of exciton-polaron states evidenced by multiple phonon replicas. In addition, we also observe an intriguing behavior where nanoflakes display spectral jumps occurring randomly in time but with a near perfect regularity in energy steps. These results establish nano-structuring as an exciting pathway for inducing & manipulating quasiparticles in van der Waals antiferromagnets.

Magnetic and Electronic Topological States in the Kagome-Net Magnet YMn_6Sn_6 Nirmal J. Ghimire; George Mason University, United States

Identification, understanding, and manipulation of novel electronic and magnetic states is essential for the discovery of new quantum materials for future spin-based electronic devices. In particular, materials that manifest an interplay of magnetism and electronic topology are subject to intense investigation; kagome net magnets are prime candidates. In this talk I will presnt the magnetotransport signatures of the magnetic and electronic topological states in the kagome net magnet YMn_6Sn_6.
YMn_6Sn_6 crystallizes in the hexagonal space group P6/mmm with Mn atoms forming a kagome net in the basal plane. The material orders antiferromagnetically at 345 K and quickly transitions into an incommensurate spiral below 333 K. For a magnetic field applied in the *ab*-plane, a series of competing phases namely distorted spiral (DS), transverse conical spiral (TCS) and Fan-like (FL) phases are stabilized before polarizing to the forced ferromagnetic (FF) state. In this field orientation, this coumpoud shows an enigmatic topological Hall effect near room temperature within the TCS phase, which we attribute to a new fluctuation-driven mechanism. In addition to this THE, YMn_6Sn_6 shows two other intuging magnetotransport features at lower temperatures: an anisotropic magnetoresistance drop due to a magnetization-driven topological phase transition (Lifshitz transition), and an interlayer MR due to the charge-spin coupling associated with the magnetic texture in the FL phase in absence of a strong spin orbit coupling. These phenomena provide a unique view into the magnetic and electronic topological states and their interplay in YMn_6Sn_6.

4:00 PM QM01.12.02
Rydberg Excitons—A Novel Platform for On-Chip Rydberg-Based Quantum Technologies Kinjol Barua[1], Jacob C. DeLange[1], Stephan Steinhauer[2] and Hadiseh Alaeian[1]; [1]Purdue University, United States; [2]KTH Royal Institute of Technology, Sweden

Strong photon-photon interaction is the holy grail of quantum optics, as it is essential for the development of photonic quantum networks and information processors which could revolutionize modern information technologies. However, photons in a vacuum do not interact with each other, so a nonlinear material is needed to mediate such interactions. Excitons, semiconductor electron-hole pairs, are promising candidates for creating such nonlinearities. Similar to their atomic counterparts, excitons can be promoted to highly excited Rydberg states with high principal quantum numbers. These states have exaggerated wavefunctions and interact strongly with each other via long-range strong dipole-dipole and Van der Waals potentials. These potentials perturb the energy level structure of nearby atoms such that they can no longer be excited to the same Rydberg state. This effect, known as Rydberg blockade, facilitates the deterministic single-photon nonlinearities required in quantum computing. Rydberg excitons in solid-state platforms incorporate the exceptional nonlinearities of Rydberg states on a scalable, solid-state host. As such, a suitable material system for Rydberg excitons is indispensable for harnessing the unique properties of excitons in scalable, on-chip quantum devices.

So far, cuprous oxide (Cu_2O) is the only known semiconductor where Rydberg excitons with principal quantum numbers up to n = 25 have been observed. It has a high binding energy and symmetric lattice structure, which allow it to host many Rydberg exciton states without undergoing thermal ionization. However, natural bulk cuprous oxide cannot be made defect-free, so a more controlled fabrication process is required to grow high-purity, customizable, synthetic, cuprous oxide. Thin-film cuprous oxide samples with thicknesses below the blockade radius are of particular interest because they more easily facilitate the observation and utilization of Rydberg blockade effect.

In this talk, we will present spectroscopic absorption and photoluminescence measurements of Rydberg excitons from a synthetic thin-film of cuprous oxide deposited on a transparent substrate. Our studies demonstrate Rydberg exciton states up to n=7, and their power and temperature-dependent behavior. We will also report the formation of cavity Rydberg polaritons and lifetime enhancement of exciton states via strong coupling with cavity photons. Finally, we will report on the behavior of Rydberg excitons in a sample of Cu_2O coated with the 2D material ruthenium chloride ($RuCl_3$) and how they behave near its magnetic phase transition temperature. Our results will pave the way for CMOS compatible, on-chip, Rydberg based quantum systems with a wide range of applications in solid-state quantum information processing, non-classical light sources, quantum simulators, quantum metrology, and quantum sensing.

Magnetic-Field Induced Phase Transition in Centrosymmetric Superconductor $PdBi_2$ Irina Grigorieva; The University of Manchester, United Kingdom

Centrosymmetric superconductor β-$PdBi_2$ has attracted much attention recently due to its topologically nontrivial band structure and predicted multiband superconductivity. However, most studies so far – typically conducted in zero magnetic field – only detect a single s-wave gap. I will review our recent studies where we used tunnelling spectroscopy and magnetic susceptibility measurements to demonstrate a magnetic-field driven transition from s-wave superconductivity in low magnetic fields to unconventional equal-spin pairing and nodal gap in parallel magnetic fields above ~0.2T. Our theory shows that the transition is associated with local breaking of the inversion symmetry and the associated reconstruction of the electronic bands in magnetic field.

Imaging 2D Magnetic Structures with a Quantum Sensor Joerg Wrachtrup; Univ of Stuttgart, Germany

Spins in wide band gap semiconductors are a leading contender in various areas of quantum technology. Most notably they have been established as a novel tool for nanoscale quantum sensing [1,2,3]. Specifically, I will discuss quantum and imaging with spins to investigate magnetism in 2D materials including the investigation domain patterns [4] and Moiré structures in twisted 2D magnetic layers [5]. Here the nitrogen vacancy center in diamond is used as a scanning probe to image electronic magnetism in mono- and multilayers of materials like $CrBr_3$ as well as twisted multilayers of CrI_3 By using dedicated measurements strategies we improve the sensitivity [6] as well as the dynamic range of the method and show its use in static as well as dynamic probing of magnetism.

Quantitative Imaging of 2D Magnets Down to the Monolayer Limit Patrick Reiser, Maerta Tschudin, David Aaron Broadway and Patrick Maletinsky; University of Basel, Switzerland

The discovery of 2D magnetic van-der-Waals systems lead to investigations of novel physical phenomena at a reduced dimensionality and enables the realization of novel heterostructures for spintronic applications [1]. Due to their intrinsic weak magnetic signal strength, advanced characterization techniques are required. Here, we use the single spin of a nitrogen-vacancy (NV) in diamond embedded into an all-diamond AFM tip to obtain images of the stray field arising from 2D magnetic systems [2]. In a scanning configuration, we obtain a spatial resolution of approximately 50 nm and a field sensitivity of 1 $\mu T/Hz^{0.5}$. Complementary to other techniques, scanning NV magnetometry is a non-invasive method that can operate in the full temperature range from mK to room-temperature and is not restricted to a specific type of material.

We investigated the properties of mechanically exfoliated chromium trihalides. We determined the out-of-plane magnetization of a single layer of CrI3 quantitatively and confirmed the unexpected antiferromagnetic interlayer coupling. We relate this behavior to its monoclinic phase at low-temperatures and could switch it to a ferromagnetic coupling by inducing a phase transition to its rhombohedral structure [3]. In preliminary work, we also studied the monolayer of CrCl3 that exhibits an easy-plane anisotropy and shows characteristics of an ideal XY magnet. We study its magnetic phase transition and show how its magnetization is stabilized below its critical temperature.

In contrast to mechanical exfoliation, molecular-beam-epitaxy can be used to grow 2D magnets on larger scales with a well-defined geometry. We studied the lanthanide metalloxene EuGe2 that is a layered 2D antiferromagnet with ferromagnetic interlayer coupling. We show that such a system can be grown on a prepatterned substrate allowing us to define its geometry to an arbitrary shape. We find that the magnetization of the monolayer is reduced compared to its bulk value consistent with previous film characterization [4] and that the monolayer behaves like an XY magnet. However, our technique reveals that the film consists of independent magnetic grains of around 100 nm size resulting in a complex stray field pattern. The field dependence of that pattern suggests that these grains possess a varying critical temperature that can explain the previous observed anomalies [5].

Overall, our technique quantitatively determines the magnetic properties of the 2D magnets down to the monolayer limit and is capable of capturing anomalies at the nanoscale. As such, our technique provides a basis for both a deeper fundamental understanding of magnetization in 2D systems and the development of future engineering of 2D magnets.

Heterobilayer with Ferroelectric Switching of Topological State Junjie Zhang and Boris I. Yakobson; Rice University, United States

The realization of multifunctional nanomaterials is both fundamentally intriguing and practically appealing to be used in nanoscale devices. Here, a heterobilayer consisting of realistic 2D-material components of matching lattice symmetry, that is, one being the β-phase antimonene β-Sb known for its strong spin–orbit coupling and ferroelectric In_2Se_3 monolayer, is designed and explored with first-principles density functional theory. The ferroelectric polarization of the In_2Se_3 layer induces distinctly different electronic properties in the bilayer. With polarization directed "inward", the bilayer is a trivial insulator with spatially-indirect band gap (potentially beneficial for photovoltaics). Surprisingly, when polarized "outward", the bilayer displays nontrivial topological state, $\mathbf{Z}_2 = 1$. This suggests that the external electric field can reversibly switch between these two states, inviting potential applications in future multifunctional devices.

9:00 AM QM01.13.05
Interfacial Magnetic Coupling Effects on the Magnetic and Magnetocaloric Properties of Rare Earth Element Doped LCMO-Mn_3O_4 Nanocomposites Md Farhan Azim[1], Jeotikanta Mohapatra[2] and Sanjay R Mishra[1]; [1]University of Memphis, United States; [2]The University of Texas at Arlington, United States

Magnetic refrigeration technology, which works on the magnetocaloric effect (MCE) of magnetic materials, has attracted the interest of numerous research groups over traditional gas refrigeration. It has several advantages, including being highly energy-efficient, environmentally friendly, and cost-effective. The major effort is directed in improving the magnetic entropy change along with the relative cooling power (RCP) of oxide magnetocaloric materials. This study reports the synthesis and magnetocaloric properties of the novel rare earth element doped LCMO composites. These tetragonal crystal structure shaped compounds were synthesized with respect to AB_2O_7 type perovskite oxides with the *I4/mmm* group via the facile autocombustion technique. This rare earth europium element expanded the curie temperatures from $La_{1.4}Ca_{1.6}Mn_2O_7$ ~ 182 K to $La_{1.3}Ca_{1.6}Eu_{0.1}Mn_2O_7$ of ~ 186 K, which consequently enhanced the RCP value. Moreover, these composites were also prepared in the presence of 10 wt. % of Mn_3O_4 nanoparticles. The presence of Mn_3O_4 at the intervening grain boundaries between $La_{1.4}Ca_{1.6}Mn_2O_7$ and $La_{1.3}Ca_{1.6}Eu_{0.1}Mn_2O_7$ phases altered the double exchange interaction between Mn^{3+} and Mn^{4+} ions. The result do show that these interfacial disordered magnetic interactions of these nanocomposites further expanded the second order paramagnetic-to-ferromagnetic phase transition temperature up to 257 K at the temperature-dependent field-cooled magnetization curve which also led to enhance the change in magnitudes of magnetic entropy - $\triangle$s to 0.52 J/kg/k under an applied magnetic field of 5T .The fundamental key of this work is to demonstrate the potentiality of enhancing the magnetic phase transition temperature and magnetocaloric effect in the framework of interfacial coupling between Mn_3O_4 and LCMO nanocomposites.

9:05 AM QM01.13.06
Study of Magnetic and Magnetocaloric Properties of Calcium (Ca) Doped $La_{0.97-x}Ca_xHo_{0.03}MnO_3$ Nanocomposites Synthesized by Facile Auto-Combustion Method Md Farhan Azim[1], Jeotikanta Mohapatra[2] and Sanjay R Mishra[1]; [1]University of Memphis, United States; [2]The University of Texas at Arlington, United States

Magnetic refrigeration technology, which works on the magnetocaloric effect (MCE) of magnetic materials, has attracted the interest of numerous research groups over traditional gas refrigeration. It has several advantages, including being highly energy-efficient, environmentally friendly, and cost-effective. The major effort is directed in improving the magnetic entropy change along with the relative cooling power (RCP) of rare earth double perovskite oxide magnetocaloric materials. This study reports the magnetic and magnetocaloric properties of different concentration of alkaline earth metal such as Ca doped $La_{0.97-x}Ca_xHo_{0.03}MnO_3$ (x = 0.3, 0.33 and 0.37) composites which were synthesized via the facile autocombustion technique. The second-order paramagnetic-to-ferromagnetic phase transition temperature appeared at the temperature-dependent field-cooled magnetization curve. The result do show that greater amount of Calcium enhanced the curie temperature, T_c up to 76 K. Ferromagnetic ordering was observed in these composites due to the existence of double exchange mechanism from both Mn^{3+} and Mn^{4+} ions that develops the electronic holes in Mn–O bands, which is favored by the doped Ca^{2+} ion. In addition, increasing the doping concentration of Calcium further increased change in magnetic entropy, $-\triangle S_m$ up to 0.21 J/Kg/K that led to have the result in higher RCP values. The fundamental key of this work is to demonstrate the potentiality of enhancing the magnetocaloric effect in the framework via spin coupling mechanism of Calcium doped rare earth perovskite compounds.

9:10 AM QM01.13.08
Fermiology Underpinning Enhanced Magnetic Ordering in Cr2Ge2Te6 van der Waals Magnets Liam Trzaska[1], Igor Marković[2], Tommaso Antonelli[1], Edgar Abarca Morales[1,3], Matthew D. Watson[4], Cephise Cacho[4], Monica Ciomaga Hatnean[5], Geetha Balakrishnan[6] and Philip D. King[1]; [1]University of St Andrews, United Kingdom; [2]The University of British Columbia, Canada; [3]Max Planck Institute for Chemical Physics of Solids,

Germany; [4]Diamond Light Source, United Kingdom; [5]Swiss Federal Institute of Technology Zurich, Switzerland; [6]The University of Warwick, United Kingdom

The recent discovery of long-range magnetic order in van der Waals layered materials, persisting to the few-layer limit, has provided a tuneable platform for the engineering of novel magnetic structures and devices. $Cr_2Ge_2Te_6$ is such a material [1]. It is known to be a ferromagnetic semiconductor with a T_C of approximately 63 K in the bulk crystal. The T_C reduces with sample thickness but remains finite down to the bilayer limit. Electrostatic gating studies on $Cr_2Ge_2Te_6$ have demonstrated how the induced carrier doping can drive a marked increase in T_C, as well as switching the magnetic anisotropy [2]. Here we show how features of the electronic structure, extracted from angle-resolved photoemission spectroscopy (ARPES), can be used to provide a direct probe of orbital-specific energy gains underpinning the magnetic ordering. We perform measurements as a function of temperature and alkali surface deposition, an analogue to electrostatic-gating, to simultaneously investigate the effects of electron doping on the near-surface band-structure, and to extract the T_C of the surface region. We find how T_C is increased in the electron-doped surface as compared to the bulk system, and image the population of the nominally unoccupied conduction band that underpins these changes in magnetic ordering.

Development of a Novel Liquid Helium Sample Holder for TEM Denys Sutter; condenZero, Switzerland

Since 2017 the team of condenZero, a spin-off company from the University of Zurich, Switzerland (founded in 2019), has been developing new design principles for liquid helium cryostats. Initially created for x-ray diffraction experiments in pulsed magnetic fields, condenZero adapts the miniaturizable cryostat design for TEM sample holder applications. The main goal of the design is to provide a stable base temperature (<10K) over long time periods, enabling new experimental possibilities for TEM research. In this talk, we outline a brief history of condenZero, current challenges, related engineering projects and future milestones for the further development of our next-generation cryo-TEM sample holders.

SESSION QM02.01: Control of Magnetic and Ferroelectric Orders I
Session Chairs: Vincent Garcia and Dennis Meier
Tuesday Morning, April 11, 2023
Marriott Marquis, Fourth Level, Pacific B

10:30 AM *QM02.01.01
3D Topological Solitons and Their Dynamics Xiuzhen Yu[1], Yizhou Liu[1], Kostatian Iakoubovskii[1], Kiyomi Nakajima[1], Naoya Kanazawa[2], Naoto Nagaosa[1,2] and Yoshinori Tokura[1,3]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan; [3]The University of Toledo, Japan

The three-dimensional (3D) topological solitons – hopfions [1]– were predicted in the chiral-lattice magnets [2] but have not been experimentally confirmed thus far. By utilizing the external magnetic field and electric current, the fractional hopfions with nonzero topological charge and their ensembles can be excited at lower temperatures ~ 100 K far from T_C (~ 278 K) [3] in a chiral-lattice magnet FeGe, in which 2D topological soliton lattice - skyrmion lattice - are thermodynamically stable near T_C [3]. Microsecond current pulses and in-plane magnetic field were employed to control dynamics of the expansion and contraction of the bundle of skyrmion and fractional hopfion, as well as its current-driven Hall motion [4]. The present work demonstrates how to manipulate and control 3D topological objects such as hopfion and its bound state in magnets.
In this talk, I will also present other topological solitons like merons, bimerons, and their current-driven dynamics in the FeGe with the Co-dopant.

Triangular-Lattice Magnetic Semiconductor Producing Giant Anomalous Hall Signals Masaki Uchida; Tokyo Institute of Technology, Japan

Magnetic semiconductors have both semiconducting and magnetic properties that support the modern information society respectively. These materials are broadly classified into two categories. One is rare-earth chalcogenides such as EuO, from which research on magnetic semiconductors started. The other is dilute magnetic semiconductors such as (Ga,Mn)As, in which a small amount of transition metal elements are doped into conventional semiconductors.
In order to develop new magnetic semiconductors, here we focus on the combination of rare-earth magnetic elements and arsenic. We then find out a new magnetic semiconductor EuAs, where Eu^{2+} ions with large magnetic moments form distorted triangular lattice. EuAs epitaxial thin films grown by molecular beam epitaxy exhibit giant anomalous Hall signals with an anomalous Hall angle exceeding of 0.13 [1]. The giant signals can be theoretically explained by spin cluster scattering [2,3] in a hopping conduction regime. Our findings shed light on magnetic semiconductors hosting topological spin textures, developing a field targeting diluted carriers strongly coupled to noncoplanar spin structures for future device applications.

11:30 AM QM02.01.04
Depth Resolved Interfacial Magnetic Spin Spiral at (111)-La0.7Sr0.3MnO3/LaFeO3 Epitaxial Thin Films Yu Liu, Mari-Ann Einarsrud and Ingrid Hallsteinsen; NTNU, Norway

To probe the emerging switchable magnetic spin spiral at the antiferromagnetic LaFeO3 layer due to interfacial effect with element specificity in (111)-La0.7Sr0.3MnO3/LaFeO3 epitaxial thin films we utilise a resonant soft X-ray reflectivity (RSXR) technique providing axial sensitivity. This emerging magnetism and magnetic anisotropy control at the ferromagnet (FM) /antiferromagnet (AFM) interface in perovskite transition metal oxides is interesting for energy efficient spintronics applications. However, studies of magnetic interactions at heterostructure interfaces are often limited by direct measurements, especially of AF spin structures. Here, we present a novel method of probe the spin structure at the AF layer on oxide heterostructures.

(111) pc-La0.7Sr0.3 MnO3/LaFeO3 (LSMO/LFO) heterostructures were epitaxially grown on (101) DyScO3 substrates by pulsed laser deposition as our model system to probe the spin alignment at the antiferromagnetic LaFeO3 layer. REED revealed layer by layer growth, and fully single crystalline epitaxy was confirmed by X-ray diffraction. Vibrating sample magnetometer measurements confirmed bulk ferromagnetism. RSXR data was collected at Advanced Light Source beamline 4.0.2 at Lawrence Berkeley Lab using linear polarized X- rays at soft x-ray energy range, with applied magnetic field parallel to the sample surface within the scattering plane using permanent magnet at 0.1 T. Data analysis was carried out with RemagX using the magnetic matrix formalism.

X-ray reflectometry data were recorded at the Fe L3 edge (708.32 eV) for the bilayer along LSMO easy and hard axis. From fitting the preliminary data on the bilayered samples, the model with a spin spiral reproduced the spin structure of the system with a weakly pronounced cross-over at Qz = 0.125 nm-1. Furthermore, a characteristic top/dip at Qz = 0.18 nm-1 in the asymmetry is reversed for the easy and hard axis, which can only be attained by axial switching indicating a directional transition in spin spirals. This suggests a translation of ferromagnetic momenta from the LSMO layer to LFO due to exchange coupling at the interface, which is controllable by rotating the applied field. We demonstratethat RSXR with linearly polarised light presents a unique means of resolving FM and AFM spins at buried interfaces in multistructures, providing valuable details about the spin texture that are necessary in order to exploit emerging interfacial phenomena towards applications.

SESSION QM02.02: Control of Magnetic and Ferroelectric Orders II

1:30 PM *QM02.02.01
Nanoscale Quantum Inductor in Helical-Spin Magnets—Latest Material Discoveries and Future Perspective Yukako Fujishiro; RIKEN Center for Emergent Matter Science, Japan

A strong coupling between spin texture and conduction electron provides a platform for various electromagnetic responses which can be exploited for future electronic devices. One recent discovery is a quantum inductor in helical-spin magnets, where the quantum-mechanical Berry phase generated by current-driven dynamics of non-collinear spin texture leads to giant inductive voltage. While it has been experimentally demonstrated in several short-period helical-spin magnets (e.g. $Gd_3Ru_4Al_{12}$ and YMn_6Sn_6), the origin of unusual properties distinct from classical inductors, especially the sign change of inductance, had remained largely elusive.
In this study, we report the latest discovery of giant emergent electromagnetic inductance (EEMI) in a new Eu-based helical-spin magnet. In particular, we have demonstrated various sign changes of EEMI within a single material, upon the commensurate-incommensurate magnetic transition as well as the domain wall formation, providing new insights into microscopic origins of EEMI. Furthermore, positive EEMI was identified without long-range magnetic order just above the magnetic transition temperature, due to thermally induced vector-spin chirality. This suggests a possibility of realizing EEMI in a wider range of magnetic compounds or systems (i.e. not limited to helical-spin magnets), paving the way for future material discoveries as well as technological applications of the quantum inductors.

2:00 PM QM02.02.02

Tuning the magnetic anisotropy, Curie temperature, and Dzyaloshinskii–Moriya interaction in the $FeCl_2$ monolayer Shubham Tyagi, Paresh C. Rout and Udo Schwingenschlögl; King Abdullah University of Science and Technology, Saudi Arabia

The emergence of magnetic ordering in two-dimensional materials offers unique opportunities for developing novel spintronics devices. However, these materials suffer from low magnetic critical temperature, in-plane anisotropy, and low magnetic anisotropy energy.
We will discuss a strategy for the ferromagnetic $FeCl_2$ monolayer (based on first-principles and Monte Carlo simulations) to enhance the **Curie temperature** to above room temperature and enhance the **magnetic anisotropy** energy by nearly three orders of magnitude, which is essential for sustaining long-range magnetic ordering. In addition, we find a **non-polar (1T)** to **polar (1H)** structural phase transition and induced **Dzyaloshinskii–Moriya** interaction, which is crucial for generating chiral magnetic structures such as skyrmions.

2:15 PM QM02.02.03
Experimental Study of Spin Orbit Torque in All Oxide Interface Mi-Jin Jin[1,2], Guang Yang[2] and Jason Robinson[2]; [1]Institute for Basic Science (IBS), Korea (the Republic of); [2]University of Cambridge, United Kingdom

Spin orbit coupling (SOC) interplays crucial role in between spin and charge currents. Also, effective spin orbit torque (SOT) can modulate magnetization in various ferromagnetic/non-magnetic bilayers. In this study, we demonstrate spin orbit torque induced magnetization switching at all oxide structure of $La_{1-x}Ca_xMnO_3$ (LCMO)/$SrTiO_3$ (STO) bilayer. Quasi 2-dimensional conducting surface of STO was prepared by Ar plasma treatment. After then, the magnetic oxide LCMO thin film was deposited by using Pulsed Laser Deposition (PLD) method. Further, possible origins of the spin orbit torque generated at the conducting interface between LCMO and STO will be discussed later. Also, we studied spin orbit torque strength by measuring ferromagnetic resonance (FMR). This all oxide magnetization switching could be one of the important approaches for future electronics/spintronics devices.

2:30 PM QM02.02.04
Interfacial Metallic Ferromagnetism Coupled to a Two-Dimensional Electron Gas Byungmin Sohn[1], Guillaume Marcaud[1], Yeongjae Shin[1], Sangjae Lee[1], Tyler Werner[1], Turgut Yilmaz[2], Jinming Yang[1], Wenzheng Wei[1], Alexei Fedorov[3], Elio Vescovo[2], Yu He[1], Sohrab Ismail-Beigi[1], Charles H. Ahn[1,1] and Frederick J. Walker[1]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States

Two-dimensional electron gas (2DEG) states at oxide interfaces have been of interest for a few decades. Here, we investigate with angle-resolved photoemission spectroscopy (ARPES) a potential ferromagnetic 2DEG state on a ferroelectric, $BaTiO_3$, induced by a layer of iron atoms. As the iron layer is introduced, orbital-selective charge transfer, coupled with magnetic signatures, appears in 2DEG states, which is well resolved by ARPES measurements. First-principles calculations show that ferromagnetic atoms such as iron can introduce magnetism in 2DEG states by interfacial coupling effects. These observations lead to an understanding of how interfacial ferromagnetism in 2DEG states can be induced, shedding light on potential platforms that use ferromagnetic 2DEG states as a spin-dependent electric channel.

Strain-Dependent Structural and Magnetic Properties of Pb_2CoTeO_6 from First Principles Md Kamal Hossain and Elizabeth Nowadnick; University of California, Merced, United States

Pb_2CoTeO_6 is a B-site ordered double perovskite that is a multiferroic candidate due to the presence of lone pair-active Pb on the A-site and magnetic Co on the B-site. However, experimental work so far has not reported a polar phase, although a sequence of structural phase transitions with different octahedral rotation patterns has been observed as a function of temperature and pressure. Going from low to high temperature, these phases include monoclinic $P2_1/c$ ($a^-a^-c^+$ octahedral rotations in Glazer notation), monoclinic I2/m ($a^0b^-b^-$ octahedral rotations), rhombohedral in R-3 ($a^-a^-a^-$ octahedral rotations), and cubic Fm-3m. To investigate potential strategies to stabilize Pb_2CoTeO_6 in a polar structure, we combine group theoretic analysis with density functional theory calculations to explore the energetics and crystal structure of bulk Pb_2CoTeO_6. We find that a $P2_1/c$ phase with A-type antiferromagnetic order is the ground state, in agreement with the experiment, and identify a competing R-3 phase that is slightly higher in energy. A systematic study of the structural and magnetic properties of Pb_2CoTeO_6 under epitaxial biaxial strain is carried out, and we investigate whether any polar instabilities arise under strain. Our results provide new insight into strain control of the structural and magnetic properties of Pb_2CoTeO_6.

Current-Driven Nonvolatile Phase Change of Electronic/Magnetic/Superconducting States Fumitaka Kagawa[1,2]; [1]Tokyo Institute of Technology, Japan; [2]RIKEN CEMS, Japan

Electrons in condensed matter have internal degrees of freedom, such as charge, spin, and orbital, leading to various forms of ordered states through phase transitions. However, in individual materials, a charge/spin/orbital ordered state of the lowest temperature is normally uniquely determined in terms of the lowest-energy state, i.e., the ground state. In this presentation, I summarize our results showing that under rapid cooling based on electric pulse, this principle does not necessarily hold, and thus, the cooling rate is a control parameter of the lowest-temperature state beyond the framework of the thermal equilibrium phase diagram [1]. Although the cooling rate utilized in low-temperature experiments is typically 2×10^{-3} to 4×10^{-1} K/s, the use of optical/electronic pulses facilitates rapid cooling, such as 10^2–10^7 K/s. Such an unconventionally high cooling rate allows some systems to kinetically avoid a first-order phase transition, resulting in a quenched charge/spin/superconducting state that differs from the ground state. It is also demonstrated that quenched states can be exploited as a non-volatile state variable when designing phase-change memory function, such as charge [2] and spin [3, 4] degrees of freedom and even superconductivity [5]. In a microfabricated sample, we found that the application of DC current can trigger a nonthermal magnetic transition from the skyrmion phase to nonskyrmion phases [6], implying that a tantalizing variety of novel nonequilibrium phenomena and their applications in quantum materials should be explored with attention to the system size. On the other hand, real-space observations using scanning Raman microscopy revealed that complex behaviors in the phase evolution may be involved in a small-sized specimen [7]; therefore, it may be necessary to confront these complexities when constructing nanodevices based on first-order transitions.

4:00 PM *QM02.02.07
Using Model Atomic Spin Systems to Learn About *in materia* Computing Alexander A. Khajetoorians; Radboud University, Netherlands

The quest to implement machine learning algorithms in hardware has focused on combining various materials, each mimicking a computational primitive, to create device functionality. These endeavors have led to the beautiful development of dedicated hardware that, working in combination with software, can perform pattern recognition tasks. Ultimately, these piecewise approaches limit functionality and efficiency, while complicating scaling and on-chip learning, necessitating new approaches linking physical phenomena to machine learning models. Likewise, this raises the question if there are new machine learning algorithms to be discovered, utilizing the particular properties of quantum properties of matter where there are no obvious links to established models. Here, I will discuss the first steps toward a new paradigm in computing, routed in fundamentals studies based on the idea of letting the physics do the work. I will introduce the concept of an atomic orbital memory and how coupling leads to tunable multi-well landscapes. I will discuss how the ensuing stochastic dynamics mimics the perennial model in machine learning, the Boltzmann machine. In this discussion, I will review the emergence of multiple and separable time scales, an adaption of long-term potentiation in biological matter, which serves the basis for self-adaption. I will also discuss more recent develops moving toward local gate control of stochastic behavior, AC response, and finally new types of orbital memory. I will conclude with an outlook on concepts that go beyond the current neuromorphic paradigm, combining concepts related to quantum coherent and quantum technologies.

Computational and Theoretical Underpinnings of the Coupling Between Deformation and Electrical Polarization in Ferroelectric Layered Material In_2Se_3. Tawfiqur Rakib[1], Edmund Han[1], Shahriar Muhammad Nahid[1], Gillian Nolan[1], Mohammad Hossain[1], SungWoo Nam[2], Andre Schleife[1], Arend M. van der Zande[1], Pinshane Y. Huang[1] and Elif Ertekin[1]; [1]University of Illinois Urbana-Champaign, United States; [2]University of California, Irvine, United States

Two-dimensional (2D) ferroelectric materials have attracted interest in the scientific community due to their ability to undergo nanoscale deformation and the coupling of this deformation to electrical polarization. For nanoscale electromechanical devices, 2D ferroelectric materials provide an alternative to conventional bulk ferroelectrics since they retain their polarization down to ultra-low thicknesses. Recently, using measurements from transmission electron microscopy (STEM) and piezoelectric force microscopy (PFM), our team has demonstrated coupling between deformation and polarization switching in the 2D ferroelectric layered material In_2Se_3. Upon bending, a sharp structural transformation from smooth arcs to sharp kinks above a critical bending angle of approximately 35° is observed. This bend-induced structural transformation is accompanied by a polarization switch in the kinked structure. In this work, we will highlight our first-principles and continuum mechanics analysis of the origin of the formation of kinks accompanied by polarization switching in bent In_2Se_3. Using density functional theory simulations, we calculate the bending energy of the smooth arcs and sharp kinks at different bending angle and find a critical bending angle of 36° above which kinks are more favorable. We explain the formation of the kinked structures in terms of the nucleation of monolayer 2D topological defects akin to wedge disclinations, serving as point sources of curvature that spatially localize the bending. We suggest a bending model that captures the structural transformation from smooth arc to sharp kink, as well as the critical angle at which it occurs. This analysis of the coupling of deformation and polarization offers pathways for manipulating electrical polarization in 2D materials through controlled mechanical deformations.

SESSION QM02.03: Domain Walls and Excitations for Unconventional Computing I

Session Chairs: Erika Covi and Fumitaka Kagawa
Wednesday Morning, April 12, 2023
Marriott Marquis, Fourth Level, Pacific B

8:30 AM *QM02.03.01

Topological Excitations in Ferroelectrics for Unconventional Computing Igor Lukyanchuk[1,2]; [1]University of Picardie, France; [2]Terraquantum AG, Switzerland

Modern electronics is currently facing a profound challenge. The demand for even smaller and more closely packed elements has hit a stumbling block: the power emitted in these devices releases more heat than can be efficiently removed; the scalability of the traditional devices cannot go below the atomic scale of 1nm; the clock rate of calculation is restricted by 100 GHz which is set by the restrictions of the frequency of the signal transmitted by a wire; big data processing volume and enormously growing data traffic amount and rate.

We propose several solutions based on the unique functionality of electrically polarised nanomaterials, nanoferroelectrics, to host complex polarization textures that are incredibly stable due to topological self-protection mediated by elasticity and electrical boundary conditions.

(i) Ferroelectric negative capacitance (NC) for low-dissipative nanoelectronics

The operational functional element of the proposed circuit is a nanodot-scale capacitor with a ferroelectric spacer.

We put forth a foundational mechanism of the NC demonstrating the inevitable emergence of the NC due to the formation of polarization domains. We establish a practical design of the stable and reversible NC FET based on the domain layout. The proposed device is tunable and downscales to the 2.5–5 nm technology node.

(ii) Ferroelectric THz vibrations for ultrafast nanoelectronics

The suggested technology employs a ferroelectric material with a ferroelectric-dielectric heterostructure as a resonator for electrons of an electrical circuit or for a terahertz electromagnetic wave. A peculiarity of the described structure is that the polarization of each ferroelectric layer variates periodically in space, forming a set of domains that exhibits a diverse wealth of oscillation modes in the terahertz spectral band. These vibration modes are directly coupled with the applied electromagnetic field. Because of its small size, the ferroelectric terahertz-generating device can be used as a resonator in wireless circuits, for instance, as a resonator in the terahertz antennas, a sensor of terahertz radiation, and a detector of the terahertz signals injected by an adjacent electrical device integrated into the same chip

(iii) Ferroelectric tunable chirality for optoelectronics

The topological chirality in nanostructured ferroelectrics is intimately related to topological polarization ordering. It emerges together with the polarization by spontaneous symmetry breaking from the non-chiral paraelectric state. This synergistic connection provides, possibly,

the most important operational feature of the topological chirality in ferroelectrics: it can be tuned and manipulated by changing the polarization ordering. Given that the latter is directly coupled to an electric field, the chirality switching, hence optical activity manipulation, by the electric field offers a remarkable operational platform, which looks extremely attractive, especially because such an opportunity is unique in nature

(iv) Ferroelectric multilevel logic unit for non von Neumann & neuromorphic computing

We establish that ferroelectric nanodots hold two, three, or even four polarization states that are energetically stable thus providing a platform for encoding information. We reveal stable configurations and how to manipulate the polarization to move it between stable positions using electric fields. The important problems we address are the novel data protection and encryption protocols implementing these states and the ways the multilevel systems can enhance machine learning capable of better-emulating systems like the human brain, since., they do not only allow basic states like yes/no, but also yes/maybe/no or even more refined multi-logic levels.

Ferroelectric Switching Paths and Domain Structure of Aurivillius-Phase $SrBi_2(Ta,Nb)_2O_9$ from First Principles Elizabeth Nowadnick and Nabaraj Pokhrel; University of California, Merced, United States

In the last decade, layered perovskite oxide materials – with crystal structures that interleave perovskite blocks with other structural units – have emerged as a family of materials the combine novel ferroelectric mechanisms with additional functionalities. Amongst layered perovskites, the Aurivillius-phase ferroelectrics have been known for decades for their fatigue resistance and robust ferroelectric properties. More recently, the ferroelectricity in two prominent members of the Aurivillius family, $SrBi_2Ta_2O_9$ and $SrBi_2Nb_2O_9$, has been shown to arise from a novel trilinear coupling mechanism between polarization and octahedral rotation distortions. This coupling also has been shown to play a key role in the complex paraelectric-ferroelectric structural phase transition sequences of these materials. However, the implications of the trilinear coupling on the ferroelectric switching mechanism in $SrBi_2B_2O_9$ (B=Ta, Nb) remains to be understood. In this work, we use group theoretic analysis and density functional theory calculations to enumerate and explore the energetics of ferroelectric switching paths in $SrBi_2B_2O_9$ and identify low-energy two-step switching pathways facilitated by structural order parameter rotations. Moreover, we show how the relative energy barriers of these switching paths can provide insight into the domain structure of these oxides. In particular, our findings indicate that three-fold domain wall vortices are energetically favorable in $SrBi_2B_2O_9$. This work provides new insight into the origin of low-energy ferroelectric switching in $SrBi_2B_2O_9$ and provides strategies to further lower the switching barrier, which is a key parameter for ferroelectric performance.

9:15 AM QM02.03.03

***Operando* Electron Holography Experiments of Dielectric and Ferroelectric Thin Films** Leifeng Zhang[1], Bumsu Park[1], Kilian Gruel[1], Rafaël Serra[1], Lucas Chapuis[1], Dong-Jik Kim[2], Ibukun Olaniyan[2], Catherine Dubourdieu[2,3], Christophe Gatel[1,4] and Martin J. Hÿtch[1]; [1]CEMES-CNRS, France; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]Freie Universität Berlin, Germany; [4]Université Paul Sabatier, France

The metal-oxide-semiconductor (MOS) capacitor, employed individually or as an element of more advanced electronic components, is one of the fundamental electrical components used in integrated circuits [1, 2]. While much effort is currently being made to integrate new dielectric or ferroelectric materials, capacitors of silicon dioxide (SiO_2) on silicon remain the most prevalent. Therefore, it is perhaps surprising that the electric field within such a capacitor has never been measured or mapped out at the nanoscale.

Here, by adopting the *operando* electron holography methodology in transmission electron microscopy (TEM) with delicate focused ion beam (FIB, ThermoFisher Helios 600i) specimen preparation, we have successfully mapped the electric potential across a working MOS nanocapacitor with unprecedented sensitivity and revealed unexpected charging of the dielectric material bordering the electrodes [3]. The extended charge layer is up to 5.5±0.5 nm, much larger than the structural or chemical width of the interface. Moreover, the charge density varies monotonically with the applied bias, with an almost linear dependence, and follows the sign of the applied bias with an opposite sign to the charges on the nearby electrodes. In our device, we find a reduced capacitance of 17 nF/cm^2 compared with an ideal capacitor (without the dielectric charge layers) of 29 nF/cm^2. Our another example using this methodology is a real nanodevice extracted from 28 nm process test chip [4].

We also applied the *operando* electron holography methodology in the Ti/$BaTiO_3$ (100)/$SrTiO_3$ (100)/SiO_2 (110)/*p*-type Si (110) system, in which the $BaTiO_3$ and $SrTiO_3$ layers were fabricated by molecular beam epitaxy (MBE) technique. The charge and potential distributions were successfully mapped for various ferroelectric or dielectric layers with the applied bias, in which SiO_2, with low dielectric constant, possesses the highest electric field. Although difficult to study the ferroelectric switching dynamics in this structure, our methodology extends its ability to deal with FIB-prepared complex device structures. Furthermore, by adopting the metal-insulator-metal-ferroelectrics-metal (MIMFM) structure, we are able to, by the first time, measure the relative permittivity of ferroelectric material upon polarization switching owing to the existence of floating gate during our *operando* electron holography analyses.

9:30 AM QM02.03.04

A Multiscale Study of Ferroelastic Domain Dynamics as a Function of Aspect Ratio John J. Scott[1], Tamsin I. O'Reilly[1], Blai Casals Montserrat[2], King-Fa Luo[1], Ekhard Salje[3] and Miryam Arredondo[1]; [1]Queen's University Belfast, United Kingdom; [2]Universitat de Barcelona, Spain; [3]University of Cambridge, United Kingdom

Akin to their sister ferroics (e.g ferroelectrics and ferromagnetics), ferroelastics are characterised by regions of differently orientated states (domains), separated by interfaces known as domain walls, that form when cooled below a critical temperature (T_C) in order to reduce its inherent free energy. Domain walls are of particular interest, exhibiting unique properties on the nanoscale from the bulk such as super-conductivity in an insulating medium[1]. When an external field is applied, domains can further nucleate, annihilate or become mobile in response to the stimuli, presenting unique possibilities for active-adaptable devices[2].

Temperature and stress are examples of such stimuli which are capable of switching the domain structure, a mechanism that mediates many of the functional properties utilised in applications such as memory devices[3], switches and sensors. The understanding of how domains behave in response to externally applied fields is critical to the development of advanced applications such as neuromorphic computing[4]; based on the jerky mobility of DWs, and by extension domains, in materials with ferroelastic components[5]. These discrete jerks emit elastic fields that can destabilise surrounding structures and trigger a cascade of switching events known as avalanches, which can be utilised in conjunction with mean-field theory to characterise the overall behaviour of these dynamics[6] which is an element of this investigation.

Within this study, we complement work achieved on manipulating bulk behaviours[6] and investigate ferroelastic domain dynamics at the microscale via *in situ* transmission electron microscopy (TEM) techniques. Varying the sample aspect ratios of free standing $LaAlO_3$ (LAO) lamella, samples were heat cycled *in situ* from room temperature, beyond T_C and back. We touch upon the effects of etched patterns within this context and explore the different domain behaviour with theoretical models. Finally, we correlate these results to the effects observed in free-standing $BaTiO_3$ lamella, to compare ferroelastic and ferroelectric systems. The results here presented highlight the inherent differences not only in domain dynamics as a function of the aspect ratio, but between different size scales, which are not comparable when mechanisms such as surface effects are considered on the microscale. Knowledge of the domain dynamics in bulk and towards micro-objects, is fundamental for the advancement of active adaptable and substrate free devices.

9:45 AM QM02.03.05
Mechanically Generated Ferroelectric Domains in van der Waals α-In_2Se_3 Shahriar Muhammad Nahid[1], Edmund Han[1], Tawfiqur Rakib[1], Gillian Nolan[1], Mohammad Hossain[1], Andre Schleife[1], Elif Ertekin[1], Pinshane Y. Huang[1], SungWoo Nam[2] and Arend M. van der Zande[1]; [1]University of Illinois Urbana Champaign, United States; [2]University of California Irvine, United States

Mechanical deformations, such as strain or strain gradient, offer a facile way to modulate the polarization of ferroelectric materials. As the sizes of the electromechanical systems approach nanoscale, strain gradient becomes important due to its inverse scaling with sample size. So, it is imperative to understand how extreme strain gradient, such as bending to a nanoscale radius of curvature, tunes the electrical polarization of ferroelectrics. Conventional perovskite ferroelectric systems are fundamentally limited in their ability to undergo nanoscale mechanical deformations before fracture. In this regard, van der Waals ferroelectric materials, such as α-In_2Se_3, provide a unique opportunity to understand the interplay between electrical polarization and mechanical deformation at strain gradients orders of magnitude higher than previously explored, due to their ability to deform to nanoscale curvatures. The key questions here are how bending multilayer α-In_2Se_3 to an extremely high and previously unexplored strain gradient regime modulates the ferroelectric domains.
In this study, we investigate the modulation of out-of-plane polarization in highly localized bends in multilayer α-In_2Se_3. Bending of the material is achieved by buckle delamination created by the residual stress from mechanical exfoliation process. We study the atomic structure, energetics of the domains, and electrical polarization using scanning transmission electron microscopy (STEM), density functional theory (DFT), and piezoelectric force microscopy (PFM). Finally, we fabricate patterned trenches and transfer α-In_2Se_3 flakes to controllably tune the material.
We show that bending multilayer α-In_2Se_3 to a nanoscale curvature leads to two different types of deformation which depends on the bending angle. Bending angle below 35° results in smooth arcs where the polarization of the material is uniformly maintained throughout the arc. However, bending above 35° results in highly localized kink formation. This kink formation is associated with a structural transformation and creation of a domain wall that results in polarization switching. Using DFT, we show the energetic favorability of kink formation at high bending angle. We also explain the origin of threshold bending angle from the geometric favorability of one disclination formation per layer. PFM measurement shows that the newly formed domain at the kink propagates inside the material and is arrested by material defects, such as crack, edge, or another kink. Finally, we demonstrate control over this bend-induced domain wall formation by transferring α-In_2Se_3 onto patterned trenches to artificially bend the material over threshold angle and subsequently create alternating domain structures.
Altogether, these results unveil the interplay between ferroelectricity and mechanical deformation at extreme curvatures between 7×10^6 m^{-1} and 3×10^9 m^{-1}, establishing opportunities of electrical polarization manipulation and domain wall engineering. These findings lay the groundwork for flexible and reconfigurable nanoelectronics based on van der Waals ferroelectric materials.

Conducting Ferroelectric Domain Walls in Neuromorphic and Conventional Logic Device Demonstrators Marty Gregg, Ahmet Suna, Conor J. McCluskey, Olivia Baxter, Jesi Maguire, Amit Kumar and Ray McQuaid; Queen's Univ Belfast, United Kingdom

The electrical conductivity of lithium niobate thin film capacitor structures depends on the density of conducting 180 degree domain walls, that traverse the interelectrode gap, and on their inclination angles with respect to the polarization axis. Both microstructural characteristics can be altered by applying electric fields, but changes are time-dependent and relax, upon field removal, into a diverse range of remanent states. As a result, the measured conductance is a complex history-dependent function of electric field and time. Here, we discuss how the complexity in the kinetics of microstructural change, in this ferroelectric system, can generate transport behavior that is strongly reminiscent of that seen in key neurological building blocks, such as synapses and neurons. We show that potentiation-depression, spike-rate-dependent plasticity (SRDP) and spike-timing-dependent-plasticity (STDP) typically seen in synapses can also be seen in domain wall-based memristors. Even Ebbinghaus forgetting (a response more typical of an entire brain) can be replicated. Not only do such capacitor structures allow for neuromorphic responses, but the strong diode-like behaviours found can also be used to construct "AND" and inclusive "OR" logic gates, where "0" and "1" output states are clearly distinguishable. Realistic device modelling allows an extrapolation of results in more complex arrangements and, although non-ideal, output states can still be distinguished even in two-level cascade logic. Thus domain wall based devices allow for new kinds of processing in which both neuromorphic and conventional notions of computation sit side-by-side.

11:00 AM *QM02.03.07
Leveraging Domain Walls and Stochasticity in Ferromagnetic Materials for Unconventional Computing Jean Anne C. Incorvia and Samuel Liu; The University of Texas at Austin, United States

Future unconventional computing systems will require computers with high energy efficiency, low compute-memory bottlenecks, can be immersed in harsh conditions, are adaptive to sensory inputs, and can perform analog computations on the edge. A leading material class to tackle these extreme conditions are ferromagnetic materials and associated devices based on magnet tunnel junctions (MTJ). Devices made from magnetic materials, for example spin transfer torque magnetic random-access memory (STT MRAM), have relatively low switching energy, are nonvolatile, can be directly integrated with silicon CMOS, and are robust to radiation. They also have dynamical behaviors that can be leveraged for new computing paradigms, such as neuromorphic computing, for real-time training and inference on the edge. They also can sense electromagnetic fields, which could eventually lead to sensor-memory-processing combined analog systems.

We will present our results on leveraging domain walls (DWs) and stochasticity in ferromagnetic materials for these applications. We will show experimental results on how DWs integrated into MTJs (DW-MTJs) can act as both artificial synapses and artificial neurons [1]. We will show our results applied the devices to neural networks, as well as to a nearer-term application of analog content addressable memory (aCAM). We will show how the stochasticity of the DW motion aids in online learning without forgetting; how the stochasticity of the MTJ can be used as a random number generator with many knobs to control its randomness; and how the combination of both stochastic DWs and stochastic MTJs can be used to implement efficient Bayesian neural networks [2]. These results elucidate the wide design space for using ferromagnetic materials for unconventional computing.

11:30 AM QM02.03.08
Ferroelastic Domain Walls in $BiFeO_3$ as Memristive Networks Jan L. Rieck[1,1], Davide Cipollini[1,1], Mart Salverda[1,1], Cynthia Quinteros[2], Lambert Schomaker[1,1] and Beatriz Noheda[1,1]; [1]University of Groningen, Netherlands; [2]Universidad Nacional de San Martín, Argentina

Within the last few years, memristors have aroused much interest in the scientific community due to the tunability of their resistive states.[1] Their hysteretic and non-volatile behaviour has made them attractive for memory applications. Recently, memristors are actively investigated due to their unique advantages as hardware in future neuromorphic computers. This emerging field comprises novel electronic circuits inspired by the human brain, motivated by its strikingly low energy consumption, high efficiency of cognitive tasks, such as image or pattern recognition, and the ability of the brain to reconfigure nervous connections, also called neuronal plasticity.[2] Prominent candidates for materials enabling neuromorphic computing on a hardware-level are ferroics,[3] in particular transition-metal oxides. A pervasive feature of ferroic material is the occurrence of domain walls (DWs) separating domains, which have different orientation of the order parameter (electric polarization in the case of ferroelectrics). Ferroelectrics have been already successfully employed for memristive devices such as ferroelectric tunnel junctions.[4] At the same time, ferroic materials paved the way for the large class of DW-based nanodevices, which can exhibit high reconfigurability as DWs can be easily written and erased.[5] Extensive works on the multiferroic oxide bismuth ferrite ($BiFeO_3$) have shown that DWs in thin films can be more conducting than the domains.[6] During thin film growth, $BiFeO_3$ self-assembles into a nanoscale network of conducting domain walls,[7] which can be tailored by varying the growth parameters. After growth, the electrical or even memristive properties[8] of the DWs can be potentially manipulated by driving electrical current through the DW network using electrodes on the film. Previous works on self-assembled $BiFeO_3$ DWs mainly focus on "vertical" (out-of-plane) DW conduction,[8,9] while the few reports on "lateral" (in-plane) conduction investigate single domain wall conduction.[10] In this work, lateral conduction (from wall to wall) through the self-assembled $BiFeO_3$ DW network is presented. The network is characterized using scanning probe techniques allowing local DW probing to investigate the memristive properties and mapping of the conductive DW network. The electrical response of the DW network is further studied by applying electrical stimuli to top electrode arrays. This project is part of the EU-funded *Innovative Training Network MANIC* ("*Materials for neuromorphic circuits*") and is embedded in the neuromorphic research initiative *Cognigron* of the University of Groningen to enable interdisciplinary cooperation from material science, mathematics and artificial intelligence.

Direct Imaging of Heterogeneous Structure and Domain Switching in Nanocrystalline Ferroelectric Thin Films Daniel B. Durham[1], Khandker Akif Aabrar[2], Suman Datta[2], Nestor Zaluzec[1], Supratik Guha[3] and Charudatta Phatak[1]; [1]Argonne National Laboratory, United States; [2]Georgia Institute of Technology, United States; [3]The University of Chicago, United States

Ultrathin doped HfO_2 ferroelectric films are gaining increasing interest for next-generation computing technologies such as transistors, memories, and neuromorphic devices thanks to their high performance, reliability, and CMOS compatibility. FerroFETs using a ferroelectric/dielectric/ferroelectric gate stack are of particular interest for analog computing applications as they exhibit highly linear potentiation and depression curves. However, the underlying structural and domain switching mechanisms in these materials as compared to ferroelectric-only gates are not well understood. We will present correlative imaging of the grain and domain structure in Zr-doped HfO_2 (HZO) films and superlattices with nm-scale resolution using advanced electron microscopy approaches, including off-axis electron holography and scanning electron nanodiffraction with in-situ electrical biasing. We will discuss links observed so far between the compositional layers, the grain structure (including size, orientation, and structural phase), and polarization domain size and behavior. Finally, we will discuss opportunities for further development of imaging approaches as well as how our initial observations can inform pathways to improve device performance and scalability.

SESSION QM02.04: Control of Magnetic and Ferroelectric Orders III
Session Chairs: Dennis Meier and Jan Schultheiß
Wednesday Afternoon, April 12, 2023
Marriott Marquis, Fourth Level, Pacific B

1:30 PM *QM02.04.01
Controlling Topological Polar and Antiferromagnetic Textures in Multiferroic $BiFeO_3$ Vincent Garcia; CNRS-Thales, France

Antiferromagnetic materials are currently emerging as a new paradigm for spintronics as they offer key advantages over ferromagnets: insensitivity to external magnetic fields, much faster spin dynamics (THz range), and higher density packing because of the absence of stray fields. Moreover, tailoring topological spin textures in antiferromagnetic materials as it was done for ferromagnetic skyrmions is generating a lot of attention in the spintronics community. As antiferromagnets are insensitive to external magnetic fields, one must find alternative ways to control them. An optimal writing mechanism would demand low current densities (or ideally no current) to generate a complete reversal of antiferromagnetic domains or textures.

Here we take advantage of the room-temperature magnetoelectric coupling in epitaxial thin films of multiferroic $BiFeO_3$ to deterministically control antiferromagnetic spin textures via the ferroelectric domains. In as-grown single ferroelectric domains, while the surface of single crystals shows an unexpected continuous rotation of the antiferromagnetic cycloid propagation vector with the presence of antiferromagnetic topological defects [1], we are able to design a single antiferromagnetic domain by imposing an anisotropic strain in (111) epitaxial thin films. This model system, containing both a single ferroelectric and cycloidal domains, opens further opportunities for investigations of the interplay between non-collinear antiferromagnetic orders and spin transport. In striped ferroelectric domains of (001) BiFeO$_3$ thin films, we use epitaxial strain to finely tune the as-grown spin textures [2]. The anisotropy induced by epitaxial strain leads to a single antiferromagnetic cycloid within each ferroelectric domain [3]. The modification of the ferroelectric landscape allows us to control the propagation vector of the spin cycloid, to switch from one type of spin cycloid to another, or to convert from a collinear antiferromagnetic texture to a spin cycloid [1]. Furthermore, using resonant elastic X-ray scattering, we reveal the existence of chiral antiferromagnetic and ferroelectric objects at the domain walls of these periodic arrays [4, 5]. Finally, in BiFeO$_3$ nanostructures, we stabilize topological centre polar states using a radial electric field with antiferromagnetic objects embedded. These results open the way for electrically-reconfigurable antiferromagnetic topological objects.

Control of Ordering in Polar Skyrmions Through the Ferroelectric Proximity Effect Peter Meisenheimer[1], Han Geyol Lee[1], Zhiyang Wang[2], Piush Behera[1], Vishantak Srikrishna[1], Yu-Tsun Shao[3], David A. Muller[3], Javier Junquera[4], Long-Qing Chen[2], Lane Martin[1] and Ramamoorthy Ramesh[1]; [1]University of California, Berkeley, United States; [2]The Pennsylvania State University, United States; [3]Cornell University, United States; [4]Universidad de Cantabria, Spain

Complex topological configurations are fertile ground for exploring emergent phenomena and exotic phases in condensed-matter physics. Topological solitons such as magnetic skyrmions have long drawn attention as stable quasi-particle-like objects, but the recent discovery of polar vortices and skyrmions in ferroelectric oxide superlattices has opened the door for new length scales and electric-field manipulation. Functional phenomena can be distinct from those of normal ferroelectrics, with properties such as collective dynamics, chirality, and negative capacitance. Topologically nontrivial ferroelectric textures are uniquely possible and manipulable by careful control of thin film boundary conditions, allowing for the exploration of phase space and order-disorder transitions with atomic precision. Here, we show controlled ordering of polar skyrmions enabled through electrostatic coupling, controlled by the ferroelectric proximity effect in incipient ferroelectric SrTiO$_3$.

Coherent Electric Field Manipulation of Single-Spins in Er^{3+} -Doped PbTiO$_3$ Thin Films Rafaela M. Brinn[1], Piush Behera[1], Peter Meisenheimer[1], Medha Dandu[2], Archana Raja[2] and Ramamoorthy Ramesh[3,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Rice University, United States

Manipulation of spins by an electric field, rather than a magnetic field, has been an active area of research due to the potential applications in low power spintronics. Existing studies have focused on the manipulation of magnetization in materials with long range magnetic order. Recently, however, the manipulation of single spins with an electric field in doped ferroelectric systems has attracted interest. Ferroelectric oxides, such as PbTiO$_3$, offer a pathway to control the spin direction by manipulation of the ferroelectric order parameter, and thus the local crystal field of the defect site. Recent work on bulk Fe^{3+} doped PbTi^{4+}O$_3$ crystals have shown that the anisotropy of the Fe spins can be controlled by rotation of the electric dipole in PbTiO$_3$[1], however this effect only appears at low temperatures and has only been observed using microwave spectroscopy. In this work, we prepared Pb$_{1.199}$Er$_{0.001}$TiO$_3$ films with a thickness of 100 nm on top of TiO$_2$-terminated single-crystalline SrTiO$_3$ (001) substrates via pulsed-laser deposition. The Er ion substitutes the *A*-site (Pb-site) of the perovskite. Er^{3+}-doped materials are heavily studied, due to long electron and nuclear spin coherence times and telecom-wavelength spin-photon interfaces, making Er-dopants a strong potential candidate for long-distance quantum communication. Using time-resolved photoluminescence, we can measure the spin-lifetime by examining the decay of our photoluminescence signal after optically exciting an electronic transition in the Er^{3+}. Previous measurements of bulk Er^{3+} doped crystals have shown spin lifetimes on the order of 100s of microseconds[2]. Though less than that of quantum emitters in state-of-the-art systems, the potential for tunability with electric field may open the path for a new way of manipulating information without using energy intensive magnetic fields or large photonic based systems.

2:30 PM QM02.04.04
Giant Conduction at 180° Domain Walls in Tetragonal PZT Controlled by Monolayer 2D Graphene Electrodes for Memristive Applications Felix Risch[1], Panagiotis Koutsogiannis[2], Yurii Tikhonov[3], Sadegh Kamaei Bahmaei[1], Adrian Ionescu[1], Cesar Magen[2], Igor Lukyanchuk[3] and Igor Stolichnov[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Universidad de Zaragoza (CSIC), Spain; [3]University of Picardie, France

Conductive domain walls (DWs) in ferroelectrics offer a promising concept for future memristive nanoelectronics in which these 2D channels function either as the nanoscale information storage units or as synaptic interconnections. The progress towards applications is impeded by relatively low DW conduction in the picoampere range as well as a lack of a precise control of the DW position.
Here we present highly conductive domain-wall-based device concept using the well-studied material Pb(ZrTi)O$_3$ (PZT) in combination with monolayer patterned graphene electrodes. The artificially created 180° domain walls in our strained 60nm PZT films (deposited on a DyScO$_3$ substrate with a SrRuO$_3$ bottom electrode) exhibit non-thermally activated currents of 200-400nA/μm for voltages $\leq$2V. They are created by electrically poling with moderate voltages of ~5V and show excellent stability enhanced by adjacent stable a- and c-domain configurations. Our recent results (Ref.1) suggest that the anomalously high conduction originates from the interplay between the interconnected a-domains and c-domains during the poling process in these thin films. This leads to the formation of nested and non-vertical 180° domain walls in the proximity of the bottom interface as well as to the distortion of a-domains, which break the domain boundary neutrality. First predicted by simulations, recent TEM studies now experimentally prove these non-trivial interdependent structures involving 180° domain walls and a-domains which lead to highly charged interfaces within the film, responsible for the extraordinary conductive response. Vertical parallel-plate capacitor devices using standard Cr/Au electrodes were tested, forming deterministically-switchable non-volatile resistive states with on/off ratios of 10^3 and tens of nanoampere read-out currents at 2V with excellent retention and stability characteristics. These functionalities were enabled by movement of a domain wall through an applied electric field. Moving towards more advanced functionalities, graphene flake electrodes were employed, allowing for a set of different resistive levels within one device by injecting and removing of more than one conductive domain wall under the electrode. More precise injection control is further offered by using patterned monolayer graphene devices as well as exploiting pressure induced conductive tuning. Thus, the multistate memristive devices are enabled by injection of the highly conductive domain walls, bridging the two electrodes of the capacitor, in combination with modified internal structure of the c-/a-domain interconnections, which

gradually alter the conductive response.
The authors gratefully acknowledge funding from the EU Horizon 2020 program under the MSCA-ITN action MANIC.

Strain Engineering of $KTaO_3$—Route to Stabilize Cooperative Polar Orders Salva Salmani-Rezaie[1], Tobias Schwaigert[1], Darrell Schlom[1], Kaveh Ahadi[2] and David A. Muller[1]; [1]Cornell University, United States; [2]North Carolina State University, United States

Potassium tantalate ($KTaO_3$) is an incipient ferroelectric perovskite in which quantum fluctuations prevent the emergence of a ferroelectric state. Because of its proximity to ferroelectricity, the structure can be tuned toward a ferroelectric state by small external perturbations, including applied stress or chemical substitution[1,2]. Despite being studied for a while, the mechanism of the emergence of ferroelectricity from the paraelectric state as a function of an external tunning parameter is not clearly understood. The lack of defect-free systems makes it difficult to distinguish between defect-induced or intrinsic off-centering of atoms and leads to an elusive picture of the ferroelectric phase transition of $KTaO_3$.
In this work, we report on using molecular-beam epitaxy to grow high-quality $KTaO_3$ films in an adsorption-controlled regime where film composition is controlled automatically via thermodynamics[3]. This growth regime for $KTaO_3$ granted us a viable means to apply epitaxial strain systematically and tune the structure toward the polar state. Here, using high-angle annual dark-field scanning transmission electron microscopy, we investigate local polar regions in a range of films with 0.5-2.1% compressive strain. We use the average deviation of the potassium column from the center of the cubic as a polar order parameter. We find that while atomic displacements are small and random in films with lower epitaxial strain, the displacements are cooperative in films with large strains forming nano-polar regions. We discuss the role of polar orders on the superconductivity of $KTaO_3$, in which a combination of large spin-orbit coupling and polar orders can give rise to intrinsic topological superconductors[4–6].

Hybrid Magnon Modes for Coherent Information Processing Axel Hoffmann; University of Illinois-Urbana Champaign, United States

Magnons are the fundamental excitations of magnetically ordered materials and span frequencies from GHz to THz at wavelengths down to the nm-regime. Because of their convenient frequencies and wavelengths, they have been considered for computational applications by encoding information into their phase and amplitude. Concurrently, magnons readily interact with a wide variety of different excitations, including microwave and optical photons, phonons, and other magnons. Such hybrid magnon dynamic excitations have recently gained increased interest due to their potential impact on coherent information processing [1]. This in turn opens new pathways for hybrid quantum information systems [2]. I will discuss two specific examples, where we developed fully integrated devices to demonstrate strong magnon-photon coupling in scalable coplanar devices [3], as well as magnon-magnon hybrid modes, which reveal new damping-like torques due to coherent spin pumping [4]. Lastly, I will show how we demonstrated strongly nonreciprocal magnon transduction using nano-scale microwave antennae. This provides a practical way for implementing high performance magnon isolation in magnetic thin-film devices for practical applications.

This work was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division under Contract No. DE-SC0022060.

9:00 AM *QM02.06.02
Ising Machines Based on Probabilistic Computing with P-Bits Giovanni Finocchio and Brahim Dkhil; University of Messina, Italy

Probabilistic computing with p-bits is a computing paradigm which has been proposed as a potential tool for dealing with different tasks such as inference. The identification of a strategy and the design of a hardware realization of probabilistic computers is very active nowadays.
In addition, it is very promising for the calculation of the ground state of an Ising Hamiltonian, i.e. to implement an Ising machine, and hence can have an impact in the solution of combinatorial optimization problems which can be mapped into the Ising model. Currently, the research on Ising machines is growing in the light of the fact they have a hardware-friendly implementation, it is necessary a binary state variable (Ising spin) together with a multiply and accumulate operation. It can be realized with semiconductor technology, optics, and spintronics. In particular, most of the efforts have been focused on the use of parametrically-driven oscillators to generate the binarization of the oscillator phase necessary to define the Ising spin. Those implementations have been mainly benchmarked with max-cut optimization combinatorial problems. Recently, it has been proposed the implementation of invertible logic gates, within the framework of probabilistic computing, with the aim to solve the classes of combinatorial optimization problems which can be described by logic circuits. The procedure, proposed for the first time for memcomputing, is based on the creation of the logic circuits representing the specific problem to solve, the replacement of the standard logic gates with the invertible logic gates, and the clamping of the outputs in order to let the circuit working in reverse.
In the talk, I will review our recent results on Ising machines (IMs) and their potential hardware implementation with spintronic technology focusing on oscillator-based IMs and IMs built with p-bits (probabilistic computing) [1].
This computing paradigm is very promising to solve combinatorial optimization problems (COPs), which are a class of mathematical problems that have important applications in a variety of industrial and scientific fields, which span from logistics to geoscience, from water distribution network design to job scheduling. Many of these, such as maximum cut (Max-Cut), maximum Boolean satisfiability (max-SAT) or the travelling salesman problem, are NP-complete or NP-hard, meaning in their worst-case instances they have no polynomial-time solution.
We show how the probabilistic computing can be used to solve max-sat instances (the other problems can be mapped on them) beating state-of-the art solvers having a time-to-solution to 95% at least one order of magnitude smaller [2].

Tail-to-Tail and Head-to-Head Domain Walls in Ferroelectric Hafnium Zirconium Oxide—A First-Principle Analysis Tanmoy Kumar Paul, Atanu K. Saha and Sumeet Gupta; Purdue University, United States

Hafnium Zirconium Oxide (HZO) is a promising ferroelectric (FE) material for future electronic devices owing to its CMOS compatibility, strong ferroelectricity in ultrathin films and rich multidomain characteristics. Due to its unique atomic arrangement, the domain walls (DW) in different spatial directions can exhibit different properties. Most of the studies so far have focused on lateral DWs in HZO based FEs [1][2]. On the other hand, Tail-to-Tail/ Head-to-Head (T-T/H-H) DWs have not been well explored. To understand domain growth mechanism in HZO more comprehensively, there is a strong need to analyze the nature and characteristics of T-T/H-H DWs formed along the polarization direction.
In this work, we use First-Principle Density Functional Theory (DFT) calculations to predict domain formation along the polarization direction in HZO. We find that, although stable T-T DWs can form in HZO, H-H DW formation is energetically unfavorable. This phenomenon originates due to the unique segmentation of FE HZO unit cells in polar and non-polar layers with different ionic charge density as well as the energy minimization through oxygen termination at the surface/interface. We substantiate this claim further by studying the electrostatic potential profiles obtained from DFT calculations. Moreover, due to the depolarization energy, the formation of T-T DW is only possible above a critical thickness. The important consequence of the instability of H-H DW is twofold. H-H/T-T DW of periodic nature cannot form. Also, the nucleation must occur from interfacial sites to avoid H-H DW formation. Previous theoretical works [3] have shown different microscopic configurations of both upward and downward polarized domains in HZO. Considering all different combinations of the domains, we obtain the most energetically favorable T-T DW as the configuration where *pbcn* phase forms between the two neighboring FE domains. We analyze both freestanding HZO and metal-HZO-metal samples to establish the conditions for the stability of T-T DW.

Decoupling Microstructure and Oxygen Vacancy Impacts to Phase Stability in Pure Hafnium Oxide Thin Films Samantha Jaszewski[1], Eric R. Hoglund[1], Anna Costine[1], Marc Weber[2], Shelby Fields[1], Alejandro Salanova[1], M. David Henry[3], Petra Reinke[1], James M. Howe[1] and Jon Ihlefeld[1]; [1]University of Virginia, United States; [2]Washington State University, United States; [3]Sandia National Laboratories, United States

The impact of oxygen content in the plasma on the crystallization and ferroelectric properties of HfO_2 films deposited by High Power Impulse Magnetron Sputtering (HiPIMS) will be shown. 20 nm HfO_2 films were sputtered from a 99.9% purity Hf metal target in Ar/O_2 atmosphere with varying O_2 content. Grazing-incidence X-ray diffraction (XRD) measurements show that films with the lowest and intermediate O_2 content are nearly 100% orthorhombic and/or tetragonal phases, while those with the highest O_2 content also contain the monoclinic phase, with a relative monoclinic phase fraction of 0.43. These differences in phase constitution produce unique polarization responses. The microstructure of these films is evaluated from scanning electron and atomic force microscopy images and grain size measurements reveal equivalent microstructures for each film, suggesting that oxygen content is responsible for the differences in phase assemblage and ferroelectric properties of these films. Several methods are used to assess the oxygen content in the films. Electron energy-loss spectroscopy (EELS) and X-ray photoelectron spectroscopy (XPS) show that oxygen content in the plasma correlates with oxygen content in the films, and that the films are significantly oxygen deficient. Quantification of the stoichiometry in the films after annealing by XPS and EELS results in values of x in HfO_x ranging from 1.3 to 1.7. Additionally, in spite of the large oxygen non-stoichiometries in these films, the leakage currents remain low ($<10^{-7}$ A/cm^2 at 2 MV/cm). XPS measurements reveal the presence of Hf^{3+} in the amorphous phase, which signifies the presence of positively charged oxygen vacancies, suggesting that the electrons compensating the oxygen point defects were delocalized from the vacancies. In the crystalline samples, however, no Hf^{3+} signature is observed, although the films are more oxygen deficient. These results, combined with the low leakage currents, indicate that the electrons are localized to the oxygen point defects and are not ionized in the samples after annealing. These results demonstrate that the properties of ferroelectric HfO_2 thin films are highly sensitive to oxygen content and that high oxygen vacancy concentrations do not necessarily lead to large leakage currents.

10:30 AM *QM02.06.05
Bio-Inspired Time Varying Networks Hermann Kohlstedt; Kiel University, Germany

As a result of a hundred million years of evolution, living animals have adapted extremely well to their ecological niche. Such adaptation implies species-specific interactions with their immediate environment by processing sensory cues and responding with appropriate behavior. Understanding how living creatures perform pattern recognition and cognitive tasks is of particular importance for computing architectures: by studying these information pathways refined over eons of evolution, researchers may be able to streamline the process of developing more highly advanced, energy efficient autonomous systems.

With the advent of novel electronic and ionic components along with a deeper understanding of information pathways in living species, a plethora of opportunities to develop completely novel information processing avenues are within reach.

Basal biological principles are highlighted, including phylogenies, ontogenesis, and homeostasis, with particular emphasis on network topology and dynamics. While in machine learning, system training is performed on virgin networks without any a priori knowledge, the approach proposed here distinguishes itself unambiguously by employing growth mechanisms as a guideline to design novel computing architectures. Within this framework, experiments on low-frequency relaxation type oscillators coupled via complex time-varying networks will be presents. The spatio-temporal development of the network results from a mutual interaction between the oscillator ensemble and the network structure. The blooming and pruning of suddenly appearing conductive bridges and their relation to the synchrony state of the oscillator ensemble will be discussed.

11:00 AM QM02.06.06

Surface-Assisted Stabilization of Epitaxial Ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ Thin Films Jesse Schimpf[1], Xuezeng Lu[2], Abel Fernandez[1], James M. Rondinelli[3] and Lane Martin[1]; [1]University of California, Berkeley, United States; [2]Southeast University, China; [3]Northwestern University, United States

HfO_2-based ferroelectric thin films have drawn recent interest due to their compatibility with silicon and robust, scalable polarization, making them strong candidates for next-generation logic and memory technologies (*e.g.*, ferroelectric tunnel junctions and field-effect transistors). The metastability of the ferroelectric phase, however, poses a challenge to reliable fabrication, as phase impurities from partial decomposition increase leakage and reduce the switchable polarization. Such defects are highly dependent on film thickness, chemistry, processing conditions, and even the underlying electrode, leaving many questions as to how the ferroelectric phase is stabilized. Recent theoretical work suggests the presence of oxygen vacancies to be integral to both the formation energy and properties of the ferroelectric phase, but little has been done to experimentally verify and understand these claims.

Here, we show that the oxygen ambient during pulsed-laser deposition and subsequent annealing of epitaxial $Hf_{0.5}Zr_{0.5}O_2$ (HZO) films does not significantly affect the resulting crystal structure and ferroelectric properties. It is found, however, that the formation of the ferroelectric phase has a strong dependence on the chemistry of the underlying layer. Specifically, HZO grown on $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) exhibits the highest crystalline quality and ferroelectric polarization compared to other perovskite oxide electrodes explored so far, and this behavior can further be tuned through epitaxial strain. While the HZO itself is not strained to the electrode, its crystalline quality and remanent polarization improve as the LSMO is subjected to higher tensile strain. This implies that strain-induced changes to electrode properties have an influence on the stability of ferroelectric HZO. To glean more into which electrode properties are important, we synthesized HZO on a variety of perovskite oxide substrates and electrodes. While trends in lattice parameter, chemistry, and electronic structure appear to not influence the stability of the ferroelectric phase, differences in electrochemical properties of the underlying material do seem to affect the crystalline quality of the HZO, leading to varying levels of decomposition. It is proposed that the electrochemical activity of the substrate layer plays a role in mediating the oxygen vacancy content in the subsequent HZO film. To further explore this concept, we provide a direct comparison to films grown on $LaNiO_3$ (LNO), which is similar in lattice parameter to LSMO but less electrochemically active and find that growth thereon does not support the formation of ferroelectric HZO. In turn, to further explore the electrochemical activity of these electrodes, we employ electrochemical impedance spectroscopy and electrical conductivity relaxation measurements through a range of temperatures and background gases/pressures to quantify the ionic conductivity and surface exchange rates of the LSMO and LNO electrodes as a function of strain, mapping the results to structure and properties of the HZO grown thereafter. While bulk ionic conductivity and surface ionic exchange both increase with tensile strain, additional studies on electrode thickness reveal that bulk electrode properties do not have a significant impact on the HZO, thereby suggesting that surface ionic exchange is the principal factor in stabilizing the ferroelectric phase. To verify this, we include a comparison to other well-studied electrochemically active perovskites, $La_{0.9}Sr_{0.1}Ga_{0.95}Mg_{0.05}O_3$ (LSGM) and $La_{0.8}Sr_{0.2}Co_{0.2}Fe_{0.8}O_3$ (LSCF), which have exceptional ionic conductivity and surface-ionic exchange, respectively. Again, we see that the higher surface exchange in LSCF produces higher quality HZO compared to LSGM. This insight is crucial to understanding the metastability of ferroelectric HZO, enabling the design of higher quality materials and devices for future technologies.

11:15 AM QM02.06.07

Chemically Inspired High Throughput Study for New Stable Ferroelectric Nitride Perovskites Bastien F. Grosso[1], Daniel Davies[1], Bonan Zhu[1], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Nitride perovskites, with ABN_3 formula, have the potential to start a new paradigm in semiconductor devices. Indeed, this new class of materials is of great interest for developing oxygen-free functional materials, integrable in microelectronic devices and able to operate at low voltage. In this talk, we present a high throughput study of (AB)-N_3compositional space and show how candidate materials can be identified using simple chemical and structural considerations. We further thoroughly explore the potential energy surface of our candidate materials using symmetry elements and ab initio random structure searching (AIRSS) in order to identify a possible ground state structure. The outcome of our workflow is twofold. On the one hand, we provide new insights on the ground state structure of already identified candidate compositions and on the other hand we propose new thermodynamically stable, likely synthesizable, nitride perovskites. We conclude our study by highlighting the interesting functionalities of our most promising candidates and in particular we evaluate their potential for being ferroelectric.

11:30 AM QM02.06.08

Ferroelectric Enhancement of Superconductivity in Incipient Ferroelectrics Athby Al-Tawhid[1], Salva Salmani-Rezaie[2], Divine Kumah[1] and Kaveh Ahadi[1]; [1]North Carolina State University, United States; [2]Cornell University, United States

A combination of broken inversion symmetry and spin-orbit coupling gives rise to a wide range of exotic superconducting states, such as mixed-parity superconductivity and superconducting diode effect which can be harnessed towards unconvensional computation. Incipient ferroelectrics e.g., $SrTiO_3$, $KTaO_3$, $EuTiO_3$, and PbTe are near a polar instability. The emergence of superconductivity has been reported in some of these incipient ferroelectrics upon doping. Many unconventional superconductors, such as the cuprates, pnictides, and heavy fermion systems, occur in close proximity to magnetic fluctuations or magnetic orders, suggesting that these are important ingredients in the superconductivity in these materials. Here, ferroelectricity and superconductivity could be connected or accidental neighbors. Furthermore, the intersection of superconductivity and topologically nontrivial states is a fertile landscape for exciting quantum phenomena, including non-abelian excitations. Topologically nontrivial states have been reported in some of these polar superconductors. First, I will introduce the emergence of superconductivity and its interplay with ferroelectricity in tuned $SrTiO_3$ thin films. The ferroelectric films reveal a doubling in the critical temperature of superconductivity. Next, I will present our recent results on the emergence of 2D superconductivity in $KTaO_3$ (111) interfaces and doped SnTe. I will discuss the nature of superconductivity in the context of electronic structure, orbital character, and spin texture in thes materials systems.

SESSION QM02.07: Ferroelectrics for Unconventional Computing
Session Chairs: Dennis Meier and Jan Schultheiß

1:30 PM *QM02.07.01
Ferroelectric Devices for Neuromorphic Edge Computing Erika Covi; NaMLab, Germany

As the world is becoming more and more interconnected, systems increasingly operate on the edge – we have many wearable and implantable devices which monitor our health or our daily routine, give us suggestions on how to improve our wellbeing, or even save our lives, e.g., by preventing heart failure. To work properly, these devices need to be able to process the data generated and use them to learn, adapt, and interact with the external environment [1]. In this scenario, the assumption of fungibility, i.e., all the machines in a network have the same capabilities and can accomplish all tasks, which is the basis of the paradigm of powerful mainframes we have used so far, does not hold anymore, since the quality of data that our devices have to process is very diverse and has to be taken into consideration. Designing intelligent systems capable of local edge computing is therefore becoming a strategic goal in next generation smart systems. Event-based neuromorphic systems provide a low-power solution by using artificial neurons and synapses to process data asynchronously in the form of spikes [2]. However, the tight memory and power constraints in edge systems call for the design of novel architectures that use emerging technologies based on new concepts and materials to extend the functionality of state-of-the-art Complementary Metal Oxide Semiconductor (CMOS) technology [3].
Thanks to its CMOS-compatible fabrication process and extreme energy efficiency, Hf-based ferroelectric devices are rapidly affirming themselves as one of the most promising technologies for neuromorphic computing [4]. Here, we present fundamental building blocks, i.e., neurons and synapses, for edge computing neuromorphic networks that combine ferroelectric and CMOS technologies. We demonstrate electrically tuneable neural and synaptic dynamics achievable by tuning the switching of the Hf-based ferroelectric devices. Finally, the main challenges to achieve a neuromorphic-ferroelectric hardware are presented, particularly in the context of optimising such systems for applications on the edge.

Quantifying the Electrode Capping Effect’s Role on Phase Stability in Ferroelectric Hafnium Zirconium Oxide Jon Ihlefeld[1], Shelby Fields[1], Truong Cai[2], Samantha Jaszewski[1], Kyle Kelley[3], Helge Heinrich[1], M. David Henry[4] and Brian Sheldon[2]; [1]University of Virginia, United States; [2]Brown University, United States; [3]Oak Ridge National Laboratory, United States; [4]Sandia National Laboratories, United States

Ferroelectric hafnia is poised to enable a next generation of microelectronic devices owing to its unprecedented compatibility with mainstream semiconductors and ability to maintain ferroelectricity to single unit-cell dimensions without the necessity of epitaxy. Realizing broad implementation, however, likely requires phase pure materials. It is widely known that ferroelectric hafnium oxide-based films exhibit larger orthorhombic phase fractions and polarization responses when crystallized with a top electrode in place. The top electrode is described as providing a ‘capping effect’ that imparts stress to the hafnia film upon cooling and prevents transformation into the non-ferroelectric monoclinic phase. While compelling evidence of the importance of the top electrode has been presented previously, the quantitative impacts of its role on phase stability are lacking. In this work, the biaxial stresses imparted by the electrode clamping effect are quantified using X-ray diffraction $\sin^2(\Psi)$ analyses measured on 20 nm thick $Hf_{0.5}Zr_{0.5}O_2$ (HZO) films processed on TaN bottom electrodes with and without top TaN electrodes. Both HZO films are in a state of biaxial stress after crystallization, however the film with a top electrode has a 70% larger (3.5 GPa) stress magnitude than the film without a top electrode (2.1 GPa). Furthermore, the film processed with a top electrode is nearly 100 vol.% the ferroelectric phase whereas the film processed without the top electrode contains only 60 vol.% of the ferroelectric phase. Removal of the top electrode results in a reduction in tensile stress in the hafnia layer by 0.8 GPa and is accompanied by a 10% reduction in ferroelectric phase fraction. On the basis of strain energy reduction, we calculate an energy barrier for the total orthorhombic to monoclinic phase transformation to be 12 meV/f.u. This quantitative assessment of the clamping effect is accompanied by wafer flexure-based stress measurements to quantify stress development for each processing step, as well as temperature-dependent X-ray diffraction and wafer flexure measurements that allow us quantify the temperatures that accompany phase formation and stress evolution. We will show that it is not an in-plane mechanical constraint imposed by the top ‘capping’ electrode that leads to the large biaxial tensile stress in the hafnia layer. Rather, the electrode serves to limit out-of-plane displacements and prevent formation of the monoclinic phase. This work provides a foundation by which phase-pure ferroelectric hafnia can be prepared by careful consideration of top electrode deposition and processing.

Phase Transformation Driven Wake-Up in Ferroelectric Hafnium-Zirconium Oxide Films Observed Using Nano-FTIR Thomas Beechem[1], Samantha Jaszewski[2], Kyle Kelley[3], Jacob Minyard[1], Fernando Vega[1], Stephanie Gilbert Corder[4], Hans Bechtel[4] and Jon Ihlefeld[2]; [1]Purdue University, United States; [2]University of Virginia, United States; [3]Oak Ridge National Laboratory, United States; [4]Lawrence Berkeley National Laboratory, United States

Ferroelectric hafnium zirconium oxide (HZO) is being pursued as a near-memory computing technology as it can be densely scaled and is compatible with silicon. The orthorhombic phase making HZO ferroelectric is metastable, however. Being metastable, the formation of this technology-enabling orthorhombic phase can be affected by several factors including dopants, stress, crystal size, and oxygen vacancies. HZO devices are typically multi-phase in their as fabricated state and require wake-up to realize a stable ferroelectric polarization. The mechanisms driving this wake-up are under debate. Maturation of ferroelectric HZO technology, therefore, requires means of observing, understanding, and ultimately controlling the wake-up process.

Here, we observe an electric-field driven transformation from the non-ferroelectric tetragonal to ferroelectric orthorhombic phase in 20 nm thick atomic layer deposited (ALD) HZO films using a combination of piezoresponse force microscopy (PFM) and tip-enhanced nanoscale Fourier transform infrared spectroscopy (nano-FTIR). HZO films were subject to varying magnitudes and polarities of electric field over 20x20 µm areas as applied by PFM within a glovebox filled with inert gas. The ferroelectric response was then measured in each of these regions with PFM, whereupon the local phase fraction was assessed with nano-FTIR. IR-spectra show that the orthorhombic phase becomes more predominant relative to its non-ferroelectric tetragonal form in areas exposed to larger electric field magnitudes. The field driven nature of the phase-transformation, in turn, suggests the central role of the charged oxygen vacancies in orthorhombic phase formation, wake-up, and ultimately device performance.

Exploring Architectural Innovations with Ferroelectronics Vijaykrishnan Narayanan[1], Yi Xiao[1], Yixin Xu[1] and Kai Ni[2]; [1]Penn State University, United States; [2]Rochester Institute of Technology, United States

Data generated over social media, biomedical monitoring, and the Internet-of-Things is increasing exponentially. The ability to extract useful information from this big data is critical towards advances in varied domains. The enormity of the data is outstripping the ability for electronic systems to process, communicate and store the data that is being generated. While historically transistor scaling helped address the growth in computational needs, with scaling now reaching its limits, new approaches are needed. To this end, this work envisions a new ferroelectric-based platform that can provide unprecedented opportunities to scale chip designs in the third dimension, to blur the gap between memory and logic functionality through seamless integration and novel beyond Von Neumann architectures to accelerate big data analytics.

Ferroelectric devices leverage the ability of an electric field to induce reversible polarization. This polarization provides a state representation of digital design. The discovery of ferroelectricity in doped hafnia, reported in 2011, has had a transformative Impact on ferroelectric driven semiconductor platforms. As hafnia is integral to advanced CMOS nodes, the prospect of rapid integration of ferroelectric elements in advanced CMOS process nodes is promising. The integration of a ferroelectric material in the gate stack of a CMOS device enables another desirable feature, that of a logic compatible, compact single device memory primitive. This capability allows fine-grain integration of logic and memory, enabling processing in memory and reducing overheads of data movement. These prospects have fueled ferroelectric innovations from new materials to novel architectures. This work will emphasize the need for co-design of materials, devices and circuits informed by architectural and application needs.

By utilizing distinct properties of ferroelectric devices such as Ferroelectric Tunnel Junction (FTJ) and Ferroelectric Field-Effect Transistor (FeFET), system-level benefits for different metrics such as performance, power, area or security will be discussed. An example of that is an FeFET-based active interconnect that supports hardware functional obfuscation by utilizing the threshold voltage programmability of the FeFET. Another example is a FeFET 1T NOR array. FeFET 1T NOR array has many potential applications: routing switches for field-programmable gate array (FPGA), weight cells in a crossbar array to accelerate multiplication-accumulation computations in machine learning accelerators, and interaction controllers between artificial spins in Ising machines. We will discuss challenges in efficient write mechanisms in such NOR arrays.

Studying the Effect of Cation Stoichiometry and Thickness Gradients on Epitaxial BaTiO3 Films Using Off-Center Pulsed Laser Deposition
Romar Angelo Avila[1], Yorick A Birkhölzer[1,2], Panagiotis Koutsogiannis[3], Menno Struik[1], Yibin Bu[1], Cesar Magen[3], Guus Rijnders[1] and Gertjan Koster[1]; [1]University of Twente, Netherlands; [2]Cornell University, United States; [3]University of Zaragoza, Spain

The growth parameters used in complex oxide thin film deposition are typically tuned to minimize heterogeneity. However, composition gradients in film thickness and stoichiometry can be created intentionally by taking advantage of the anisotropic expansion of the plasma plume in pulsed laser deposition (PLD). Here, we apply off-center PLD to study epitaxially grown $BaTiO_3$ (BTO) thin films on (001) oriented $SrTiO_3$ single crystal substrates. Instead of aligning the substrate symmetrically in front of the ablated target area, we deliberately offset the substrate by several millimeters from the central position while keeping the target and substrate surfaces parallel. The Ba:Ti ratio was measured as a function of laser fluence by microfocus X-ray photoemission spectroscopy at multiple positions along the sample length. We managed to obtain a stoichiometric film, i.e. 1:1 cation ratio, all across the 10 mm long sample once the fluence was increased above a threshold value. Microfocus X-ray diffraction shows a monotonic decrease in the out-of-plane lattice parameter when measuring further away from the central position at which the plume impinges on the substrate at the shortest distance. Furthermore, scanning transmission electron microscopy was used to elucidate the microstructural defects present in the nonstoichiometric samples and their localized effect on the lattice parameter by comparing lamella obtained from different locations along the sample length. This study highlights the potential of off-center PLD as an efficient way to study the effect of compositional gradients on the material properties of BTO and other multi-cation functional oxides.

Optimizing Monolayer Ferroelectric ZrO_2 on Si (001) Kidae Shin, Frederick J. Walker and Charles H. Ahn; Yale University, United States

A single atomic layer of ZrO_2 grown directly on an abrupt Si (001) surface shows ferroelectric switching behavior.[1] Being at the ultimate thickness limit of a monolayer (ML), this system has the potential to aggressively scale down device size. Motivated by density functional theory (DFT) calculations that attribute the polarization switching to displacements of Zr-O dipoles, we aim to control the magnitude of capacitance – voltage (C-V) hysteresis by controlling the density of Zr-O dipoles in the ML ZrO_2 film. We report that the Zr-O dipole density in the ML ZrO_2 can be controlled by varying film annealing conditions and characterized using x-ray photoelectron spectroscopy (XPS) measurements of Zr 3d core level energies. Results show that the Zr^{4+} XPS relative intensity can vary from about 30% to 90% depending on the film annealing conditions. Using C-V measurements, we show that the magnitude of the hysteresis is proportional to the density of Zr-O dipoles as characterized by XPS, and thus can be optimized by varying the annealing conditions.

Identifying Local Structural Features to Characterize Phase Transitions and Energy Landscape in the Thiophosphate Ferroelectric $Sn_2P_2S_6$
Albina Borisevich[1], Blair Tuttle[2], Andrew O'Hara[3], Sabine M. Neumayer[1], Rama K. Vasudevan[1], Sokrates Pantelides[3] and Petro Maksymovych[1]; [1]Oak Ridge National Laboratory, United States; [2]Pennsylvania State University Behrend, United States; [3]Vanderbilt University, United States

Recently ferroelectric materials from the thiophosphate and related families have attracted considerable attention due to their rich functional behavior and related potential for applications. For example, for the layered ferroelectric material $CuInP_2S_6$, a quadruple-well potential was discovered, with four distinct polarization states that are stable at room temperature [1]. For $Sn_2P_2S_6$, a 3D ferroelectric, a triple-well potential was predicted, where both a polar and a non-polar state coexist below the Curie temperature [2]. In this work, we explore local structural features of $Sn_2P_2S_6$ to identify the relevant descriptors that correlate with polar order and observe their evolution across the phase transition using high-resolution scanning transmission electron microscopy (STEM) and density-functional-theory (DFT) calculations.
$Sn_2P_2S_6$ has a monoclinic structure that changes in complex ways as a function of strain/pressure and polar state. Observing $Sn_2P_2S_6$ flakes below and above the phase transition temperature in the electron microscope, we can identify changes in the diffractogram (overall structure) that is consistent with the published structures of the low-[3] and high-temperature[4] forms. We then use a combination of high-resolution STEM and theoretical studies to find promising candidates for local structural correlates of ferroelectric behavior. In particular, Sn_2 dimers are easily identifiable on high-resolution images for multiple zone-axis orientations. DFT calculations conducted for both polar and non-polar states show that Sn_2 dimer rotations with respect to lattice direction correlates with changing isostatic pressure on the system and lattice polarization and that the rotation angles are measurably distinct for polar and non-polar states. STEM imaging across the phase transition yielded a complex picture of Sn_2 rotations below the Curie temperature, while above it the rotations correspond closely to those expected for the non-polar state, suggesting the coexistence of different states below the transition.
*This work was funded by MSED of the DOE BES and conducted in part at the CNMS, a DOE Office of Science User Facility. The theoretical work was funded by DOE BES grant No. DE-FG02-09ER46554.

Enhancement of Optical Activity and Properties of Barium Titanium Oxides to Be Active in Sunlight through Using Hollandite Phase Instead of Perovskite Phase Adil Alshoaibi; King Faisal University, Saudi Arabia

The present study aims to enhance the optical properties of barium titanate through
narrowing its band gap energy to be effective for photocatalytic reactions in sunlight and be useful for solar cells. This target was achieved through growth of the hollandite phase instead of the perovskite phase inside the barium titanate crystals. By using solvent thermal reactions and thermal treatment at different temperatures (250 �C, 600 �C, and 900 �C), the hollandite phase of barium titanate was
successfully obtained and confirmed through X-ray diffraction (XRD), Raman spectra and scanning electron microscopy techniques. XRD patterns showed a clear hollandite phase of barium titanium oxides for the sample calcined at 900 �C (BT1-900); however, the samples at 600 �C showed the presence of mixed phases. The mean crystallite size of the BT1-900 sample was found to be 38 nm.
Morphological images revealed that the hollandite phase of barium titanate consisted of a mixed morphology of spheres and sheet-like features. The optical properties of barium titanate showed that its absorption edge shifted to the visible region and indicated band gap energy tuning ranging from 1.75 eV to 2.3 eV. Photocatalytic studies showed the complete and fast decolorization and
mineralization of green pollutants (naphthol green B; NGB) in the prepared barium titanate with hollandite phase after illumination in sunlight for ten minutes. Finally, it can be concluded that the low band gap energy of barium titanate having the hollandite phase introduces beneficial structures for optical applications in sunlight.

Designing High-T_c Bulk and Two-Dimensional (2D) Superconductors with BCS-Inspired Screening, Density Functional Theory, Deep-Learning and Experiments Daniel Wines, Kamal Choudhary, Adam Biacchi, Kevin Garrity and Francesca Tavazza; National Institute of Standards and Technology, United States

High-throughput density functional theory (DFT) calculations allow for a systematic search for conventional Bardeen–Cooper–Schrieffer (BCS) superconductors. With the recent interest in bulk and two-dimensional (2D) superconductors, we develop a multi-step workflow for the discovery of conventional superconductors. After screening over 55,000 bulk and 1,000 2D materials in the JARVIS-DFT database, we perform electron-phonon coupling (EPC) calculations and use the McMillan-Allen-Dynes formula to calculate the superconducting transition temperature (T_c) for 1,736 bulk and 172 2D materials. From this, we identify 112 bulk and 33 monolayer structures that are dynamically stable with superconducting transition temperatures above 5 K, including bulk materials such as VTe, KB_6, Ru_3NbC, V_3Pt, ScN, LaN_2, RuO_2, and TaC and 2D materials such as W_2N_3, NbO_2, ZrBrO, TiClO, $NaSn_2S_4$, $Mg_2B_4C_2$ and the previously undiscovered $Mg_2B_4N_2$, which has a T_c of 22.51 K. Additionally, we demonstrate that deep-learning models can predict superconductor properties, including the Eliashberg function, thousands of times faster than direct first principles computations for bulk materials. Finally, we performed experiments to determine the T_c of selected layered superconductors (2H-$NbSe_2$, 2H-NbS_2, ZrSiS, FeSe) and discuss the measured results within the context of our DFT computed results. We aim that the outcome of this workflow can guide future computational and experimental studies of new and emerging superconductors by providing a roadmap of high-throughput DFT data.

Piezoelectricity in Li-based Layered Perovskite Oxides from First Principles Kishwar-E Hasin, Nabaraj Pokhrel and Elizabeth Nowadnick; University of California, Merced, United States

Layered perovskite oxides such as the $A_3B_2O_7$ n=2 Ruddlesden-Popper family have generated significant recent interest because they host a variety of novel properties such as hybrid improper ferroelectricity, competing structural phases, and complex domain structures. A closely related family of materials are the Li-based layered perovskites $Li_2AB_2O_7$, with crystal structures characterized by alternating perovskite and lithium oxide layers. Recent experiments have reported a competition between ferroelectric and non-polar phases in $Li_2SrNb_2O_7$, mediated by coupled octahedral rotation distortions, polarization, and antipolar distortions. In this work, we use density functional theory to explore piezoelectricity in $Li_2SrNb_2O_7$ and the related Li-based layered perovskites $Li_2CaNb_2O_7$, $Li_2SrTa_2O_7$, and $Li_2CaTa_2O_7$. We investigate both the clamped-ion and internal strain contribution of the piezoelectric coefficients, and determine how the piezoelectric tensors depend on crystal structure and chemical composition. Our results advance fundamental understanding of piezoelectricity in this novel family of Li-based ferroelectric oxide materials.

5:00 PM QM02.08.06
In-Plane and Out-of-Plane Magnetic Behavior in Iron Borate Single Crystal Jacob Pfund, Jacob Franklin, Joshua Bedard, Ilya Sochnikov and Menka Jain; University of Connecticut, United States

Iron Borate ($FeBO_3$) is a unique material with promising applications in magnetic memory and magneto-optical devices. Single crystal of FeBO3 is transparent and green with rhombohedral calcite-type structure (space group D^6_{3d}). It is a room temperature ferromagnet with an optical band gap of 2.9 eV and plate-like growth. Neutron studies have shown that $FeBO_3$ becomes antiferromagnetic (AFM) below T_N ~348 K, with weak ferromagnetism in which the magnetic moments of the sublattice lie in the basal plane. However, there is lack of in-plane and out-of-plane magnetic data at low temperatures. In this work, we present the detailed in-plane and out-of-plane magnetic behavior in single crystal of $FeBO_3$. Temperature-dependent magnetic measurements show applied magnetic field dependent behavior at low temperatures (T< 25 K). Low temperature SQUID images are presented to identify the canting of magnetic moment and novel behavior near the ground state. Detailed magnetic properties, such as magnetic moment, exchange interaction parameters, and canting angles are calculated and presented.

5:00 PM QM02.08.07
Storage Charge Boosting Dependence of Ferroelectric-Based Capacitors on Various Electrical Input Pulse Yoomi Kang, Minjeong Kang, Jisu Byun and Seung Eon Ahn; Tech University of Korea, Korea (the Republic of)

With the development of high-technology industries, advanced semiconductor studies to further reduce power consumption in nanoscale devices and store extremely large amounts of data are actively conducted. In DRAM technology, the efforts to overcome the reduced storage charge caused by scaling down are increasing. Recently, the negative capacitance (NC) effect of Ferroelectric is attracting attention as a solution that can provide operation with large capacitance density and low power consumption by improving energy efficiency. The NC effect based on Landau-Ginzburg-Devonshire Theory (LGD) is related to the intrinsic double-well shape of the Ferroelectric polarization-energy landscape. In addition, electrical measurements under certain conditions occur charge boosting by controlling the depolarization field. Many studies have demonstrated the possibility of direct NC effect observation and charge boosting due to the polarization switching of ferroelectricity. However, the key factor of the direct correlation between the polarization switching of ferroelectricity and charge boosting, according to input energy, is still not identified. In this study, polarization switching and charge boosting according to pulse conditions applied to Ferroelectric capacitors were analyzed from an energy perspective. A Zr-doped HfO_2-based Ferroelectric capacitor was developed, and the effect of controlling charge boosting was observed depending on the artificial electrical signals. With These results, we will present the applicability of DRAM cell CAP of Ferroelectric capacitors.

5:00 PM QM02.08.08
Understanding the Effects of Polar Topological Phases in Epitaxial Oxide Superlattices on Phonon Scattering Rate Sara Makarem[1], Eric R. Hoglund[1], Peter Meisenheimer[2], Patrick E. Hopkins[1] and Ramamoorthy Ramesh[2]; [1]University of Virginia, United States; [2]University of California, Berkeley, United States

Epitaxial oxide superlattices and heterostructures give rise to spatially complex topological configuration such as polar skyrmions and vortices. Some of the emergent properties of these stable quasi-particle objects in epitaxially grown (PbTiO3)n/(SrTiO3)n (PTO/STO) superlattices have been extensively studied[1,2]. However, a detailed study of the effects of these topological phases on the scattering mechanisms and resulting thermal properties was unexplored. Since The type of topology introduces different long to medium range order, in this study we aim to investigate phonon relaxation time as one of the key parameters involved in both thermal transport and coherent phonon phenomena. We perform Time-domain Brillouin scattering (TDBS), an ultrafast laser spectroscopy technique, on the (PTO/STO) superlattices and trilayers to interrogate the underlying changes in phonon dynamics. The displacements and the length scales associated with the existing topological phases in these superlattices change phonon lifetimes where all of these phases have collective topological modes. In other words, we reveal the effect of (anti)ferroelectric displacements near phase boundaries on phonon dampening due to different degrees of frustrated acoustic phonons.

Charge Boosting Effect with Polarization Switching Properties of Zr Doped HfO_2 based Ferroelectric Capacitors for DRAM Cell Capacitor Application Minjeong Kang, Yoomi Kang, Jisu Byun and Seung Eon Ahn; Tech University of Korea, Korea (the Republic of)

As the 4th industry accelerates, there are continuous requirements to enhance the density and performance of DRAMs. Efforts to increase integration density and improve the performance of DRAM have continued, but the development of a new concept of cell-cap due to the limitation of scaling down of Cell-CAP EOT is necessary. In recent studies, the possibility of increasing the amount of storage charge using the negative capacitance (NC) effect of ferroelectrics has been suggested to overcome this issue. However, a direct association between charge boosting and the ferroelectric characteristics such as domain switching distribution at the coercive field (Vc), and remanent polarization (Pr) has not been proved. Therefore, in this study, we analyzed the correlation of charge boosting according to ferroelectric properties in a cap for DRAM (TiN/Hf0.5Zr0.5O2/TiN) of less than 10nm. The dependence of the switching slope at Vc and storage charge amplification on Pr was confirmed. In this study, we show the charge boosting according to the device characteristics and propose conditions to maximize them.

5:00 PM QM02.08.10
Imaging Ferroelectric Switching in Transition Metal Dichalcogenide Moiré Bilayers Using 4D-STEM Nikta Khaloo, Madeline Van Winkle and Kwabena Bediako; University of California, Berkeley, United States

Interfacial ferroelectricity is a relatively new phenomenon that has been observed in two-dimensional (2D) materials, including group VI transition metal dichalcogenide (TMD) moirsuperlattices. While H-phase TMDs are not inherently ferroelectric, artificially stacking two TMD monolayers with a near 0° (3R-like) alignment between the lattices produces a moiré bilayer with broken inversion symmetry and a spontaneous, switchable out-of-plane polarization at room temperature. Further, the size of polarized domains, and resulting coercive field, can be controlled by changing the interlayer twist angle, making this a highly tunable platform for studying ferroelectric behavior in the 2D limit. Previous scanning probe and electron microscopy experiments have provided a microscale picture of polarization switching in TMD moiré bilayers, illustrating localized motion of domain walls within the moiré superlattice upon application of an external electric field. However, a detailed understanding of this structural response on an atomic to nanoscale remains outstanding. There is also an open question of how intralayer strain evolves during the switching process, which would have significant implications for the (opto)electronic properties of the system. Here we use interferometric four-dimensional scanning transmission electron microscopy (4D-STEM) to image ferroelectric switching and map intralayer strain distributions in TMD moiré bilayers with sub-nanometer resolution. This work offers fundamental insight into how an electrical stimulus produces a modified moiré structure and opens avenues for imaging other electrically controllable phenomena in moiré architectures.

5:00 PM QM02.08.13
Exploring a New Polar Symmetry for $BiInO_3$ Deokyoung Kang[1], Megha Acharya[1,2], Piush Behera[1,2], Ching-Che Lin[1] and Lane Martin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

While there are numerous perovskite oxides known to exhibit polar symmetry already, the search for new polar materials continues with urgency due to the range of advanced functional properties exhibited by these materials (*e.g.*, piezoelectricity, pyroelectricity, ferroelectricity, *etc*.) and the slew of applications that such materials can be used in. Modern high-throughput workflows based on density-functional theory (DFT) calculations are now identifying new candidate ferroelectrics with emerging functionalities[1]. One example is $BiInO_3$ which is an underexplored perovskite oxide that was predicted to show Rashba effects and persistent spin texture with high spin-orbit coupling when stabilized in the polar $Pna2_1$ phase[2]. Initial efforts to synthesize $BiInO_3$, however, reveal that thin films tend to adopt a non-polar orthorhombic *Pnma* structure which, of course, precludes the observation of such exotic properties[3]. Here, we explore routes to manipulate the energy landscape of $BiInO_3$ and induce polar symmetry by controlling the growth kinetics.
While the goal was still to achieve the polar $Pna2_1$ phase of $BiInO_3$, we have observed a new polar phase of $BiInO_3$ when it is epitaxially grown as a thin film on perovskite substrates at high growth temperatures using pulsed-laser deposition. Detailed X-ray diffraction studies reveal that the resulting films exhibit what appears to be $LiNbO_3$-type structure with space group $R3c$ (henceforth R-$BiInO_3$) which was neither reported in computational work nor in other thin-film studies (*Pnma*, henceforth, O-$BiInO_3$). This new phase has a smaller pseudocubic lattice parameter (~3.95 Å) than that of *Pnma* phase (4.2 Å), which allows the R-$BiInO_3$ phase to have a smaller lattice mismatch with conventional perovskite substrates with pseudocubic lattice parameters generally between 3.6-4 Å. X-ray-based reciprocal space mapping studies indicate that the R-$BiInO_3$ phase has a larger than usual rhombohedral distortion angle (~3.7°) due to it having a low tolerance factor value (~0.78) which makes the film fully relaxed on all perovskite substrates tested regardless of the lattice mismatch. The R-$BiInO_3$ phase has a monoclinic distortion along the $<110>_{pc}$, where the structural variants and the domain structure are determined by the symmetry of the substrate. The R-$BiInO_3$ phase was found to exhibit four structural variants when grown on $SrTiO_3$ (001) and only two structural variants when grown on $GdScO_3$ (110) and $DyScO_3$ (110) substrates. The polar nature of the R-$BiInO_3$ phase was further confirmed using second harmonic generation (SHG) polar mapping and is found to be consistent with rhombohedral symmetry with 109° domain structures as measured in X-ray diffraction studies. We observed from dielectric and transport studies that the R-$BiInO_3$ phase exhibits lower resistivity ($\sim 10^4$ Ω●cm) than O-$BiInO_3$ ($\sim 10^7$ Ω●cm) and higher dielectric constant (~110) than O-$BiInO_3$ (~40). We further study the optical and ferroelectric properties to fully understand this new phase. While this phase is different from the desired $Pna2_1$ phase, this work on a $LiNbO_3$-type $BiInO_3$ still motivates future research efforts on emerging functionalities including piezoelectricity, ferroelectricity, and Rashba effect. Furthermore, since it has isosymmetric phase with $BiFeO_3$, a room-temperature multiferroic material, $BiIn_xFe_{1-x}O_3$ solid solution system can potentially exhibit novel magnetic and ferroelectric properties by modifying lattice structure.

Ferroelectric Synapses in Neuromorphic Circuits—Integration of Perovskite- and Hafnia-Based Crossbars Laura Bégon-Lours[1], Mattia Halter[1,2,3], Cécile Carretero[4], Donato F. Falcone[1], Marilyne Sousa[1] and Bert Offrein[1]; [1]IBM Research - Zurich, Switzerland; [2]ETH Zürich, Switzerland; [3]Lumiphase AG, Switzerland; [4]Centre National de la Recherche Scientifique, France

Training neural networks nowadays demands a large time and energy budget, slowing the spread of so-called “neuromorphic computing”. Efforts have been put in developing bio-inspired devices supporting neuromorphic computers, targeting a nano-sized (5x50x50 nm^3), low-power (~20 W/petaflop), non-volatile (>1 year), fast (100 ns set/read pulses) and analog (>5 bits) memory. In Mbit arrays, such devices will co-locate storage and computing. Today’s options rely on ion-motion (e.g. red-ox reactions or phase change materials) with intrinsic limitations in terms of endurance and stochasticity. In contrast, the ferroelectric memristor is a purely electronic concept.
In this talk, we present integration schemes for crossbar arrays based on two ferroelectric memristors technology. The first one is based on epitaxial ($BiFeO_3$) on an oxide electrode ($Ca_{0.96}Ce_{0.04}MnO_3$), grown on 1x1cm^2 single crystal substrates ($YAlO_3$). The synaptic functionality of such heterostructure was demonstrated earlier using simple nanocapacitors (shared bottom electrode)[1]. The second technology is on based polycrystalline $HfZrO_4$, also on an oxide electrode (WO_x), but directly integrated on Silicium. It follows the Back-End-Of-Line compatible process-flow proposed by Bégon-Lours *et al*.[2]. Passive crossbar arrays are fabricated for both technologies, with different constraints on the processing conditions.
The dynamics and the synaptic behavior of the devices are presented, and the functionality of small-scale cross-bar arrays are compared for both technologies. The memristors have comparable On/Off ratio (5-10) and resistance ranges (10-100 MOhms), although their footprint differ by two orders of magnitude. They both show gradual, long-term plasticity upon the application of pulses of increasing amplitude: despite a similar film thickness (~4 nm), the voltage required to operate the hafnia devices is 2V, compared to 5 to 8V for the perovskite. The conduction mechanisms across the ferroelectric thin films are interpreted from temperature dependent measurements. The reliability is also different, with a limited effect of fatigue and retention on the $HfZrO_4$ devices[3], but a relatively strong aging effect on the $BiFeO_3$.
Remarkably, the $BiFeO_3$ thin films have a single crystalline orientation, whereas the hafnia film is polycrystalline. The texture affects the coercive field distribution, with consequences on the multi-level functionality and on the cross-talk in passive crossbars. The prospects of these technologies for

neuromorphic computing are discussed: if epitaxial perovskites are promising for unsupervised learning schemes in a passive crossbar array configuration, the back-end compatibility of hafnia synaptic weights offers the possibility of using selectors, with excellent predicted accuracy in tasks such as pattern recognition[4].

8:30 AM *QM02.09.02
Reservoir Computing with Magnetic Skyrmions Karin Everschor-Sitte; University of Duisburg-Essen, Germany

Novel computational paradigms in combination with proper hardware solutions are required to overcome the limitations of our state-of-the-art computer technology [1-3]. In this talk, I will focus on the potential of magnetic skyrmion structures for reservoir computing. Reservoir computing is a computational paradigm that, in contrast to neural networks, requires fewer computational resources while considerably reducing computing time by several orders of magnitude. By means of simulations, we have shown that random skyrmion fabrics provide a competitive ultra-low power physical implementation of the key ingredient of reservoir computing – the reservoir [4-6]. We developed efficient task-agnostic metrics benchmarking the reservoir's key features – non-linearity, complexity, and fading memory [7]. For the benchmark test of classifying spoken digits, we demonstrated the highest performance ever reported for in-materio reservoir computers using a multi-input channel skyrmion reservoir architecture [8]. Our results are on par with state-of-the-art non-in-materio reservoir systems.
Experimental realizations of skyrmion reservoirs further highlight the potential for energy-efficient high-performance skyrmion-based reservoir computing [9,10].

9:00 AM *QM02.09.03
Ferroelectric Tunneling Junctions for Beyond vonNeumann Computing Stefan Slesazeck; NaMLab gGmbH, Germany

The discovery of ferroelectricity in doped HfO_2 that was firstly published in 2011 by Böschke et al. strongly increased the interest in ferroelectricity. The polarization reversal in ferroelectric HfO_2 films can be adopted to store information in three distinct device classes. Depending on the material stack composition different devices can be constructed from the very same ferroelectric layer - ferroelectric capacitors (FeCAP), ferroelectric field effect transistors (FeFET) and ferroelectric tunnel junctions (FTJ). The electrical characteristics of these devices are strongly influenced by the whole material stack, rather than being dictated by the properties of the ferroelectric layer itself. In this talk I will shed some light on the design and electrical characteristics of HfO_2-based FTJ bi-layer devices. Specifically, the interplay between charge trapping and ferroelectric switching and its impact on device on- and off-currents as well as on reliability in terms of data retention, and cycling endurance will be discussed. Based on these insights I will review the constraints on the circuit design for beyond von-Neumann architectures that arise from the specific FTJs device properties. Specifically, the application of FTJs in more digital applications like ternary adders or hyper dimensional computing architectures, and in more analogue application cases like synaptic devices will be considered.

9:30 AM QM02.09.05
Role of Processing Conditions on the Chemistry of Interfaces, Crystallinity and Ferroelectric Polarization of $Hf_{0.5}Zr_{0.5}O_2$-based Tunnel Junctions
Wassim Hamouda[1], Ines Häusler[2], Florian Maudet[1], Hafiz Muhammad Hamid Raza[1], Keerthana Shajil Nair[1,3], Marco Holzer[1,3], Zora Chalkley[1,3], Christoph Schlueter[4], Adnan Hammud[5], Christoph T. Koch[2], Veeresh Deshpande[1] and Catherine Dubourdieu[1,3]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Freie Universitat Berlin, Physical Chemistry, Germany; [4]Photon Science, Deutsches Elektronen-Synchrotron DESY, Germany; [5]Fritz-Haber Institute of the Max-Planck Society, Germany

Ferroelectric tunnel junctions (FTJs) have been intensively explored for future low power non-volatile data storage and information processing applications. Among various studied ferroelectric (FE) materials, polycrystalline HfO_2 and $Hf_{0.5}Zr_{0.5}O_2$ (HZO) solid solution thin films have the advantage of CMOS process compatibility and remarkable energy efficiency.
Ferroelectricity in these systems has been attributed to the stabilization of a polar orthorhombic phase. However, the remnant polarization and the overall device performance depends strongly on several parameters such as the nature of the bottom and top electrodes, the presence of interfacial layers (whether intentional or not), and the oxygen defect content.
In this study, we discuss the role of processing conditions of double layer FTJ devices consisting of 10 nm $Hf_{0.5}Zr_{0.5}O_2$ (HZO) / 3 nm Al_2O_3 with bottom TiN and top W electrodes on the chemistry of interfaces, on the crystallinity and the ferroelectric polarization in HZO. The latter is crystallized at a low temperature of 400C for full CMOS back-end of-line compatibility.
First, as observed in electrical characterization, processing of the ultrathin Al_2O_3 tunneling barrier plays a key role in the ability to stabilize and switch the electrical polarization in the HZO layer. Moreover, a strong dependence of the remnant polarization with the voltage pulse width is observed, which points to the major role of charge traps in minimizing the depolarizing field. Soft and hard X-ray photoelectron spectroscopy techniques were therefore used to probe the physical chemistry of the different buried interfaces and to quantify the oxygen vacancy content across the stack. We performed measurements at

different synchrotron X-ray energies and beam angles to probe various depths of the HZO layer while the top alumina/W layers were investigated by combining laboratory XPS with low energy Ar ion sputtering. In addition, scanning transmission electron microscopy and electron energy loss spectroscopy (EELS) were performed to further investigate the chemistry of the films and interfaces. Based on the electrical, XPS and STEM/EELS measurements, we will discuss the influence of the processing conditions on providing the needed amount of electronic traps for sufficient screening charges, essential to maintain the non-volatile property of the device.

Superconducting Four-Fold Fe(Te,Se) Films on Six-Fold Topological Insulator Bi2Te3 and Magnetic MnTe via Hybrid Symmetry Epitaxy
Seongshik Oh; Rutgers Univ, United States

It is challenging to grow an epitaxial four-fold compound superconductor (SC) on six-fold topological insulator (TI) platform due to stringent lattice-matching requirement. Here, we demonstrate that Fe(Te,Se) can grow epitaxially on a TI (Bi_2Te_3) layer as well as magnetic MnTe due to accidental, uniaxial lattice match, which is dubbed as “hybrid symmetry epitaxy”. This new growth mode is critical to stabilizing robust superconductivity with T_C as high as 13 K. Furthermore, the superconductivity in this system survives in Te-rich phase with Se content as low as x = 0.03 but vanishes at Se content above x = 0.56, exhibiting a phase diagram that is quite different from that of the conventional Fe(Te,Se) systems. This unique heterostructure platform that can be formed in both TI-on-SC and SC-on-TI sequences opens a route to unprecedented topological heterostructures. Furthermore, this result opens another possibility of combining topological superconductivity of Fe(Te,Se) with the rich physics of topological magnetism in the $(MnTe)_n(Bi_2Te_3)_m$ family, a recently emerging platform as intrinsic (anti)ferromagnetic topological insulators.

11:00 AM *QM03.01.02
Quantum Non-Reciprocal Responses in Moire Matter Justin Song; Nanyang Technological University Singapore, Singapore

Nonreciprocity lies at the heart of device technology, allowing means to differentiate between forward and backward flows of signals and information. I will describe how the pronounced quantum geometry found in moire quantum matter lead to large non-reciprocal quantum responses that go beyond that of classical means. One striking example is non-reciprocal plasmonics. While traditionally non-reciprocity is traditionally effected using a magnetic field, I will describe how the large quantum metric dipole in twisted bilayer graphene heterostructures enables non-reciprocal bulk plasmons. Strikingly, the strong non-reciprocity persists even for relatively narrow bands underscoring its wavefunction quantum geometric origins. This non-reciprocity of a quantum origin grants a magnetic-field free and passive platform for plasmonic manipulation and opens the door to host of other non-reciprocal responses.

11:30 AM *QM03.01.03
Electron Correlation in Graphene/hBN Moire Superlattices Long Ju; Massachusetts Institute of Technology, United States

ABC-stacked trilayer graphene/hexagonal boron nitride moiré superlattice (TLG/hBN) has emerged as a playground for correlated electron physics. A spectroscopy study of this system is, however, challenging due to the device configuration. In this talk, I will introduce our recent efforts on FTIR photocurrent spectroscopy measurements of dual-gated TLG/hBN. We observed strong gate-tunable optical transitions that originated from the moire flat band. At half-filling of the valence flat band, a broad absorption peak emerges at ~18 meV, indicating direct optical excitation across an emerging Mott gap. Furthermore, I will talk about a unique moire-enabled interlayer electron-phonon coupling in this system and its implications.

SESSION QM03.02: Spin and Orbital Effects in Correlated Oxides

The Orbital Degree of Freedom in High Entropy Perovskites RVO_3 Jiaqiang Yan; Oak Ridge National Laboratory, United States

The extreme local compositional disorder in high entropy compounds can be employed to induce novel phenomena such as tunable magnetism, coherent symmetry breaking, metal-insulator transition and superconductivity. This has attracted intense attention in the last decade. However, how this strong local disorder affects the orbital degree of freedom has not been studied in transition metal oxides. In this talk, I will use RVO_3 perovskite as an example to show how the cooperative Jahn-Teller distortion of t-electrons reacts to the local disorder of the rare earth site.

2:00 PM *QM03.02.03
Nonlinear Terahertz Emission Spectroscopy on Chiral Multifold Semimetals Liang Wu; University of Pennsylvania, United States

The absence of mirror symmetry, or chirality, is behind striking natural phenomena found in systems as diverse as DNA and crystalline solids. A remarkable example occurs when chiral semimetals with topologically protected band degeneracies are illuminated with circularly polarized light. Under the right conditions, the part of the generated photocurrent that switches sign upon reversal of the light's polarization, known as the circular photogalvanic effect (CPGE), is predicted to depend only on fundamental constants. The conditions to observe quantization are non-universal, and depend on material parameters and the incident frequency. In my talk, I will discuss nonlinear terahertz emission spectroscopy with tunable photon energy from 0.2 eV - 1.1 eV in the chiral topological semimetals CoSi and RhSi. Particularly, we identify a large longitudinal photocurrent peaked at 0.4 eV reaching around 550 $\mu A/V^2$ at room tempreture in CoSi , which is much larger than the photocurrent in any chiral crystal reported in the literature. Using first-principles calculations we establish that the peak originates from topological band crossings, reaching 3.3 ± 0.3 in units of the quantization constant. Our calculations indicate that the quantized CPGE is within reach in CoSi upon doping and increase of the hot-carrier lifetime. Finally, I will present our most recent experiments to explore the quantization and interaction effects in these chiral crystals with doping at low temperature.

SESSION QM03.03: Tuning the Electronic Structure and Magnetism

Session Chairs: Antia Botana and Liang Wu
Tuesday Afternoon, April 11, 2023
Marriott Marquis, Fourth Level, Pacific C

3:30 PM *QM03.03.01
Topological Switch in a van der Waals Ferromagnet Ming Yi; Rice University, United States

Symmetries are fundamental to how we define phases of matter. More recently, symmetries and the active tuning of which have played an important role in realizing and tuning topological phases of matter. Previously, such tuning in quantum materials have been realized via the application of magnetic field, uniaxial strain, and pressure. Here we report the observation of quantum phase switching between a Weyl nodal line phase and a topological flat band phase in a van der Waals ferromagnet via a thermal annealing process. We further demonstrate that the switching of the electronic properties to be associated with a crystal symmetry change driven by an site ordering that is modified in the thermal annealing process. The presence or absence of the ordering modifes the global symmetry of the crystal and give rise to either magnetic Weyl nodal lines in one case and geometrically frustrated flat bands in the other. We further demonstrate that this topological switching is reverseably controlled via the thermal annealing and quenching method. Our work not only reveals a rich range of quantum phases emergent in 2D van der Waals ferromagnets, but also uncovers the potential of utilizing site occupancy as a novel degree of freedom for tuning symmetry and therefore topology in quantum materials for the realization of exotic emergent phases.

4:00 PM *QM03.03.02
Optical Creation and Probing of Non-Equilibrium Superconductors and Topological Semimetals Joel Moore[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The high intensity and versatility of optical pumping allows the creation of new states in a material that may not exist anywhere in the equilibrium phase diagram. This talk focuses on electronic phases and on pump pulses, or alternately current drives, that are chosen to modify the symmetry of a material. For example, circularly polarized light provides a means to induce broken time-reversal symmetry in a non-magnetic material, while current drive breaks both time-reversal and inversion symmetries. Examples discussed include current-induced linear optical effects in semimetals and superconductors, where they provide important probes of topological band structure and order parameter symmetry respectively. These effects can be viewed as part of the nonlinear optical tensor, and we then turn to other kinds of nonlinear optical effects and a unique quantization effect obseved in certain Weyl semimetals. The closing discussion will attempt to illustrate the value that the general class of beyond-linear-response measurements is bringing to the investigation of quantum materials.

(The work reported includes previous collaborations with Michal Papaj, Kazuaki Takasan, Takahiro Morimoto, Tianrui Xu, and others, as described in the talk.)

4:30 PM *QM03.03.03
Layer-by-Layer Disentanglement of Bloch States via Frequency-Domain Photoemission Shuolong Yang; The University of Chicago, United States

Layer-by-layer material engineering has enabled exotic quantum phenomena such as interfacial superconductivity and the quantum anomalous Hall effect. Meanwhile, deciphering electronic states layer-by-layer remains a fundamental scientific challenge. This is exemplified by the difficulty in understanding the layer origins of topological electronic states in magnetic topological insulators, which is key to understanding and controlling topological quantum phases. Here, we report a layer-encoded frequency-domain ARPES experiment on a magnetic topological insulator $(MnBi_2Te_4)(Bi_2Te_3)$ to characterize the layer origins of electronic states. Infrared laser excitations launch coherent lattice vibrations with the layer index encoded by the vibration frequency; photoemission spectroscopy tracks the electron dynamics, where the layer information is decoded in the frequency domain. This layer-frequency correspondence reveals a surprising wavefunction relocation of the topological surface state from the top magnetic layer into the buried second layer, reconciling the controversy over the vanishing broken-symmetry energy gap in $(MnBi_2Te_4)(Bi_2Te_3)$ and its related compounds. The layer-frequency correspondence can be harnessed to disentangle electronic states layer-by-layer in a broad class of van der Waals superlattices.

SESSION QM03.04: Poster Session
Session Chairs: Matthew Brahlek and Yue Cao
Tuesday Afternoon, April 11, 2023

5:00 PM QM03.04.01
Blockades on Spin-to-Charge Conversion Signal in MoS_2 ML Inserted NM/FMI Heterostructures Chanho Park, Sang Kwon Lee, Jae Won Choi, No-Won Park, Si-Hoo Kim and Yun Ho Kim; Chung-ang University, Korea (the Republic of)

In analogy to charge current, spin current carries information with its spin components polarized. This has been already observed in materials via spin-orbit coupling, separating up and down spin-polarized electrons transverse to electric current. Many papers in spintronics have suggested schematics with normal metal (NM) deposited on ferromagnetic (FM) substrate, such that one makes the magnetization out of the equilibrium state, generating quantum properties for magnetization distribution called magnons.[1] The injection of magnons to the interface of the NM/FM heterostructures is usually referred to as injection of the spin current, since the magnons themselves contain spin-polarized quantities for each component.[1] The injected spin current transverse to the interface plane, then converted into voltage signal, named as inverse spin hall effect signal. (E_{ISHE}).
From our previous work, the 2D WSe_2 interlayers between Pt and YIG were discussed in the longitudinal spin Seebeck voltage scheme, indicating that the effect of TMDC monolayers (ML) is substantial in the spin Seebeck effect (SSE) measurement in a Pt/YIG structure.[2] In this paper, we conducted SSE signal-detecting experiments on basic well-known Pt/YIG structure and Pt/MoS_2 ML/YIG structure, and observed their temperature dependence ranging from 190K ~ 300K. In particular, the Pt/MoS_2 ML/YIG structure is adequate for discussing the origin of the signal, i.e. Rashba Edelstein effect (REE) or SSE, since the Pt/TMDC ML layer is considered as an intermediate between Pt /YIG and Pt/multilayer MoS_2/YIG. In other word, The Pt/YIG structure exhibits a perfect 3D spin-to-charge conversion, whereas the Pt/multilayer MoS_2/YIG tends to possess more other magnetic proximity effects (MPE) [3] and magnetoresistance (MR), due to the blockage of spin current from MoS_2 with more thickness.
We firstly assumed both samples (i.e., Pt/YIG structure, Pt/MoS_2 ML/YIG) to obey 3D spin-to-charge conversion. In order to observe the maximum SSE voltage on both samples, out of plane temperature gradient (ΔT) is maintained at 1K. Our results show that Pt/MoS_2 ML/YIG yields much less spin Seebeck voltage than that of Pt/YIG. This is attributed to the significant block of the injection of spin current in the MoS_2 monolayer. Interestingly, wavy signals are observed in the Pt/MoS_2 ML/YIG structure even though MR effects were excluded. This phenomenon is related to the different magnetic properties of MoS_2 crystals in previously reported literature.[4]

5:00 PM QM03.04.02
Analyzing the Effects of Atomic Reconstruction on CDW Behavior in TaX_2 Moiré Bilayers Nikita Dowlatshahi, Madeline Van Winkle and Kwabena Bediako; University of California, Berkeley, United States

Two-dimensional (2D) moiré bilayers are constructed by stacking two monolayers with an interlayer rotation (or "twist") and/or lattice constant mismatch. In moiré materials with a relatively small lattice misalignment, spontaneous periodic deformations, also known as lattice reconstruction/relaxation, occur to reduce the interlayer stacking energy. In turn, this lattice reconstruction has significant effects on the electronic band structure of the system. While reconstruction has been well-studied in moiré superlattices of bilayer graphene and those of semiconducting transition metal dichalcogenides (TMDs), there is minimal information on lattice relaxation in metallic TMD systems, such as H- and T-phase TaX_2 (X = S, Se). In addition, members of the TaX_2 family can exist in a charge density wave (CDW) state, where there are electronically driven periodic lattice distortions, raising the question of how reconstruction might affect CDW behavior in moiré superlattices of these materials. In this work, we demonstrate how changing the interlayer twist angle or lattice mismatch tunes emergent CDW properties in TaX_2 moiré bilayers using a combination of electron microscopy, optical spectroscopic methods, and electronic transport measurements. This project provides insight into the correlation between atomic and electronic structure in moiré superlattices of metallic TMDs as well as the interplay between different types of lattice deformations in 2D moiré materials more broadly.

SESSION QM03.05: Light Induced Lattice Dynamics

Marriott Marquis, Fourth Level, Pacific C

8:30 AM *QM03.05.01
Light-induced Ultrafast Phase Transformation Study using X-ray Free Electron Laser Hyunjung Kim; Sogang University, Korea (the Republic of)

A significant challenge in understanding the phase transformation of materials is whether one can identify and characterize the fine details of the complex ultrafast dynamics of molecules and materials. Many existing techniques only measure the initial and final states of the material transformations. The recent advance of X-ray free electron laser makes it possible to obtain critical information on the intermediate states or pathways during the phase transformation. In this talk, we show the recent results of a transition from a topological insulator to a standard insulator in Bi_2Se_3 followed by carrier-induced contraction and vibration modes and the crystalline-amorphous phase transformation of a phase change material as examples.

This research was supported by the National Research Foundation of Korea (NRF-2021R1A3B1077076).

Evidence of Opto-Mechanical-Driven Topological Phase Transition in SnSe Jiaojian Shi[1,2], Yijing Huang[2,1,2], Christian Heide[1,2], Carl-Friedrich Schön[3,4], Haowei Xu[5], Yuki Kobayashi[1,2], Andrew May[6], Pooja Donthi Reddy[1], Duan Luo[1,2], Eamonn Hughes[7], Kunal Mukherjee[1], Mariano Trigo[2,2], Ju Li[5,5], Jian Zhou[8], Shambhu Ghimire[2], Matthias Wuttig[3,4], David Reis[2,1,2] and Aaron Lindenberg[1,2,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]RWTH Aachen University, Germany; [4]Forschungszentrum Jülich GmbH, Germany; [5]Massachusetts Institute of Technology, United States; [6]Oak Ridge National Laboratory, United States; [7]University of California Santa Barbara, United States; [8]Xi'an Jiaotong University, China

Important advances have been recently made in the search for materials with complex multi-phase landscapes that host photoinduced metastable collective states with exotic functionalities, such as high-temperature superconductivity or topological switches. In almost all cases so far, the desired phases are accessed by exploiting light-matter interactions via the imaginary part of the dielectric function, through above-bandgap or resonant mode excitation. Recently, inspired by optical tweezers, a novel non-resonant optomechanical driving force was theoretically proposed to drive topological phase switching in tin selenide (SnSe) by using off-resonant light excitation, mediated by the real part of the dielectric function. The absence of direct absorption via the imaginary part signifies the potential of this approach over traditional methods in selectively driving transitions with reduced energy consumption and ultrafast switch speed. Here we study mid-infrared-excited SnSe with time-domain Raman scattering and a suite of advanced spectroscopies sensitive to the dynamic structure and symmetry of the light-induced phase. The abrupt suppression of A_g Raman modes above a critical MIR field strength without discernible softening is consistent with a structural distortion towards a higher symmetry phase with dramatically modified optical properties via a non-thermal driving mechanism. The high reflectivity contrast emphasizes the potential of harnessing these phase control handles for telecommunication applications. Further corroborated with transient reflectivity measurements and state-of-the-art first-principles calculations, our study provides evidence for an opto-mechanical-driven topological phase transition, defining novel opportunities for inducing hidden quantum phases with unique functional properties.

9:15 AM QM03.05.04
Band-Selective Electron-Phonon Couplings in an Excitonic Insulator Probed by Ultrafast Broadband Extreme-Ultraviolet Absorption Spectroscopy Michael Zuerch[1,2], Alfred Zong[1,2], Sheng-Chih Lin[1,2], Shunsuke Sato[3], Sasawat Jamnuch[4], Emma Berger[1,2], Yun Cheng[5], Wei Xia[6], Yanfeng Guo[6], Dao Xiang[5], Jie Zhang[5] and Tod Pascal[4]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Tsukuba, Japan; [4]University of California, San Diego, United States; [5]Shanghai Jiao Tong University, China; [6]ShanghaiTech University, China

The strength of electron-phonon couplings (EPC) constitute one of the most fundamental physical quantities in solids, accouting for a wide range of phenomena from superconductivity to polaronic transport. However, experimental determination of its value is challenging, which heavily depends on the theoretical model used. Recently, a model-free measurement of band-selective EPC becomes possible based on excitation of coherent phonons by a femtosecond laser pulse, which is in turn probed by time-resolved photoemission and diffraction. However, only the coupling between occupied electronic bands and phonons is accessible due to constraints of photoemission, whereas information for unoccupied bands, which play an important role in determining carrier relaxation pathways, is missing. Here, we provide a new method to quantitatively measure electron-phonon coupling strength using ultrafast broadband extreme-ultraviolet absorption spectroscopy, where phonon-induced shifts of unoccupied electronic states can be accurately determined in a band-, mode-, and element-resolved fashion. Using the putative excitonic insulator $1T$-TiSe_2 as a model system, we discovered disctinct coupling strengths of its A_{1g} phonon to unoccupied Ti and Se bands, where the coupling vanishes completely for select electronic states. Our approach provides a robust methodology for determining EPC of previously inaccessible states in a wide range of solids, opening new ways for unbiased evaluation of the role of EPC in emergent phenomena in quantum materials.

10:30 AM *QM03.06.01
Phase Transition Dynamics in $\mathrm{SrCoO}_{3-\delta}$ Heterostructures Dillon D. Fong[1], Qingteng Zhang[1], Guoxiang Hu[2], Vitalii Starchenko[3], Gang Wan[1], Eric Dufresne[1], Yongqi Dong[1], Huajun Liu[4], Hua Zhou[1], Hyoungjeen Jeen[3], Kayahan Saritas[3], Jaron Krogel[3], Fernando Reboredo[3], Ho Nyung Lee[3], Alec Sandy[1], Irene C. Almazan[1] and Panchapakesan Ganesh[3]; [1]Argonne National Laboratory, United States; [2]The City University of New York, United States; [3]Oak Ridge National Laboratory, United States; [4]Institute of Materials Research and Engineering, A*STAR, Singapore

The brownmillerite phase of strontium cobaltite ($\mathrm{SrCoO}_{2.5}$) is an insulating antiferromagnet while the perovskite phase (SrCoO_3) is a ferromagnetic metal. Relatively small changes to the oxygen concentration can drive a reversible, topotactic phase transition, making $\mathrm{SrCoO}_{3-\delta}$ a material of interest for neuromorphic applications. While the redox behavior of such oxides has been the subject of considerable interest, much concerning the kinetics and dynamics of these materials remain unknown.

Utilizing in situ coherent X-ray scattering at the Advanced Photon Source, we monitored speckle from epitaxial $\mathrm{SrCoO}_{3-\delta}$ thin films grown on both $\mathrm{SrTiO}_3(001)$ and $(\mathrm{LaAlO}_3)_{0.3}(\mathrm{Sr}_2\mathrm{TaAlO}_6)_{0.7}(001)$ as oxygen was incorporated and evolved (switching the environment from O_2 to N_2) to gain insight into the dynamics of oxygen-induced phase evolution in complex oxide materials. We found that the kinetics of the brownmillerite to the perovskite phase transition could be varied from tens of minutes to several hours over a small temperature range (300°C to 350°C), observing pronounced differences between the oxidation and reduction behaviors, the latter involving substantial incubation times to re-nucleate the brownmillerite phase. From X-ray photon correlation spectroscopy performed at the brownmillerite superlattice reflection, we find that the two-time correlation function differs greatly between the two different substrates. We will discuss the kinetics and dynamics of the oxygen ion / vacancy-ordering phase transition and the methods used to distinguish the different atomic and electronic mechanisms taking place.

X-ray photon correlation spectroscopy (XPCS) offers insight into materials dynamics at the mesoscale by the analysis of speckles, but has been largely limited to equilibrium or steady-state dynamics. In this work we extend XPCS by conducting experiments at the Advanced Photon Source (APS) and Linac Coherent Light Source (LCLS) on materials undergoing dynamics induced by external pumps. In this work, we describe work done on $SrTiO_3/PtTiO_3$ (STO/PTO) superlattices. This material system offers a platform with a large phase space of configurations, including polar vortices, supercrystals, and skyrmions. With the high brilliance, high degree of coherence, and short pulse duration available at LCLS we observed novel time scales emerging from mesoscale dynamics during an irreversible phase transition in $SrTiO_3/PtTiO_3$ superlattices from the vortex phase to the supercrystal phase. We then conducted experiments investigating the dynamics of polar vortices and skyrmions in STO/PTO under voltage excitation. Together, these measurements reveal the spatial pinning nature during the transition and the formation and growth of domains as a function of time and voltage excitation. These experiments also revealed the effect of excess charge in the system. These measurements extend XCPS towards probing functionality in materials as it relates to mesoscale structural order.

11:15 AM QM03.06.03
Imaging Light-Induced Metastable Nanostructures in $PbTiO_3/SrTiO_3$ Superlattices Marc Zajac[1], Tao Zhou[1,1], Sujit Das[2], Tiannan Yang[3], Yue Cao[1], Burak Guzelturk[1], Vladimir A. Stoica[3], Mathew Cherukara[1], John Freeland[1], Venkatraman Gopalan[3], Ramamoorthy Ramesh[4], Lane Martin[4], Long-Qing Chen[3], Martin V. Holt[1,1], Stephan Hruszkewycz[1] and Haidan Wen[1,1]; [1]Argonne National Laboratory, United States; [2]Indian Institute of Science, India; [3]The Pennsylvania State University, United States; [4]University of California, Berkeley, United States

Ultrafast light-matter interactions can synthesize novel metastable states of matter [1,2]. For example, when nanoscale phase mixtures of polar vortices and a_1/a_2 ferroelectric domains in $(PbTiO_3)/(SrTiO_3)$ (PTO/STO) superlattices are driven by a 400 nm wavelength optical excitation with sufficient fluence, a metastable 3D ordered phase or “supercrystal” is created [2]. It remains unknown how this photoinduced metastable state nucleates, grows, and is affected by the initial heterogeneity in real space. To gain microscopic insight, we used the recently enabled laser-pump, nano x-ray diffraction imaging capability with 25 nm spatial resolution to perform in-situ hard x-ray diffraction with controlled optical excitation [3].
We show that an intermediate phase characterized by in-plane ordered stripe domains forms when excited by an optical excitation with a wavelength of 343 nm at a repetition rate of 54 kHz. The nanoscale x-ray diffraction imaging reveals that this intermediate phase nucleates within the a_1/a_2 ferroelectric domains after five seconds of optical exposure at a fluence of 3 mJ/cm^2. Upon longer exposure times, the intermediate phase expands into and consumes the polar vortex domains, and after about 1000 seconds of exposure, finally transforms into a 3D nanostructure consistent with the previously reported supercrystal phase. Because 343 nm light excites both PTO and STO layers while 400 nm light only excites the PTO layer, the distinct intermediate phase can arise from different charge screening dynamics at the superlattice interface. Our work of imaging nanoscale phase evolution shows how new light-induced ferroelectric phases with unique optical and electronic properties form and transform in real space. This will lead to new ways of optically controlling phase transformations in emerging ferroelectric technologies.

Mesoscale Inhomogeneity Across Morphotropic Phase Boundary in Relaxor Ferroelectrics Hao Zheng[1], Tao Zhou[1], Dina Sheyfer[1], Travis Frazer[1], Zhonghou Cai[1], Martin V. Holt[1], Eric Dufresne[1], Jieun Kim[2], Zishen Tian[2,3], Jiyeob Kim[2], Lane Martin[2,3] and Yue Cao[1]; [1]Argonne National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Relaxor ferroelectrics have drawn much attention due to the intriguing physics underneath their giant piezoelectric properties. The extraordinary electromechanical responses are facilitated by metastable polarization states around the morphotropic phase boundary between rhombohedral and tetragonal symmetries. The highly frustrated lattice distortions give rise to a hierarchical evolution of polar order and make mesoscale mechanism especially important for relaxor ferroelectrics. In this talk, I will provide a comprehensive picture of the spatial ordering heterogeneities in the canonical relaxor ferroelectric $0.68PbMg_{1/3}Nb_{2/3}O_3\text{-}0.32PbTiO_3$ (PMN-PT) film epitaxially synthesized on $SmScO_3$ substrate. Combining X-ray nanodiffraction and X-ray photon correlation spectroscopy (XPCS), we resolved the detailed lattice distortions of both strain and lattice tilt in the nanoscale. Our result showed a continuous distribution of entangled polarization without hard domain walls. The in-operando evolution of the strain and lattice under applied electric field further revealed an inhomogeneous evolution of polarization rotation enhanced by local structural variation across the morphotropic phase boundary. I will also discuss how nanoprobe and XPCS could work cooperatively in probing the polar order distribution and providing a more comprehensive picture of domain response under applied electric fields.

SESSION QM03.07: Realizing the Floquet and Topological States of Matter
Session Chairs: Long Ju and Joel Moore
Wednesday Afternoon, April 12, 2023
Marriott Marquis, Fourth Level, Pacific C

1:30 PM *QM03.07.01
Optical Control of Band Topology and Magnetism in Correlated Two-Dimensional Materials Gregory Fiete; Northeastern University, United States

In this talk I will discuss recent theoretical developments in the Floquet engineering of two-dimensional materials, including those with a “twist” between the layers. With the scenario of a laser driving the material in mind, I will focus on two distinct regimes: (1) A "direct" regime where the dominant coupling of the laser is to the electronic degrees of freedom and (2) and "indirect" regime where the dominant coupling of the laser is to the lattice degrees of freedom. In regime (1), I will present some methods to describe low-frequency drives (where a Magnus expansion typically fails), an approach to change the interlayer hopping in a twisted material using a waveguide, and a treatment of electronic and lattice coupling on equal footing. In regime (2), I will present a non-linear phononics approach to modifying magnetism and electronic band topology in two-dimensional materials through direct coupling of the light to IR phonons that couple non-linearly to Raman modes which in turn induce magnetic and band topology transitions. I will focus on the examples of CrI3 for magnetism change, and MnBi2Te4/MnSb2Te4 for a magnetism combined with band topology change induced via non-linear phononics. Our theoretical study includes a symmetry-based component as well as first principles calculations. I will conclude with an outlook on the field, including challenges for both theory and experiment in the optical control of correlated two-dimensional materials.

We gratefully acknowedge funding from NSF DMR-1720595 and NSF DMR-2114825.

2:00 PM *QM03.07.02

Floquet-Engineered Topological Transport in Quantum Materials B. Schulte[1], M.W. Day[1], K. Kusyak[1], F. Sturm[1], D. Shin[1], H. Bretscher[1], G. Jotzu[1], T. Matsuyama[1], G. Meier[1], A. Cavalleri[1], D. Kennes[1,2], M.A. Sentef[1], A. Rubio[1] and J.W. McIver[1,3]; [1]Max Planck Institute for the Structure and Dynamics of Matter, Germany; [2]RWTH Aachen University, Germany; [3]Columbia University, United States

Quantum materials exhibit remarkable phenomena when driven by the strong fields in femtosecond pulses of light. Examples range from the emergence of metastable hidden phases in complex oxides [1] and dichalcogenides [2] to signatures of light-induced superconductivity in cuprates [3] and fullerides [4]. Recent years have seen a surge of interest in using long-wavelength laser pulses to create photon-dressed “Floquet-Bloch” states in quantum materials [5]. Much of this excitement is driven by the predictive power of Floquet theory, which has been used, for example, to correctly predict the formation of topological edge states in periodically-driven systems that exhibit no topological properties in equilibrium [6-7]. Many of these proposals have been verified in quantum simulation settings [8-9], but are only just beginning to be explored in quantum materials [10].

In this talk, I will present results on the electrical transport properties of quantum materials driven by ultrafast pulses of mid-infrared light. These results were achieved using a device architecture based on laser-triggered photoconductive switches and waveguides, which allows transport measurements on microstructured quantum materials to be performed on femtosecond timescales. In monolayer graphene, we observe an anomalous Hall effect induced by circularly polarized light in the absence of an applied magnetic field [11]. The dependence of the effect on a gate potential used to tune the Fermi level reveals multiple features that reflect a Floquet-engineered topological band structure. The results are a critical first step towards realizing and controlling light-induced topological edge states in quantum materials.

In the second part of the talk, I will discuss our recent results on the Weyl semimetal $MoTe_2$. We observe a rectified, circular dichroic photocurrent response that scales linearly (as opposed to quadratically) with the applied laser field, which is consistent with the formation of Floquet-Bloch states in this material. Furthermore, we find that when pumping the material strongly enough, the interlayer shear phonon mode couples to the transport properties of the out-of-equilibrium states. Pumped above a certain threshold, this phononic motion induces a permanent structural phase transition that changes the band structure topology, which we directly probe in the nonlinear transport sector. Our results demonstrate multiple ways in which ultrafast light-matter interaction can manipulate the topological responses of quantum materials via the breaking of symmetry.

Order-by-Disorder and Potts-Nematicity in the MPX3 van der Waals Magnets Jörn Venderbos; Drexel University, United States

The family of layered transition-metal trichalcogenides (MPX3) has recently attracted much attention as a versatile platform for exploring magnetism in van der Waals materials, and offer a potential venue for realizing intrisinc two-dimensional magnetism. This talk will discuss the magnetic phases observed in these honeycomb magnets, highlighting in particular the accidental degeneracy of classical ground states in a frustrated honeycomb lattice Heisenberg model. Fluctuations lift this degeneracy via the order-by-disorder mechanism, which is demonstrated by developing a systematic spin wave theory. As a result of the accidental degeneracy at the classical level, linear spin wave theory is insufficient to accurately describe the spin wave dispersion---an experimentally relevant characterstic. Indeed, at the quadratic level pseudo-Goldstone modes are present, which are gapped by higher order quantum corrections. This talk will further address the nature of the quantum phase transition between a paramagnet and a rotation symmetry broken ordered state of the kind observed in some members of MPX3 family. In particular, this talk will show that this transition can proceed in two steps, with the rotation symmetry broken first as the ordered state is approached, thus giving rise to a Potts-nematic phase.

Thursday Morning, April 13, 2023
Marriott Marquis, Fourth Level, Pacific C

9:00 AM *QM03.09.02
Light Induced Ultrafast Phenomena in Quantum Materials Matteo Calandra[1] and Giovanni Marini[1,2]; [1]Università di Trento, Italy; [2]Istituto Italiano di Tecnologia, Italy

The successful prediction and design of broken symmetry states induced by femtosecond laser light could lead to an unprecedented control and manipulations of the physical properties of materials. To phase this challenge, we developed a constrained density-functional perturbation theory scheme [1] for the calculation of structural (energy, forces and stress tensor) and harmonic vibrational properties (phonon frequencies and electron-phonon coupling) of insulators in the presence of an excited and thermalized electron-hole plasma. In this talk we present the application of the methods and comparison with TDDFT calculations for the case of low dimensional materials, thermoelectrics and phase change materials.

We show that irradiation of the insulating 2H phase in MoTe2 stabilizes multiple transient charge density wave orders with light-tunable distortion, periodicity, electronic structure and bandgap. Moreover, optical pumping of the semimetallic 1T' phases generates a transient charge ordered metallic phase composed of 2D diamond clusters. For each transient phase we identify the critical fluence at which it is observed and the specific optical and Raman fingerprints to directly compare with future ultrafast pump-probe experiments.
Moreover, we demonstrate that ultrafast pulses can be used to induce a magnetic state in the non-magnetic compound V2O5. We show which criteria must the materials satisfy to show the occurrence of ultrafast magnetization, a much less common effect that the widely studied ultrafast demagnetization.

Finally we present applications to phase change materials and demonstrate that ferroelectricity in GeTe can be easily tuned with fs pulses[4].

9:30 AM QM03.09.03
Rational Design of Materials with Coexisting Delocalized and Localized States via Extrinsic Polarons Shuaishuai Yuan and Kirk H. Bevan; McGill University, Canada

Free and self-trapped electrons usually coexist in intrinsic polaronic materials. The transition between delocalized and localized states is of great interest to both theoretical and experimental efforts in the field. However, it is difficult to tune the transition between coexisting delocalized and localized states within intrinsic polaron materials. In this study, we provide an innovative approach for designing extrinsic materials in which the coexistence between delocalized and localized states may be engineered. Through comprehensive ab initio calculations, utilizing hybrid functionals and supporting tight-binding insights, trapping properties in this class of tailored materials are investigated with respect to variations in the lattice strain and doping concentration. In this regard, the energy level of the defect and its bandwidth are shown to play a dominant role in the associated transition barrier and the relative stability between delocalized and localized states. Overall, this work explores the means by which the coexistence of free and trapped carriers can be tuned at the atomic scale, with direct applications in resistive switching, memristive, and related computing devices.

SESSION QM03.10: The Collective Dynamics of Magnetism
Session Chairs: Gregory Fiete and Wanzheng Hu
Thursday Morning, April 13, 2023
Marriott Marquis, Fourth Level, Pacific C

10:30 AM *QM03.10.01
Engineering Magnetic Excitations and Entanglement in Quantum Materials Yao Wang; Clemson University, United States

The rapidly evolving quantum material research calls for precise control of collective electronic properties. Among various control knobs, an ultrafast laser pump is a promising approach due to its rich degrees of freedom. Unlike equilibrium spectroscopies, ultrafast pump-probe spectra involve more theoretical complexity and are limited by more experimental constraints. In this talk, I will discuss the application of time-resolved resonant inelastic x-ray scattering (trRIXS) in quantum magnets. Specifically, I will introduce how one can engineer magnetic excitations with and without long-range orders. The transient states driven by laser pulses exhibit more entanglement than equilibrium states, which can be witnessed by trRIXS.

11:00 AM *QM03.10.02
Engineering Magnetic Ground States in Iridium Oxides Alberto De la Torre[1,2]; [1]Brown University, United States; [2]Northeastern University, United States

Competing exotic phases of matter emerge in quantum materials due to complex interactions between charge, lattice, spin, and orbital degrees of freedom. The control of their macroscopic properties via external perturbations is essential to achieving new technological applications [1]. Traditional approaches include hydrostatic pressure, strain, and chemical doping. Most recently, ultrafast light-matter coupling enables unique mechanisms to access new out-of-equilibrium phases of matter in a controlled and reversible manner [2].

In this talk, I will focus on two strategies to control the magnetic interactions and ground state of two 5d5 iridium oxides: α-Li_2IrO_3 and Sr_2IrO_4. In the former, we use resonant x-ray spectroscopy measurements to study how the introduction of intralayer H atoms ($H_3LiIr_2O_3$) nudges this material toward a Quantum Spin Liquid phase [3]. In the latter, by using resonant ultrafast excitations, we discover new nonthermal critical behavior, which has potential implications for future THz spintronic technology [4]. These results highlight the unique potential of quantum materials for future technological applications.

SESSION QM03.11: THz and Strain Control Over Quantum Phenomena
Session Chairs: Yue Cao and Keith Nelson
Thursday Afternoon, April 13, 2023
Marriott Marquis, Fourth Level, Pacific C

1:30 PM *QM03.11.01
Toward Multimodal Control Over Quantum Phenomena Keith A. Nelson; Massachusetts Institute of Technology, United States

Quantum phases and phase transitions are exquisitely sensitive to coupled degrees of freedom that mediate key properties and dynamical behavior. Control over the relevant modes through applied pulsed fields can provide fundamental mechanistic insights and offer intriguing prospects for applications involving either transient or persistent induced responses. Electromagnetic and strain fields, applied through optical and acoustic pulses respectively, can exert profound effects on quantum materials.

Terahertz light fields are extremely well matched to the excitations and dynamics characteristic of many cooperative systems. Strong THz fields can induce responses that may reveal important mode-mode couplings, hidden quantum phases, and other phenomena of interest. Recent results involving collective electronic, vibrational, and spin degrees of freedom will be presented. A THz-induced transition into a topological insulator phase of the transition metal dichalcogenide $MoTe_2$ will be discussed. A single THz pulse drives the phase transition electronically, after which the new phase persists indefinitely [1]. A persistent optically-induced change in TaS_2 will also be discussed briefly. The transition is monitored on a single-shot basis with both optical and THz probe light [2]. Strong THz fields drive a “soft” lattice vibrational mode to induce a transition from the quantum paraelectric phase of $SrTiO_3$ to a transient ferroelectric phase [3]. Recent ultrafast x-ray diffraction measurements provide information beyond what could be determined through optical probes. Finally, THz-induced nonlinear responses of collective spin waves (magnons) have revealed coupling that is inherent in canted antiferromagnetic materials [4]. Two-dimensional THz spectroscopy, conducted using single-shot readout of the time-dependent signal field, reveals the coupled spin responses.

Many quantum (and other crystalline) phase transitions involve changes in the lattice parameters. In such cases, strain can play a key role in controlling which phase is present. We have developed a facile method for laser generation of compressional or surface acoustic wave (SAW) shocks [5] that focus in the plane of a sample to reach stresses sufficient to cause material fracture, chemical decomposition, and other effects [6-8]. We have demonstrated a SAW-induced insulator-to-metal persistent phase transition in V_2O_3, extending prior study of a reversible transition induced by quasi-static high pressure [9]. In very recent work, we have developed a method for non-destructive generation of large-amplitude acoustic waves [10]. The approach permits repeated shocks to be delivered to the same sample region, and has been used to observe cumulative effects (i.e. fatigue) caused by hundreds or thousands of shocks. The shocks also may be used to drive phase transitions by themselves or in conjunction with THz or optical excitation. The combination of multimodal excitation and control with probing from THz to x-ray spectral ranges and with real-time single-shot measurement capabilities offers fascinating prospects for fundamental study and potential practical applications of collective quantum dynamics.

A Thermodynamic Framework to Establish Phase Diagrams for Strain Engineering Bo Wang[1,2] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]Lawrence Livermore National Laboratory, United States

Strain engineering has been established as a viable way to stabilize hidden phases and induce exotic phenomena in many low-dimensional solid-state materials. A phase diagram describing the equilibria of phases and domain variants as a function of strains and other thermodynamic variables is invaluable to guide the strain engineering. Here, we propose a universal theoretical framework based on thermodynamics to establish the strain phase diagrams of any solid-state functional materials, without *a priori* assumptions on the multi-phase/multi-domain coexistence or substantial computational workload. We apply this approach to establish the strain phase diagrams of various functional materials that undergoes structural transformations, including ferroelectric and multiferroic perovskite oxides (e.g., $BaTiO_3$, $PbZr_{1-x}Ti_xO_3$, and $BiFeO_3$), unconventional HfO_2-based ferroelectrics, and strongly correlated electronic materials such as VO_2. Based on the strain phase diagrams, we discuss the generalized Gibbs phase rules, critical and multi-critical points, universal topological characteristics of the diagrams, and demonstrate a graphical approach to determine the content fractions of the coexisting phases/domain variants. Our theoretical approach offers a universal understanding of the phase equilibria of solid-state materials subject to arbitrary anisotropic strains, enabling efficient construction of strain phase diagrams in high dimensions that would be tremendously useful for strain engineering of quantum materials. Part of this work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

SESSION QM03.12: Emergent Phases Viewed Through Electron Scattering

3:30 PM *QM03.12.01
Classification of Nonequilibrium Phase Transitions in Quantum Materials Using Ultrafast Electron Microscope Platform Chong-Yu Ruan, Shuaishuai Sun and Xiaoyi Sun; Michigan State University, United States

The quantum materials are featured by their complex phase diagrams where multiple electronic phases often occur adjacently. The rich variety of ordered states —including superconductivity, electronically and magnetically ordered phases—emerge as a consequence of the astounding properties of quantum many-body physics. Harnessing the collective behavior thus may lead to functionalities beyond the conventional semiconductors. In particular, recent discoveries of the quantum phases strongly interacting with light fields gave rise to a new dimension of emergent phases, including the light-induced metastable or even long-lived hidden phases brought in with properties never seen under equilibrium conditions.

Bridging the connections between different microscopic initiations and macroscopic responses is central toward elucidating the organizing principle behind the light-induced phases. Here, we present a path toward such understanding using a joint experiment-theory framework to explore the nonequilibrium states of quantum materials. The investigations leverage a new ultrafast electron microscope, which gives a unified platform to cross-examine the microscopic dynamics and the outcomes in a control-feedback fashion, thus establishing a mapping between the microscopic tuning knobs and emergent functions. The predictive framework is based the phenomenological mean-field theory (Landau-Ginzburg equation) modelled on the dynamics of the order parameter fields . In a generic pump-probe scheme, the ultrafast control is enacted upon pumping the nanostructured materials where optical interference effect shapes the excitation profile. Three classes of materials (RTe_3, TaS_2 and VO_2) were thus investigated to offer valuable insights on different broken-symmetry systems. The ultrafast electron microscopy setting gathers information by judiciously selecting the scattering channels: with coherently scattered electrons, one captures the evolution of order parameter (diffraction and dark-field imaging), whereas collecting the inelastically scattered electrons, sensitivity falls primarily on incoherently excited electronic dynamics directly connected with the pump laser field control. Alternatively, bright-field imaging of local fields, strain profiles or morphology plays a role to inform the potential feedback mechanism. These different modalities, executed over the same incident beams and the pump fields, offer causality-linked sequences pertaining to nonequilibrium phase transitions which are crucial to establish the mechanistic insight.

We can categorize the nonequilibrium phase transitions based on the dynamical behavior of symmetry breaking in respond to different triggers as a mean to classify controls. In the studies of $CeTe_3$, we observe dynamical critical phenomena associated with the emergence of a hidden order parameter field. The new broken-symmetry state appears by suppressing the predominant order over a critical level, thus revealing the competitive nature between the two. In TaS_2, we witness an entirely different scenario where the laser pulses lead to a transient vestigial order without breaking the existing order parameter, i.e., no order-disorder phase transition involved, to obtain a new topological arrangement. The dynamics are mediated by amplitude modes and the transformation does not suffer from extended criticality and so maintain a high degree of coherence in transitions from one energy basin to another. In VO_2, the quasi-1D nature of the active system subjects its phase change behavior to the presence of light-induced defects. The new form of instabilities offers a mechanism for feedback control. The insulator to metal transition in the excited dynamical system becomes self-regulating and exhibit memory effect.

Ultrafast Electron Microscopy Studies of Quantum Materials Yimei Zhu; Brookhaven National Laboratory, United States

In this presentation I will give an overview of our recent work on symmetry-guided, photoinduced manipulation and control of transient and metastable quantum states and phenomena in strongly correlated quantum materials using ultrafast electron diffraction and microscopy. Several examples will be given. 1) Using fs temporal gating via photoinduced nearfield electron microscopy (two-color PINEM) to achieve 10^{-21} m×s spatiotemporal resolution to probe nanoscale-femtosecond dielectric response and metal-to-insulator transition in VO2 [1,2]. 2) Probing photoinduced electronic transition from a topological insulating state to a Dirac semimetal state in ZrTe5 [3] using MeV ultrafast electron diffraction. 3) Analyzing photoinduced transient and metastable states based on time-resolved diffuse scattering in thermoelectric SnSe and manganites [4,5]. I will also report our latest development on the laser-free electron pulser that can be retrofitted into a commercial transmission electron microscope for ultrafast stroboscopic diffraction, imaging and GHz excitations. I will show an example of the interdigitated comb device that is widely used as an antenna or sensor in mobile platforms for direct visualization of its interactions with microwave and electromagnetic wave dynamics [6]. The ability to probe materials dynamic responses under RF and microwave excitations has promising applications for qubit devices and quantum information science.

Understanding the Phase Transformation Dynamics in NiTi using *In Situ* 4D-STEM Jennifer Donohue[1], Didier Perrodin[2], Colin Ophus[2], Sean Mills[1], Benjamin Savitzky[2], Steven Zeltmann[1] and Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

There has been much focus on the development of caloric cooling technologies as an environmentally-friendly alternative to conventional vapor compression technologies owing to their use of benign solid-state refrigerants[1]. Elastocaloric materials (eCMs) in particular have garnered much interest for this application due to its ability to produce high temperature and entropy changes when subjected to an external mechanical stress while not utilizing expensive or toxic elements[1]. Shape memory alloys (SMAs) are well known to exhibit the elastocaloric effect by undergoing a stress-induced martensitic phase transformation. This has made SMAs, binary NiTi alloys in particular, some of the most well studied and most promising eCMs. While NiTi demonstrates a respectable adiabatic temperature change of ~25K with possible improvements, short fatigue life and hysteresis losses limit practical applications. Much research has been done into functional fatigue and high hysteresis in NiTi supplying many theories, however, the origin of these phenomena still remains unclear.

Current theories state that the origin of hysteresis and functional fatigue in NiTi is microscopic strain incompatibility at the interface of the parent and product phase and potential residual martensite. This strain incompatibility causes the accumulation of defects at the phase boundary[2-4] which then stabilize martensite above the transition temperature. Understanding how the nanoscale strain landscape develops at and before the transformation front in these materials is necessary to fully understand the origin of the high hysteresis and short fatigue life in these systems. This understanding could be critical to the design of improved fatigue-resistant low-hysteresis materials with high recoverable strains.

Here we use four-dimensional scanning transmission electron microscopy (4D-STEM) with high precision bullseye apertures[5] to map the nanoscale structure of NiTi during *in situ* cooling through the phase transformation from the high temperature B2 austenite to the low temperature B19' martensite. Using 4D-STEM and advanced data processing tools, we map the nanostructure of NiTi as it approaches and proceeds through the phase transformation during cooling, demonstrating the first structurally-resolved imaging of the local transformation in this system. With this method, we map the phase distribution of austenite & martensite variants during the transformation. We also map the development of local diffuse streaking, and the local strain landscape at the transformation front. With continued cycling, we observe the variation in the resulting martensite structure. Finally, we correlate diffuse scattering, strain, and phase distribution granting insight into the phase transformation dynamics in the eCM NiTi.

Disentanglement of Electronic and Structure Orders in Photoinduced Phase Transition of VO_2 Xiaoyi Sun[1], Shuaishuai Sun[2], Ian Gonzalezafanador[1], Gerardo T. Morales[1], Nelson Sepulveda[1] and Chong-Yu Ruan[1]; [1]Michigan State University, United States; [2]Institute of Physics, Chinese Academy of Sciences, China

The insulator-to-metal transition (IMT) in vanadium dioxide with a resistivity change of more than three orders of magnitude is typically accompanied by a structural phase transition (SPT) from the monoclinic phase (M) to the rutile phase (R). This cooperative phase transition is well established in the equilibrium states under monotonic tuning parameters, such as applying pressure or chemical doping, or change in temperature. However, recently intriguing evidences for decoupling between IMT and SPT emerged when the systems were exposed to strong ultrashort laser pulses, casting in doubt the fundamental nature of this cooperativity both in and out of equilibrium.
Here, to address this issue we examine the emergences of cooperativity or its lack thereof through a dual-probe setting employing ultrafast electron diffraction (UED) and optical transmittance (TR-OT) measurements to obtain simultaneously the structural and electronic responses to the static and transient perturbations. To set the stage for comparing equilibrium and nonequilibrium phase transitions we benchmark the VO2 system reaching metallic status while gaining the rutile (R) structural motif from the initial monotonic (M) state under the steady-state heating (and cooling) where we invariably confirmed the cooperativity based the same critical temperature obtained for IMT and SPT. The same VO2 system is then subject to the optical excitation for the nonequilibrium investigations where we switch the control parameter from temperature to laser fluence (F).
Our results unambiguously show the two transitions characterized in the fashion defined in the equilibrium studies are decoupled in the observation of two thresholds respectively assigned to IMT and SPT. The first threshold, Fc1 ~ 4 mJ/cm2, defines the IMT based on TR-OT reaching the equilibrium metallicity, which is distinctly below the threshold, Fc2 ~ 7 mJ/cm2, for SPT, as identified by the UED structure factor losing monoclinic. This classification is based on the intermediate time behavior (+ 500 ps) where one expects the thermal energy provided by the optical excitation is sufficiently redistributed. While this apparent decoupling might confirm some of the earlier studies regarding the establishment of a distinct electronic order status away from SPT, we also found subtle structural distortion closely accompanying the IMT dynamics in all ranges of the excitation. This surprising result points to yet a new type of cooperativity on the microscopic level without the conventional motif changes observed in equilibrium, namely M-to-R. Judging from the early onset of the distinct light-induced electronic order (< 1 ps), the process is clearly nonthermal, likely mediated by the photo-hole generation. Based on the simultaneous structural data, the hole dynamics are heavily dressed by the ambient lattice field, resulting in a polaronic-like response leading to transient cooperativity with IMT on the local level. Separately, the structured ordering to obtain the R phase requires the development of a long-range correlation in the new motif along the V-V chain, which is not a critical ingredient for the IMT. Although, on the thermodynamical timescale, or in the strongly driven regime (over a much higher fluence than FC2) the IMT and SPT may seem to proceed simultaneously. The research conducted here points out the importance of non-equilibrium physics and the different collective behaviors in order to comprehensively address the multi-faceted aspects of the VO2 phase-change phenomena.

Ultrafast Spin-Shear Coupling in van der Waas Antiferromagnets Haidan Wen; Argonne National Laboratory, United States

The symmetry of magnetic order and underlying lattice structures in van der Waals magnets intertwines and mutually gives rise to a plethora of exotic phenomena that are absent in 3D materials. However, among multiple structural degrees of freedom, it remains elusive which structural parameters primarily couple to magnetism and the impact of this coupling on the ultrafast dynamics of vdW magnets. Here, we discover a strong coupling between interlayer shear and magnetic orders using a set of ultrafast measurements including ultrafast electron diffraction and microscopy, ultrafast x-ray diffraction and optical linear dichroism. On the picosecond time scale, a seesaw-like rotational motion was observed in the reciprocal lattice of $FePS_3$, which exhibits a thirty-fold amplification of its gigahertz structural resonance upon cooling below the Neel temperature [1]. The rotation in reciprocal space manifests as an unusually large interlayer shear in real space, where individual micro-patches of the film behave as synchronized shear oscillators that are phase-locked and deform along the same in-plane axis. On nanosecond time scales, we found the recovery of the lattice shear and magnetic order exhibit concurrent slowing down at the Neel temperature with the same critical components [2]. The time-dependent Ginzburg-Landau theory shows that this concurrent critical slowing down arises from a linear coupling of the interlayer shear to the magnetic order, which is dictated by the broken mirror symmetry intrinsic to the monoclinic stacking. Our work not only offers the first microscopic view of the spin-mediated mechanical motion of an antiferromagnet, it also identifies a new route towards realizing high-frequency resonators up to the millimeter band, where the capability of controlling magnetic states at the ultrafast timescale can be readily transferred to engineering the mechanical properties of nano-devices.

Magnetic Proximity Effects Between Topological Insulators and Insulating Antiferromagnet Ryan T. Van Haren and David Lederman; University of California, Santa Cruz, United States

Magnetic proximity effects between topological insulators and insulating antiferromagnets can open the way to new spintronic functionalities, including THz communication and data storage technology. Here we report on magnetotransport measurements of $MnF_2/(Bi,Sb)_2Te_3$ antiferromagnetic/ topological insulator heterostructures. MnF_2 is a canonical uniaxial antiferromagnet with a tetragonal crystal structure, whereas $(Bi,Sb)_2Te_3$ is a topological insulator whose Fermi level can be brought into the bulk gap to access the topologically-protected surface states by varying the Sb concentration. The samples were grown using molecular beam epitaxy on MgF2 (110) substrates. The MnF_2 layer was grown epitaxially the substrate using a $(Mn,Ni)F_2$ graded layer to reduce the strain on the MnF_2, resulting in (110) growth with the [001] crystallographic direction in the plane of the sample, corresponding to the magnetic anisotropy easy axis. We find evidence for coupling between the MnF_2 layer and the $(Bi,Sb)_2Te_3$ surface states by measuring the planar Hall effect with the external magnetic field applied parallel to the MnF_2 easy axis, where a sudden change is measured at the MnF_2 spin-flop field. We will also present measurements with the field perpendicular to the plane of the samples, where the Hall effect is observed. Possible interpretations of these measurements and the influence of the topological nature of the surface state carriers will be discussed.

Balandin[1]; [1]University of California, Riverside, United States; [2]Institute of High-Pressure Physics, Poland; [3]University of Georgia, United States

The charge-density-wave (CDW) phase is a macroscopic quantum state consisting of a periodic modulation of the electronic charge density accompanied by a periodic distortion of the atomic lattice. The early work on CDW effects, performed with bulk samples of the quasi-one-dimensional (1D) metallic crystals, revealed many spectacular phenomena — nonlinear electron transport, oscillating electric current for constant voltages, and giant dielectric response. Recent years witnessed a rebirth of the field of CDW materials and devices, partially driven by an interest in layered quasi-2D van der Waals materials where CDW phases can manifest themselves at room temperature (RT) and above [1-3]. However, despite numerous attempts, the electrical gating of the CDW phases remained elusive. The main difficulty of electrical gating of the CDW phases van der Waals materials is associated with the fact that different phases still have a rather high concentration of charge carriers. We succeeded in electrical gating of the CDW phases and currents in *h*-BN capped three-terminal $1T\text{-}TaS_2$ heterostructure devices. It was demonstrated that the application of a gate bias can shift the source-drain current-voltage hysteresis associated with the transition between the nearly commensurate and incommensurate CDW phases [4]. The evolution of the hysteresis and the presence of abrupt spikes in the current while sweeping the gate voltage suggest that the effect is electrical rather than self-heating. We attributed the gating to an electric-field effect on the commensurate CDW domains in the atomic planes near the gate dielectric. The transition between the nearly commensurate and incommensurate CDW quantum phases can be induced by both the source-drain current and the electrostatic gate. Since the CDW phases are persistent in $1T\text{-}TaS_2$ at room temperature, one can envision memory applications of such devices when scaled down to the dimensions of individual commensurate domains and few-atomic plane thicknesses.

Iontronics—Control of Lattice Symmetry and Hidden Phases in Oxide Thin Films Hyeon Han and Stuart S. Parkin; Max Planck Institute, Germany

Transition metal oxide thin films reveal intriguing physical phenomena by control of their lattice symmetry, as their physical and structural properties are strongly intertwined. Iontronics has emerged as a novel concept to tailor lattice symmetry and the associated physical properties of oxide thin films [1]. Here, we demonstrate ionic liquid gating of $T\text{-}Nb_2O_5$ thin films, revealing multi-step hidden phase transitions by intercalation of lithium ions into the lattice [2]. We realize growth of single crystalline $T\text{-}Nb_2O_5$ thin films critically with vertical ionic transport channels, leading to a fast and colossal insulator-metal transition with an eleven orders of magnitude change in resistivity. A change in lattice symmetry from orthorhombic to monoclinic along with electronic phase transitions are revealed by various *in situ* characterizations. Furthermore, by employing a hydrogen spillover method, we present itinerant ferromagnetic $SrRuO_3$ (SRO) thin films whose resistivity and magnetism are extensively tuned by hydrogen ion intercalation [3]. The hydrogenated SRO films reveal a reversal of the sign of the anomalous Hall effect coupled with a distinct lattice symmetry change from orthorhombic to tetragonal via octahedral tilting. These studies open a new path towards the exploration of hidden phases and suggest a new approach to tailor lattice symmetry and emergent physical phenomena via iontronics.

Nonlinear Optical Detection of Dual Magnetic Ground States in a Magnetic Weyl Semimetal $Co_3Sn_2S_2$ Youngjun Ahn[1], Xiaoyu Guo[1], Rui Xue[2], Kejian Qu[2], Kai Sun[1], David Mandrus[2,2,3] and Liuyan Zhao[1]; [1]University of Michigan–Ann Arbor, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

The symmetry properties of ground states of material systems lie at the essence of condensed matter physics. Nonlinear second harmonic generation techniques have successfully characterized crystallographic point groups, but mostly on systems without inversion symmetry using the leading-order electric dipole contribution. The symmetry studies of recently realized topological centrosymmetric semimetal systems are in demand to provide a clear understanding of their ground states and electronic band topology. In this talk, rotational anisotropy (RA) second harmonic generation (SHG) study of the magnetic Weyl semimetal $Co_3Sn_2S_2$ will be presented to resolve the debate on its magnetic ground state. In this study, the RA SHG patterns of this centrosymmetric compound are identified to contribute from the leading-order electric quadrupole. By tracking temperature dependence of the RA SHG with the focus on the intensity (time-reversal invariant) and orientation (time-reversal broken), out-of-plane ferromagnetism at $T_{C,1}$ = 175 K and in-plane antiferromagnetism at $T_{C,2}$ = 120 K are revealed, both belonging to -3m' magnetic point group. Finally, the critical exponents of ferromagnetic and antiferromagnetic order parameters are extracted from the intensity and orientation of the RA SHG, which are represented by even and odd powers of order parameters, respectively, providing insight into the characteristics of these two phase transitions.

New Synthesis Pathways Through High-Pressure Floating Zone Growth Stephen D. Wilson; University of California-Santa Barbara, United States

High-pressure floating zone growth can provide nonequilibrium synthesis pathways capable of creating an array of new functional and quantum materials. The ability to access ultrahigh processing temperatures in high pressure reactive gas environments can, in many cases, provide a unique processing environment for realizing new materials. In this talk, I will discuss some of our group's recent work in the growth of quantum materials via high pressure floating zone techniques. Select examples of our recent research will be given and potential opportunities for driven states enabled by advances in high pressure floating zone instrumentation will be highlighted.

11:30 AM *QM03.14.03
Switching Topological Phases in Quantum Materials by Phonons Qiang Li; Stony Brook University/Brookhaven National Laboratory, United States

Zirconium pentatelluride ($ZrTe_5$) is a material at the phase boundary between topological insulator and Dirac semimetal. It was shown theoretically that atomic displacements corresponding to five of the six zone-center A_g (symmetry-preserving) phonon modes can drive a topological transition from a strong to a weak topological insulator with a Dirac semimetal state emerging at the transition.[1] Experimentally, a few-cycle THz-pulse-induced phase transition was demonstrated by the excitation of the lowest Raman active mode.[2] Above a critical THz-pump field threshold, there emerges a long-lived metastable phase, approximately 100 ps, with unique Raman phonon-assisted topological switching dynamics. Using first-principles and effective Hamiltonian methods, it is shown that lattice distortions corresponding to all three types of zone-center infrared optical phonon modes can drive the system from a topological insulator to a Weyl semimetal.[3] Experimentally, the light induced switching to Weyl phase was dynamically created by B_{1u} phonons that led to helicity-dependent current, orthogonal to the dynamical inversion symmetry breaking axis, via circular photogalvanic effect. Such phononic control breaks ground for coherent manipulation of Weyl nodes and robust quantum transport without application of static electric or magnetic fields, which is desirable for high-temperature fault-tolerant multi-qubit computation and communication.

Ultrafast Dynamics and Floquet Engineering Enabled by Ultrafast Time- and Angle-Resolved Photoemission Spectroscopy Shuyun Zhou; Tsinghua University, China

Revealing the ultrafast dynamics of quantum materials and further controlling the transient electronic states by ultrashort laser pulses can extend our understanding of the fundamental physics to the nonequilibrium state, with the intriguing possibility to manipulate material properties in the picosecond (ps) to femtosecond (fs) time scale. Time-resolved ARPES (TrARPES) is a powerful tool for capturing the nonequilibrium electronic structures and for investigating possible light-induced new electronic states with energy-, momentum- and time-resolved information. In this talk, I will present our recent progress in developing cutting-edge TrARPES instrumentation, with particular efforts focusing on extending the pump and probe photon energy ranges. I will also present our recent progress on the ultrafast dynamics and Floquet engineering of quantum materials which are made possible by such instrumentation development.

8:30 AM *QM03.15.02
Light Induced Symmetry Reduction in Cr2O3 by Time Resolved Second Harmonic Generation Anshul Kogar; University of California, Los Angeles, United States

Intense light pulses offer the ability to manipulate materials on ultrafast timescales using various protocols. In this talk, I will outline some work our group has undertaken in inducing novel optical effects in magnetoelectric compounds. I will present some data on parity-breaking antiferromagnet, Cr2O3, in which the magnetoelectric effect was first discovered. We demonstrate that by pumping the system below the electronic gap, that the original threefold symmetry of the crystal can be reduced. The symmetry changes are monitored by rotational anisotropy second harmonic generation (SHG), which is a sensitive tool of electronic symmetry breaking. Pumping below the gap gives the ability to manipulate the optical phase, which we demonstrate using second harmonic interferometry. Two anti-ferromagnetic domains, which are indistinguishable at equilibrium with linearly polarized light, give different responses to the pump. Additionally, the rotational anisotropy of the second harmonic light can be controlled with the incident pump polarization. Our work points towards a new dissipationless scheme by which to manipulate the properties of materials on ultrafast time scales.

Raman Spectroscopy of Twisted Double Bilayer CrI3 Moiré Superlattices and Nematicity in 2D XY-Type Magnet NiPS3 Rui He; Texas Tech University, United States

Two-dimensional (2D) materials with intrinsic ferromagnetism/antiferromagnetism have attracted strong interest because of their potential applications in data storage and spintronic devices. In the first part of this talk, I will present our magneto-Raman and magnetic circular dichroism (MCD) spectroscopy studies of twisted double bilayer (tDB) CrI_3. We identify Raman signatures of a new magnetic ground state that is distinct from those in natural two-layer (2L) and four-layer (4L) CrI_3. Results from Raman and MCD both reveal the emergence of finite net magnetization that originates from spin frustrations and noncollinear spin texture introduced by moiré superstructures in tDB CrI_3. In the second part of this talk, I will show our studies of spin-induced nematicity in few-layer XY-type magnet $NiPS_3$. Our findings suggest that spin fluctuations in few-layer $NiPS_3$ at low temperature are so strong that they destroy the static, long-range antiferromagnetic order for 3D, but instead, introduce a nematic state in 2D $NiPS_3$. Our studies offer an unprecedented venue for realizing novel magnetic states and phases in 2D magnets.

8:30 AM QM03.16.03
Ultraweak Electron-Phonon Coupling Strength in Cubic Boron Arsenide Unveiled by Ultrafast Dynamics Jimin Zhao; Institute of Physics, Chinese Academy of Sciences, China

We report a time-resolved ultrafast quasiparticle dynamics investigation of c-BAs, which is a recently discovered highly thermally conducting material. The excited-state ultrafast relaxation channels dictated by the electron-phonon coupling (EPC), phonon-phonon scattering, and radiative electron-hole recombination have been unambiguously identified, along with their typical interaction times. Significantly, the EPC strength is obtained from the dynamics, with a value of $\lambda_{T2}= 0.008$ (corresponding to $\lambda\langle\Omega^2\rangle = 1.18 \pm 0.08\ ps^{-2}$), demonstrating an unusually weak coupling between the electrons and phonons. As a comparison, an ultraweak EPC strength for graphene is also expected. We propose that preserving an ultrasmall EPC strength may be a prerequisite for exhibiting an ultrahigh thermal conductivity. Our investigation provides insight for searching and designing ultrahigh thermal conductivity materials. Notably, during our analysis we have generalized the fluence-dependence method for obtaining the EPC strength to room temperature, which can be applied to many other types of quantum materials in the future.

Ferroelastic Twin-domain Patterns and Polar Domain Walls in $BiVO_4$ Films via Phase-field Simulations Ren-Ci Peng[1], Fei Xue[2], Xiaoxing Cheng[2], Pao-Wen Shao[3], Ying-Hao Chu[3] and Long-Qing Chen[2]; [1]Xidian University, China; [2]The Pennsylvania State University, United States; [3]National Yang Ming Chiao Tung University, Taiwan

Polar domain walls in centrosymmetric ferroelastics (e.g., $BiVO_4$ films) give rise to inhomogeneity and offer promises for energy conversion applications via inducing charge-carrier separation. However, the origin of polar domain walls and the relationship between them and spontaneous strain during the phase transition remain elusive at the mesoscale. Here, from the perspective of the phenomenological thermodynamics, the relationship between the four variants of monoclinic (M) phase and the corresponding lattice constants during the tetragonal-monoclinic (T-M) phase transition is revealed. Using phase-field simulation, it suggests that the formation of four variants of ferroelastic twin domains originates from spontaneous strain during phase transition from T phase to M phase in $BiVO_4$ films. It also reveals that variant 1 and variant 2 forms a striped-like twin-domain pattern while variant 3 and variant 4 form the other twin; every variant has two perpendicular orientations, resulting from mechanically compatible ferroelastic domain walls. The orientation angle of ferroelastic twin domain walls from phenomenological thermodynamics is in agreement with that of phase-field simulation, which is also consistent with the experimental results. Moreover, the phase-field simulations demonstrates that (1) the origin of polar domain walls in $BiVO_4$ films arises from strain gradient across the domain walls during phase transition process; (2) especially shear strain gradient mainly contributes to the magnitudes of polarization vectors and the polarization orientations depend on the relative magnitude ratio of two types of shear strain gradient. Our results not only provide in-depth insights on the formation mechanisms of ferroelastic twin-domain patterns but also reveal the origin of polar domain walls induced by strain gradient at the ferroelastic domain walls.

Epitaxial Growth of 2D van der Waals Magnets and Heterostructures with Topological Insulators Roland Kawakami; The Ohio State University, United States

I will discuss our latest advances on the epitaxial growth of 2D van der Waals (vdW) magnets and their integration with topological insulators (TI). This work is motivated by the realization of topological phases such as the quantum anomalous Hall effect and highly efficient spin-orbit torque produced by TIs.
Our initial studies of $MnSe_2$ growth on Bi_2Se_3 showed a tendency for the interdiffusion of Mn into the Bi_2Se_3. This ultimately led to the synthesis of $MnBi_2Se_4$ (MBS), a new magnetic TI. Interestingly, the vdW phase is not the thermodynamically stable phase and bulk crystals do not exist, so the epitaxial stabilization of MBS creates the opportunity to explore the magnetic and topological properties of this material. We find that MBS is a layered antiferromagnet, similar to $MnBi_2Te_4$, but a difference is that the magnetic moments lie in the plane of the film. Angle resolved photoemission experiments show the presence of a topological surface state with Dirac dispersion.
For bilayers of 2D magnets and TIs, we have developed FGT films on Bi_2Te_3. We first optimized FGT by studying its growth on Ge(111) substrates, where we find that kinetic considerations play a major role. Using cross-sectional scanning transmission electron microscopy and scanning tunneling microscopy, we optimize the FGT films to have atomically smooth surfaces and abrupt interfaces with the Ge(111). Subsequently, we have developed the growth of FGT on Bi_2Te_3 for the integration of 2D magnets with TIs. Interestingly, we observe room temperature ferromagnetism in FGT/Bi_2Te_3 heterostructures by varying the growth conditions.

Three-Dimensional Twistronic Photogalvanic Effect - A New Paradigm of Light-Matter Interaction Ritesh Agarwal; University of Pennsylvania, United States

We will start by discussing nonlocal photogalvanic spectroscopies where the photon momentum of engineered optical beams can be utilized to probe quantum materials (e.g., Weyl semimetals and supertwisted spirals of 2D materials) uncovering new aspects of light-matter interactions.Specifically, we will discuss the nonlinear optical Hall effect in self-assembled supertwisted WS_2 system formed by a screw-dislocation-driven mechanism. The optical Hall current reflects the structural handedness of the supertwisted system, and an unusual photon-momentum dependence of the nonlinear optical response in the moire potential was observed. Furthermore, signatures of thickness-dependent exciton-polaritons and the associated strong photon momentum-lattice interaction dependent photocurrent response were measured, which suggest a fundamentally altered light-matter interaction in 3D moire systems. Our response function theory can explain the origin of the photon momentum dependent nonlinear response, revealing new observables of the system going beyond Berry curvature and other conventional band geometrical quantities. Our study seamlessly connects 2D and 3D twistronics and provides a bridge connecting the electrons and photons by overcoming their significant length scale differences in conventional systems. These measurements also demonstrate the versatility of 3D moire systems for exploring new aspects of light–matter interaction phenomena in condensed matter systems, which are important in realizing extreme large optical nonlinearities for a variety of quantum and classical photonic applications.

11:30 AM *QM04.01.02
Chiral Spin Textures Stuart S. Parkin; Max Planck Institute of Microstructure Physics, Germany

Chiral domain walls are just one member of an ever-expanding family of chiral spin textures that are of great interest from both a fundamental as well as a technological perspective [1]. Recently a zoology of complex spin textures stabilized by volume or interface Dzyaloshinskii-Moriya interactions have been discovered including, in our work, anti-skyrmions [2], elliptical Bloch skyrmions [3], two-dimensional Néel skyrmions [4] and fractional antiskyrmions [5]. Such nano-objects are potential candidates as magnetic storage bits on the racetrack [6]. Recently we have observed Néel skyrmions in two distinct but closely related 2D van der Waal's ferromagnetic compounds that should not allow for such structures. We show that the crystal structures are substantially modified by self-intercalation, lowering their symmetry and thereby allowing for chiral spin textures that require acentric structures [7, 8]. Finally we discuss the unusual properties of chiral Kagome antiferromagnets and how their magnetic structures can be manipulated by a previously unobserved seeded spin orbit torque mechanism [9].

Direct Observation of Strain-Induced Ferroaxial Transition in Quasi-1D $BaTiS_3$ Guodong Ren[1], Gwan-Yeong Jung[1], Huandong Chen[2], Chong Wang[3], Boyang Zhao[2], Rama K. Vasudevan[4], Andrew Lupini[4], Miaofang Chi[4], Di Xiao[3], Jayakanth Ravichandran[2], Jordan A. Hachtel[4] and Rohan Mishra[1]; [1]Washington University in St. Louis, United States; [2]University of Southern California, United States; [3]University of Washington, United States; [4]Oak Ridge National Laboratory, United States

The properties of ferroic materials are dictated by their symmetry, particularly, a broken symmetry results in a phase transition that can be represented using an order parameter. Ferroelectricity is characterized by an electric polarization vector that is invariant under time-reversal operation. Ferromagnetism is described by a magnetization vector that is invariant under spatial-inversion operation. In contrast to these two well-studied ferroic orders, the ferroaxial transition — that is characterized by a rotational structural distortion with an axial vector symmetry — is relatively unexplored. The symmetry requirement for a ferroaxial transition is broken mirror symmetry in a plane parallel to the rotation axis, and ferroaxial order is invariant under both spatial- and time-reversal operations. Ferroaxial order has shown an intimate ties with emergent properties, such as magnetoelectric couplings in multiferroicsand chiral materials.[1-2] Here, we report direct, atomic-scale observation of a strain-induced ferroaxial transition in a single crystal of a quasi-1D chalcogenide, $BaTiS_3$. Using a combining aberration-corrected scanning transmission electron microscope imaging and density-functional-theory calculations, we show that a biaxial strain of 2% along a plane perpendicular to 1D chains of TiS_6 octahedra in $BaTiS_3$ transforms it from a higher symmetry $P6_3cm$ phase to a ferroaxial $P6_3$ phase, which is characterized by a rotational distortion of the TiS_6 octahedra along the axis containing the chains.
The global refinement of X-ray diffraction suggests an average structure with a space group of $P6_3cm$. To induce a biaxial strain, we welded a $BaTiS_3$ lamella to two lateral sides of a TEM half-grid. For another lamella, we attached it to a TEM half-grid with only one lateral side fixed such that strain relaxation was possible through the unconstrained side. We performed atomic resolution high-angle annular dark-field imaging of both samples and performed local crystallography by extracting and analyzing the atomic positions from the acquired images. In the biaxially strained sample, we observe a rotational distortion of TiS_6 octahedra accompanied with an outward displacement of the Ba sublattice, suggesting the presence of ferroaxial order. We also observe nanoscale (~10 nm) domains consisting of three ordered distorted Ba sublattice configurations separated by an undistorted Ba sublattice. By comparing the average Ba-Ba distance in the strained $BaTiS_3$ lamella to the unstrained one, we find the presence of ~3.45 % tensile strain in the former $BaTiS_3$ lamella.
We used DFT calculations to gain further insights into the microscopic details of this ferroaxial transition in $BaTiS_3$ under biaxial strain. We find that the ferroaxial transition from $P6_3cm$ to $P6_3$ space group can be accomplished through the freezing of two distortion modes ($\Gamma 1$ and $\Gamma 2$) in the high-symmetry $P6_3cm$ phase. These modes involve the rotational distortion of TiS_6 octahedra and outward displacements of Ba atoms in *ab*-plane, both of which are observed in the STEM images. Using DFT calculations, we show that ferroaxial order in $P6_3$ phase can be stabilized over the $P6_3cm$ phase for biaxial strains >2%, which further supports the STEM observations. We will also discuss the effect of the ferroaxial transition on the electronic and optical properties of $BaTiS_3$.

Stochastic Dynamics of Nano-Ferroelectrics Jorge Iniguez[1,2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]U. of Luxembourg, Luxembourg

My group is interested in the behavior of ferroelectric materials that present non-trivial polar orders (vortexes [1], skyrmions [2]) and properties (chirality [3], negative capacitance [4,5]) in situations of reduced dimensionality (ultra-thin layers or films) or subject to suitable electric and mechanical boundary conditions. In this talk I will review our most recent theoretical results for one of the model systems in the field, the $PbTiO_3$/$SrTiO_3$ ferroelectric/dielectric superlattices where many of the above effects were first demonstated. In particular, I will discuss the dynamical behavior of these nano-ferroelectrics, paying especial attention to the state we call "domain liquid" [4], which is characterized by a spontaneous stochastic motion of the domains. I will show quantitative resuls for domain life and diffussion times, illustrate ways in which those
characteristic times can be controlled, and briefly discuss potential applications in unconventional computing.

Dislocations as Natural Quantum Wires in Diamond Sevim Polat Genlik, Roberto Myers and Maryam Ghazisaeidi; The Ohio State University, United States

Dislocations as natural quantum wires in Diamond
The one-dimensional complex bonding environment, within the core region of dislocations, has unique and localized properties that is different from that in bulk. Thus, dislocations and low dimensional (1D) quantum materials should exhibit similar features, except for the fact that dislocations are naturally occurring and environmentally protected by their host material. This makes dislocations advantageous as the fabrication and storage of low dimensional materials has remained challenging over the last two decades.Here we systematically investigate electronic properties of the glide set of partial dislocations in diamond with first principles calculations using hybrid exchange correlation functionals. The electronic band structure of dislocations and the anisotropic carrier mobilities are calculated and compared with the host crystals band structure and carrier mobilities. The results reveal that dislocations create one-dimensional (1D) metallic and semiconducting wires based on the character and position of defect states which heavily depend on the local core structures. 1D metallic bands appeared within the core of unreconstructed 30 partial dislocations, with a characteristic 1D density of states (1/). Map of charge density distribution along the cross-plane of dislocation line reveal that spatially localized 1D chain of overlapping pz orbitals creates conduction pathway for 1D Fermi gas. On the other hand, unreconstructed pure edge dislocation in diamond is found to be semiconducting with a band gap of 3.21 eV. These results open the door for exploitation of dislocations as 1D active components in functional devices.

Phase-field Method of Mesoscale Polar Topological Transformations and Phase Diagrams of Ferroelectric Thin Film Heterostructures Long-Qing Chen; The Pennsylvania State University, United States

This presentation will discuss the thermodynamic stability and transformations of polar topological structures in ferroelectric thin films and heterostructures. The focus will be on the applications of phase-field method to predicting the mesoscale transformation pathways and mechanisms among the different ferroelectric polar structures such as conventional nanotwins, vortex lattices, skyrmions, supercrystals, etc., under mechanical, electric, and thermal stimuli as well as light. The possibility of establishing the thermodynamic stability and phase diagrams of polar topological structures at different temperature, strain, and film thickness using both classical thermodynamics and phase-field method will be illustrated. One of the main advantages of the phase-field method is the fact that it allows one to analyze the primary strain, electrostatic, and domain wall energy contributions that are responsible for the thermodynamic stability of specific polar structures and thus can be utilized to guide the design and tuning of the polar topological structures and properties.

4:00 PM QM04.03.02
Mechanically Tunable Elastic Modulus of Freestanding $Ba_{1-x}Sr_xTiO_3$ Membranes via Phase-field Simulation Kena Zhang and Ye Cao; The University of Texas at Arlington, United States

The freestanding ferroelectric membranes with super-elasticity show promising applications in flexible electronic devices such as transducers, memories, etc. While there have been recent studies on the effect of mechanical bending on the domain structure evolutions and phase transitions in ferroelectric membranes, its influence on Young's modulus of these freestanding membranes is less explored, which is crucial for the design and application of flexible electronics. Here, a phase-field model is developed to simulate the tunability of Young's modulus of freestanding $Ba_{1-x}Sr_xTiO_3$ membranes under mechanical bending. It is demonstrated that the bent membrane shows a uniform Young's modulus compared with the unbent membrane. By increasing the bending angle, Young's modulus tunability is enhanced, which can be attributed to the vortex-like domain structures induced by mechanical bending. These vortex-like domains with large domain wall energy inhibit the subsequent domain switching under externally applied tensile strain and reduce the eigenstrain variation, which leads to a large Young's modulus. In addition, the formation of vortex domain structure is suppressed with increasing Sr^{2+}

content in $Ba_{1-x}Sr_xTiO_3$ membranes at the same bending degree, resulting in a decrease in Young's modulus tunability. Our work reveals that the tunability of Young's modulus of freestanding ferroelectric membranes can be achieved by mechanical bending, which provides guidance for designing flexible electronic devices.

4:15 PM *QM04.03.03
Anomalous Polar Textures and Exotic Phases in Quasi-1D Chalcogenide Gwan-Yeong Jung[1], Chong Wang[2], Guodong Ren[1], Boyang Zhao[3], Batyr Ilyas[4], Huandong Chen[3], Nuh Gedik[4], Jayakanth Ravichandran[3], Di Xiao[2] and Rohan Mishra[1]; [1]Washington University in St. Louis, United States; [2]University of Washington, United States; [3]University of Southern California, United States; [4]Massachusetts Institute of Technology, United States

Topological structures in ferroic materials have been studied extensively and garnered much attention due to their multiple prospective applications ranging from low-power electronics to high-performance optoelectronic devices. Specifically, topological patterns of electric dipoles such as polar vortices and polar skyrmions have been recently demonstrated in oxide superlattices and thin films. These patterns form a few to tens of nanometer-scale polar textures due to their long-range dipole interactions and geometrically confined boundary conditions. In this work, we explore the anomalous polar textures in quasi-1D $BaTiS_3$, where several competing structural distortions lead to different exotic phases such as charge-ordered phase consisting of atomic-scale polar vortices, a high-mobility ground-state phase, and a strain-induced chiral phase. Starting from high-symmetry room-temperature phase ($P6_3cm$), the quasi-1D $BaTiS_3$ undergoes two phase transitions, (i) second-order transition (240-250 K) to a charge-ordered phase ($P3c1$) and (ii) a first-order transition (150-190 K) to a high-mobility ground-state phase ($P2_1$).[1] Combining the single-crystal XRD and first-principles calculations, we identified the underlying structures of each three phases. Room temperature $P6_3cm$ phase consists of the anti-polar displacements along the *c*-axis with ferrielectric polarization along the out-of-plane direction. In the charge-ordered $P3c1$ phase, the atomic-scale polar vortices emerge with different chiralities on a larger size unit cell. In the ground state high-mobility phase ($P2_1$), striped pattern of antipolar displacements are observed both along in-plane and out-of-plane directions, making the net dipole moment as zero. This high-mobility phase exhibits chiral optical Raman response, implying an anomalous polar textures with optical activity. Notably, using a scanning transmission electron microscope (STEM) imaging, we directly observed a strain-induced ferroaxial transition, which is characterized by rotational distortion of the TiS_6 octahedra and Ba outward movements in the *a-b* plane.
Next, we will focus on the evolution of atomically thin clockwise counter-clockwise (CW-CCW) vortex pairs in the second-order transition. These polar vortices lie on a triangular-lattice network of Ti atoms along in-plane direction, which intrinsically hosts the frustration of electric dipoles in neighboring atoms. This resembles small skyrmions in magnetic materials, which often arises by resolving the exchange frustrations.[2,3] Using the first-principles electronic structure calculations and Monte Carlo simulations, we will discuss the possible mechanism to form the polar vortices on a 2D triangular lattice. We find that the coupling between several collinear antiferroelectric modes is the key to realize the non-collinear dipole textures such as vortices. Using group theoretical methods, we extracted three primary order parameters (K_3, Λ_3, M_2^-), which are all located at zone-boundaries, and developed a Landau model to microscopically understand the couplings between these modes. Based on the results, we find the CW-CCW vortex pairs can be further stabilized with more complex orders, involving non-coplanar orders along the in-plane direction with a finite scale macroscopic polarization along the out-of-plane direction. We expect that these results could pave the way to control the polar textures with multiple functionalities in ferroelectrics.

Electron- and Hole-Doped Hexagonal $TbInO_3$ from First Principles Nabaraj Pokhrel and Elizabeth Nowadnick; University of California, Merced, United States

In materials hosting frustrated magnetism, localized spins are acted upon by competing exchange interactions that cannot be satisfied at the same time, leading to a highly degenerate ground state. This can give rise to a fluid-like state of matter with no magnetic ordering known as a *spin liquid*. Spin liquids have been proposed to host exotic properties such as fractionalized charges and superconductivity upon doping, which are both of fundamental interest and may be of potential interest for quantum computing applications. However, the experimental confirmation of spin liquid states remains challenging, and there is a strong need for the identification of more candidate materials that may host spin liquids. Recent research has shown that hexagonal $TbInO_3$, with anisotropic exchange interactions, significant spin-orbit coupling, and f-electron magnetism, may be a spin-liquid candidate. $TbInO_3$ has a hexagonal crystal structure consisting of layers of corner-sharing non-magnetic InO_5 trigonal bipyramids, separated by layers of Tb^{3+} ions in a distorted triangular lattice with two inequivalent Tb sites. In this work, we use density functional theory (including spin-orbit coupling) to investigate the structural, electronic, and magnetic properties of hexagonal $TbInO_3$. We explore both undoped $TbInO_3$ as well as the effect of electron- or hole-doping by adding (removing) electrons from the calculation. By analyzing the density of states and band structure of doped $TbInO_3$, we explore whether added charge carriers are localized or form a metallic conducting state. Our work advances our fundamental understanding of charge-doping spin-liquid candidate $TbInO_3$.

Investigating the Structural and Magnetic Properties of CrxTaS2 when x ≤ 0.25 Cameron Mollazadeh, Lilia Xie and Kwabena Bediako; UC Berkeley, United States

Moore’s Law states that the number of transistors in an integrated circuit will double approximately every two years. Although this trend has held steady since the mid-twentieth century, in the past decade, it was observed that new technologies are needed to maintain this growth while minimizing energy consumption. A promising avenue to address this issue is the field of spintronics, which take advantage of an additional degree of freedom, that is spin, as a way to store and retrieve information.
We propose that Cr-intercalated TaS2 (CrxTaS2) is a promising material for spintronics due to its unique structural and magnetic properties. CrxTaS2 has a layered structure containing Cr3+ions between two-dimensional sheets of TaS2. Typically, TaS2is a nonmagnetic material, but when spin-bearing Cr3+ ions are introduced between layers, the resultant material becomes magnetic. Layered magnets present an exciting alternative to current materials, as one can tune their magnetic properties based on intercalant stoichiometries. Preliminary data shows that when x = 0.25, the Cr intercalants order structurally in a 2 x 2 superlattice, and the material enters a spin glass state below 100 K. A spin glass is a magnetic state in which competition between ferromagnetic (FM) and antiferromagnetic (AFM) interactions causes spins to order randomly.
Several spintronic device designs utilize spin glasses interfaced with FMs or AFMs. Therefore, materials with tunable spin glass properties that can form clean interfaces with other magnetic materials are highly desired. We hypothesize that as the Cr amount decreases below 0.25, the material will exhibit more disorder and glassy behavior.

We aim to study how varying intercalant stoichiometry affects the magnetic and structural properties of CrxTaS2. Three batches of crystals were grown using chemical vapor transport, targeting stoichiometries of 0.25, 0.20, and 0.15. Cr ratios were then confirmed using energy-dispersive X-ray spectroscopy (EDX). Raman spectroscopy was used to probe the structures of the crystals. The x = 0.25 crystals contained a feature at 156 cm-1, demonstrating an ordered 2 x 2 superlattice. However, in the x = 0.20 crystals, this feature was red-shifted, suggesting the presence of a defective superlattice.
The x = 0.15 crystals grew in the expected hexagonal shape, but the Raman spectra were highly disordered. Golden-tinted, ribbon-like crystals were also obtained, which appear to be a side product based on Raman, EDX, and morphology.
Thus, we predict that lower Cr intercalant crystals may have transition temperatures lower than 100K due to enhanced disorder. The results of the x = 0.25 stoichiometry of Cr hold promise for application in next-generation devices. Further structural and magnetic characterization on stoichiometries consisting of x < 0.25 will unveil how these crystals can be tuned to our needs by varying the compositions.

5:00 PM QM04.04.04
Synthesis and Characterization of Polymeric Nanofibers Templated Along Topological Defects in Ultrathin Liquid Crystalline Film Arit Patra and Joerg Lahann; University of Michigan–Ann Arbor, United States

Formation of point defects, line disclinations and vortices are frequent in liquid crystalline materials, however application of these charged topological defects to synthesize materials has been rarely explored. In this work we have utilized substrate supported spin coated ultrathin E7 liquid crystal (LC) film (nematic) as a template to guide synthesis of nanofibers along the defect lines using chemical vapor polymerization (CVP) of [2.2]Paracyclophane based monomers. Such defects take on significant prominence for our system (60-300 nm LC films) because of the higher number density of defects in ultrathin films even after time-dependent annihilation of defects during the polymerization time. We predict that the polymerization would proceed exactly along the defect lines and to avoid artifacts such as changes in the nanofiber orientation after templating, critical point drying (CPD) has been used for removal of the LC phase. We have used polarizing optical microscope to characterize defect structures which allows for direct observation of darker lines or brushes in mixed LC/nanofiber phases (prior to LC removal3) and compared with the scanning electron microscope (SEM) images of the nanofibers to confirm that the defect structures get templated by the CVP process. We have observed that these distinctly identifiable short nanofibers can map 3-dimensional space of defect lines which shows presence of all different kind of LC defects including s = ±1, ±1/2 that appear to align with mathematically predicted defect patterns. We believe, understanding the nature and structure of LC defects will pave the path towards understanding of inducible defects, such as those created by particles immersed in a LC phase and how particle-loaded LC templating phases can be leveraged to design defects that template novel nanofiber patterns during CVD polymerization.

5:00 PM QM04.04.06
Impact of Grain Boundary Atomic Structure on the Formation of Conductive Pathways in Memristive Devices Robert Eilhardt[1], Alexander Zintler[1], Stefan Petzold[1], Eszter Piros[1], Nico Kaiser[1], Tobias Vogel[1], Keith McKenna[2], Lambert Alff[1] and Leopoldo Molina-Luna[1]; [1]Darmstadt University of Technology, Germany; [2]University of York, United Kingdom

One of the most promising emerging non-volatile memory technologies is Resistive Random Access Memory [1]. A major challenge is to improve device reliability and device-to-device variability [2]. Grain boundary (GB) engineering the dielectric layer in oxide thin film resistive switching devices is a novel approach to overcome these flaws [3]. The main objective here is to reveal insight why grain boundaries impact resistive switching properties. By using reactive molecular beam epitaxy (RMBE) and sputter coating stack combinations of a 50 nm TiN bottom electrode, a 10 nm thin HfO_2 layer and a top electrode of Pt (100 nm) were grown on *c*-cut sapphire. By combining ultra-high-resolution experimental and theoretical methods, we established a direct correlation between the grain boundary atomic and electronic structures with the resistive switching behavior of TiN/*m*-HfO_2/Pt memristors with defined HfO_2 textures. First principles calculations reveal that oxygen vacancies readily segregate to grain boundaries in (11-1) textured HfO_2 leading to reduced forming voltages which might also be influenced by local strain states at the grain boundaries [4]. This unique approach of combining advanced atomic-scale imaging and first principles theoretical calculations to understand the resistive switching properties of memristors yields invaluable guidance in improving device performance.

8:00 AM *QM04.05.01
Direct Imaging of Charge Distribution at Crystalline Defects by Scanning Transmission Electron Microscopy Naoya Shibata[1,2]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan

Differential phase contrast imaging in aberration-corrected scanning transmission electron microscopy (DPC STEM) enables to directly probe local charge distribution around crystalline defects down to the atomic dimensions. In the present study, we introduce recently developed magnetic-field-free STEM with tilt-scan averaging system and demonstrate quantitative imaging of local charge distribution around crystalline interfaces at sub-nm resolution. We further show the possibility of local magnetic structure imaging near crystalline defects by the technique. Several on-going STEM developments and material application results will be also presented.

8:30 AM QM04.05.02
Nano-ARPES Visualization of Chiral Electronic Domains and Defects on Layered Chalcogenides Yi Lin[1], Luca Moreschini[1], Junze Zhou[1], Sushant Behera[1], Sean Mills[2], Steven Zeltmann[2], Cheng Hu[1], Maximilian Huber[1], Alexander Weber-Bargioni[1], Andrew M. Minor[2], Sinead Griffin[1], Aaron Bostwick[1], Chris Jozwiak[1] and Alessandra Lanzara[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Topological defects have been extensively studied in ferromagnets, liquid crystals and ferroelectric materials. Analogically, it is interesting to understand if charge orders can also form topological structures and how they can be visualized. In this work, we use nano-ARPES to map spatially resolved electronic structure in layered chalcogenides. We find rotational electronic domains that are degenerate in energy. Further characterized by atomic force microscope and electron diffractions, we find these domains are likely on the surface and form defects where chirality can be defined. The observations of the energy degeneracy and the chirality highly resemble the Kibble–Zurek conditions for identifying topological defects.

8:45 AM QM04.05.03
Harnessing Dislocation Motion Using an Electric Field Yu Zou; University of Toronto, Canada

Dislocations, line defects in crystalline materials, play an essential role in the mechanical, electrical, optical, thermal, and phase transition properties of these materials. Dislocation motion, an important mechanism underlying crystal plasticity, is critical for the hardening, processing, and application of a wide range of structural and functional materials. For decades, the movement of dislocations has been widely observed in crystalline solids under mechanical loading. However, the goal of manipulating dislocation motion via a non-mechanical field alone remains elusive. Here, we present real-time observations of dislocation motion controlled solely by an external electric field in single-crystalline zinc sulfide (ZnS). We find that 30{\deg} partial dislocations can move back and forth depending on the direction of the electric field, while 90{\deg} partial dislocations are motionless. We reveal the nonstoichiometric nature of dislocation cores using atomistic imaging and determine their charge characteristics by density functional theory calculations. The glide barriers of charged 30{\deg} partial dislocations, which are lower than those of 90{\deg} partial dislocations, further decrease under an electric field, explaining the experimental observations. This study provides direct evidence of dislocation dynamics under a non-mechanical stimulus and opens up the possibility of modulating dislocation-related properties.

9:00 AM QM04.05.04
Ultrafast Formation of Topological Defects in a 2D Charge Density Wave Alfred Zong[1,2], Yun Cheng[3], Lijun Wu[4], Qingping Meng[4], Wei Xia[5], Fengfeng Qi[3], Pengfei Zhu[3], Xiao Zou[3], Tao Jiang[3], Yanfeng Guo[5], Jasper van Wezel[6], Anshul Kogar[7], Michael Zuerch[1,2], Jie Zhang[3], Yimei Zhu[4] and Dao Xiang[3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Shanghai Jiao Tong University, China; [4]Brookhaven National Laboratory, United States; [5]ShanghaiTech University, China; [6]University of Amsterdam, Netherlands; [7]University of California, Los Angeles, United States

In solids, transient defects are known to generate a variety of hidden orders not accessible in equilibrium, but how defects are formed at the nanometer lengthscale and femtosecond timescale remains unknown. Here, we employ an intense laser pulse to create topological defects in a 2D charge density wave (CDW), and track their morphology and dynamics with ultrafast electron diffraction. Leveraging its high temporal resolution and sensitivity in detecting weak diffuse signals, we discover a dual-stage growth of 1D domain walls within 1 ps, a process not dictated by the CDW amplitude but instead mediated by a nonthermal population of longitudinal optical phonons. Our work provides crucial insights into ultrafast engineering of topological defects based on selective excitation of collective modes, opening avenues for dynamical control of nonequilibrium phases in correlated materials.

9:15 AM *QM04.05.05
New Methods for Imaging Polar Topological Textures in Oxide Heterostructures Yu-Tsun Shao[1,2], Sergei Prokhorenko[3], Lucas Caretta[4,5], Yousra Nahas[3], Sujit Das[6], Zijian Hong[7], Ruijuan Xu[8], Fernando Gomez-Ortiz[9], Pablo Garcia-Fernandez[9], Long-Qing Chen[10], Harold Y. Hwang[11], Javier Junquera[9], Lane Martin[4], Laurent Bellaiche[3], Darrell Schlom[1], Ramamoorthy Ramesh[4,12] and David A. Muller[1]; [1]Cornell University, United States; [2]University of Southern California, United States; [3]University of Arkansas, Fayetteville, United States; [4]University of California, Berkeley, United States; [5]Brown University, United States; [6]Indian Institute of Science, India; [7]Zhejiang University, China; [8]North Carolina State University, United States; [9]Universidad de Cantabria, Spain; [10]The Pennsylvania State University, United States; [11]Stanford University, United States; [12]Rice University, United States

Polar topological textures such as polar skyrmions and merons in ferroelectric heterostructures emerge resulting from the interplay of elastic, electrostatic and gradient energies. These dipolar textures not only have mathematical beauty but also exhibit exotic functionalities such as emergent chirality and local negative capacitance for potential applications in next generation nanodevices. To understand and explore the microscopic details of such topological textures requires a characterization method which can track their detailed 3D structures at the atomic scale.

A popular approach for mapping polar distortions in ferroelectrics has been to use high-angle annular dark field (HAADF) scanning transmission electron microscopy (STEM), which directly image the atomic displacements with a precision of a few picometers. Although conceptually straightforward, because of the small depth-of-field and strong dechanneling of the probe scattered by heavy cations, HAADF-STEM only samples the top surface of the sample, which can have a very different polar order from the middle of a 3D structure such as skyrmion, for example Néel (top) versus Bloch (middle) characters.

Here, by utilizing the full 4-dimensional phase space information collected by a new design of direct electron detector that can measure the momentum transfer distributions at every probe position (4D-STEM), we can solve the inverse multiple scattering problem and retrieve the 3-dimensional electrostatic potential of the sample, yielding a lateral resolution of <20 pm. This allows us to determine both the cation displacements and octahedral tilts. To further improve the sensitivity to polar order, we combine scanning diffraction with dynamical diffraction simulations to robustly image the polarization and chirality in each polar texture. I will show how 4D-STEM-based approach allows us to image dipolar waves, polar skyrmions and merons in ferroelectric thin films that are unable to measure by conventional methods.

Research supported by AFOSR Hybrid Materials MURI (FA9550-18-1-0480) and ARO ETHOS MURI (W911NF-21-2-0162), facilities support from the NSF (DMR-1429155, DMR-1719875, DMR-2039380). Researchers at the University of Arkansas also thank the Vannevar Bush Faculty Fellowship Grant No. N00014-20-1-2834 from the Department of Defense.

9:45 AM QM04.05.06
Emergent Atomic Scale Polarization Vortices Boyang Zhao[1], Gwan-Yeong Jung[2], Chong Wang[3], Huandong Chen[1], Shantanu Singh[1], Guodong Ren[2], Nick Settineri[4], Simon Teat[4], Di Xiao[3,5], Rohan Mishra[2] and Jayakanth Ravichandran[1,1,1]; [1]University of Southern California, United States; [2]Washington University in St. Louis, United States; [3]University of Washington, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Department of Physics, United States

Topological defects, such as vortices and skyrmions, enable emergent electronic and photonic functionalities in materials [1,2]. Magnetic and dipolar vortex-anti-vortex structures have geometric bounds on their stability [3,4]. Understanding the scaling limits of such topological structures is critical to enable microscopic functional units towards novel device architectures. In this work, we report the existence of atomic-scale vortex-anti-vortex dipolar structures in a quasi-1D hexagonal chalcogenide, $BaTiS_3$, from the refined crystal structures of X-ray synchrotron single-crystal diffraction studies. We observe large displacements of Ti in the TiS_6 octahedra of $BaTiS_3$, comparable to ferroelectric perovskite oxides, along and across the quasi-1D TiS_3 chain.

$BaTiS_3$ undergoes a series of TiS_6 dipole-ordering from a room temperature ferrielectric phase to a intermediate phase with the vortex-antivortex dipolar structures below ~250 K through a second-order phase transition, and then, transforms into a lower symmetry phase below 180 K through a first-order transition. The observation of dipolar vortices in $BaTiS_3$ shows that the ultimate scaling limit for dipolar topological structures is down to the atomic scale. We will discuss the role of different electrostatic interactions and soft-phonon modes in stabilizing the emergent polarization textures in $BaTiS_3$. We will also discuss the accessibility of similar structural and electrical characteristics in charge density wave materials such as $1T$-$TiSe_2$ [5] and $BaTiSe_3$. Our work sets up complex charge density waves with d^0 filling as a playground for realizing and understanding quantum polarization topologies.

The Multiwells—Switching Portraits of the Thiophosphate Family Petro Maksymovych; Oak Ridge National Laboratory, United States

Multiwell potentials make ferroelectrics fundamentally interesting, diverse and unique. In particular, multiwells can give rise to metastable states that control ferroelectric switching and the structure of domain walls. In this sense ferroelectric materials gain field-induced functionality by design, which is particularly promising for applications in microelectronic, electrocaloric and energy-storage functions. We have recently come across several distinct multiwell potentials in ferroelectrics comprising P_2S_6 anion building blocks [1]. Although the materials in this family include both van der Waals and continuous solids with very different polarization properties [1], their multiwells share two common features – uniaxiality and substantial tunability with strain and chemical composition. On a fundamental level, the uniaxiality of the potential nearly guarantees new behaviors of domain walls and can give rise to polarization dynamics that may be unachievable in a double-well potential.
In this talk, we will first show how nanoscale microscopy methods play central role in inferring the existence of multiwell potentials in thiophosphates [2-4], through direct and indirect observables. Indeed, despite almost two decade history of $CuInP_2S_6$, many functional properties such as giant negative electrostriction, multiplicity of the domain structure and strongly time-dependent switching, were first revealed with scanning probe techniques. These findings then led to computational predictions of the 4-well with first principles modeling, with subsequent quantitative verificaition by microscopy measurements [2]. Meanwhile unique features of switching hysteresis in $Sn_2P_2S_6$ consituted the first direct evidence of the proposed triple-well in this material, which enables coexistence of antiferroelectric-like switching loops with ferroelectric-like domain structure. Subsequently, we will focus on the interesting aspects of polarization dynamics that can be expected and observed in a multiwell potential, such as volatile and time-dependent polarization switching [3,4], field-induced order-disorder [4] and noise-induced restructuring of domain walls [5]. These properties collectively represent new prospects for ferroelectric applications, particularly in tunable and neuromorphic computing elements, while also posing a fresh frontier for revisiting and further understanding the emergence and dynamics of metastable polarization states. Finally, we will address the need for continued development of scanning probe methods capable of reproducible measurements of relatively more complex switching dynamics in multiwell systems, including combined piezoelectric and microwave microscopy, topological methods for data analysis and atomically-resolved imaging of materials with increased density of domain walls. The experiments were supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Division, and conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility. Theoretical work at Vanderbilt University was supported by Department of Energy grant DE-FG02-09ER46554 and by the McMinn Endowment.

Towards Spatially Resolved Measurements of Domain Wall Thermal Transport Using Scanning Thermal Microscopy Rebecca Kelly[1,2], Fran Kurnia[1], Amit Kumar[1], Marty Gregg[1] and Ray McQuaid[1]; [1]Queen's University Belfast, United Kingdom; [2]University of Glasgow, United Kingdom

It is now a well-established idea that ferroelectric domain walls can be considered as extended structural defects that affect thermal transport through phonon scattering[1]. Additionally, the fact that some types of domain walls exhibit dramatically enhanced electrical conductivity suggests enhanced thermal transport within the wall due to charge transport might be plausible.
Measurement approaches used to date to investigate domain wall thermal properties, such as time-domain thermoreflectance and steady state heat flow setups, typically measure large sample areas and domain wall contributions to the overall sample response must be back extracted. Direct, local measurements of domain wall thermal transport properties have not yet been reported and would require thermal imaging with sufficiently nanoscale spatial resolution.
Scanning Thermal Microscopy is a promising technique for mapping thermal properties of a sample with nanoscale spatial resolution. Here, we describe an

approach for locally mapping variations in thermal properties associated with microstructural heterogeneity. A thin gold bar is deposited on the sample surface and is periodically Joule heated, allowing lock-in measurements of temperature to be mapped locally using the scanning probe as a temperature sensor[2]. To validate that spatial heterogeneity in thermal properties can be imaged, a multilayer ceramic capacitor was used due to the expected variation in thermal response between the metal electrode and ceramic layers. We find that temperature contrast between the metal and ceramic layers can indeed be resolved and that the lock-in temperature measurements help mitigate against topographical crosstalk issues seen in static temperature measurements. Exploratory measurements are also currently underway to image thermal signal contrast associated with electrically conducting domain walls in ion-sliced $LiNbO_3$ thin films.

11:15 AM QM04.06.03
Confinement-Driven Inversion of the Domain Scaling in Polycrystalline $ErMnO_3$ Jan Schultheiß[1,2], Fei Xue[3], Håkon Ånes[2], Frida Danmo[2], Sverre M. Selbach[2], Long-Qing Chen[3] and Dennis Meier[2]; [1]Universität Augsburg, Germany; [2]Norwegian University of Science and Technology, Norway; [3]The Pennsylvania State University, United States

The functionality and physical properties of ferroelectric materials are intimately coupled to their domain morphology. Recently, precipitates and dislocations have been identified as an effective mean to control the domain pattern in ferroelectrics. In addition, more complex topological structures have drawn interest, giving a new dimension to the control of ferroelectric domains and their responses.
Here, we demonstrate that topologically protected vortex/anti-vortex cores can be used to engineer the domain structure in polycrystalline improper ferroelectric $ErMnO_3$. We find a one-to-one correlation between the grain size and the type of domain structure, allowing us to induce mono-, vortex-like- or stripe-like domain states on demand. Interestingly, and in contrast to proper ferroelectrics, such as $BaTiO_3$ and $Pb(Zr,Ti)O_3$, we observe an inverted domain-size / grain-size dependence, leading to the formation of smaller domains in larger grains. Phase field simulations show that this unusual behavior originates from the interaction of topologically protected vortices with elastic strain fields. The topology-driven inverted scaling behavior is intriguing as it provides a conceptually new handle for tuning the electromechanical and dielectric performance of ferroelectrics, giving a new dimension to capacitor applications and domain wall-based nanoelectronics.

11:30 AM QM04.06.04
Novel Scanning Probe Investigations of Domains and Domain Walls in Lithium Niobate Jesi Maguire[1], Hamza Waseem[1], Charlotte Cochard[2], Ray McQuaid[1], Amit Kumar[1] and Marty Gregg[1]; [1]Queen's University Belfast, United Kingdom; [2]University of Dundee, United Kingdom

Over the last 25 years, scanning probe microscopy techniques have revolutionised the way in which we understand ferroelectric domains and domain walls. This trend shows no sign of stopping. Here, for example, we have used two key imaging modes to investigate new characteristics of charged (head-to-head) conducting domain walls in single crystal $LiNbO_3$: Kelvin Probe Force Microscopy (KPFM) and Charge Gradient Microscopy (CGM).

In detail, newly configured “high-voltage” in-situ KPFM (imaging relatively large voltages while driving current) has allowed us to explicitly determine the resistivity of conducting lithium niobate domain walls for the first time (without the confounding influence of contact resistance): conducting domain walls were written in x-cut lithium niobate films by partial poling between coplanar thin film electrodes. In-situ KPFM mapping of the interelectrode region was then performed, while driving current along the conducting walls. Knowing the current density and the potential gradient developed allowed room temperature "four-probe" wall conductivity to be explicitly determined.

Equally, the combination of KPFM and CGM has revealed interesting surface potential profiles, associated with the microstructure around the charged walls, and forced us to reconsider the fundamental imaging mechanism responsible for CGM contrast [1]: KPFM scans revealed a triangular potential profile perpendicular to a head-to-head wall, which was an almost perfect match to the integrated CGM signal obtained in the same region. This strongly suggests that CGM does not actually measure charge gradients, but rather potential gradients.

[1] Maguire, J.R., Waseem, H., McQuaid, R.G., Kumar, A., Gregg, J.M. and Cochard, C., 2022. Imaging Ferroelectrics: Reinterpreting Charge Gradient Microscopy as Potential Gradient Microscopy. *Advanced Electronic Materials*, p.2101384.

11:45 AM QM04.06.05
Deep Tomographic Piezoresponse Force Microscopy—A New Approach to Unveil Novel Topological Structures in Uniaxial Ferroelectrics Conor J. McCluskey[1], Jesi Maguire[1], Yurii Tikhonov[2], James McConville[1], Haidong Lu[3], Dennis Meier[4], Anna Razumnaya[5], Alexei L. Gruverman[3], Valerii Vinokur[5], Igor Lukyanchuk[2], Amit Kumar[1] and Marty Gregg[1]; [1]Queen's University Belfast, United Kingdom; [2]University of Picardie, France; [3]University of Nebraska–Lincoln, United States; [4]Norwegian University of Science and Technology, Norway; [5]Terra Quantum AG, Switzerland

With the development of scanning probe microscopy and related techniques (piezoresponse force microscopy, conductive atomic force microscopy), we now have access to nanoscale images of ferroelectric domain structure and in-situ electrical, mechanical or magnetic properties with unprecedented resolution. While representing an incredible leap forward in our understanding of these systems, the information available is quite literally superficial: the entire subsurface structure is traditionally inaccessible by these techniques. Recently, researchers have been interested in experimentally revealing the third dimension of ferroelectric domain structures [1,2] to understand the complex networks that exist below the surface.

Here, we develop tomographic piezoresponse force microscopy to reveal and reconstruct the subsurface ferroelectric domain structure in two well-known uniaxial ferroelectrics: lead germanate and triglycine sulfate. Pioneered by Huey et al. [3], tomographic atomic force microscopy methods involve scanning the surface of a sample with an atomic force microscopy tip in contact with a sample, while employing a significant compressive force from tip to sample. This “machines” the surface of the material, meaning subsequent images are collected at different depths into the material. If carried out in conjunction with standard piezoresponse force microscopy imaging of the ferroelectric domain structure, the 3D domain structure can be recreated. We take this tomographic method to new depths, milling in excess of 5 microns into the surface of the ferroelectric, where previously 100’s of nanometres had been typical [3].

In the case of lead germanate, we find evidence for the theoretically predicted domain wall saddle point features. Models suggest that this is the consequence of the mutual bifurcation of head-to-head domains, and accompanying rotation of polarisation away from the singular polarisation axis. This prevents the build-up of bound charge at head-to-head or tail-to-tail sections of domain walls, and gives the polarisation network a topological character[4]. In triglycine sulphate, we find charged sections of domain walls, which contradicts the notion that domain walls in this material are uncharged, fully penetrating the crystal along the polar axis. Tomographic atomic force microscopy adds a new dimension to scanning probe studies on ferroelectrics, and can reveal topological features which may have been previously unexpected, especially in uniaxial ferroelectrics.

SESSION QM04.07: Physical Properties and Applications I

Session Chairs: Huandong Chen and Han Wang
Wednesday Afternoon, April 12, 2023
Marriott Marquis, Fourth Level, Pacific E

1:30 PM QM04.07.01
Imaging the Emergent Functionality in Bulk Ferroelectrics Trygve M. Ræder and Hugh Simons; Technical University of Denmark, Denmark

Emergent behaviour in ferroelectrics can be imaged at surfaces by scanning probe microscopy (SPM), and in thin lamella by transmission electron microscopy (TEM). Despite tremendous advances in these techniques over the past decades, SPM and TEM remain unsuitable for investigation of the bulk. X-ray-based techniques, on the other hand, penetrate through the material and are well suited for investigation of the bulk. Multiple X-ray techniques are now able to image strain and orientation deep in the bulk. Dark-field X-ray microscopy (DF-XRM) is one such technique, which has previously been applied to ferroelectrics and has produced images of domains and strain deep in the bulk [1]. Here, we present our efforts to functionalize DF-XRM and image the polarization in addition to strain. Functionalized DF-XRM will allow us to image exotic topological structures deep inside the sample or at a buried interface. A more expansive analysis of the interplay between strain, stress, and polarization can then be explored in the 3D bulk of the material. The interplay between ferroelectric domain walls, line defects, and vacancies in the bulk is of particular interest, and this is difficult to approach using other techniques.

We will present proof-of-concept experimental results from our ongoing efforts to image the polarization of $BaTiO_3$ in-situ using DF-XRM. Our experimental work is guided by a theoretical framework, which we will also present together with simulations of realistic experimental conditions. Furthermore, we will describe how a stroboscopic configuration can be used to image material dynamics. Finally, this work has implications for any material imaged in DF-XRM with an applied electric field. In a general case, the electric field will perturb the X-ray structure factor, which is assumed to be constant when calculating strain maps from a DF-XRM image series. We will show how this perturbation can be quantified and addressed, so that accurate strain maps may still be produced in the presence of an electric field.

1:45 PM *QM04.07.02
Stripes, Gaps and Orderly Disorder—Tuning Magnetic Textures in Intercalated TMDs Berit H. Goodge[1,1], Oscar Gonzalez[1], Lilia Xie[1] and Kwabena Bediako[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Intercalated transition metal dichalcogenides (TMDs) have been proposed as promising platforms for next-generation spintronic devices based on a wide range of electronic and magnetic phases which can be tuned by varying the host lattice or the species, amount, and ordering of intercalants [1]. Several compounds have been shown to host chiral magnetic order, namely a helical winding of in-plane magnetic moments along the *c*-axis of the layered crystal structure. Previous studies have shown that different intercalant concentrations can have a dramatic impact on, for example, chiral domains [2] and magnetic properties [3], but a deeper and more predictive understanding of these effects will be necessary for any future applications of these materials. Here, we leverage a combination of imaging modes in the (scanning) transmission electron microscope (S/TEM) to directly probe (dis)order across multiple length scales and show how subtle changes in the atomic lattice can have dramatic impact on mesoscale magnetic textures.

2:15 PM QM04.07.03
A Class of Magnetic Topological Material Candidates with Hypervalent Bi Chains Jason F. Khoury[1], Bingzheng Han[1], Milena Jovanovic[1], Ratnadwip Singha[1], Xiaoyu Song[1], Raquel Queiroz[2], Nai-Phuan Ong[1] and Leslie Schoop[1]; [1]Princeton University, United States; [2]Columbia University, United States

The link between crystal and electronic structure is crucial for understanding structure–property relations in solid-state chemistry. In particular, it has been instrumental in understanding topological materials, where electrons behave differently than they would in conventional solids. Herein, we identify 1D Bi chains as a structural motif of interest for topological materials. We focus on Sm_3ZrBi_5, a new quasi-one-dimensional (1D) compound in the Ln_3MPn_5 (Ln = lanthanide; M = metal; Pn = pnictide) family that crystallizes in the $P6_3/mcm$ space group. Density functional theory calculations indicate a complex, topologically nontrivial electronic structure that changes significantly in the presence of spin–orbit coupling. Magnetic measurements show a quasi-1D antiferromagnetic structure with two magnetic transitions at 11.7 and 10.7 K that are invariant to applied field up to 9 T, indicating magnetically frustrated spins. Heat capacity, electrical, and thermoelectric measurements support this claim and suggest complex scattering behavior in Sm_3ZrBi_5. This work highlights 1D chains as an unexplored structural motif for identifying topological materials, as well as the potential for rich physical phenomena in the Ln_3MPn_5 family.

Ultrafast Dynamics and Dispersion of Collective Modes in Polar Skyrmions Haidan Wen; Argonne National Laboratory, United States

Collective excitation is important for understanding many-body interactions as well as inspiring new functionalities in condensed matter systems. Novel collective excitations can arise from competing interactions in ferroelectric nanostructures. For example, polar vortex stabilized in $PbTiO_3/SrTiO_3$ superlattices can host collective atomic motions involving hundreds of unit cells, emerging as a vortexon mode [1]. However, the collective excitation of topologically nontrivial polar skyrmions [2] is not yet known. Here, using terahertz-field excitation and femtosecond x-ray diffraction probe technique, we discover the collective dynamics of polar skyrmions, featuring a 0.3-THz mode with coherent vibrating domain walls and a stable core. The Pb atomic displacement forms a transient vortex structure in skyrmions. The broad diffuse scattering satellite peaks from polar skyrmions allow us to probe the dispersion of this collective mode. The distinct dispersion relations for skyrmion cores and domain walls evident the significant phononic properties of $PbTiO_3$ layer, indicating possible phonon localization. The dynamical response is significantly reduced at the sample temperature of 360 K, corresponding to the loss of skyrmion topological charge due to the deformation of skyrmions at high temperatures. The dynamical phase-field modeling reproduces the key experimental observations and gives microscopic insight into the polar skyrmion modes. Our work opens opportunities for engineering phononic properties and controlling collective dynamics in topological nanostructures.

4:00 PM *QM04.08/QM02.05/QM03.08.02
Unconventional Properties of Nominally Charged Domain Walls in Uniaxial Ferroelectric Lead Germanate Alexei L. Gruverman; University of Nebraska-Lincoln, United States

Application of the scanning probe microscopy techniques, such as Piezoresponse Force Microscopy (PFM), opens a possibility to re-visit the ferroelectrics previously studied by the macroscopic electrical testing methods and establish a link between their local nanoscale characteristics and integral response. Here, we report the nanoscale PFM studies and phase field modeling of the static and dynamic behavior of the domain structure in the well-known ferroelectric material - lead germanate, $Pb_5Ge_3O_{11}$ (PGO). Several unusual phenomena were revealed: (1) domain formation during the paraelectric-to-ferroelectric phase transition, which exhibits an atypical cooling rate dependence; (2) unexpected electrically-induced formation of the oblate domains due to the preferential domain walls motion in the directions perpendicular to the polar axis, contrary to the typical domain growth behavior observed so far; (3) absence of the bound charges at the head-to-head (H-H) and tail-to-tail (T-T) domain walls, which typically exhibit a significant charge density in other ferroelectrics due to the polarization discontinuity. This strikingly different behavior is rationalized by the phase field modeling of the dynamics of uncharged H-H and T-T domain walls. Our results provide a new insight into the emergent physics of the ferroelectric domain boundaries, revealing unusual properties not exhibited by conventional Ising-type walls.

Ultrafast Manipulation of Multiferroic $BiFeO_3$ Through Light-Driven Phonons Wanzheng Hu; Boston University, United States

Manipulating coupled orderings by external fields, or exploring methodologies to achieve ultrafast control of ferroic orderings have driven significant research activities for understanding the physics of multiferroicity. $BiFeO_3$ shows strong couplings of the lattice structure, electronic and magnetic properties to external fields, which make it appealing for potential applications to encode and access information using a multiferroic bit.
Nonlinear phononics is an emerging approach, in which intense mid-infrared or teraherz laser pulses are used to resonantly excite optical phonons. The high peak electric fields drive phonon oscillations to large amplitudes. This leads to quasistatic lattice distortion due to strong anharmonic couplings between phonons. The lattice deformation modifies the microscopic Hamiltonian of the system on average, offering a unique platform to engineer novel functionalities which may not exist in equilibrium, and to achieve selective control of quantum phases such as ferroelectric polarization and magnetic orderings. In this talk, I will present our recent results on the ultrafast manipulation of multiferroic $BiFeO_3$ by nonlinear phononics.

A New Era in Ferroelectrics Ramamoorthy Ramesh and Peter Meisenheimer; Rice University, United States

Complex topological configurations are a fertile playground to explore novel emergent phenomena and exotic phases in condensed-matter physics. I will describe the discovery of polar skyrmions in a lead-titanate layer confined by strontium-titanate layers by atomic-resolution scanning transmission electron microscopy (STEM). Phase-field modeling and second-principles calculations reveal that the polar skyrmions have a skyrmion number of +1 and resonant soft X-ray diffraction experiments show circular dichroism confirming chirality. Such nanometer-scale polar skyrmions exhibit a strong signature of negative permittivity at the surface of the skyrmion, which is furthermore highly tunable with an electric field. They are a new state of matter and electric analogs of magnetic skyrmions, and may be envisaged for potential applications in information technologies.

8:30 AM QM04.09.02
Topological States in Nanostructured Ferroelectrics of Different Dimensions Igor Lukyanchuk; University of Picardie, France

Past decade marked breakthrough discoveries of novel topological polarization structures in nanostructured ferroelectrics. These findings lie at the crossroad of the forefront of the physics of nanostructured materials, advanced topological concepts, and cutting-edge industrial nanotechnologies. The observed polarization structures have been interpreted in terms of the real-space vector field topology as multiple combinations of vortices, skyrmions, merons, and other topological formations. This topological approach was successfully used in the physics of dislocation, liquid crystals, and magnetism. Ferroelectricity has been viewed as an electric dual of magnetism; however, this visible analogy misses ferroelectricity's cornerstone, the dominant role of the long-range electrostatic forces. We establish a topological foundation of ferroelectricity arising from its electrostatic essence and discuss the observed topological phenomena. We point out at the shortcomings of the existing topological approaches widely utilized for the description of the polarization vector fields. We establish that the physics of ferroelectrics can be constructed in the framework of topological hydrodynamics, an advanced formalism of the topology of an incompressible flow of the vector fields, introduced by Arnold. Based on the introduced topological identity of the electrostatics of ferroelectrics and hydrodynamics of the incompressible liquid, we set up a unified approach for the explanation of topological states in ferroelectrics. We give a comprehensive description of the observed polarization topological structures and show that their rich variety can be exhaustively described by the foundational Arnold theorem in terms of fundamental formations of topological hydrodynamics, vortices, and Hopfions. We outline the prospects of implications of topological hydrodynamics to the physics of ferroelectrics and their diverse applications to the related emergent technologies.

8:45 AM QM04.09.03
Emergent Energy Storage and Conversion in Polar-Topology-Contained Oxide Multilayers Yiqian Liu, Junfu Liu, Ce-Wen Nan and Yuan-Hua Lin; Tsinghua University, China

Polar topologies such as vortices, skyrmions and merons in multilayered ferroelectrics have attracted enormous attention recently as a promising alternative for high-density storage media. However, polar-topology-contained multilayers as ferroelectrics themselves have not been well explored. Herein, using phase-field simulations, we report that polarization hysteresis profiles of these multilayers can be flexibly tailored from ferroelectrics (FE) to relaxor ferroelectrics (RFE), antiferroelectrics (AFE) and paraelectrics (PE), and render potentials to outperform in many ways conventional ferroelectric materials. In bismuth ferrite/strontium titanate trilayers, strain-engineered polar vortices and spirals possess distinct electric coercivity, generating RFE-, AFE- and PE-like behaviors. Ultimately, an ultrahigh energy density of 178 J cm^{-3} with an efficiency of over 95% is achieved. Similarly, simultaneously high energy density and efficiency can be realized in oxide superlattices. These tremendous energy storage performances are owing to the triple-well energy landscape as a result of the extra eigenstate of polar topologies.
In potassium niobate/potassium tantalate oxide superlattices, a continuous FE-AFE-PE phase transition is observed, along with a drastic change in polarization across the AFE-PE boundary. Therefore, an ultrahigh pyroelectric figure of merit of ~10^4 C^2 m^{-4} K^{-2} at an electric field of 2 MV cm^{-1} and an equivalent zT of nearly 6.0 at a temperature difference of 50 K near room temperature. Symmetrically, the inverse effect, electrocaloric cooling, is also remarkable, with a ΔT of nearly 40 K per MV cm^{-1}. This excellent electro-thermal interconversion is caused by the ample polarization profile of polar topologies.
Our findings have indicated that polar-topology-contained multilayers are utilizable in miniaturized energy devices, serving as a possible substitution for RFEs. We hope that our simulations can beget more experimental attempts and realizations.

9:00 AM *QM04.09.04
Ferroelectric Domain Patterns for Brain-Inspired Information Processing Beatriz Noheda; University of Groningen, Netherlands

Ferroelectric thin fims can be engineered to combine several key features of relevance for efficient information processing: they provide non-volatile memory addresasble by electric fields and they self-organize in domain patterns, whose periodicity can be made of the order of nanometers for ultra-thin layers. In addition, in ferroelectric oxides, the domain walls have been often found to be conducting and memristive due to ion migration driven by strain gradients and internal bias field, therefore, showing multistate resistance and synaptic functionality. In addition, these materials can be tuned to exist the verge of a phase transition, by means of chemical composition or epitaxial strain. As shown by Kinouchi and Copelli (Nature Physics 2006), the dynamical range is maximized at non-equilibrium phase transitions and, it is well known that the dynamics of a system slows down by many orders of magnitude near critical points, where the correlation lengths reach the size of the entire system. Therefore, materials that undergo phase transitions are of great interest to achieve the largest sensitivity to input signals, the greatest non-linearities in their responses and, at the same time, the largest variations in the time scales of their output signals, all of these very useful ingreients for efficient learning. Here I will show two examples of ferroelectric systems with domain patterns that show some of these aspects: $BaTiO_3$ films at a boundary between two differently modulated domain phases that show signatures of edge-of-chaos dynamics and $BiFeO_3$ films that provide a dense network of interconnected (conducting) domain walls intersecting memory bits.

9:30 AM QM04.09.05
Observation of Surface Superconductivity in Planar Honeycomb Layer Structured AeCuBi (Ae = Ca and Sr) Nahyun Lee and Sung Wng Kim; Sungkyunkwan University, Korea (the Republic of)

Planar honeycomb layer structured materials have received much attention in the past decades due to their unique physical properties such as massless Dirac state, three-dimensional (3D) topological Dirac semimetal (TDS), thermoelectricity, and superconductivity. In particular, the recently reported 3D TDS KZnBi (space group P6$_3$/*mmc*) showed the surface superconductivity at 0.8 K. Herein, we report the superconductivity of newly synthesized AeCuBi (Ae = Ca and Sr) composed of CuBi planar honeycomb layers, analogous to 3D TDS KZnBi [1]. It is demonstrated from the magnetic susceptibility and heat capacity measurements under ambient pressure, the superconductivity exclusively occurs at the surface region, showing the T_c of 2.1 K for SrCuBi compound. Furthermore, the superconducting transition temperature of the SrCuBi compound was largely enhanced, showing the T_c of 4.8 K at 6.18 GPa. Compared to the high-pressure superconductivity of 3D TDS Cd_3As_2 [2] and KZnBi [3], we found a common feature, which is the linear temperature dependence of the upper critical field, suggesting that the surface superconductivity is of non-s-wave character. Our discovery serves a distinctive platform to study the interplay between 3D TDS and superconductivity, anticipating possible topological superconductivity.

Exploring Topological Insulating Perovskite Oxides Grown on Silicon Substrate Towards Quantum Applications Clement Merckling[1,2], Islam Ahmed[1,2], Luca Ceccon[1,2], Moloud Kaviani[1] and Stefan De Gendt[1]; [1]imec, Belgium; [2]KU Leuven, Belgium

With the slowing down of Moore's law, related to conventional scaling of integrated circuits, alternative technologies will require research effort for pushing the limits of new generations of electronic, photonic and quantum devices. Perovskite oxides with the ABO_3 chemical formula have a very wide range of interesting intrinsic properties such as metal-insulator transition, ferroelectricity, pyroelectricity, piezoelectricity, ferromagnetic and superconductivity. For the integration of such oxides, it is of great interest to combine their properties with traditional electronic, memory and optical devices on the same silicon-based platform.

In this work, we will discuss the use of perovskites oxide in the field of topological based qubits which is one of the promising methods for realizing fault-tolerant computations. It is recognized that superconductor/topological insulator heterostructure interfaces may be a perfect host for the exotic "Majorana" particles. These have relevant topological protection nature as required for processing information. Therefore, the physics at the superconductor/topological insulator heterostructure interface need to be studied further, starting at the material level. In this work, a candidate material Barium Bismuthate (BBO) is studied utilizing the Oxide Molecular Beam Epitaxy (MBE) process. The perovskite structure provides opportunity for easily tailored functionality through substitutional doping. Incorporation of potassium into the lattice of BBO results in a superconducting phase with Curie temperature as high as ~ 30K. In addition, BBO is according to DFT based studies, predicted to form topological surface states when doped with Fluorine. In our work, we integrate BBO perovskite on Si(001) substrate, using an epitaxially grown strontium titanate (STO) single-crystalline buffer layer and discuss the structural and chemical properties of the heterostructure will be established by utilizing physical characterization techniques such as AFM, Raman, XRD, TEM and ARPES in later stages. This will go hand in hand with the understanding of related surface reconstruction of BBO observed by RHEED as a criterion for the high-quality films.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreements N° 864483 and 742299)".

Methods for Characterization of Dislocations in 3 Dimensions Zachary J. Barringer, Edwin Fohtung, Nimish P. Nazirkar, Xiaowen Shi and Skye Williams; Rensselaer Polytechnic Institute, United States

Dislocations are an important class of crystal defects that have a significant impact on the mechanical, chemical, kinetic, and electronic properties of materials. The study of dislocations has historically been rooted in Transmission Electron Microscope based approaches. However, TEM gives limited information about the 3-dimensional nature of dislocations and has strict geometric and experimental constraints on the sample size. To overcome this limitation, other methods of characterization have been employed to probe dislocations in 3 dimensions. In this paper we will review methods used to probe dislocations in 3 dimensions, including both x-ray and electron-based techniques. The applications and limitations of the techniques will be discussed, and some future prospects will be presented. Particular attention will be paid to the ability of techniques to distinguish charged dislocation cores in ionic crystals.

Novel Phases and Applications of Ferroelectric Perovskite Oxide Membranes Yuefeng Nie; Nanjing University, China

The synthesis of high-quality freestanding oxide membranes provides unprecedented opportunities for the exploration of novel phases and applications of transition meatal oxides[1,2]. In this talk, I will present the synthesis of freestanding perovskite membranes with high crystalline quality and discuss their great potential electronic applications. By integrating freestanding $PbTiO_3/SrTiO_3$ bilayers with silicon wafer, we obtained high-density skyrmion-like polar nanodomains. Moreover, an external electric field can reversibly switch these nanodomains into the other type of polar texture, which substantially modifies their resistive behaviours[3]. We also explored the ferroelectric size effects in ultrathin $SrTiO_3$ membranes[4] and the integration of conducting charged domain walls of $BaTiO_3$ membranes on silicon wafers[5]. All these new advances demonstrate the great potential of ferroelectric oxide membranes in nonvolatile memory and related electronic applications.

11:00 AM *QM04.10.03
Enhanced or Tailored Superconductivity in 2D Materials via Ionic Liquid Cation Intercalation Shuyun Zhou; Tsinghua University, China

Dimensionality and carrier concentration have been two most important control knobs for engineering the electronic properties of layered materials and inducing novel properties. So far, the control of the interlayer interaction is mainly achieved by reducing the sample thickness to atomic scale, however, such atomically thin samples are usually difficult to obtain, unstable in air and with extremely low T_c. In this talk, I will report our recent experimental progress to control both the interlayer coupling and carrier concentration in layered materials through intercalation of organic cations from ionic liquids to transition metal dichalcogenides. The intercalated organic-inorganic hybrid materials exhibit tailored properties beyond the bulk crystals and monolayer films. I will provide a few examples for enhanced or tailored superconductivity in topological semimetals $MoTe_2$ and WTe_2 [1,2], semiconducting $SnSe_2$

[3] and $NbSe_2$ [4].

From Bound to Topological Charges in Ferroelectric Flatlands Sergei Prokhorenko, Yousra Nahas and Laurent Bellaiche; University of Arkansas, United States

Ultra-thin ferroelectrics represent a paradigmatic materials platform for realizing nontrivial polar topologies. Owing to strong electrostatic interactions, the local electric dipoles in these systems are oftentimes forced to adopt swirling configurations in order maintain the right balance of bound charges both within the material and at its interfaces. As a result, one observes formation of such topological defects as electric vortex tubes and polar disclinations or skyrmion-like bubble solitons.

While sharing many similarities with their magnetic counterparts, these polar states have a fundamentally different, *electric*, nature which opens new opportunities to control ferroelectric topologies but also poses a question of their possible technological applications. Here, we explore these questions using effective Hamiltonian simulations of ultra-thin $Pb(Zr,Ti)O_3$ films under residual depolarizing fields. On the one hand, our results reveal how the screening and local electric fields can be tuned to induce topological transitions and control the dynamical behavior of polar topological defects and solitons. On the other hand, we inquire into the role of bound electric charges intrinsically associated with polar disclinations and bubbles. Namely, we explore the effect of such charges on interactions between electric topological defects and discuss possible implications of such charge on functional properties of polar topologies.

Polymer Platforms for 3D Printing Engineered Living Materials Alshakim Nelson; University of Washington, United States

The convergence of synthetic biology with polymer science has led to the rapid emergence of engineered living materials (ELMs), which are composite materials of engineered cells encapsulated within a polymeric matrix. ELMs have the potential to attain a level of precision, control, and sustainability that is not achieved with traditional abiotic materials. While the minimum requirements for fully living ELMs are cell viability and metabolic activity, the integration of ELMs at their fullest potential in future biomanufacturing also requires processing into desired form factors and spatial control over multiple engineered cell populations.
Additive manufacturing (or 3D printing) has re-emerged into the spotlight in the last 10 years driven by the rapid progress in hardware and software. While off-the-shelf polymeric materials have been utilized as inks and resins for additive manufacturing, there is still a need to develop functional materials that are specifically designed for these processes. In this seminar, I will present two different polymer platforms that we have developed to 3D print ELMs. In the first part of my seminar, I will discuss the development of stimuli-responsive triblock copolymer hydrogels for fabricating immobilized cell bioreactors.

These hydrogels were used to incorporate engineered microbes that served as cellular factories for the on-demand bio-production of chemical products. In the second part of my seminar, I will discuss a two-step additive manufacturing process to fabricate protein-based constructs using a commercially available laser-scanning SLA printer. Methacrylated bovine serum albumin (MA-BSA) was synthesized and formulated into aqueous resins that was used to print complex 3D geometrical constructs with a resolution comparable to a commercially available resin. Compression studies of hydrated and dehydrated constructs demonstrated a broad range of compressive strengths and Young's moduli that could be further modulated by adjusting the type and amount of co-monomer. These protein-based matrices served as biodegradable scaffolds for 3D printing ELMs, and I will present strategies for fabricating bio-augmented and bio-sustained ELMs.

9:30 AM SB01.01.02
Optimizing *Sporosarcina pasteurii* Biology and Growth for Shelf-Stable Preparations for Biocement Applications Michael Carter, Matthew J. Tuttle, Adriana Joson, Joshua Mancini, Rhett L. Martineau, Chia-Suei Hung and Maneesh Gupta; Air Force Research Lab, United States

Contemporary concrete production, which accounts for ~8% of the world's CO_2 production, relies on Portland cement to bind aggregates. Biocement is an environmentally friendly material that relies on biological structures (enzymes, cells, and/or cellular superstructures) and/or biologically generated structures ($CaCO_3$ crystals) to bind aggregates. Current biocementation protocols require addition of living cultures to aggregates, which requires on-site culturing expertise and infrastructure. We have developed a strategy for producing a shelf-stable preparation of *Sporosarcina pasteurii*, a biocementation workhorse bacterium, that can be combined on-site with feedstocks and aggregates to form biocement. Scaling up and enhancing the efficacy of our novel biocementation protocol will require optimization of *S. pasteurii* growth and biology. Here, we discuss our progress toward improving the growth and biology of *S. pasteurii*, an alkaliphile with distinct nitrogen requirements, and our progress toward understanding relevant physiological characteristics of *S. pasteurii*.

9:45 AM SB01.03.08
Tailoring the Growth of Living Materials Towards Sustainable Manufacturing Suitu Wang, Manivannan Sivaperuman Kalairaj, Mustafa Abdelrahman and Taylor H. Ware; Texas A&M University, United States

Traditional manufacturing of polymer composites relies on valuable precursors derived from fossil fuels and energy-intensive processes. Innovation in polymer composites manufacturing strategies should focus on resource recyclability and low carbon footprint procedures. Here, a new paradigm of polymer composite manufacturing valorizing local wastes and using biological growth of living materials to dictate the final product form has been proposed. Living materials comprised of living *Saccharomyces cerevisiae* (baker's yeast) within a hydrogel matrix cultured in media derived from bread waste can achieve volume and mass increase through in-situ cell proliferation. The final object shape can be tailored through controlled growth of living materials. For example, by digitally programming the cell viability through UV irradiation or photodynamic inactivation, growth-induced shape control can be achieved. This growth-dictated manufacturing process can be powered by wasted chemical energy present in substances such as food waste, which stands in stark contrast to the energy-intensive processes used for synthetic material manufacturing. After growth, the final material is up to 96 wt% biomass and 590% larger in volume than the initial object. Subsequent enzymatic hydrolysis and regeneration of yeast cell walls within the grown structures enable shape reconfiguration. The proposed biomanufacturing strategy utilizing the growth of living materials with food waste may pave the way for future ecologically friendly manufacturing of materials.

From Bones to Stones—Towards Surmounting Challenges in Designing Engineering Living Building Materials Chelsea Heveran; Montana State University, United States

Microbial induced calcium carbonate precipitation (MICP) is commonly used to seal cracks, stabilize soils, and sequester contaminants. Increasingly, MICP is used to engineer living building materials. These biomineralized structures have the potential for greater functionality and sustainability than conventional building materials. However, several challenges persist in efficiently and precisely manufacturing these biomineralized materials and in keeping the living component alive for a prolonged time. We look to bone, which maintains living cells within a load-bearing stiff matrix for decades, as an inspiration for surmounting these obstacles. Bone tissue is strong, tough, and lightweight, and both self-assembles and self-repairs at body temperatures. Bone achieves these remarkable properties through scaffolds secreted by bone cells that dictate where, when, and how the structure is biomineralized. We are working towards engineering biomineralized building materials that utilize several strategies inspired by bone. In this talk, we will focus on several bone-inspired scaffolding approaches that influence bacterial biomineralization. In a first strategy, we functionalize aggregate surfaces to form a bacterial monolayer that scaffolds the initial biomineralization and improves the efficiency of strength development. In a second strategy, we use fungal mycelium as a scaffold for biomineralization. These scaffolds are either self-mineralized by the living mycelium or mineralized by bacteria that attach to the scaffold surface. Finally, we will explore ongoing efforts and next steps in producing bone-inspired sustainable living building materials.

2:00 PM SB01.02.02
Production of Biocement Using a Shelf-Stable Formulation of the Soil Bacterium *Sporosarcina pasteurii* at Laboratory and Field-Scales for Ground Improvement Matthew J. Tuttle[1,2], Brandon M. Bradow[1,2], Rhett L. Martineau[1], Michael Carter[1,2], Joshua Mancini[1,2], Chia-Suei Hung[1] and Maneesh Gupta[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Manufacturing of traditional cementitious materials is an energy-intensive and unsustainable process. Cement is the third largest source of anthropogenic carbon dioxide emissions globally, accounting for an estimated 8% of emissions. To help mitigate the environmental impacts of cement and concrete, more environmentally-friendly materials are needed. Biocement shares many similar physical properties with traditional cement and may be useful as an alternative material for a variety of applications in construction and the development of infrastructure. It is produced via microbially-induced biomineralization of calcite. *Sporosarcina pasteurii* is a soil bacterium that has emerged as the model organism for biocement production. While there has been considerable interest in biocement as a green material, producing it at industrial scales is challenging and there is a lack of ready-mix formulas similar to those that exist for traditional cement. Here we developed a shelf-stable preparation of *S. pasteurii* that has been preserved via lyophilization. At the laboratory-scale, we see that this formulation performs similarly to live cell cultures, precipitating an equivalent amount of calcite and resulting in biocement with the same level of mechanical strength. We further demonstrate the applicability of this formulation at precipitating calcite under non-ideal conditions in the field, leading to *in situ* production of biocement with increased bearing capacity of the ground. The strength and depth of cementation achieved using this formulation can be modulated by altering the treatment regime used in biocement production. Altogether, these results indicate that stabilized preparations of bacteria are a viable means by which biocement may be manufactured. This is advantageous as it has the potential to be used as a ready-mix formula for the creation of biocement that is accessible to nontechnical professionals. Shelf-stable formulas such as this will make the process of biocement production easier, paving the way for more widespread adoption of biocement as a construction material as the technology surrounding it continues to mature.

2:15 PM SB01.02.03
Multiplex Genome Editing in Diatoms for Sustainable Production of Designer Mesoporous Silica Jernej Turnsek[1,1] and Krishna K. Niyogi[1,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Evolutionary and ecological success of diatoms—ubiquitously distributed photosynthetic single-celled algae and dominant primary producers in the contemporary ocean—has been attributed to their silica-based cell wall called a frustule. Diatoms exhibit a dazzling variety of frustule morphologies. How they construct this ornate organic-inorganic hybrid material at mild temperatures and pressures is a fascinating question, a bridge between nanoscale and planetary scale biological and geological processes. Additionally, the biocompatibility and hierarchical mesoporous structure of naturally produced diatom silica represents a basis for applications in drug delivery, biosensing, industrial catalysis, energy storage, and bioremediation.

To advance our understanding of diatom cell wall biogenesis and to facilitate our ability to control diatom silica morphogenesis, we implemented a straightforward multiplex genome editing technique in the model marine diatom *Thalassiosira pseudonana*. We first present successful use of bacterial conjugation as an emerging genetic transformation method in *T. pseudonana*. We then describe SpCas9- and tRNA-gRNA array-expressing vectors for bacterial conjugation-based multiplex genome editing. Here, a single transcript, which is processed into sgRNAs by endogenous tRNA nucleases, can be scaled to simultaneously target any number of loci. We applied this molecular engineering system to edit a nitrogen and silicon metabolism-related urease-encoding gene in *Thalassiosira pseudonana*, which led to a clean genome excision event. Finally, we show that urease-deficient *T. pseudonana* cell lines cannot grow on urea as the sole nitrogen source and discuss our strategy to simultaneously edit two *T. pseudonana* genes.

Facile multiplex genome editing gives fresh momentum to studying molecular mechanisms of complex multigene metabolic processes in diatoms such as cell wall biogenesis. It paves the way for new biomedical, industrial, and environmental diatom-based applications rooted in tuning silica properties and structure (e.g., pore size) via precise targeted genome manipulations.

Improving Engineering Resilience and Sustainability with Engineered Living Materials Qiming Wang; University Southern California, United States

Modern society demands engineering materials with high resilience and sustainability; however, most of the existing engineering materials exhibit undesirable resilience and sustainability. For example, typical materials used in the urban infrastructure are continuously aging and failing under environmental hazards (www.engineeringchallenges.org/challenges/infrastructure.aspx). Most of the widely-used commodity plastics feature extremely low biodegradability, leading to a long-standing sustainability issue. On the other hand, biological living materials naturally exhibit extraordinary resilience and sustainability. For example, biological living materials consist of living cells to support their metabolisms, thus enabling self-growing, self-remodeling, self-healing, and self-strengthening in response to environmental hazards. Biological living materials typically feature rapid biodegradation, without leaving environmental pollution. In this talk, we present a strategy by integrating living components, such as living microorganisms and plants, into traditional engineering materials to design several types of engineered living materials. The vision is that these engineered living materials will differ from traditional engineering materials, but behave like biological living materials to enable extraordinarily high resilience and sustainability in response to environmental hazards. For example, assisted by living bacteria, 3D-printed polymers can self-grow into structural composites with extremely high toughness like shells. Assisted by living chloroplasts, 3D-printed polymers can behave like a tree to harness carbon dioxide to enable photosynthesis for self-remodeling and self-strengthening. Assisted by living microorganisms, commodity plastic waste can be upcycled into a class of new materials that feature full recyclability and giant energy generation.

DIY 3D Printing of Complex Living Materials for Degrading Bioplastic Anne S. Meyer; University of Rochester, United States

3D printing of engineered bacteria is an evolving field that employs the tools of synthetic biology to express desired proteins and peptides while maintaining control over the shape and spatial organization of the resultant biomaterials. Previous bacterial 3D printers have been limited to producing low aspect ratio prints that become unstable and collapse under their own weight at greater heights. By leveraging open-source hardware and software, we have designed and modified a low-cost, commercial 3D printer into a bacterial bioprinter that can print complex, free-standing structures with high aspect ratios. To print complex structures with sharply defined edges, a novel syringe mount was designed with retraction functionality that pauses bio-ink extrusion during non-printing periods. Our new printer deposits bio-ink within gel slurries with viscoplastic properties, allowing delivery of bio-ink gellification agents immediately upon printing. This technique allows us to print stable, high aspect ratio (15:1), free-standing structures with sharper resolutions and internal cavities. We have applied our 3D bacteria printers to construct living materials containing marine microbes that can metabolize the bioplastic poly-3-hydroxybutyrate (PHB). These printed materials can act as living stickers that degrade bioplastics in oceanic conditions, a notoriously difficult environment for carrying out plastic biodegradation. These materials will pioneer a new way of thinking about material design by explicitly incorporating microbial metabolism and degradability at the outset, with potential to transform the plastics industry as a whole.

Towards the Development of Engineered Living Carbon Materials Monsur Islam[1], Mohammadreza Taale[2], Jan G. Korvink[1], Christine Selhuber-Unkel[2] and Andrés D. Lantada[3]; [1]Karlsruhe Institute of Technology, Germany; [2]Universität Heidelberg, Germany; [3]Universidad Politécnica de Madrid, Spain

Engineered living materials (ELMs) is considered to be one of the most relevant contemporary revolutions in the field of materials science. ELMs aim to outperform current examples of “smart”, active, or multifunctional materials, enabling countless industrial and societal applications [1]. Current examples of ELMs have mostly focused on either cell-derived biofilms or polymer-based hybrid living materials (HLMs) [2]. Here we postulate carbon as an ideal material for the abiotic counterpart in an HLM system due to its unique properties, including excellent biocompatibility, adjusted electromechanical properties, and tunable electrochemical properties [3]. 3D printing of carbon structures allows the fabrication of customizable geometrical features, which can further facilitate the printing of shape-morphing carbon structures, leading to 4D architectures. Upon culturing living cells, 3D and 4D carbon structures can work synergically with the cells to express novel functionalities, which can be highly important for several biomedical and biotechnological applications. Here, we aim to develop a hybrid living carbon material by integrating a novel 4D printing approach for glassy carbon and the self-beating properties of living muscle cells.

To date, we have demonstrated the capability of fabricating 4D printed glassy carbon and their capability to host muscle cells leading to improved proliferation and differentiation. Here, 4D printing refers to the shape-morphing capabilities of a 3D printed structure. The 4D printing of glassy carbon included 3D printing of unique mechanically shape-morphing precursor epoxy structures using laser microstereolithography, followed by carbonization at 900°C in an argon environment. Upon pyrolysis, 60-75% geometrical shrinkage of individual microlattices occurred, leading to even smaller features. For example, a printed lattice diameter of 100 µm shrank to ~35 µm after carbonization. The shape-morphing capability of the structures was retained despite such significant shrinkage. C2C12 myoblast cells were cultured on the 3D/4D printed carbon structures to investigate the biocompatibility of the carbon scaffolds. The cells adhered to the carbon scaffold and populated within the pores between adjacent lattices, leading to 3D cell colonization. Furthermore, the cultured myoblast cells fused to myotubes on the carbon scaffolds after 14 days. This is highly promising as the presence of myotubes suggests the possibility of the beating motion of the cells on carbon scaffolds. Our current efforts are towards synergizing the beating movement of the cells on the 4D carbon scaffolds leading to a stimuli-responsive motion of the biohybrid structures, the genesis of a novel family of living carbon materials.

Pattern Formation and Stability of Algae-Laden Hydrogels due to Differential Growth Nakhiah Goulbourne; University of Michigan, United States

There is an emerging class of engineered living materials that can grow, self-heal, sense, and adapt to their surroundings similar to biological organisms. Recent reports have repeatably demonstrated successful 3D printing of hydrogels containing microorganisms, such as, algae, yeast, and bacteria. The 3D printed living materials support growth once manufactured. Growth within a hydrogel matrix can generate stress due to interactions of the living matter with the surrounding nonliving matter. These stresses can induce shape instabilities in the growing medium. The changes in the 3-dimensional shapes will vary depending on the morphology and composition of the hydrogel, and the morphology of the living material. We seek to gain mechanistic insights into the pattern formation and stability of algae-laden hydrogels. To gain better insight into growth-induced instabilities due to algae-hydrogel interactions, we study the growth of an elastic shell embedded in a soft elastic medium. The contact stress from the hydrogel interaction is calculated as a function of geometric and growth parameters. We obtain critical values for instabilities and the modes of instability.

SESSION SB01.03: Session III: Poster Session
Session Chairs: Marie-Eve Aubin-Tam and Srikanth Singamaneni

Tissue-Attachable Intestinal Organoids as Injectable Therapeutics for Reconstruction of Intestinal Injuries Myeong Jae Baek, Min Beom Kim and Yun Kee Jo; Kyungpook National University, Korea (the Republic of)

Crohn's disease, a type of inflammatory bowel disease, can often lead to loss of intestinal function due to impaired intestinal barrier performance and exposure to noxious antigens that cause chronic inflammation. Organoids transplantation has emerged as a promising strategy for restoration of the damaged intestinal epithelial barrier in treating several intestinal diseases. However, most organoids culture commonly relies on the use of an ill-defined tumor-derived basement membrane extract, Matrigel, which restricts practical applications to transplantation with aim of regenerating tissues *in vivo*. Here, we develop tissue-adhesive hyaluronic acid (HA) hydrogels for generation and *in vivo* transplantation of intestinal organoids as an alternative substitute to Matrigel. The morphological and functional features of intestinal organoids cultured in the well-defined, biocompatible HA hydrogels are comparable to those in Matrigel by providing extracellular matrix-mimetic microenvironments. Moreover, superior tissue-adhesion ability of catechol-functionalized HA facilitates their use in transplantation of intestinal organoids to target tissues even under wet conditions. These results suggest the possiblity of only a single hydrogel in generating and transplanting intestinal organoids to accomplish an effective recovery of small intestinal wounds. Therefore, our chemically-defined, tissue-adhesive HA hydrogels can be a novel, simple therapeutic platform for organoids-based regeneration of intestinal injuries with further expansion to general tissue recovery.

5:00 PM SB01.03.03

Tissue Extracellular Matrix-based Microribbon Scaffolds for Bone Regeneration via Immunomodulation Cassandra Villicana, Andrew Yang, Ni Su, Xinming Tong and Fan Yang; Stanford University, United States

Introduction: The immune system plays a critical role in bone regeneration as the mediator of the body's inflammatory response to injury. Previous biomaterials research on bone tissue engineering has largely focused on enhancing stem cell osteogenesis rather than modulating immune cell responses. Tissue-derived extracellular matrix (ECM) has been used in nanoporous hydrogels and demonstrated advantages over synthetic hydrogels in promoting regenerative immune responses when injected in muscle [1]. However, previous tissue ECM-based research has been limited to soft tissue models and nanoporous hydrogels. How ECM modulates immune cell response and bone regeneration in macroporous scaffolds have not been investigated before. Our lab has reported gelatin microribbon (µRB) scaffolds that contain macroporosity and enhance endogenous bone regeneration *in vivo* compared to nanoporous gelatin hydrogels [2]. We hypothesize that incorporating ECM into µRB scaffolds would modulate immune responses and bone regeneration. To test this hypothesis, the present study seeks to develop µRB scaffolds containing tissue-derived ECM, and assess the effect of varying ECM dosage and tissue type on immunomodulation and bone regeneration *in vitro* and *in vivo*.

Materials and Methods: To derive ECM from multiple tissue types (bone, muscle, articular cartilage, and meniscus cartilage), juvenile bovine stifles were used. Bone was first demineralized, and all tissues were decellularized and digested following previous protocols. Gelatin µRBs were synthesized by wet spinning as we previously reported [2]. To incorporate ECM, two methods were evaluated including co-spinning a mixture of bone ECM (bECM) containing gelatin solution, or coating ECM from various tissue types onto gelatin µRBs through physical adsorption. To characterize ECM incorporation, immunostaining of various tissue markers was performed. For *in vitro* studies, mouse MSCs or macrophages were encapsulated in µRB scaffolds with varying ECM dosages or tissue types. To assess immunomodulation, macrophage phenotype was assessed using gene expression and ELISA. MSC osteogenesis was assessed using histology of bECM markers. Leading compositions that led to regenerative immune responses and enhanced osteogenesis were further validated *in vivo* using a mouse critical size cranial defect model. Samples were harvested at weeks 1 and 6. Immunomodulation and bone formation *in vivo* were assessed using histology and microCT imaging.

Results and Discussion: Immunostaining confirmed both co-spinning and coating methods enable successful incorporation of tissue ECM into macroporous µRB scaffolds. The coating method induces more homogenous ECM presentation relative to the co-spinning method. Incorporating bECM promotes macrophage polarization towards the regenerative M2 phenotype while promoting MSC osteogenesis in a dose-dependent manner *in vitro*. We found intermediate bECM concentration led to enhanced MSC osteogenesis, yet further increase of bECM inhibited osteogenesis. Adding tricalcium phosphate particles synergized with a low dosage of bECM to accelerate bone formation *in vivo*. Varying tissue ECM further enhances MSC osteogenesis *in vitro*, with the most mineralized bone formation found in meniscus cartilage and muscle-derived ECM-coated groups. Together, these results support our hypothesis, and future studies will evaluate the effect of varying ECM type on immunomodulation *in vitro* and bone formation *in vivo*. While the present study focuses on bone as a target tissue for regeneration, the ECM-coated macroporous µRB scaffolds may be broadly applied to enhance regeneration of other tissue types.

5:00 PM SB01.03.04
Sensory Artificial Octopus Suckers with Highly Adaptive Soft Micro-Denticles Gui Won Hwang[1], Heon Joon Lee[1], Sangyul Baik[1], Da Wan Kim[1], Tae-Heon Yang[2] and Changhyun Pang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea National University of Transportation, Korea (the Republic of)

Geometric and material adhesion mechanisms inspired by natural organisms have been shown to be effective and useful by providing adaptive switchable adhesion and versatile applications. Several biologically inspired devices with high adaptability and robust dry and wet adhesion have been reported. However, it is still difficult to achieve stable and switchable attachments to objects with curved, rough, and irregular surfaces, especially in dry and aquatic environments. Here, an electronically sensory switchable adhesive device with an adaptable soft microstructure inspired by the geometric and material properties of micro-denticles on the surface of an octopus sucker is presented. The contact interface of artificial octopus suckers (AOS) is imprinted with soft micro-denticles that interact appropriately with very rough or curved surfaces. AOS with soft micro-denticles (AOS-sm) provides strong and controllable attachment to dry and wet surfaces of various shapes and conformal attachment to highly rough curves and soft objects. The carbon nanotube-based strain sensor with a three-dimensional structure formed to mimic nerves-like functions of an octopus in the AOS architecture does decision-making capabilities to predict the weight and center of gravity for samples with diverse shapes, sizes, and mechanical properties through machine learning. Also assembled with octopus-arm-inspired soft actuators, the AOS-sms reliably grips and transports complex polyhedrons, rough objects, and soft, delicate, and slippery biological samples.

5:00 PM SB01.03.05
Graphically-Encoded Biodegradable Microspheres with Hydrogel Shell for Sustained Release of Drugs at Controlled Rates Yoonjin Oh and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Biodegradable microparticles have been widely used as an efficient drug delivery platform. Several biocompatible and biodegradable polymers, including polylactic acid (PLA), poly(lactic-co-glycolic acid) (PLGA), and polycaprolactone (PCL), have been used as matrix materials to encapsulate lipophilic drugs and control their release. To create microparticles containing the drugs, polymers are dissolved in a volatile organic solvent in conjunction with drugs, then emulsified and consolidated. Lipophilic drugs are released from the microparticles over a sustained period of time. As the polymer matrices biodegrade from the surface by the hydrolysis of ester groups in the backbones of the polymers, the microparticles impede an initial burst of drugs which can exert damaging effects on the biological integrity of the protein.

These microparticles are generally in the form of oil-in-water emulsion templated microbeads. When the polymeric microbeads are implanted into tissue, however, the surfaces can undergo uneven degradation and the rate of drug release will vary particle by particle. It deteriorates the controllability over a consistent rate of release.

Here, we microfluidically produce PLA microspheres enclosed by a hydrogel shell for sustained release at controlled rates. As the PLA microspheres do not directly contact with other microspheres due to the presence of the hydrogel shell, it reduces particle-by-particle variation regarding the degradation rate. Also, the hydrogel shell slows down the release rate as the degradation of the PLA core proceeds only by slow diffusion through the hydrogel shell. In this regard, we control the density of the hydrogel shell to elaborately alter the degradation rate of PLA. As the density of the hydrogel shell increases, the rate of degradation decreases so that the encapsulants can be released for an extended period of time. Therefore, the release rate can be adjusted to suit the type and dose of the drugs. To distinguish each microsphere with a different concentration of encapsulants and shell density, we graphically encode the PLA microspheres with different types of photolithographically featured SU-8 particles. These particles work as an indicator to readily recognize the content of the PLA microspheres and the release behavior of the drugs with the naked eye.

Using a glass capillary microfluidic device, monodisperse oil-in-water-in-oil (O/W/O) double-emulsion droplets are produced. PLA and alpha-tocopherol (aTOC), which is an antioxidant that supports the immune system and reduces the risk of blood clots, are dissolved in toluene and used as the innermost phase of double-emulsion droplets. As the toluene evaporates completely, PLA is consolidated to form a solid microsphere. To enclose the PLA microspheres with a hydrogel, an aqueous solution of biocompatible sodium alginate and a complex of calcium-ethylenediaminetetraacetic acid (Ca-EDTA) is used as the middle water phase. When the double-emulsion droplets are collected in the mineral oil containing acetic acid, alginate is crosslinked by calcium ions dissociated from the Ca-EDTA complexes, forming the hydrogel shell. To further crosslink the alginate gel and make the hydrogel shell denser, the microcapsules are transferred to an aqueous solution of calcium chloride which can provide additional calcium ions to the alginate chains.

We disperse different types of alphabet-shaped SU-8 particles in the innermost phase depending on the concentration of aTOC in the core and calcium chloride in the aqueous medium. For example, the microcapsules containing 1, 5, and 10 w/w% of aTOC in the core are encoded with ‘a’, ‘b’ and ‘c’ particles, respectively. When the microcapsules are transferred to 0, 20, 50 w/w% of aqueous calcium chloride solutions, they are encoded with ‘A’, ‘B’ and ‘C’ particles. Therefore, we can easily and precisely differentiate the composition and release rate of each microcapsule even if they are all mixed.

5:00 PM SB01.03.06
Nutrient Transport for Increasing the Active Lifespan of Engineered Living Materials Ellen van Wijngaarden and Christopher Hernandez; Cornell University, United States

Engineered living materials (ELMs) are materials synthesized and/or populated by living cells. While early examples of ELMs have been promising, prior demonstrations have a short service life, often single use, due to the limited lifespan of resident cells. To replace traditional engineering materials that require longer service lives, methods of maintaining the viability of resident cells inside the ELM are needed.

Bone is a living material in which resident cells survive for decades, receiving nutrients through micro-scale pores networks, connected to one another and free surfaces by nanoscale channels. Cyclic mechanical loading applied to bones causes deformations of the pores, forcing fluid through the connecting channels and back, thereby allowing for transport and mixing even when there is no net fluid transport through the pore network [1-3]. Nutrient delivery through this mechanism has so far only been examined for the pore geometries specific to bone. Here we perform an analysis to identify pore/channel network geometries that allow for nutrient distribution. The microfluidic pore networks (0.05 -1 mm) were modelled and analyzed via hydraulic circuit simulations and fluid flow modelling using COMSOL.

In the absence of cyclic loading, transport to peripheral pore networks is negligible and limited to diffusion. In contrast, cyclic mechanical loading, results in volumetric strain in the network, causing fluid mixing in the material pores, allowing for transport far exceeding that achieved through diffusion. The fluid displacement through the channels during a loading cycle is determined as: $D = \sigma V / BnA$, where D is the fluid displacement, σ is the stress applied to the material, V is the undeformed pore volume, B is the material bulk modulus, n is the number of connecting channels and A is the cross-sectional area of a single channel. To achieve any nutrient transport, the value of must exceed the length of the channel so that upon unloading, nutrients are transported from one pore to the next. Increasing the loading magnitude resulted in greater volumetric strain and more solute transport per cycle. Higher loading frequencies resulted in decreased transport by limiting the time for fluid to flow through channels. The effects of applying a cyclic pressure, sufficient to induce deformation within the material pores and channels, was also investigated. The cyclic fluid pressure results in volumetric strain within the porous network similar to mechanical loading. However, lower solute transport was observed for pores further from the source channel during cyclic flow, relative to cyclic mechanical loading.

Maintaining the viability of resident cells is the key challenge to applications of engineered living materials beyond single use. Here we demonstrate that regular mechanical stress and strain has the potential to extend the viability of living cells within an ELM.

Enhancing Microbially-Induced Calcite Precipitation (MICP) Using Protein and Peptide Additives Joshua Mancini[1,2], Matthew J. Tuttle[1,2], Brandon M. Bradow[2], Rhett L. Martineau[1], Karen A. Holley[2], Michael Carter[1,2], Chia-Suei Hung[1] and Maneesh Gupta[1]; [1]Air Force Research Lab, United States; [2]Biological and Nanoscale Technologies Division, UES Inc, United States

Sporosarcina pasteurii is a soil bacterium capable of cementing soils using an enzymatic reaction that hydrolyzes urea into ammonium and bicarbonate ions. The elevated pH caused by ammonia accumulation causes calcium ions to interact with carbonate to form a crystalline precipitate (calcite). These crystals can form bridges between soil particles, resulting in high-strength biocement. This processes is known as microbially induced calcite precipitation (MICP). Cementation by S. pasteurii in this manner shows promise for the erection of cemented structures in an environmentally-friendly, non-energy-intensive manner. Features of the cementation process include an aqueous reaction environment and harnessing of microbial activity from native soil microbes. At the Air Force Research Laboratory, we are employing microbial and protein engineering strategies to enhance MICP for the production of biocements. This presentation details our efforts using recombinant proteins to assist with calcite nucleation and promotion of desirable crystal morphology to reduce the amount of urea required and to improve the mechanical properties of the material.

Controlling Shape Morphing and Cell Release in Engineered Living Materials Laura Rivera Tarazona[1], Manivannan Sivaperuman Kalairaj[1], Tyler Corazao[1], Mahjabeen Javed[1], Philippe Zimmern[2], Sargurunathan Subashchandrabose[3] and Taylor H. Ware[1,1]; [1]Texas A&M University, United States; [2]The University of Texas Southwestern Medical Center, United States; [3]Texas A&M College of Veterinary Medicine & Biomedical Sciences, United States

Engineered living materials (ELMs) are a class of materials that incorporate living organisms into biomaterial matrices to derive functions from both living and non-living components. By combining and tuning the properties of both living and non-living components, desired functionalities can be achieved for biosensing, therapeutic, self-healing, and shape-morphing applications. Here, we introduce a method to control the delivery of bacteria from ELMs by varying the cell loadings and matrix stiffnesses. Controlling the long-term delivery of bacteria could potentially be used in biomedical applications to modulate microbial communities within the human body. We fabricate ELMs by encapsulating *E. coli* DH5α within a non-degradable crosslinked acrylic hydrogel matrix. Growing these ELMs for 1-day results in a volume change of >100%, due to cell proliferation. The forces that drive these shape changes can also release the cells found on or near the surface of the ELMs to the surrounding growth media. When the ELM was introduced to fresh growth media every 24 h for 10 days, the ELM was able to release ~10^4 colony forming units / mL to the surrounding media within 30 min. Finally, with controlled cell delivery from ELMs, we demonstrated a potential therapeutic material by releasing a probiotic *E. coli*, asymptomatic bacteriuria (ABU 83972), which could then modulate the proliferation of a uropathogenic E. coli strain, CFT073, *in vitro*. The ELMs will also be implanted in the urinary bladder of a mouse model and the therapeutic performance will be studied.

5:00 PM SB01.03.11
Manufacturing a Three-Dimensional Bioprinted and Oriented Electrospinning Dual-Scale Scaffold to Promote Cellular Alignment and Enhance Structural Elasticity for Muscular Functioning Evan Fair, Elizabeth Ricci, Eliza Hogan, Ryan jaworski, Naser Haghbin, Isaac Macwan and Shelley Phelan; Fairfield University, United States

Every day, at least 22 people pass away while waiting for a vital organ donation. Biomanufacturing artificial organs have the potential to address the organ scarcity crisis and save lives. This study investigates muscle tissue engineering by combining 3D bioprinting and electrospinning methods to create a dual-scale scaffold (a porous block of 10 mm × 10 mm × 3.5 mm). The dual-scale scaffold contains multiple layers of 3D bioprinted microstructures and an integrated polycaprolactone (PCL) electrospun nanofiber matrix. The most significant limitation of using 3D-printed scaffolds relates to the ineffectiveness of cellular elongation resulting in resistance to the adsorption of muscle bundles. Synthetic nanofibers used in this study have the potential to influence the alignment of the cells in a specific direction, which improves the effectiveness of holistic muscle functioning through cooperative contraction and relaxation of the muscle cells. The 3D bioprinted microstructures serve as a gap collector and a flexible structure to allow extension and contraction of the cellular structure. Electrospun nanofibers form aligned mesh networks within the 3D printed scaffold's pores and are deposited perpendicular to the direction of the 3D bioprinted scaffold layer lines. The three-dimensional dual scaffold will be manufactured, characterized, sterilized, and then used as a scaffold for muscle cell culturing. The attachment, growth, viability, proliferation, and alignment of muscle cells are examined using fluorescence microscopy, scanning electron microscopy, and cellular assays to verify these characteristics.

5:00 PM SB01.03.12
3D Bioprinting Human Blood Vessel Using a Collagen Bioink to Optimize Growth Conditions of Two Primary Cell Lines of HUVEC and HASMC
Alana Hayes, Grace Lombardi, Elia Haghbin, Elizabeth Ricci, Eliza Hogan, Naser Haghbin, Isaac Macwan and Shelley Phelan; Fairfield University, United States

Traditional vein grafts are a complicated surgery as doctors should deeply cut a patient's legs and neck to harvest a vein, which puts patients at risk of additional traumatic surgery. Therefore, creating a personalized vein using their body cells is essential. This research will create a simulated blood vein using collagen bioink as a scaffold for cell growth. Collagen (i.e., an abundant protein) is the main structural element of the Extracellular Matrix (ECM) found in the vessel wall. Collagen provides a support structure with a tensile strength that controls the cell growth direction as cells adhere and elongate. Our preliminary study showed collagen bioink does not lose its structural integrity when submerged in DMEM (Dulbecco′s Modified Eagle′s Medium) cell media. Human umbilical vein endothelial cells (HUVEC) and Human Aortic Smooth Muscle Cells (HASMC) are two primary cell lines used in blood vessel research. The HUVEC and HASMC will be co-cultured, mixed with collagen-based bioink, and printed in a tube-like arrangement to simulate the geometry of an actual blood vessel. A step-by-step procedure for cell co-culturing on a 3D-printed scaffold with the collagen bioink is being developed. The two cell lines' attachment, viability, and proliferation are examined using fluorescence and scanning electron microscopy.

5:00 PM SB01.03.15
Engineered Extracellular Vesicles for Safe and Efficient Chemo-Sonodynamic Cancer Therapy via Stimuli-Responsive Drug Release Thuy Giang Nguyen Cao[1], Ji Hee Kang[2], Wangyu Kim[3], Su Jin Kang[1], Quan Truong Hoang[1], Jun Min[1], Won Jong Rhee[1], Chulhong Kim[3], Young Tag Ko[2] and Min Suk Shim[1]; [1]Incheon National University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of); [3]Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Sonodynamic therapy (SDT) is a novel non-invasive cancer treatment that utilizes ultrasound to activate sonosensitizers and generate reactive oxygen species (ROS) to damage tumor cells. Nanocarriers-assisted delivery of sonosensitizers has gained considerable attention because it can significantly improve the physicochemical properties and anticancer activities of sonosensitizers. Extracellular vesicles (EVs), a class of naturally occurring nanoparticles secreted by cells, were extensively employed as biocompatible nanocarriers for drug delivery as an alternative to synthetic nanocarriers. Combination of SDT with chemotherapy has shown great promise to achieve synergistic therapeutic outcomes for cancer treatment. In this study, stimuli-responsive EVs that can selectively release chemotherapeutic agents and sonosensitizers into cancer cells were developed for safe and efficient chemo-sonodynamic cancer therapy. The engineered stimuli-responsive EVs facilitated the release of chemodrugs and sonosensitizers in response to acidic pH in the endo/lysosomes or redox potentials in the cytoplasm. *In vivo* studies using tumor-bearing mouse models demonstrated that the stimuli-responsive EVs preferential accumulated in tumors and exhibited efficient anticancer activity without significant systemic toxicity. These findings demonstrate that stimuli-responsive EVs are promising platforms for safe and efficient chemo-sonodynamic combination cancer therapy.

5:00 PM SB01.03.16
ZnL_2-BPs Integrated Bone Scaffold under Sequential Photothermal Mediation—A Win-Win Strategy Delivering Antibacterial Therapy and Fostering Osteogenesis Thereafter Yuzheng Wu and Paul K. Chu; City University of Hong Kong, Hong Kong

Implant-related infections are serious complications after bone surgery and can compromise the intended functions of artificial implants, leading to surgical failure and even amputation in severe cases. Various strategies have been proposed to endow bone implants with desirable antibacterial properties, but unfortunately, most of them inevitably suffer from some side effects detrimental to normal tissues. In this study, a multifunctional bone implant is designed to work in conjunction with sequential photothermal mediation, which can deliver antibacterial therapy (<50 °C) in the early stage and foster bone regeneration (40–42 °C) subsequently. Black phosphorus nanosheets (BPs) are coordinated with zinc sulfonate ligand (ZnL_2), and the ZnL_2-BPs are integrated into the surface of hydroxylapatite (HA) scaffold to produce ZnL_2-BPs@HAP. In this design, BPs produce the photothermal effects and ZnL_2 increases the thermal sensitivity of peri-implant bacteria by inducing envelope stress. The biosafety of the antibacterial photothermal treatment is improved due to the mild temperature, and furthermore, the gradual release of Zn^{2+} and PO_4^{3-} from the scaffold facilitates osteogenesis in the subsequent stage of bone healing. This strategy not only broadens the biomedical applications of photothermal treatment but also provides insights into the design of multifunctional biomaterials in other fields.

5:00 PM SB01.03.18
Mechano-Responsive Hydrogel for Direct Stem Cell Manufacturing to Therapy Andy Tay; National University of Singapore, Singapore

Bone marrow-derived mesenchymal stem cell (MSC) is one of the most actively studied cell types due to its regenerative potential and immunomodulatory properties. Conventional cell expansion methods using 2D tissue culture plates and 2.5D microcarriers in bioreactors can generate large cell numbers, but they compromise stem cell potency and lack mechanical preconditioning to prepare MSC for physiological loading expected *in vivo*. To overcome these challenges, in this work, we describe a 3D dynamic hydrogel using magneto-stimulation for direct MSC manufacturing to therapy. With our technology, we found that dynamic mechanical stimulation (DMS) enhanced matrix-integrin β1 interactions which induced MSCs spreading and proliferation. In addition, DMS could modulate MSC biofunctions including directing MSC differentiation into specific lineages and boosting paracrine activities (e.g., growth factor secretion) through YAP nuclear localization and *FAK-ERK* pathway. With our magnetic hydrogel, complex procedures from MSC manufacturing to final clinical use, can be integrated into one single platform, and we believe this 'all-in-one' technology could offer a paradigm shift to existing standards in MSC therapy.

5:00 PM SB01.03.19
Parallel, Scalable and Customizable Production of Gel-Encapsulated Cells for Advanced Biomanufacturing and Therapeutics Stephen A. Morin and Ruiguo Yang; University of Nebraska – Lincoln, United States

Gel-encapsulated cells are at the heart of several emergent biotechnologies including cell-based therapeutics and bioprinting; however existing techniques such as microfluidics and batch emulsification cannot provide scalability and tunability simultaneously. An advanced manufacturing scheme to produce gel-encapsulated cells that is both scalable and universally compatible with encapsulants of different chemistry, mechanics, volumes, and/or shapes, and cargos that may include a range of cell lines or different molecular and biomolecular agents is needed. We report a universal strategy that enables the biomanufacturing of packageable and deployable bio-suspensions of gel-encapsulated cells and molecular/biomolecular cargos capable of meeting the demands of cell-based therapeutics and tissue printing. At the heart of our approach is an elastomeric chemical template that enables the simultaneous collection/assembly of spray-deposited liquid pre-polymer/cellular suspensions into photocrosslinkable microdroplets which can readily access liter-scale volumes of microgel product (10^{11} microgels/hour). The procedure we report enables the manufacture of application-specific, customized bio-suspensions for next-generation therapies and tissue printing/engineering systems that promise to make personalized cell therapeutics and tissue regeneration/organ replacement procedures a reality.

Insights into Growth Regulation by Connecting Simulations of Plant-Growth to the Plant Gall Life Cycle Richard W. van Nieuwenhoven and Ille C. Gebeshuber; TU Wien, Institute of Applied Physics, Austria

In Nature, plants must cover all their necessities from locally available resources. They can extract their main structural building elements, such as carbon, from thin air. Many non-plant organisms have found ways to manipulate plant growth to their advantage. Gall wasps, for example, can reprogram plants to grow tailored breeding chambers using biochemical substances. Plant growth simulation algorithms have proven to be successful in modeling plant development. This study will investigate a minimum distortion in these established algorithms to simulate the effect of the mechanism used by gall wasps. Connecting the simulation results with detailed observations of galls in Nature is expected to help us understand the effects of the control mechanism exerted by gall wasps. Future research can bridge these findings with advances in biochemical research of gall growth to gain deeper insight into plant growth regulation. Utilizing such natural resource control strategies could solve many of humanity's sustainability problems.

5:00 PM SB01.03.21
Optimizing the Scale-Up Production of the Biocementing Bacterium Sporosarcina pasteurii Adriana E. Joson[1,2], Michael Carter[1,2], Joshua Mancini[1,2], Karen A. Holley[1,2], Matthew J. Tuttle[1,2], Rhett Martineau[1], Chia-Suei Hung[1] and Maneesh Gupta[1]; [1]AFRL, United States; [2]UES, Inc., United States

Cement is one of the most consumed materials globally, second only to water. The production and maintenance of cement is unsustainable, costly, and a major contributor to greenhouse gas emissions. As urbanization and cement consumption continue to increase, the need to identify a sustainable, comparable, and environmentally friendly alternative becomes increasingly evident. Biocement is a sustainable biomaterial with properties similar to traditional cement. This technology relies on the CaCO3 production resulting from the growth and enzymatic activity of Sporosarcina pasteurii, a bacterium known for its capability of microbially induced calcite precipitation (MICP). The process exploits urease enzymes to catalyze a reaction that produces the ideal basic environment for this alkaliphile to thrive and drive CaCO3 formation. While the process of biocementation is still in its genesis, optimization of biocementation begins with optimizing production of the bacteria responsible for this technology. Here, we propose the optimization of large scale industrial growth through the use of 10 liter bioreactors to serve as a transitional step. By implementing and modifying specific growth parameters, we are able to monitor specific idiosyncrasies of S. pasteurii to produce the largest biomass yields in the shortest time possible, all while maintaining cementation (MICP) efficacy. To curb toxic ammonia production, we decreased the urea concentration that was recommended in previous literature, resulting in a 90% reduction of the produced ammonia with nominal effects to growth rate or cementation efficacy. Even in the absence of urea, bacterial growth is robust, so long as the environment is basic (9.5 pH), with the only detriment being an increase in lag time. With these basic parameters in mind, we were able to evaluate growth in alternative media. These low cost production techniques will further provide the building blocks for this contemporary technology and pave the way for a green and economically feasible alternative construction material.

5:00 PM SB01.03.22
Utilizing Poly Glutamic Acid for Enhancement of *Sporosarcina Pasteurii* Induced Biocementation Karen A. Holley[1,2], Joshua Mancini[1,2], Matthew J. Tuttle[1,2], Brandon M. Bradow[1,2], Rhett Martineau[1], Michael Carter[1,2], Chia-Suei Hung[1], Maneesh Gupta[1] and Laura Lang[1,2]; [1]Air Force Research Laboratory, United States; [2]UES Inc., United States

Biocementation is a process that utilizes microorganisms to bind soil particles together, leading to the formation of a more stable and cohesive soil structure through a cement-like matrix. *Sporosarcina pasteurii* is a bacterium we use for our cementation at the Air Force Research Laboratory. S. pasteurii has the ability to produce calcium carbonate, which helps to bind the particles together, resulting in increased strength and stability. The use of biocementation has several advantages over traditional stabilization methods, including reduced energy and material inputs, improved sustainability, and increased durability. This works demonstrates that poly glutamic acid can be added to the biocementation solution to facilitate an increase in precipitation of calcium carbonate. This increase leads to more stable sand columns and will allow us to decrease the amount of urea and calcium that is used in the biocementation solution, further decreasing the material inputs of biocemented structures.

5:00 PM SB01.03.23
High-Throughput, Multiscale Testing and Evaluation of Living Cemented Materials Brandon M. Bradow[1,2], Rhett Martineau[1], Laura Lang[1,2], Matthew J. Tuttle[1,2], Joshua Mancini[1,2], Michael Carter[1,2], Karen A. Holley[1,2], Adriana E. Joson[1,2] and Maneesh Gupta[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Microbially-induced calcite precipitation (MICP) has been recognized as an alternative to traditional cements; reversibly and quickly achieving cementation at room temperature with a lesser degree of CO_2 emissions. Low-carbon materials created using this technology may be useful for erecting impromptu structures, development of sites for humanitarian relief, or any other application requiring rapid, unintrusive ground improvement. However, improving and scaling up the biocementation process requires the development of faster-paced iterative testing devices for assessing methods production. In this study, we investigated variously scaled apparatus, which allows for gradually upscaled testing and increasing resolution with respect to evaluation of materials. These devices generally take the form of walled openings with a liquid-permeable mesh in the lower portion, allowing percolation of bacterial suspension solutions and cementation solutions. To increase throughput of experimentation, we used a pipetting robot to apply solutions between 176 microliter to 8 milliliter scale. This allowed for various methods and solutions to be tested simultaneously with numerous replicates. Experimental manipulation included the growth environment of the bacteria, growth media, and soil conditions. Using this process, it is possible to alter formulations to target specific traits and features of biocement. In our results, we found that strength is largely proportional to the amount of Ca^{2+} administered to the system, in addition to preconditions such as urea availability during growth, growth media type, and soil moisture content. Some conditions thought to not be viable for cementation are now considered viable, such as bacterial cultures grown without urea. Not only is this method viable, but it has comparable strength values to the average 60-80 PSI (unconfined compressive strength, UCS) achieved with conditions considered average per our results with a standard treatment. Using these methods, our standard treatment has improved by 160% from an average of 50 PSI to an average of 80 PSI, with strengths of 300 PSI being recorded outside of standard conditions. Our automated method allows testing of high-impact questions at a low-stakes opportunity cost by removing the restrictions imposed by time and material commitment.

5:00 PM SB01.03.24
Tuning Properties of Iridescent Biofilms for Material Applications Kennedy Brown[1], Claretta J. Sullivan[1], Chia-Suei Hung[1], Nicholas Posey[2], Matthew Dickerson[2], Patrick Dennis[1] and Nancy Kelley-Loughnane[1]; [1]AFRL/RXE, United States; [2]AFRL/RXN, United States

Nature employs hierarchical assembly as a successful strategy for enhancing the physical properties of its materials. Scientists study these natural materials, including morpho butterfly wings and mollusk nacreous shells, in an effort to replicate their properties in functional materials. Though mechanistic insights from these studies have led to significant progress, translating nature's design principles into scalable platforms for manufacturing hierarchical materials remains a bottleneck. We previously demonstrated the potential of iridescent *Cellulophaga lytica* biofilms to circumvent this issue with facile growth and scalability. In particular, their ability to self-assemble into hierarchically ordered communities in ambient conditions make them attractive candidates for templating ordered materials at industrial scales. Bacteria evolved strategies for precisely controlling morphology and dimensions on scales that are difficult to achieve in industrial manufacturing. In the current study, we demonstrate how biofilm functionality can be tuned by altering the morphology, dimensions and chemistry of its constituent bacteria. This study further strengthens the case for using these biofilms as platforms for sustainably manufacturing photonic materials and ordered templates.

5:00 PM SB01.03.25
Engineered Consortia for Enhanced Function of Iridescent *Cellulophaga lytica* Biofilms as a Living Sensing Material Claretta J. Sullivan, Kennedy Brown, Patrick Dennis and Nancy Kelley-Loughnane; AFRL/RXE, United States

Gliding bacteria such as *C. lytica* form intensely iridescent biofilms by packing themselves into polycrystalline domains. We have shown that these biofilms respond to environmental cues including salinity and temperature by dynamically changing the color reflected. As such, the biofilms offer a visible readout of its sensing status. In the current study, our goal was to develop these iridescent biofilms into living, sensing materials where *C. lytica* serves as a colorimetric reporter. Toward that end, we added genetically tractable *E. coli* to *C. lytica* biofilms, making a functional consortia in which each organism has a distinct role. Initial results address the challenges of incorporating *E. coli* into the biofilms without disturbing the iridescence generated by *C. lytica*. In addition, efforts to increase the cooperation between the two organisms will be presented. The engineered consortia made up of a non-canonical color-generating organism and a genetically tractable one could be a strategy for making living sensors suitable to a variety of environments.

Biologically Fabricated Materials from Engineered Microbes Neel S. Joshi; Northeastern University, United States

The intersection between synthetic biology and materials science is an underexplored area with great potential to positively affect our daily lives, with applications ranging from manufacturing to medicine. My group is interested in harnessing the biosynthetic potential of microbes, not only as factories for the production of raw materials, but as fabrication plants that can orchestrate the assembly of complex functional materials. We call this approach "biologically fabricated materials", a process whose goal is to genetically program microbes to assemble materials from biomolecular building blocks without the need for time consuming and expensive purification protocols or specialized equipment. Accordingly, we have developed Biofilm Integrated Nanofiber Display (BIND), which relies on the biologically directed assembly of biofilm matrix proteins of the curli system in *E. coli*. We demonstrate that bacterial cells can be programmed to synthesize a range of functional materials with straightforward genetic engineering techniques. The resulting materials are highly customizable and easy to fabricate, and we are investigating their use for practical uses ranging from bioremediation and biodegradable bioplastics to engineered therapeutic probiotics.

8:45 AM *SB01.04.02
Manipulating Growth and Mechanical Properties of Plants with Genetic Engineering Meredith N. Silberstein, Bex Pendrak, Isabella Burda, Si Chen and Adrienne H. Roeder; Cornell University, United States

In plant developmental biology, a growing field of interest is how the growth and mechanical properties of various plant tissues and organs are influenced by mutations, with the understanding that these closely couple and have strong implications for plant function. In the engineered living materials field, this same fundamental knowledge can be used to program structures of desired properties. Plant tissue growth is an organic process that produces non-uniform tissues with varying cellular compositions. It is therefore of interest the understand the distribution of constituents, constituent properties, and the aggregate macroscale properties.

In this talk, we will present a study of the mechanical properties of *Arabidopsis thaliana*. *A. thaliana* is a model organism frequently used by plant biologists because of its simple structures, fully sequenced genome, and susceptibility to genetic modifications. Wild-type and two different mutations of *A. thaliana* at various developmental stages were tested to investigate the role of plant age and mutations on the tissue-scale material properties. To characterize leaves specifically, rectangular specimens were cut from the center of leaves, avoiding the midvein which has been shown to significantly affect tensile properties of leaf tissues. The samples were mounted on paper frames to stabilize the material, with a similar technique to that used in the tensile testing of fibers. Speckle patterns were applied to enable the use of the Digital Image Correlation (DIC) technique, which tracks strains across the surface of the samples. Samples were deformed under uniaxial tension at a constant strain rate until failure. They were then analyzed in terms of elastic modulus, Poisson's ratio, ultimate strength, failure progression, and homogeneity of the strain field. We will also present results on the cell size, shape, and growth patterns underlying the tissues in these mutants to help form structure-function relationships in this genetically modified material system.

9:15 AM SB01.04.03
Tuning the Mechanical Behavior of Extracellular Matrix Composite Scaffolds for 3D-Bioprinting Grace Hu[1], Zeqing Jin[2], Austin J. Graham[3,4], Zev Gartner[1,3,4] and Grace Gu[1,2]; [1]University of California, Berkeley & San Francisco, United States; [2]University of California, Berkeley, United States; [3]University of California, San Francisco, United States; [4]Chan Zuckerberg Biohub, United States

3D-bioprinting facilitates the construction of scaffolds with complex geometries and at high precision. Design and process parameters for 3D-bioprinted materials must be carefully considered and characterized for each specific application.[1] Given the critical mechanical and physiological roles of type I collagen and laminin within the native extracellular matrix (ECM), we investigate how the printability and stiffness of composites of type I collagen and laminin is controlled through various printing process parameters. Numerical simulations are first implemented to characterize the swelling behavior of collagen, which are then compared to experimental testing. With an eye towards translation and ease-of-use, we utilize the commercially-available CellInk BioX bioprinter to control infill density, concentration, nozzle diameter, and heating duration throughout printing, observing vastly different mechanical properties in the resultant hydrogels.

Building from this work, we also seek to establish a reliable framework for 4D-bioprinting, in which the structure undergoes programmable mechanical and biochemical transformations over time. To this end, we computationally analyze and experimentally validate origami-inspired tissue folding mechanisms. Mouse embryonic fibroblasts (MEFs) are employed due to their contractile behavior that can be predictably modeled using finite element methods.[2] Collagen-Matrigel composites are prepared to investigate how MEF clusters contract the surrounding matrix as a function of material stiffness and mechanical cell state. The MEFs exhibit excellent cell viability, proliferation, and ability to dependably remodel the matrix over 24 hours. Ultimately, these results inform strategies for 4D tissue printing for biofabrication, developmental models, and regenerative medicine.

9:30 AM SB01.04.04

The Development of 3D Printable Living Microreactors for the Detoxification of Organophosphates Adam W. Perriman[1,2,2], Mark Shannon[1] and George Klemperer[1]; [1]University of Bristol, United Kingdom; [2]The Australian National University, Australia

Engineered Living Materials (ELMs) present an exciting opportunity to integrate and scale outputs from synthetic biology. However, ELM fabrication and performance are somewhat limited by the need for both matrix cytocompatibility and fabricability. Idealy, the living component should interface with and modulate the bulk structure of a material. Accordingly, we present the rational design and testing of living composites where expression of an artificial oxidoreductase by E. coli suspended in an ionogel bioink drives redox-mediated formation of a self-healing interpenetrating double network. Moreover, we demonstrate that this new class of ELMs can be 3D bioprinted to produce perfusable bacterial microreactors that actively detoxify organophosphates.

Spatially Organized Photosynthetic Living Materials Jeong-Joo Oh, Satya Ammu, Vivian Vriend, Roland Kieffer, Kunal Masania and Marie-Eve Aubin-Tam; Delft University of Technology, Netherlands

Engineered living materials (ELMs) are emerging class of functional materials, often fabricated by incorporating living cells within an inert polymer matrix to form desired functions. Unraveling the formation, spatial localization, and behavior of cellular populations within an artificial niche is a prerequisite for predicting and intensifying the functions of living materials. This study focuses on the growth and spatial distribution of eukaryotic microalgae *Chlamydomonas reinhardtii* within hydrogel networks for the strategic fabrication of living materials with intensified CO_2 capture. Existing unicellular microalgae within scaffolds form multicellular algal aggregates, called palmelloid, around the surface of bioprints, which play a crucial role in forming the functional surfaces of materials. With increasing depth of the matrix, the number and volume of cellular clusters decrease due to photon attenuation and limited air transfer. By tailoring material thickness and increasing the exposure of palmelloid to its circumjacent environments, the CO_2 capturing performance of bioprints can be enhanced. Interestingly, material designs to regulate photosynthetic activity show similarities to the strategies for intensifying photosynthetic activity inspired by plant leaves. Our results imply that the spatial control of cell population can control the function of ELMs and can be exploited for biomimetic structural research for leaf mimicry.

10:30 AM SB01.04.06

Plasmonic Stimulation of Gold Nanorods for the Photothermal Control of Engineered Living Materials Selim Basaran[1], Sourik Dey[1], Shrikrishnan Sankaran[1] and Tobias Kraus[1,2]; [1]INM–Leibniz Institute for New Materials, Germany; [2]Universität des Saarlandes, Germany

Composites of living cells in polymer gel matrices are called "Living Materials"[1]. They are useful for the controlled release of drugs that are produced by the cells while protecting them and their environment. Here, we demonstrate an optically triggered Living Material based on thermoresponsive bacteria. A "core" of a pluronic hydrogel with engineered *Escherichia coli* was enclosed in "shell" of a composite hydrogel that contained gold nanorods (AuNR) that were 41 nm long and 10 nm in diameter. The absorption spectrum of the AuNR coincides with the transparent window of human tissues. The plasmonic rods absorb laser light, heat the shell, and activate the bacteria, inducing the production of mCherry proteins or darobactin. Living materials were prepared in structured microslides that enabled both quantitative studies of spatial and temporal temperature variation and protein expression.

First, we characterized the thermoplasmonic composite and determined its overall photothermal conversion efficiency and the resulting thermal response with a AuNR concentration equivalent to an optical density of $OD_{808\text{ nm}} = 4$. Infrared thermography and embedded thermocouples were combined to obtain temperature distributions at a sampling rate of 0.2 Hz and an accuracy of 0.1 K. Illumination with a collimated laser spot of 5 mm diameter at 808 nm heated the cylindrical core-shell Living Material from an initial 20°C to a steady-state temperature of 40°C in air in 300 seconds. The IR camera indicated a lateral temperature gradient from center to the border with a maximum temperature difference of 4.7°C.

The genetically engineered *E. coli* contained in the core were activated by heating and produced the fluorescent protein mCherry. In a second set of experiment, we quantified its production as a function of laser power, time, and position via *ex situ* fluorescence microscope. The fluorescence intensity correlated with the temperature distribution measured above. The maximal protein expression rate for the living material with this *E. Coli* strain was found to be between 39-44°C, consistent with reference experiments in suspensions. Protein production at 0.6 W/m^2 was maximal at the center of the illuminated area and declined at its borders, where temperature dropped. Increasing laser power first led to an increase of fluorescence intensity at the borders. A uniform fluorescence intensity was reached across the illuminated area at 0.7 W/m^2. Protein expression continued for at least 4 h, with a linear increase of fluorescence that indicated sustained expression activity of the bacteria. Further increasing power density reduced the fluorescence intensity at the center. The decline occurred when the center temperature exceeded 45°C, the maximum viable temperature for the bacteria.

In a third set of experiments, we compared the results obtained for the model compound mCherry to the antibiotic darobactin that was produced by a different strain of engineered *E. Coli*. After photothermal triggering, darobactin was expressed, diffused through the gel, and into surrounding media, where we detected its presence via ESI-MS as a function of laser irradiation time. The results will be discussed in view of possible applications in therapies for chronical inflammations, e.g. in periodontitis.

Membrane Targeted Azobenzene Drives Optical Modulation of Bacterial Membrane Potential Giuseppe M. Paternò[1,2], Tailise Carlina de Souza-Guerreiro[3], Gaia Bondelli[2], Iago Grobas[4], Guglielmo Lanzani[2,1] and Munehiro Asally[3]; [1]Politecnico di Milano, Department of Physics, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]University of Warwick, United Kingdom; [4]University of Oxford, United Kingdom

The possibility to control living matter with exogenous stimuli can have tremendous impact on synthetic biology, medicine and materials science, among others. For instance achieving control over cells behaviour remains a challenge at the interface between living and non-living matter,[1] and would enable the development of new bio-mimetic and bio-enabled materials able to perform tasks.[2] Within this context, bacteria have arisen as "active and actively-controllable materials", exhibiting neuro-like behaviour, extended bioelectric signalling[3,4] and tunable assembly properties.[5] In the last decade, it has been observed that the regulatory element of such an active behaviour is the electrical potential across the membrane, which governs bacteria electrophysiology, metabolisms and bioenergetics.[6] Light can be a powerful tool in these regards, as one can control the membrane potential and, thus, cell function and behaviour remotely and with relatively high spatiotemporal precision.
Here, I will show that a membrane-targeted azobenzene can be used to photo-modulate precisely the membrane potential in cells of the Gram-positive bacterium *Bacillus subtilis*. We found that upon exposure to blue- green light, the isomerization reaction in the bacteria membrane induces hyperpolarisation of the potential ($\Delta V = 20$ mV), within a bio-mimetic mechanism reproducing the initial fate of retinal. Apart from being promising results in the view to photocontrol bacterial motion and assembly behavior in consortia, this approach also highlights the role of previously uncharacterized ion channels in bacteria electrophysiology.[7]

Development and Strategies to Improve Cellular Uptake of an Artificial Membraneless Organelle-Based Bioreactor Manisha Abesekara and Ying Chau; Hong Kong University of Science and Technology, Hong Kong

Liquid-liquid phase separated microcompartments inspired by membraneless organelles is a promising tool in developing bioreactors. They have liquid-like interior, sequestrate biomolecules, exchange materials with external environment and confine biochemical reactions. Adapting the sticker-spacer model of intrinsically disordered proteins, artificial membraneless organelles (aMLOs) were developed using a polymer-oligopeptide hybrid material consists of a dextran backbone and two oligopeptides. The capacity of aMLO to perform biochemical reactions was evaluated by a CRISPR reaction within the microcompartment. For the translation of CRISPR technology for therapeutic use, the core challenge is the development of an effective and safe delivery approaches. The CRISPR reactive complex loaded micron-size bioreactors in cytosol of target cell would be a noninvasive delivery approach with high effectivity. Cas9, sgRNA and target oligo-duplex were enriched within aMLOs with 720-fold, 865-fold and 835-fold increased concentrations, respectively. Consequently, the CRISPR cleavage reaction was achieved within the aMLOs under physiological conditions.
Additionally, strategies of cytosolic delivery of aMLOs were studied. To tap membrane fusion pathway, aMLOs were wrapped with macrophage cell membranes. The wrapping did not change the native enrichment/exclusion functions of the aMLOs but improved the stability from ~9 hours to up to 3 days. Wrapped aMLOs found to be internalized by source cells with intact cargo-molecules. Cellular uptake was further improved by sonoporation with low frequency (40 kHz) ultrasound of mechanical index (MI) and peak pressure of 0.4 and 75 kPa, respectively. Low frequency ultrasound can increase activity of mechanosensitive channels and induce pore formation at membrane protein-lipid interface to improve uptake. In the sonoporation experiment, above 80% cells were viable under continuous ultrasound treatment up to 5 min. Overall, results imply the possibility of developing deliverable bioreactors made of aMLOs and strategies to improve its cellular uptake.

2:00 PM SB01.05.03
Optimization of the Laser-Induced Forward Transfer Process for the Printing of Living Cells Adrien Casanova[1], Lucas Duvert[1], Ahmed Al-Kattan[1], Stefano Testa[2], Frédérique Magdinier[2] and Anne-Patricia Alloncle[1]; [1]Aix-Marseille University, CNRS, LP3 UMR 7341, Campus de Luminy, Case 917, France; [2]Aix-Marseille University, INSERM, MMG, Marseille Medical Genetics, France

Printing techniques applied to biology have begun to develop since the 2000s and hold great promise in a near future. They are based on interdisciplinary approaches and use a combination of cells, chemistry, engineering and sophisticated protocols to create artificial tissues.
In that scope, it has been more than a decade since Laser-Induced Forward Transfer (LIFT) is studied in lab scale for its ability to print biomaterials and more specifically living cells [1], [2]. This method uses a short laser pulse to transfer tiny amounts of material from a thin film donor to a receptor substrate. Under appropriate conditions, the pulse induces the formation of a jet propagating perpendicularly to the donor substrate. The targeted material is then deposited as a droplet on the collector. Due to its nozzle free non-contact direct writing technique, it is considered as a suitable method to print three dimensional cellular structures with a very high spatial resolution. Combined with stem cells technology this innovative printing process opens new perspectives for the creation of complex bio-models strongly mimicking the *in-vivo* environment with numerous applications ranging from regenerative

medicine to pharmaceutic study and drugs screening. However, the optimization of its performance and its use with living cells require a deep understanding of the ejection dynamic depending on several laser parameters (laser fluence, repetition rate, laser spot size, laser wavelength, pulse duration, absorption mechanism…) and of the effects of living cells on the bio-ink printability. At LP3 (Marseille-France) and in close collaboration with MMG (Marseille-France), we took advantages of our expertise in LIFT process [3] to master the printing by LIFT of living cells in good condition (high spatial resolution, high printing resolution and high cellular viability after printing) [4].
Here, we will present the LIFT process and its optimization allowing to master the bio-ink deposition in order to create reliable ordered patterns of bio-ink micro-droplets containing stem cells with a high spatial resolution. By changing the film concentration in cells and the laser pulse energy, we can control the droplet size and the number of cells in each droplet (from tens of cells down to the single cell level). Then, we will present a complete viability study of the printed cells after transfer to prove the ability of this process to create relevant bio-models.

Smart Sampling Capsule for Small Intestinal Bacteria Overgrowth Detection Sina Nejati, Aleena Masaeng and Rahim Rahimi; Purdue, United States

Small intestinal bacterial overgrowth (SIBO) is the condition when the bacteria in the upper gastrointestinal tract grow excessively beyond 10^5 colony forming units (CFU)/mL. The high population of bacteria then leads to malabsorption, indigestion, constipation, and a decrease in the efficiency of the immune system. Currently available techniques for the diagnosis of SIBO rely on jejunal aspiration and breath tests for measuring the hydrogen and methane produced through the bacterial metabolism of carbohydrates. However, these approaches commonly suffer from invasiveness, high expense, and poor accuracy by yielding false-positive results. Here, to sidestep the issues associated with discomfort to the patient, contamination, and unreliable results, we designed and developed a new 3D-printed sampling device to site-selectively collect small intestinal bacteria. The capsule's pH-responsive enteric coating served as an actuation mechanism to open the device in the region of the small intestine to facilitate bacteria collection while maintaining its integrity in the highly acidic environment of the stomach. A water-soluble glue was used to maintain the compression of a biocompatible polyetheretherketone (PEEK) spring, which was then inserted inside the capsule. When the enteric coating disintegrated and the GI tract fluid collected, the water-soluble glue was dissolved, causing the spring to expand. Upon expansion, the bonded flexible disc on top of the spring effectively sealed the capsule preventing contamination from the lower GI tract. Once the device has been discharged, the device could be readily opened to collect the small intestinal bacteria and quantify the CFU/mL. To achieve the least amount of deformation after the expansion of the spring, various materials were tested under compression for different time points and the length variation was recorded. Additionally, a series of systematic force profile studies was performed with different glue thicknesses to identify the exerted force for proper sealing of the device as well as understand the duration of the sampling. To demonstrate the non-selective sampling capability of the device, different dye concentrations as well as two bacterial strains including Escherichia coli and Pseudomonas aeruginosa with different concentrations were investigated. The results showed an excellent matching concentration between the collected sample and the sampling environment. The targeted bacterial sampling performance and spring-assisted sealing mechanism were validated using both realistic in vitro GI tract models with bacteria cultures and ex vivo with dissected porcine small intestines. Here, it is envisioned that such smart sampling capsule technology will offer new ways to gather specific bacteria from the small intestine to identify the potential for SIBO disease more accurately.

Engineering Microbial Communities in Biofilms Meghna Thakur[1,2], Lina J. Bird[1], Brian J. Eddie[1], Isabel R. Baker[1], Anthony P. Malanoski[1] and Sarah Glaven[1]; [1]U.S. Naval Research Laboratory, United States; [2]George Mason University, United States

Engineering living bacteria within biofilms has remained a challenge owing to difficulty in their cultivation under laboratory conditions due to reliance on syntrophic partners. In order to develop these bacteria for technological use, tools to genetically manipulate them directly, without the need for standard laboratory isolation and cultivation, are required. Here we describe our efforts toward *in situ* genome editing of autotrophic bacteria in an electrode biofilm. We first demonstrate a CRISPR-based genome editing tool called INTEGRATE in a biofilm-forming marine bacteria, *Marinobacter atlanticus* in pure culture. Next, we tracked the introduction of a fluorescent marker protein superfolder GFP (sfGFP) into *M. atlanticus* biofilm cells via conjugation with a fluorescent donor *E. coli* strain using confocal microscopy. Utilizing a fluorescent *M. atlanticus* biofilm, the genomic integration of sfGFP in the cells could be monitored in real-time. Lastly, we targeted an electroautotroph *Candidatus* Tenderia electrophaga that exists in a consortia of ca. 20 other species, and can only grow from CO_2 fixation and electron uptake from an electrode, and showed, for the first time, successful genome integration of a fluorescent marker protein in this uncultivated electroautotroph. This work represents the first step towards *in situ* genome editing of microbial communities that form electroactive biofilms as an approach towards developing living catalytic materials.

The Mechanical Theory of Nonequilibrium Coexistence Ahmad Omar; University of California, Berkeley, United States

Nonequilibrium phase transitions are routinely observed in both natural and synthetic systems. The ubiquity of these transitions highlights the conspicuous absence of a general theory of phase coexistence that is broadly applicable to both nonequilibrium and equilibrium systems. In this talk, we present a general mechanical theory for phase separation rooted in ideas explored nearly a half-century ago in the study of inhomogeneous fluids. The core idea is that the mechanical forces within the interface separating two coexisting phases uniquely determine coexistence criteria, regardless of whether a system is in equilibrium or not. We demonstrate the power and utility of this theory by applying it to active Brownian particles, predicting, from first principles, a quantitative phase diagram for motility-induced phase separation in both two and three dimensions. Finally, we extend and apply this mechanical perspective of phase coexistence to nonequilibrium order-disorder transitions and systems comprised of particles with nonreciprocal interactions.

3:45 PM SB01.05.07
Augmenting Adoptive T Cell Therapy in Solid Malignancies via Cell Nanoengineering and Photoacoustics Jinhwan Kim, Kelsey Kubelick, Anamik Jhunjhunwala, Jeungyoon Lee and Stanislav Emelianov; Georgia Institute of Technology, United States

Cancer immunotherapy using adoptive T cell transfer has shown remarkable success in many hematologic malignancies, however, this has not reliably translated to solid tumors. There are two main reasons that hinder T cell therapy translation in solid malignancies: 1) inability to visualize and track the infused T cells within tissues, and 2) limited delivery of T cells into deep-seated tumors that are not adjacent to vasculature. To address these two points, we introduce an approach, termed “cell nanoengineering”, based on a synergistic combination of adoptive T cells and functional nanoparticles coupled with

an imaging system to track the delivery and therapy *in vivo*. Specifically, we modify T cell surfaces with light-absorbing, anticancer chemotherapeutic drug-loaded functional nanoparticles that can penetrate deeper into a 3D solid tumor, and introduce a real-time ultrasound-guided photoacoustic (US/PA) imaging system. This combined approach enables the tracking of nanoengineered adoptive T cells with excellent spatial resolution at great imaging depths to improve understanding of infused T cell trafficking, followed by selective drug release into the entire 3D tumor microenvironment for combinatorial cancer chemo-immunotherapy in solid malignancies.
As a PA contrast agent and drug loading vehicle, mesoporous silica-coated, miniaturized gold nanorods (mSiO$_2$-AuNRs) with an aspect ratio of 6 (λ_{max} = 1064 nm) were synthesized. As an anticancer drug, 5-fluorouracil (5FU) or doxorubicin molecules were loaded in the mesoporous silica layer. For T cell nanoengineering, maleimide-modified mSiO$_2$-AuNRs were conjugated to the free thiol groups on the surface of T cells. To test the biological impact of T cell nanoengineering, T cell functions (i.e., viability, target cell killing) were tested at different nanoparticle concentrations: control cells and nanoengineered T cells at optical densities (ODs) of 1, 5, 10, and 20. Nanoengineered T cells at OD=1 and 5 showed negligible toxicity. At OD=10 and 20 significant T cell death was induced, and these nanoengineering conditions were eliminated from further analysis. Furthermore, T cell killing of matched B16-OVA cells at various ratios was maintained following cell nanoengineering, and no significant difference was observed in control vs. nanoengineered T cells. The addition of chemotherapeutic drugs (i.e., 5FU or doxorubicin) enhanced the target cell killing *in vitro* due to combinatorial chemo-immunotherapy. Furthermore, the loading of chemotherapeutic drugs selectively affected B16-OVA and not T cells at various drug amounts.
In vivo US/PA tracking, tumor regression study, and survival monitoring were carried out in ovalbumin (OVA)-expressing tumor-bearing C57BL/6 mice after intravenous injection of nanoengineered and matched OT1 murine primary T cells or the same amount of drug-loaded mSiO$_2$-AuNRs without T cells, followed by US/PA imaging (40 MHz, 680–970 nm and 1064 nm, Vevo LAZR, Visualsonics Inc.). Multiwavelength PA imaging successfully visualized nanoengineered T cells or nanoparticles delivered into solid tumor region. Nanoengineered T cells showed 3-fold higher PA signal (i.e., successful delivery) than the mSiO$_2$-AuNRs in the solid tumor, indicating the natural homing ability of matched T cells can be harnessed to improve the delivery of combination therapeutics. It followed that mice treated with nanoengineered T cells showed the best tumor regression and survival compared to other controls: T cell only or drug-loaded mSiO$_2$-AuNRs only.
Our results indicate that nanoengineered T cells can be successfully detected within the range of pre-clinical injection doses with high sensitivity for *in vivo* US/PA tracking. Also, the ability of T cells to home to the tumor site enables better delivery of nanoparticles into solid tumors, thus achieving greater tumor regression and enhanced survival.

4:00 PM SB01.05.09
Cell Encapsulation and Functionality in Engineered Living Microfibers by Uniaxial Electrospinning Daniel Verrico[1], Catherine Reyes[2], Fang Qian[2] and Gary Wnek[1]; [1]Case Western Reserve University, United States; [2]Lawrence Livermore National Laboratory, United States

The ability to print living materials in architected geometries enables superior control over cell functionality that will surely enhance the future of biofuel, pharmaceutical, and biocatalyst production. Bulk living materials – or biocompatible hydrogels with encapsulated microbes – may face the challenge of slow mass transfer that limits their production capacity. Cell functionality can be greatly improved when living materials are fabricated in precise geometries such as lattices & scaffolds, which also favor biocatalysis. Here, we present a novel uniaxial electrospinning approach to developing microfibrous poly(ethylene glycol) (PEG) constructs for single cell-level encapsulation and bioprocess intensification. This approach allows PEG microfibers to be generated from an aqueous solution of poly(ethylene glycol) diacrylate (PEGDA), which cannot be conventionally electrospun on its own. By adding a sufficient amount of salt, surfactant, and high molecular weight poly(ethylene oxide) (PEO) to the solution; we can obtain micron sized PEG/PEO fibers loaded with viable yeast cells and having an average fiber diameter of 0.8 µm. Upon photo-curing with a water-soluble initiator, the PEO can be washed away to produce swellable PEG microfibers with encapsulated microbes. Since yeast can be genetically modified to produce a variety of other valuable products, like biofuels or pharmaceuticals, this material could find use as a biocatalyst in industrial processes or as a platform for designing bioinspired materials with other lifelike functions.

SESSION SB01.06: Virtual Session I
Session Chairs: Maneesh Gupta and Taylor Ware
Tuesday Morning, April 25, 2023
SB01-virtual

8:00 AM *SB01.06.01
Functionalization of Bacteria by Surface Modification Jinyao Liu; Shanghai Jiao Tong University, China

The gut microbiota has been demonstrated to be an important regulator in human health. Disorders in the gut ecosystem have been implicated in various diseases, such as inflammatory bowel disease, diabetes, Alzheimer's disease, and cancers. Although fecal microbiota transplantation has demonstrated effective to positively modulate the gut microbiome, the implementation has been largely restricted by invasive operation and indeterminate composition, which inevitably result in low patient compliance and severe safety issues. Oral delivery of probiotic species to the gut microflora is an alternative to address these limitations, unfortunately, environmental complexity and a continuous flow within the gastrointestinal tract result in low oral bioavailability and limited intestinal colonization. Synthetic bioengineering is the most commonly used and feasible strategy to modify bacteria to tackle these challenges. However, the number of bacterial strains that can be genetically engineered is limited so far. Furthermore, many biomacromolecules especially eukaryotic proteins cannot be highly expressed and folded preciously and functionally by bacteria resulting from inefficient post-translational modifications, codon usage issues, and the formation of inclusion bodies that are not functional. Most importantly, engineered bacteria confront with potential risk of gene contamination via horizontal gene transfer, particularly with respect to in vivo applications. The focus of my research group is the use of biomaterials to modify or restructure the surface of bacteria to introduce exogenous functions that are naturally unachievable, which can increase bacterial survival and colonization in vivo following oral administration.
For example, probiotics individually coated with a self-assembled lipid membrane exhibit significantly improved survival against environmental assaults (e.g., gastric acid, bile acid, antibiotics, etc.) and almost unchanged viability and bioactivity, demonstrating enhanced efficacies in oral delivery and treatment of intestinal mucositis. Moreover, probiotics wrapped with a yeast membrane-derived biomaterial can be delivered into lymphoid follicles after oral ingestion and promote robust mucosal immune responses and the production of secretory immunoglobulin A, which can prevent and treat gut barrier impairment. In addition, in-situ co-deposition with dopamine can generate a hybrid multifunctional coating, which can provide a dual protection and targeting ability to modified bacteria for locally modulating the gut microbiota around the inflamed tissue and enhancing the treatment of colitis. Also, oncolytic bacteria camouflaged with a cell membrane-derived biomaterial show a low inflammatory response, slow elimination by macrophages, increased accumulation in tumor tissue, and almost unchanged inherent bioactivities, which generate greatly enhanced antitumor efficacy under a safe dosage. Briefly, the main focus of my research is the development of functional coatings to modify bacteria, which can be endowed with various exogenous functions and applied as editable bacterial therapeutics for intervening gut microbiome imbalance and the associated diseases.

8:30 AM SB01.06.02
Evaluation of Photochemical Activity of Algae and Grass-Chloroplasts when Encapsulated into Hierarchical Silica- Monoliths Cynthia Cervantes and Alicia Sommer; Yachay Tech University, Ecuador

The photosynthetic activity of plants and microalgae can be widely exploited to produce biomaterials with varied properties such as the absorption of CO_2 and the removal of metals such as Cu and Ni in wastewater. In this study, microalgae species Chlorella Vulgaris and chloroplasts extracted from Pennisetum Clandestinum turfgrass residues were immobilized into silica monoliths with hierarchical porosity by the high internal phase emulsion (HIPE) method. Optical and fluorescence microscopy as well as UV-Vis, diffuse reflectance and fluorescence spectroscopy were used to monitor the preservation of photosynthetic activity in the monoliths. The results demonstrate that the monoliths synthesized are capable of maintaining their photosynthetic activity and producing O_2 even after 90 days of encapsulation.

8:45 AM SB01.06.04
The Biomechanics of Ultra-Stretchable Nerves Rakesh Das, Amir Ayali, Moshe Guershon, Amjd Ibraheem, Eran Perlson and Bat-El Pinchasik; Tel Aviv University, Israel

When digging in the ground during egg laying the female locust extends her abdomen to 2-3 times of its original length. How the abdominal nervous system accommodates such extreme elongation remains unknown. We characterized and quantified the system's biomechanical response using controlled ex vivo elongation and force measurements. The microstructure of the nerves was studied using histology and high-resolution confocal microscopy. Although the nervous system of sexually mature females demonstrated fully reversible hyper-extensibility of up to 275%, the elongation observed in premature females and males was much more limited. The unique extension dynamics of the different groups were captured by their very different force-displacement curves. Confocal microscopy suggested that elongation is not owing to undulations of the nervous system structure. Thus, the exceptional resistance to deformation and rupture presents the female locust abdominal nervous system as a valuable model for understanding the functionality and pathology related to nerve extension and reversible elongation.

Material Design Criteria for Living Therapeutic Devices Aránzazu del Campo; INM-Leibniz Institute for New Materials, Germany

Engineered Living Materials, where active biofactories are contained in diffusive matrices, open new opportunities to design therapeutic wearable devices and implants for comfortable treatment of chronic diseases. In this talk, fundamental design parameters and demonstrated properties of the encapsulating matrix to guarantee functionality and safety of living therapeutic devices will be presented, together with current examples developed in the group.

9:30 AM SB01.06.06
Fabricating Mycelium-Agrowaste 3D Composite Materials for Use in Building Construction Insulation. Kumba B. Bonga, Despina Fragouli and Athanassia Athanassiou; Italian Institute of Technology, Italy

Environmental degradation is occurring at an alarming rate due to the unsustainable activities of the construction industry posing a serious threat to our ecosystem, human health, and economy[1]. Its adverse consequences propel the three planetary crises we are encountering currently: climate change, biodiversity loss, and pollution[2]. The building sector accounts for 39% of gross annual carbon emissions worldwide including emissions created in producing construction materials[3]. The strides toward attaining zero net carbon emissions and a toxic-free environment include mainstreaming sustainability, efficient energy use, and an integrated waste management system. The focus of the building industry is recently directed towards the development of bio-based materials to be used in the construction of eco and health-friendly building structures. Traditional polymeric foams, such as polystyrene and polyurethane, are commonly used for thermal insulation in infrastructure and housing construction[4]. Nonetheless, such materials are non-renewable, and their production and use involve complex manufacturing processes with substantial energy inputs. Furthermore, it has been proved that they leach out several toxins, which can bio-accumulate in fish and wildlife, presenting a well-documented environmental health problem[5]. Recently, new environmental-friendly bio-based insulation materials are introduced which often require less energy to be produced than traditional materials. The development of sustainable biopolymer materials is a vital mitigation strategy to achieve clean and profitable solutions to the threats of plastic pollution by polymeric foams in our environment.This work is focused on the development of self-growing materials based on Mycelium-Coffee silverskin combinations that could replace traditional insulation materials. It involves the development of sustainable biopolymer composites composed of Lignocellulosic Agrowastes (Coffee silverskin), obtained from roasted coffee seeds, and fungal mycelium derived from non-pathogenic fungal strains (*Pleurotus ostreatus*). *Pleurotus ostreatus* is suitable for growth on coffee silverskin as it produces a diversity of extracellular digestive enzymes, which play important role in lignocellulose degradation. Different mixed proportions of the Agrowaste and mycelium were considered to determine the best condition, which supports the growth of *Pleurotus ostreatus* on Coffee silverskin to produce the composite material with low thermal conductivity and density suitable for thermal insulation applications. Studies on the thermal conductivity revealed that the values of the biocomposites were quite low ranging between 0.04 to 0.12 k(W/mK). Other characterization analyses including mechanical characterization tests and humidity sorption capacity, were also conducted to determine the physico-chemical properties of the developed composite material. The results from the material characterization indicated that the Mycelium-Agrowaste composites can be appropriate for use in building insulation and other suitable applications.

10:30 AM *SB02.01.01
Fabricating Silicon Nanoneedle Arrays for Cellular Manipulation Nicolas Voelcker; Monash University, Australia

The presentation will review nanofabrication technologies combining colloidal or electron beam lithography techniques with wet or dry etching (wet: metal-assisted chemical etching; dry: deep reactive ion etching) to fabricate arrays of silicon-based nanoneedles and nanotubes with adaptable and programmable designs.

11:00 AM SB02.01.02
A Biodegradable Flexible Porous Silicon Nanoneedles Platform for Topical Delivery of Biologicals Cong Wang, Salman Mustfa, Davide Martella, Chenlei Gu, Priya Vashisth and Ciro Chiappini; King's College London, United Kingdom

Vertically aligned porous Si nanoneedles (pSi NNs) arrays have attracted great interest in biomedicine and is capable for intracellular and intratissue delivery of biomolecules. Extensive research has focused on the construction of pSi NNs on rigid and opaque Si carrier, which restricts potential benefits and limits the functionality of the NNs array in clinical systems. The rigidity of NNs arrays makes the application to tissue less effective as they cannot conform to the non-planar tissue surface, resulting in a mechanical mismatch. Also, the opacity of NNs arrays restrict the possibility of tracking dynamic cellular processes at the nanoneedle interface and real-time assessment of cell behaviour. Herein, we report a robust, rapid and precise methodology to generate well-ordered vertical pSi NNs on flexible and transparent substrates with desired flexibility, tuneable optical transparency, good cell and tissue compatibility. These devices are manufactured by first forming porous silicon nanoneedles on Si carriers through metal assisted chemical etching (MACE) and reactive ion etching (RIE), followed by the formation of an underlying porous silicon and a detachment layer by electrochemical etching (EC), to transfer NNs onto recipient substrates. We explored the role of synthesis parameters including MACE, electrochemical etching and RIE conditions in controlling the porosity, transparency, and geometry (length, diameter, density) of pSi NNs to understand the relationships among the structure, property and performance of NNs to achieve the desired scalability, stability and controllability. This method can generate pSi NNs onto different receiving platforms to unlock the potential of nanoneedles on arbitrary substrates, while preserving the original spatial arrangement (i.e., vertical orientation, geometry, density), while providing a mechanically elastic interface that compensates the large mismatch in contact with the biological systems, allowing for the interaction of NNs for intracellular drug delivery. The tuneable transparency enables the direct observation of real-time interactions which are hampered by the opaque carrier. *In vitro* data showed the efficient delivery of biomolecules into living biological cells and tissues, indicating the utility of this flexible pSi NNs platform for therapeutic applications. Comprehensive demonstrations of various recipient substrates (e.g., polydimethylsiloxane, hydrogel, polylactic acid, medical bandages) indicated this proposed method to be readily adaptable for facilitating the fabrication of high-density nanostructures onto diverse substrates, not limit to the flat surface, to shed the lights on the future applications including clinical systems, nanomedicines, drug delivery, tissue engineering and implantable devices.

11:15 AM SB02.01.04
Magnetically Actuated Single-Cell Microgrippers Robin Liu[1], Wangqu Liu[2], Xin Song[1], Ruili Zhang[2], David H. Gracias[2] and Eric Diller[1]; [1]University of Toronto, Canada; [2]Johns Hopkins University, United States

Microtools that can manipulate single cells can be used to probe tissue heterogeneity and investigate cell mechanobiology questions of broad relevance to tissue engineering and the understanding and development of several diseases. Existing tools are either large or manipulated by hand, limiting throughput and scalability. Here, we report the development of single-cell scale microgrippers with precise and reversible magnetic actuation for cellular manipulation and mechanoresponse study. The microgrippers consist of flexible nanoscale thin-film hinges and rigid arms integrated with magnetic materials. With the appropriate use of sacrificial films, the arms of the grippers can be released from the substrate. Pre-stressed hinges power the microgripper and allow it to self-fold into a half-open pyramidal 3D cavity, small enough to encapsulate a single cell. Using an external magnetic field, we show that we can control the arms to exert force precisely on the encapsulated cell. The motion and force output of microgripper arms are predictable by a theoretical model. We discuss studies of microgrippers capturing and exerting forces on micro-objects such as cells and microbeads and show that the arms of the microgripper can be reversibly actuated over hundreds of cycles. Moreover, the lithographic fabrication and small dimensions of microgrippers allow us to fabricate them *en masse* using wafer-scale scalable processes, improving experimental throughput and cost-effectiveness. We envision that these new microtools can be readily integrated with lab-on-a-chip devices and advance single-cell studies.

SESSION SB02.02: Fabrication II
Session Chairs: Bianxiao Cui and Song Li

1:30 PM *SB02.02.01
3D Mesoscale Functional Frameworks as Interfaces to Organoids John A. Rogers; Northwestern University, United States

Three-dimensional (3D), sub-millimeter-scale tissue constructs derived from human stem cells are of rapidly growing importance in biological and medical research. Despite their great potential for studies of topics with both fundamental and translational interest, such types of miniaturized, fragile 3D living biosystems cannot be examined easily using conventional methods based on planar technologies, such as conventional multi-electrode arrays. An ideal solution would involve complaint, shape-matched device platforms in 3D geometries that can gently envelop the organoids as multifunctional electronic, optoelectronic, microfluidic, thermal, mechanical and biochemical interfaces. This talk summarizes our recent work on a 3D technology platform of this type, where reversible, engineering control over shapes, sizes and complex geometries can be tailored to match organoids of interest and also to support interconnected collections of them. Various aspects of the materials associated with these systems, and their applications to cortical and cardiac spheroids will be discussed.

2:00 PM *SB02.02.02
Bioelectronic Tools to Study the Gut-Brain Axis Róisín Owens; University of Cambridge, United Kingdom

The human gut microbiome has emerged as a key player in the bidirectional communication of the gut-brain axis, affecting various aspects of homeostasis and pathophysiology. Until recently, the majority of studies that seek to explore the mechanisms underlying the microbiome-gut-brain axis relied almost exclusively on animal models, and particularly gnotobiotic mice. Despite the great progress made with these models, various limitations, including ethical considerations and interspecies differences that limit the translatability of data to human systems, pushed researchers to seek for alternatives. Physiologically relevant in vitro human models, as well as advanced tools to study in vivo animal models, are urgently required. In this talk I'll discuss a new generation of electronic tools, based on organic electronic materials, for understanding the gut-brain-microbiome axis. First, I'll discuss our progress towards generating a complete platform of the human microbiota-gut-brain axis with integrated monitoring and sensing capabilities. Bringing together principles of materials science, tissue engineering, 3D cell biology and bioelectronics, we are building advanced models of the GI and the BBB/NVU, with integrated real-time and label-free electronic monitoring, aiming to elucidate the role of microbiota in the gut-brain axis communication. Second, I'll discuss conformable electronic devices we've developed for both ex-situ measurements of GI tissue from rats, as well as in vivo experiments in live rats. These devices allow highly sensitive monitoring of impedance of the tissue (as an indicator of gut health) as well as the enteric nervous system.

2:30 PM *SB02.02.03
Nanostructured Heterojunctions for Biological Modulation Bozhi Tian; University of Chicago, United States

Biointerface devices can facilitate a deeper understanding of biological dynamics and improve the quality of life. My research group integrates nanoscience with biophysics and bioengineering to study semiconductor-based biointerfaces. We have previously identified and quantified the photothermal, photofaradic, and photocapacitive effects of nanostructured semiconductors, which can be used to modulate electrical activities in neurons and cardiomyocytes at the semiconductor-based biointerfaces.

In this talk, I will describe two heterojunction platforms that have recently been developed in our lab for photostimulation of cells and tissues. A heterojunction plays a crucial role in semiconductor-based devices such as diodes, solar cells, photodetectors, and light-emitting diodes. Compared with homojunction semiconductor devices, heterojunction devices can produce minority carriers (for example, through light illumination) that can be used in critical applications such as energy harvesting. There are, however, still several opportunities for the future development of semiconductor-based heterojunctions in biointerface studies. One of our heterojunctions uses porosity-based silicon structures, while the other uses titania/gold multilayered membranes. I will illustrate the photostimulation mechanisms in cells and tissues for both heterojunctions. Finally, I will present future biointerface developments in our lab.

3:00 PM BREAK

SESSION SB02.03: Biophysics I

3:30 PM *SB02.03.01
Membrane Curvature Initiated Mechanotransduction in Cells Bianxiao Cui; Stanford University, United States

Membrane curvature in the range of tens to hundreds of nanometers is involved in many essential cellular processes. At the cell-matrix interface, where the cells make physical contact with extracellular matrices, the membrane may be locally deformed by matrix topography or mechanical forces, and this deformation may actively regulate signal transmission through the interface. We explore nanofabrication to engineer vertical nanostructures protruding from a flat surface. These nanostructures deform the plasma membrane to precisely manipulate the location, degree, and sign (positive or negative) of the interface curvature in live cells. We found that these membrane curvatures significantly affect the distribution of curvature-sensitive proteins and modulate mechanotransduction in live cells. These studies show a strong interplay between membrane curvature and mechanotransduction and reveal molecular mechanisms underlying the connection.

4:00 PM SB02.03.02
Dynamically-Driven Osteoblast Attachment and Stress Fibers Formation on 3D Nano-Architected Scaffold-On-Chip Ottman Tertuliano; University of Pennsylvania, United States

The underlying mechanisms leading to bone density loss, which increases bone fracture susceptibility, are not well understood at the cellular level. Decades of cell studies on relatively compliant 2D surfaces and hydrogels have led us to believe mechanical stimulation of bone can reverse bone loss. To date, an understanding of the stimuli that promote adhesion of bone like cells on 3D surfaces remains elusive . Here we employ tunable 3D nano-architected materials as platforms to examine the effects of different dynamic loading conditions on osteoblast-like (SAOS-2) cell proliferation and adhesion. After cyclic compression, stress fibers formation increased across material systems regardless of constant strain or stress. Increasing loading frequency from 0 to 3Hz resulted in a 50 % increase in stress fibers formation, suggesting that osteoblasts might be most sensitive to changes in loading frequency. These findings demonstrate that 3D architected materials offer an innovative platform to study complex cellular behaviors and can contribute to understanding the role that mechanical stimulation plays in cytoskeletal reorganization.

4:15 PM *SB02.03.03
Mechano-Epigenetics for Cell Engineering Song Li; University of California, Los Angeles, United States

Cell reprogramming into induced pluripotent stem cells or into a completely different lineage has wide applications in regenerative medicine, disease modeling and drug screening. Although the roles of transcriptional factors and chemical compounds in cell reprogramming have been widely studied, the effects of biophysical factors are not well understood. We have demonstrated that micro-structured materials can modulate the morphology of cell nuclei and epigenetic state, which in turn enhances cell reprogramming efficiency. In addition, we show that active forces such as a millisecond squeezing of cell nucleus in microfluidic devices can help overcome the epigenetic barrier and promote cell reprogramming. These findings have important implications in mechano-genomics, and may lead to the development of new technologies for cell engineering.

4:45 PM SB02.03.04
Poster Spotlight: Fast and Accurate Noninvasive Monitroing System for Early Detection of Epithelial-Mesenchymal Transition of Cancer Cell
Andrew Choi, Daeeun Shin and Joon Ho Kang; Korea Institute of Science and Technology, Korea (the Republic of)

A cascade of studies has revealed a distinct form of cell morphogenesis during each stage of cancer. In conquering cancer, the analysis of the physical/mechanical properties (stiffness and volume) which govern the migration, proliferation, differentiation, and cellular transition of the cancer cells experiencing morphogenesis has become more than essential. To analyze the aforementioned properties, various approaches based on the utilization of an atomic force microscope, optical stretching, shear stress, and the particle tracking method have been utilized. However, these approaches are mostly applied to fixed cells only and often require expensive staining reagents or equipment. Furthermore, the invasive manner of these approaches inevitably stresses live-cells overtime during the observation; ergo, it limits the monitoring time and the field of observation.

Acknowledging the current drawbacks of the monitoring system of cancer cell morphogenesis and the physical stresses exposed to individual cancer cells during the observation, we designed/fabricated a microfluidic chip containing a unique micro-pillar structure and suggested a noninvasive method of observing the morphology of individual label-free cancer cells in real-time at a resolution of ~ 100 nm scale. A different intensity level of the cell culture medium mixed with FITC-Dextran 4 kDa inside of our microfluidic chip precisely evaluated the morphology (area, volume, height) of the cultured cancer cell. And the isotropic micro-pillar within the fabricated microfluidic chip perfectly separated the “object filled zone” (height = 23 μm) having the lowest intensity level and the “object cleared zone” (height = 0 μm) having a maximum intensity level. The morphogenesis of the cancer cells during the different stages of epithelial-mesenchymal transition (EMT) upon the treatment of transforming growth factor beta (TGF-β) was clearly observed *via* our fabricated microfluidic chip and the volume changes of individual cells were additionally observed through our noninvasive, label-free approach. With the utilization of our monitoring system, we were able to find the dominant physical parameters of morphogenesis for detecting early EMT action. To this end, we herein, with an eagerness to assuage the grief of patients suffering from cancer, suggest a novel method of exploiting microfluidic chips for precisely observing erratic cancer.

4:50 PM SB02.03.05
Poster Spotlight: Electroactive Nanoinjection Platform for Intracellular Delivery and Genetic Editing Ali-Reza Shokouhi[1], Yaping Chen[1], Nicolas Voelcker[1] and Roey Elnathan[2]; [1]Monash Institute of Pharmaceutical Sciences, Australia; [2]Deakin University, Australia

Nanoinjection—the process of intracellular delivery using vertically configured nanostructures—is a physical route that efficiently negotiates the plasma membrane, with minimal perturbation and toxicity to the cells. Despite the implementation of nanoinjection tools and their assisted analogues in diverse cellular manipulations, there are still substantial challenges in harnessing these platforms to gain access into cell interiors with much greater precision without damaging the cell’s intricate structure. Here, we propose a low-voltage, simple, scalable, and reusable electroactive nanoinjection (ENI) platform based on vertically configured conductive nanotubes (NTs) that allows for rapid influx of targeted biomolecular cargos into the intracellular environment, and for successful gene editing. The localization of electric fields at the tight interface between conductive NTs and the cell membrane drastically lowers the voltage required for cargo delivery into the cells, from kilovolts (for bulk electroporation) to only ≤10 V; this enhances the fine control over membrane disruption and mitigates the problem of high cell mortality experienced by conventional electroporation. Through both theoretical simulations and experiments, we demonstrate the capability of the ENI platform to locally perforate GPE-86 mouse fibroblast cells and efficiently inject a diverse range of membrane-impermeable biomolecules with efficacy of ~63% (antibody), ~56% (mRNA), and ~52% (plasmid DNA), with minimal impact on cells’ viability post nanoscale-EP (>90%). We also show gene editing through the delivery of siRNA that targets TRIOBP, yielding gene knockdown efficiency of ~41%. We anticipate that our ENI platform is set to offer a new path to intracellular delivery with broader selection of cargo and cell types, and will open opportunities for advanced *ex vivo* cell engineering and gene editing.

SESSION SB02.04: Poster Session: Nanotechnologies for Cell Manipulation

5:00 PM SB02.04.01
Endometrial Organoids Generated within Microfluidic Droplets as a High-Throughput Screening Platform to Overcome Female Infertility
Myeong Jae Baek[1], Leekang Jeon[2], Hyo Min Lee[2] and Yun Kee Jo[1,1]; [1]Kyungpook National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Endometrial diseases, such as Asherman's syndrome and endometrial cancer, are the main cause of infertility. Numerous therapeutic drugs have been developed to overcome the endometrial disease-derived infertility, which leads to the increasing necessity of highly accurate screening for new drugs. Organoids, *in vitro* three-dimensional self-assembled constructs that mimic the structural and functional features of the corresponding organ, have emerged as a reliable test-bed to evaluate therapeutic performance and safety of drugs. However, conventional dome cultures have faced to the poor reproducibility and maturity of organoids mainly due to non-uniform supply of medium. Here, we propose a homogenous organoid culture platform using microfluidically fabricated microgels to establish a reproducible test bed for screening of female infertility-associated drugs. The endometrial organoids cultured within the highly uniform microgels exhibited the phenotypic and genotypic features specific to endometrial epithelium, as well as high level of homogeneity. Moreover, we confirm the hormone-responsiveness of endometrial organoid, suggesting the reliability to recapitulate functional features of endometrial tissues. In addition, we confirmed hormone-responsive changes of endometrial organoids in thickness, which suggest the reliability to recapitulate functional features of endometrial tissues. Taken together, our endometrial organoids can be a powerful high-throughput screening platform of drugs for female infertility treatment with further expansion to precise personalized medicine.

5:00 PM SB02.04.02
Photoacoustic Modulation of Alzheimer's Beta-Amyloid Aggregates Structure Using MOF-Derived Carbon Nanoparticles Yonghan Jo, Jinhyeong Jang and Chan Beum Park; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Photoacoustic materials release acoustic waves onto the surroundings by converting absorbed photon energy. In an aqueous environment, light-induced acoustic waves form cavitation bubbles by altering the localized pressure to trigger the phase transition of water from liquid into vaporous phase. Herein, this study report the photoacoustic dissociation of beta-amyloid (Aβ) aggregates, a prominent hallmark of Alzheimer's disease, the most pervasive type of dementia, by metal−organic framework-derived carbon (MOFC) nanoparticles. MOFC nanoparticles, which possess defect-rich and entangled graphitic layers, exhibit a near-infrared (NIR) light-responsive photoacoustic characteristic and generate intense photoacoustic cavitation under tissue-penetrable NIR light irradiation. Our analysis exhibits that photoacoustic cavitation induced by MOFC occurs in the water within milliseconds, and is controllable by the dose of NIR light. The photoacoustic cavitation effectively denatures extremely robust β-sheet-dominant neurotoxic Aβ aggregates into nontoxic debris by altering the asymmetric distribution of water molecules around the amino acid residues of Aβ. Furthermore, the cellular metabolic activity test confirmed that photoacoustic cavitation alleviated Aβ-induced neurotoxicity. This work reveals the therapeutic potential of spatiotemporally controllable NIR-driven photoacoustic cavitation as a modulator of the Aβ aggregate structure.

5:00 PM SB02.04.03
Application of a Reduced Graphene Oxide Mask to Cells as an Effective Barrier to Cytotoxins Jeremy S. Marshall[1], Keith Whitener[2], Dhanya Haridas[2], Woo-Kyung Lee[2] and Matthew Thum[2]; [1]Nova Research Inc., United States; [2]Naval Research Laboratory, United States

Toxic exposure damages tissues and cells. Deployment of a physical diffusion barrier on cell surfaces provides a simple method for inhibiting these cytotoxic effects. We have previously shown that thin (< 250 nm) films of thermally reduced graphene oxide (rGO) have low permeability to small molecules, and that these rGO films can be integrated with cells in a biocompatible manner using gelatin as a cell protectant. Here we use rGO films as diffusion masks to inhibit exposure of various mammalian cell types to a number of cytotoxins, in an effort to gauge the cytoprotective effect of the films. In separate trials, rGO-masked cells were exposed to 70% ethanol and 2.5% glutaraldehyde to determine the effectiveness of the rGO mask. We also evaluated the impact of mask thickness as well as the incorporation of other polymers with the mask on overall cytoprotective effectiveness. Applying LIVE/DEAD stain to cells exposed to 70% ethanol revealed clearly defined areas of live- and dead-stained cells corresponding to the areas with and without rGO coverage, respectively. LIVE/DEAD staining of glutaraldehyde-exposed cells indicated a significant amount of cell death occurring in cells underneath the mask. Further examination revealed isolated spots where the gelatin cell protectant was heavily crosslinked as a result of glutaraldehyde exposure. These results suggest that rGO masks can be strongly protective against certain cytotoxins such as ethanol, whereas others such as glutaraldehyde might penetrate the mask along defects.

5:00 PM SB02.04.04
Synthesis of Bismuth Nanoparticles for Adsorption to a Novel Chemotherapy Mary Elizabeth Kane and Molly Roesch; Rochester Institute of Technology, United States

Magnetically steerable nanoparticles as drug carriers have become increasingly popular in recent years. The ability to selectively guide them to afflicted sites allows for the treatment of diseases such as cancer that have been historically difficult to cure due to high healthy cell death rates. The synthesis of bismuth nanoparticles has been explored for this purpose. Bismuth metal is biologically inert and highly diamagnetic; nanoparticles with a 2 - 5 nm diameter could be directed through the body, including across the blood brain barrier, and subsequently used to remove the drug to which it is conjugated. These nanoparticles will be conjugated with D112, a chemotherapeutic dye that displayed a high selectivity ratio as developed by Kodak but was found to be hepatotoxic in mice. The magnetic steerability of the particles could be useful for the treatment of brain cancer and other cancers that are exceedingly difficult to treat. The most promising synthesis system uses a modified polyol method with a propylene glycol and metformin solvent, bismuth hydroxide feedstock, a D112 fragment as the stabilizer, and hydrazine reductant. Hydrazine drives the burst nucleation of the particles, and an additional stabilizer is used to quickly quench the growing nanoparticles in the desired size range. The reaction pH is critical for reduction and is controlled with sodium hydroxide. This system has achieved relatively stable particles about 13.9 nm in diameter according to Dynamic Light Scattering (Photon Correlation) Spectroscopy. Further tests are needed to optimize the stabilizer ratio, pH, and reaction duration to produce a particle dimension at the desired size. The high cancer to healthy cell death selectivity of the dye, directibility and potential translocation properties across a patent blood-brain barrier coupled with X-Ray detectability of the nanoparticles, and the ability to remove both from the body before liver or kidney failure can set new precedents in the field of cancer treatment and beyond.

5:00 PM SB02.04.06
Poster Spotlight: Fast and Accurate Noninvasive Monitroing System for Early Detection of Epithelial-Mesenchymal Transition of Cancer Cell
Andrew Choi, Daeeun Shin and Joon Ho Kang; Korea Institute of Science and Technology, Korea (the Republic of)

A cascade of studies has revealed a distinct form of cell morphogenesis during each stage of cancer. In conquering cancer, the analysis of the physical/mechanical properties (stiffness and volume) which govern the migration, proliferation, differentiation, and cellular transition of the cancer cells experiencing morphogenesis has become more than essential. To analyze the aforementioned properties, various approaches based on the utilization of an atomic force microscope, optical stretching, shear stress, and the particle tracking method have been utilized. However, these approaches are mostly applied to fixed cells only and often require expensive staining reagents or equipment. Furthermore, the invasive manner of these approaches inevitably stresses live-cells overtime during the observation; ergo, it limits the monitoring time and the field of observation.

Acknowledging the current drawbacks of the monitoring system of cancer cell morphogenesis and the physical stresses exposed to individual cancer cells during the observation, we designed/fabricated a microfluidic chip containing a unique micro-pillar structure and suggested a noninvasive method of observing the morphology of individual label-free cancer cells in real-time at a resolution of ~ 100 nm scale. A different intensity level of the cell culture medium mixed with FITC-Dextran 4 kDa inside of our microfluidic chip precisely evaluated the morphology (area, volume, height) of the cultured cancer cell. And the isotropic micro-pillar within the fabricated microfluidic chip perfectly separated the “object filled zone” (height = 23 μm) having the lowest intensity level and the “object cleared zone” (height = 0 μm) having a maximum intensity level. The morphogenesis of the cancer cells during the different stages of epithelial-mesenchymal transition (EMT) upon the treatment of transforming growth factor beta (TGF-β) was clearly observed *via* our fabricated microfluidic chip and the volume changes of individual cells were additionally observed through our noninvasive, label-free approach. With the utilization of our monitoring system, we were able to find the dominant physical parameters of morphogenesis for detecting early EMT action. To this end, we herein, with an eagerness to assuage the grief of patients suffering from cancer, suggest a novel method of exploiting microfluidic chips for precisely observing erratic cancer.

5:00 PM SB02.04.07
Local Electrochemical Generation of Reactive Oxygen Species for Targeting Cancer Cells Eva Miglbauer[1], Oliya S. Abdullaeva[2] and Eric D. Glowacki[1,3]; [1]Linköping University, Sweden; [2]Luleå University of Technology, Sweden; [3]Central European Institute of Technology, Brno University of Technology, Czechia

Cancer is one of the leading death causes worldwide. Therefore the de,velopment and advancement of anti-tumor treatments, which can be applied supplementary to surgery and also minimize the harm to the patient, are of importance.
One approach to achieve this goal is the application of reactive oxygen species (ROS) -mediated cell death. At elevated concentrations ROS can induce damage to cells due to oxidative stress and can further lead to apoptosis. Due to the high reactivity of especially hydroxyl radicals, the molecules' lifetime is rather short resulting in a very small transport distance and consequently to a confined range in the body. ROS-mediated therapies like photodynamic therapy or Fenton nano particle-based systems are already widely investigated. However, they might be either limited by the penetration depth of the light, lack efficiency due to constrained availability of reactants or suffer from particle aggregation.
To address these problems, we introduce implantable electrochemical devices for direct current anti-tumor treatment with local ROS generation. On a metal cathode H_2O_2 is produced via $2e^-$ oxygen reduction reaction which ensures sufficient availability of peroxide with simultaneous oxygen deprivation. Concurrently, a metal serves as a sacrificial counter electrode and dissolves due to oxidation. The released metal ions and H_2O_2 react in a Fenton-like way, leading to formation of hydroxyl radicals.
Here, we present a novel platform for local ROS delivery based on the electrogeneration of H_2O_2 and metal dissolution followed by radical formation and show proof-of-concept on a A375 cell line.

5:00 PM SB02.04.08
Membrane Targeted Nanoactuators for Cellular Photostimulation Matteo Moschetta[1], Arianna Magni[1,2], Valentina Sesti[2,1], Giuseppe M. Paternò[2,1], Fabio Benfenati[1], Chiara Bertarelli[2] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Photostimulation has recently attracted interest for its possible application in the biomedical field. Several approaches have been proposed to perturbate cellular activity using light in a spatiotemporal precise manner. Organic semiconductors (films, nanoparticles) and photochromic molecules (azobenzene and its derivates) have been revealed to be able to perturb the plasma membrane electrical properties under light stimulation. Light absorption by these materials can be converted into an electrical, mechanical, or thermal stimuli leading to a change of membrane electrical properties. In this regard, Ziapin2 an amphiphilic alkyl-substituted 4,4'-diaminoazobene was recently developed. Ziapin2 inserts properly in the cell membrane persisting in a cis configuration. The insertion in the membrane and the consequent formation of Ziapin2 dimers lead to a shrinkage of the membrane and an increase of the membrane capacitance. Light stimulation induces a cis-trans isomerization with a significant perturbation of the cell membrane potentials, able to trigger action potential firing in excitable cells without directly affecting local temperature. Moreover, capacitance increase after Ziapin2 portioning in the membrane induces stable changes in cellular physiology even under dark conditions. We propose to modify Ziapin2 to obtain a push-pull molecule able to overcome such limitations. The new molecule, named PP-2Pyr, reveals be more soluble in water to improve its biocompatibility and clearance. The substitution of the amino group with a nitro group increases the red-shift absorption avoiding the need to use UV light, not suitable for applications in living cells. Here, we report a study of PP-2Pyr biological functions, going through biocompatibility assays and electrophysiological characterization using an immortalized cell line (HEK cells) as cellular model of investigation. In accordance with the theoretical design of the molecule, the absorbance/emission spectra display a significant red-shift in PP-2Pyr absorbance with a peak at 517nm and an emission peak at 600nm. The biological investigation reveals that PP-2Pyr are able to enter properly in cells after few minutes of incubation with no evident cytotoxicity at two different concentrations (5 and 10μM) until 5 days after the exposure. In addition, after molecule internalization cells exposed to an acute light stimulation lasting 30s do not display evidence of a significant phototoxicity. We also demonstrated that in cells loaded with the compound, millisecond pulses of visible light induce a transient and defined depolarization of the membrane potential followed by a delayed and slight hyperpolarization. The amplitude of the membrane depolarization is dependent of both the light power density and the molecule concentration. Despite further studies of the push-pull photophysical features and biological behavior are in progress, data so far available indicate PP-2Pyr as a promising tool for photo-excitation of cells for both in vitro and in vivo applications.

5:00 PM SB02.04.09
Poster Spotlight: Electroactive Nanoinjection Platform for Intracellular Delivery and Genetic Editing Ali-Reza Shokouhi[1], Yaping Chen[1], Nicolas Voelcker[1] and Roey Elnathan[2]; [1]Monash Institute of Pharmaceutical Sciences, Australia; [2]Deakin University, Australia

Nanoinjection—the process of intracellular delivery using vertically configured nanostructures—is a physical route that efficiently negotiates the plasma membrane, with minimal perturbation and toxicity to the cells. Despite the implementation of nanoinjection tools and their assisted analogues in diverse cellular manipulations, there are still substantial challenges in harnessing these platforms to gain access into cell interiors with much greater precision without damaging the cell’s intricate structure. Here, we propose a low-voltage, simple, scalable, and reusable electroactive nanoinjection (ENI) platform based on vertically configured conductive nanotubes (NTs) that allows for rapid influx of targeted biomolecular cargos into the intracellular environment, and for successful gene editing. The localization of electric fields at the tight interface between conductive NTs and the cell membrane drastically lowers the voltage required for cargo delivery into the cells, from kilovolts (for bulk electroporation) to only ≤10 V; this enhances the fine control over membrane disruption and mitigates the problem of high cell mortality experienced by conventional electroporation. Through both theoretical simulations and experiments, we demonstrate the capability of the ENI platform to locally perforate GPE-86 mouse fibroblast cells and efficiently inject a diverse range of membrane-impermeable biomolecules with efficacy of ~63% (antibody), ~56% (mRNA), and ~52% (plasmid DNA), with minimal impact on cells’ viability post nanoscale-EP (>90%). We also show gene editing through the delivery of siRNA that targets TRIOBP, yielding gene knockdown efficiency of ~41%. We anticipate that our ENI platform is set to offer a new path to intracellular delivery with broader selection of cargo and cell types, and will open opportunities for advanced *ex vivo* cell engineering and gene editing.

SESSION SB02.05: Biophysics II

Moscone West, Level 2, Room 2011

9:00 AM SB02.05.02
Generating Human iPSC-Derived Neurons on Nanowire Arrays—What is the Impact of Nanowire Length, Diameter and Array Pitch on the Cells? Malte Siegmund[1], Jann Harberts[1], Carina Hedrich[1], Wonjong Kim[2], Anna Fontcuberta i Morral[2], Robert Zierold[1] and Robert H. Blick[1,3]; [1]Universität Hamburg, Germany; [2]EPFL (École polytechnique fédérale de Lausanne), Switzerland; [3]University of Wisconsin-Madison, United States Minor Outlying Islands

Nanowire (NW) arrays interfaced with biological cells have been demonstrated to be potent tools for advanced applications such as sensing, stimulation, or drug delivery. Many implementations, however, have so far only been studied with rather robust basic cell models. Here, the generation of human induced pluripotent stem cell (iPSC)-derived neurons was presented on various types of NW arrays despite the sensitive nature of such cells.[1] Specifically, ordered NW arrays featuring combinations of three NW lengths (1, 3, and 5 µm), three array pitches (1, 3, and 5 µm), and two NW diameters (thin/thick pairs, 270–600 nm/590–1070 nm) were utilized in our study. The geometrical characteristics of the different NW arrays majorly influenced the interaction between cell and substrate. Overall, three interaction regimes were found, namely, fakir-like where the cells only are in contact with the very NW tips, encapsulating where the NWs heavily deformed the cell membrane and the nucleus, and intermediate regimes in between. In general, the induced topographical stress on the cells increased with the NW length. The specific settling regimes of the neurons were predominantly governed by the array pitch. Despite the substantial differences in the cellular arrangement, the cultures showed equal proportions of neuronal marker-positive cells (MAP2, NeuN, TH) after 8–9 days of terminal differentiation on the NW arrays (14–15 days in total) compared to planar controls. In addition, the generated neurons [2] were functional with similar kinetics of the action potentials highlighting the equivalence of the NW arrays for neuronal differentiation and rendering them suitable for advanced applications. The herein presented work expands our previous studies on human iPSC-derived neurons grown on (non-)ordered (spiky) NW arrays.[3],[4] In the future, stem cell research and regenerative medicine might substantially benefit from further functionalized NW arrays enabling the well-established mechanisms such as NW-mediated *in vitro* gene editing or intracellular delivery of biomolecules to further control and/or to enhance neuronal differentiation.

9:15 AM *SB02.05.03
Micro and Nanomechanical Cues in Driving Collective Cell Migration Chwee Teck Lim; National University of Singapore, Singapore

Cells migrating in sheets or large cohorts tend to behave very differently from cells migrating individually, especially under different geometrical features and physical constraints at the micro and nanoscales. Such distinctive behavior of cells migrating in a collective manner underlies several important biological processes such as developmental processes, wound closure, maintenance of intestinal epithelium and cancer metastasis. As such, they can also provide important insights towards better tissue repair, regenerative medicine and even cancer therapy. Here, we characterize the kinematic behavior of epithelial cell cohorts migrating under well defined geometrical and physical confinements in both two- and three-dimensions and at the micro and nanoscales. We also explore the differences in collective cell migration between normal and cancer cells.

9:45 AM SB02.05.04
Mimicking the Cell Signaling Environment with Spatially-Encoded DNA Hydrogels Namrata Ramani, C. Adrian Figg, Alex Anderson, Peter Winegar, EunBi Oh and Chad Mirkin; Northwestern University, United States

Extracellular matrix (ECM) biochemical and biophysical cues play a key role in cellular processes, including cellular proliferation, differentiation, migration, and apoptosis. Yet understanding the specific role among the hundreds of biochemical cues is incredibly complex. Synthetic hydrogels offer a route to recapitulate the ECM through incorporation of user-defined biochemical cues in biologically relevant physical environments. Patterning biomolecules in hydrogels offers a route to visualizing and measuring the role of how spatially organized cue presentation can modulate cell behavior. However, the number of orthogonal bioconjugation chemistries limits the ability to probe the role of many biochemical cues at once. To this end, we have developed a technique for spatially encoding PEG hydrogels with oligonucleotides using thiol-yne photochemistry, where the sequence specificity of DNA enables chemical control over individual patterned domains. Herein we demonstrate that these hydrogels can be rapidly photo-patterned using mask-free digital photolithography with high resolution DNA features (1.5 mm) over centimeter-scale areas, with control over DNA density and feature depth. Moreover, we exploit the sequence dependent properties of DNA to reversibly tether DNA strands, localize protein-DNA conjugates, and bind unmodified proteins with DNA aptamers. Importantly, we observe that localized cell signaling protein-DNA conjugates can selectively activate cells on patterned domains. This work highlights that this approach is capable of isolating biochemical cues allowing one to observe spatially confined cell signaling processes, which may lead to a better understanding, and control, over the complex signaling environments that determine cell fate.

10:00 AM BREAK

10:30 AM *SB02.05.05
Photoacoustic Interface for High Precision Neural Stimulation Chen Yang; Boston University, United States

Neuromodulation at high precision poses great significance in advancing fundamental knowledge in the field of neuroscience and offering novel clinical treatments. Here we reported our research on developing the photoacoustic neural interface based on highly efficient photoacoustic materials and applying them in neural stimulation in vitro and in vivo. Specifically, four different platform technologies with either implantable and noninvasive potentials will be discussed, including fiber based photoacoustic emitters, nanocomposite based photoacoustic films, photoacoustic nanotransducers and optic-generated focus ultrasound (OFUS) based on photoacoustic lenses. Our technologies employ the photoacoustic process, in which pulsed light is delivered into an absorbing layer, generating a localized acoustic wave at ultrasonic frequency. High spatial resolution of sub-millimeter up to single neuron and sub-cellular structures, such as axons and dendrites, have been achieved. Single acoustic pulse of sub-microsecond converted from a single laser pulse of 3 ns is shown as the shortest acoustic stimuli so far for successful neuron activation. Direct photoacoustic stimulation of brain target, electrophysiology recording and behavior responses have been demonstrated in vivo. Specifically, in OFUS, a curved photoacoustic film forms a concave ultrasound lens to achieve the ultrasound focus with a size of 70 micron and a pressure of 21 MPa at the focus transcranially, opening up new opportunities for high precision non-invasive neural stimulation. New insights on the cellar mechanism was obtained using the sonogenetic method. Our work demonstrated that photoacoustic stimulation is a high precision and non-genetic neural stimulation offering various neural interfaces with a non-invasive potential.

11:00 AM *SB02.05.06
Nanoscale Spatio-Mechanical Regulation of the Immune Response in Cytotoxic Lymphocytes Mark Schvartzman; Ben-Gurion University of the Negev, Israel

Cytotoxic lymphocytes – the sentinels of our immune system – differentiate between pathogens and healthy cells by sensing biochemical cues delivered by the ligands expressed on the surface of target cells. Yet, it is becoming progressively clear that lymphocytes also sense physical environmental cues, such as ligand arrangement, mechanical stiffness, and topography. To shed light on this sensing mechanism, we explored the role of the ligand arrangement in the immune function of Natural Killer (NK) cells using nanoengineered stimulating platforms based on patterned arrays of ligands. The first generation of such platforms was based on arrays of nanoimprinted metallic nanodots functionalized with activating ligands. This platform allowed us to discover the minimal spatial requirement of ~ one ligand per sq. micron needed to activate NK cells[1]. The next, more advanced generation of arrays came to examine how the segregation between activating and inhibitory ligands affects the inhibition of activating signaling in NK cells. The platform was based on ordered arrays of nanodots of two metals selectively functionalized with activating and inhibitory ligands, whose segregation was systematically tuned between 0 nm to 40 nm[2]. Surprisingly, we found that inhibition efficiency increased with the spacing between the ligands within the probed range and rationalized this finding by physical modeling of the ligand-receptor binding kinetics.

We also studied the role of environmental elasticity and topography in the function of cytotoxic lymphocytes. Here, we engineered a stimulating platform based on ligand functionalized nanowires. The nanowires deliver chemical, nano-topographical, and mechanical cues, whose combination produces an enhanced immune response of NK cells [3]. While patterned in microdomains, these nanowires spatially guide the cytotoxic activity of NK cells [4]. To separately reveal the effect of each cue, we recently stimulated NK cells and CD8+ T cells on nanowires with varied length and bending moduli and found that these physical parameters of nanowires significantly affect the signaling and the immune function of the lymphocytes [5],[6]. Overall, our work provides an important insight into the way the physical cues regulate the function of NK cells and T cells.

Cellular Recording in Space and Time via Genetically Encoded Protein "Ticker Tapes" Dingchang Lin; Johns Hopkins University, United States

A longstanding goal in biology is to map the dynamics of cell signaling throughout a tissue or organism. Such maps could reveal mechanisms of spatial and temporal patterning, for example in brain activity, embryonic development, or disease progression. Fluorescent protein-based markers are a powerful tool for mapping gene expression. However, optical imaging of fluorescent reporters faces a tradeoff between temporal and spatial information. Imaging in fixed tissue can report organ-wide patterns of gene expression but typically at only one or, at most, two timepoints. Time-lapse in vivo microscopy can report longitudinal gene expression dynamics but only in a small optically accessible region, limited by light-scatter and optical instrumentation, and in vivo imaging typically requires surgery and/or immobilization of the animal. Theoretical analyses have explored the possibility of encoding organ-wide dynamics in DNA or RNA sequences, but, despite progress, such ideas have not yet been realized. Tools to record the dynamics of large numbers of cells, without constraints from in vivo imaging, could transform our ability to study ensemble dynamics in the nervous system and in other tissues. In this talk, I will share with the audience our recent progress in filling this technological gap via engineering a protein-nanostructure-based recording scheme that can store the history of cellular activities locally within individual cells for retrieval at a much later time. As proof of concept, the history of neural activation was written into growing protein assemblies in live neurons at an unprecedented temporal resolution better than 30 min. The genetically encodable nature of the tool also unlocks the capability to record from a large population of cells simultaneously. In all, this tool offers a tenable solution toward organ-wide cellular level activity mapping in space and time, which is hitherto not achievable.

SESSION SB02.06: Drug Delivery

1:30 PM *SB02.06.01
Nanostructures for Probing and Transfecting Living Cells Christelle Prinz; Lund University, Sweden

Interacting with cells in a minimally invasive manner is key to performing longitudinal studies in biomedicine. Nanotubes and nanostraws are increasingly used to transfect cells with better efficiencies and cell viabilities compared to existing transfection methods (liposomes, viral vectors and electroporation) . Here, a review of our work using nanowires and nanostraws for biosensing and transfection will be presented.

2:00 PM SB02.06.02
mRNA Delivery by Laser-Induced Poration Using Porous Silicon Nanoparticles Chantelle Spiteri, Valeria Caprettini, Martti Kaasalainen and Ciro Chiappini; King's College London, United Kingdom

A diversity of physical, chemical and viral methods have been developed to transport membrane-impermeable payloads into the cells leading to great progress in stem cell research, regenerative medicine and therapeutic applications. However, most of these techniques are for bulk poration rather than single-cell resolution; therefore, understanding individual cells remains a challenging platform to explore for tissue engineering and modelling human development *in vitro***.** One of the physical techniques investigated for spatial and temporal control over intracellular delivery is optoporation. Optoporation is a light-mediated technique whereby a high-intensity laser pulse induces transient pores and hence increases the cell membrane permeability allowing exogenous cargo molecules to diffuse and access the cell. Moreover, nanomaterials are used to enhance the coupling of the focused light leading to greater optoporation efficiency and also preserving the cell's viability by reducing the laser energies required for cell membrane permeabilization. Yet, the commonly used nanomaterials for optoporation such as gold and carbon-based nanoparticles are not biodegradable and can be genotoxic limiting their applicability in advanced therapies and modelling.

To overcome these challenges, we fabricated biodegradable and biocompatible mesoporous silicon nanoparticles of approximately 300 nm through electrochemical etching. Assessing the toxicity of the nanoparticles revealed that a 24-hour interaction between MCF-7 breast cancer cells and nanoparticles of concentrations up to 150 µg/mL showed no significant impact on cell death or proliferation. Coupling the nanoparticles with a femtosecond laser at 800 nm resulted in a 40% delivery efficiency of propidium iodide into the targeted cells within a 2D single-cell layer system. This patterned delivery of propidium iodide was also achieved in individual cells making up the 3D cancerous spheroid model. The short-term viability (30 minutes) and subsequently the long-term viability post-optoporation is demonstrated in the 2D system through calcein-AM retention and the transfection and expression of eGFP mRNA respectively. Altogether, we demonstrate that porous silicon nanoparticles coupled with the femtosecond laser in the NIR region attain spatial-selective delivery and expression of the genetic material. Our nano-sensitised optoporation paves the way toward patterned mRNA delivery in a 3D cell system which holds promising potential for biomedical research and cell-based engineering applications.

2:15 PM *SB02.06.03
Biodegradable Silicon Nanoneedles for Ocular Drug Delivery Chi Hwan Lee[1], Dong Rip Kim[2] and Woohyun Park[1]; [1]Purdue Univ, United States; [2]Hanyang University, Korea (the Republic of)

Ocular drug delivery remains a grand challenge due to the complex structure of the eye. Here, we introduce a unique platform of ocular drug delivery through the integration of silicon nanoneedles (Si NNs) with a tear-soluble contact lens. The Si NNs can penetrate into the cornea in a minimally invasive manner and then undergo gradual degradation over the course of months, enabling painless and long-term sustained delivery of ocular drugs. The tear-soluble contact lens can fit a variety of corneal sizes and then quickly dissolve in tear fluid within a minute, enabling an initial burst release of anti-inflammatory drugs. We demonstrated the utility of this platform in effectively treating a chronic ocular disease, such as corneal neovascularization (CNV), in a rabbit model without showing a notable side effect over current standard therapies. This platform could also be useful in treating other chronic ocular diseases.

2:45 PM SB02.06.04
Efficient Non-Viral CAR-T Cell Generation via Silicon-Nanotube-Mediated Transfection Yaping Chen; Monash University, Australia

The advances in engineered nano–bio cellular interfaces—driven by vertically configured nanostructure arrays—have fostered unprecedented progress in modulating and regulating cellular processes at the nanoscale. In particular, nanoinjection has been developed to realize delivery of diverse bioactive payloads into a wide range of cells and tissues both *in vitro* and *in vivo*. Nevertheless, progress has been slow in relation to nanoinjecting primary T lymphocytes, which are central players during adaptive immune responses and hold great clinical potential in fighting diseases including cancer. In particular, chimeric antigen receptor (CAR)-T therapy holds great promise in treating cancer and other diseases; but the current viral-based method raises a significant cost and safety hurdle. In this study, we show for the first time successful CAR transfection into primary T cells via vertically aligned silicon nanotube (SiNT) arrays. By co-culturing with target lymphoma Raji cells, we prove that transfected CAR-T cells can suppress Raji cell growth, indicated by significant increase in effector:target (E:T) ratio (by up to 30.7-fold). SiNT-generated CAR-T cells using non-activated (N_SiNT) T cells perform comparable or even higher lymphoma suppression compared with pre-activated (A_SiNT) T cells, indicating that SiNT-mediated transfection can bypass the requirement of antigen stimulation and preserve higher immune potency. N_SiNT CAR-T cells produce significantly higher amounts of cytotoxic agents, demonstrating stronger inhibition on Raji cells' luciferase expression, compared to their A_SiNT counterparts or those generated by electroporation, particularly with a larger E:T ratio (4:1) and a longer co-culture period (72 h). The results demonstrate the capacity of SiNT-mediated transfection of generating effective anti-lymphoma CAR-T cells. Considering the growing potential of cell-based therapies, we expect that a non-viral nanoinjection platform such as ours will facilitate the full realization of their therapeutic promise.

High Aspect-Ratio Nanostructures for Genetic Engineering Andy Tay; National University of Singapore, Singapore

Background: Chimeric antigen receptor T cell (CAR-T) therapy is a treatment using genetically reprogrammed T cells for cancer immunotherapy. However, it is challenging to transfect T cells with high efficiency while preserving critical biological polyfunctionalities. Viruses and bulk electroporation offer low transfection efficiency, induce aberrant cytokine productions, and delay cell proliferation, leading to less efficacious and more costly treatments. Emerging methods such as nanoparticles suffer from poorly controllable intracellular release of cargo while microfluidics run into high operating costs from use of biomolecule concentrates in continuous flow.

Methods: Here, we describe a high aspect-ratio nanostructure-based method named magnetic nano-electro-injection (MagNEI) platform for T cell immuno-engineering. During MagNEI transfection, localized electric fields transiently open membrane pores of cells magnetically stabilized onto hollow nanochannels. The electric fields then electrophoretically inject DNA into T cells. Once DNA enters the cells, magnetic forces are applied *via* FDA-approved Dynabeads to preferentially transport them into the nuclei.

Results: MagNEI provided up to 90/80/50% delivery efficiency for high molecular weight proteins, mRNA, and DNA. The long-term, stable expression of DNA plasmids was 3-4 folds better than gold standard AAVs and Lonza bulk electroporation. While viruses and Lonza bulk electroporation adversely reduced T cell proliferation by 30% and T cell migration by 80%, MagNEI did not. MagNEI also did not cause significant increase in IL-6 cytokine productions or changes in gene expression relative to untreated control T cells.

Conclusions: Our results demonstrate the technical and biological superiority of MagNEI as a transfection method. We envision that the use of MagNEI platform can overcome transfection difficulties for genetic engineering of primary immune cells to advance CAR-T therapy.

Magnetically-Induced Brownian Motion of Iron Oxide Nanocages in Cells and Their Application for Efficient siRNA Delivery Min A. Kang[1], Justin Fang[1], Aloka Paragodaarachchi[1], Keita Kodama[2], Yuko Ichiyanagi[2] and Hiroshi Matsui[1,3]; [1]Hunter College-CUNY, United States; [2]Yokohama National University, Japan; [3]Cornell University, United States

While nanoparticle carriers have been used widely to deliver therapeutic RNAs for gene therapy, overcoming endosomal escape to enhance transfection efficiency remains a major challenge. Most RNA carriers are trapped in endosomes, fused with lysosomes, and degraded before they can be released into the cytoplasm, which is the major reason of low transfection efficiency.
Lipids have been the golden standard for transfection reagents, and it has been reported that lipid nanoparticles could alter intracellular transport along cytoskeleton and avoid lysosomal degradation due to their random Brownian movement. Thus, we developed the concept that efficient endosomal escape of nanoparticle carriers and the improvement of efficiency of therapeutic reagent delivery could be achieved if their Brownian motion and diffusion could be externally optimized to release them to cytoplasm.
Superparamagnetic iron oxide nanoparticles (SPIONs) can undergo two types of magnetic relaxations in alternating magnetic fields (AMFs). At a certain range of frequencies of AMFs along with specific sizes of SPIONs, the phase difference of the oscillating magnetic moment with respect to the field direction of AMF can be dissipated by either Néel relaxation or Brownian relaxation. Here, we investigated whether superparamagnetic cage-shaped iron oxide nanoparticles (IO-nanocages), previously demonstrated to carry payloads inside the cavity for therapeutic molecular delivery, can be controlled to undergo magnetically-induced Brownian motion, dependent on size at the conventional AMF frequency of 335 kHz. The combination of SQUID (superconducting quantum interference device) measurement and computational simulation of the magnetic relaxation time for superparamagnetic IO-nanocages reveals their size-sensitivity to these two relaxation modes.
The motivation for this application is to trigger endosomal escape by externally-driven Brownian motion of nanoparticles and deliver siRNAs to cytoplasm efficiently. Superconducting quantum interference device (SQUID) measurements reveal the size-sensitivity of Brownian relaxation, and magnetically-driven Brownian motion of IO-nanocages improved siRNA delivery efficiency in cells by reducing luciferase expression to 51% while endosomal membranes were observed to be compromised to release IO-nanocages to cytoplasm in the presence of AMF. This magnetic delivery system was also applied to deliver anti-cancer therapeutic siRNAs, silencing mGluR5 expression in human and mouse osteosarcoma cell lines, and the proliferation of both human and mouse osteosarcoma cells decreased significantly to 20% with the silencing efficiency via magnetic delivery of IO-nanocages. This outcome suggests that this magnetic delivery method can be further used in future clinical applications in cancer therapy, and we are also exploring the applications of IO-nanocages to intracellular mechano-responsive applications such as mechanotransduction with magnetic fields.

4:15 PM *SB02.06.07
Deterministic Mechanoporation for Intracellular Delivery Masaru P. Rao; University of California, Riverside, United States

Microfluidic intracellular delivery approaches based on plasma membrane poration have shown promise for addressing the limitations of conventional cellular engineering techniques in a wide range of applications in biology and medicine. However, the inherent stochasticity of the poration process in many of these approaches often results in a tradeoff between delivery efficiency and cellular viability, thus potentially limiting their utility. Herein, we present a novel microfluidic device concept that mitigates this trade-off by providing opportunity for deterministic mechanoporation (DMP) of cells en masse. This is achieved by the impingement of each cell upon a single needle-like penetrator during aspiration-based capture, followed by diffusive influx of exogenous cargo through the resulting membrane pore, once the cells are released by reversal of flow. Massive parallelization enables high throughput operation, while single-site poration allows for delivery of small and large-molecule cargos in difficult-to-transfect cells with efficiencies and viabilities that exceed both conventional and emerging transfection techniques. As such, DMP shows promise for advancing cellular engineering practice in general and engineered cell product manufacturing in particular.

4:45 PM SB02.06.08
Nanoneedle-Mediated Gene Editing in Epidermolysis Bullosa Fibroblasts Ciro Chiappini, Salman Mustfa, Marija Dimitrievska, Cong Wang, John A. McGrath and Joanna Jackow; King's College London, United Kingdom

Gene therapy can address the unmet clinical need for non-invasive treatments in dystrophic epidermolysis bullosa(DEB), a rare skin disease associated with trauma-induced erosions and blisters, which progress to chronic wounds and cancer. All forms of DEB, whether autosomal dominant(DDEB) or recessive(RDEB), result from mutations in the *COL7A1* gene, which encodes type VII collagen(C7). For RDEB, a small number of early phase gene therapy trials has been reported[1,2] while DDEB treatments are limited. In DDEB, glycine substitutions within the C7 triple helix compromises C7 assembly through dominant-negative interference.

Base editing is a highly effective approach to restore functionality of the mutated allele. The targeted nature of this approach is well suited for gene therapy for RDEB, if supported by an effective delivery strategy. Nanoneedles are a “bed of nail” substrate that interface tightly with cells and the superficial layers of tissues to directly transfer payloads with minimal perturbation of cell function[3]. Intracellular delivery using nanoneedles, known as nanoinjection, yields efficient transfection for a broad range of nucleic acids including RNAs in primary, hard to transfect cells[4] and to the exposed layers of tissues[5]. Nanoinjection is highly biocompatible, with minimal cell toxicity and perturbation of cell function, making it an ideal candidate for efficient base editing in DEB cells[6].

Here we develop nanoinjection for base editing of DEB fibroblasts. Nanoinjection to RDEB fibroblasts is highly efficienct without observable toxicity, providing significant improvement over cationic lipid transfection. We edited fibroblasts form an RDEB patient harbouring the compound heterozygous mutation for c.5047C>T (p.Arg1683*) and c.7344+4G>A (IVS95+4G>A). Our nanoinjection approach of adenine base editing (ABE) targeted the c.5047C>T mutation using conical nanoneedles (5µm height, 600nm base, 20nm tip, 2µm spacing).
The fibroblast cultured on nanoneedles showed retained morphology, high viability and proliferative capacity indicative of good cytocompatibility. We compared the ABE7.10 and ABE8e editors (mRNA + gRNA) targeting the c.5047C>T mutation loaded at different ratios and concentrations of mRNAs and gRNA on nanoneedles, using lipofection as control. Nanoneedles interfaced with the cells delivered the ABEs directly to the intracellular space. At 48h, the optimal editing efficiency for ABE7.10 by nanoinjection was 17%, as compared to 6% by lipofection. When using ABE8e nanoinjection, editing efficiency increased to 46%, resulting in 82% total of the wild-type G allele as compared to 65% for lipofection. The edited cells were expanded to assess C7 production DEJ assembly in organotypic skin models *in vitro*.

Engineering a Nanobiopsy Platform for Non-Destructive Biosensing in Tissue Chenlei Gu[1,2], Davide Martella[1], Cong Wang[1] and Ciro Chiappini[1,2]; [1]King's College London, United Kingdom; [2]London Centre for Nanotechnology, United Kingdom

Nowadays, a broad range of molecular assays, e.g., lipids, nucleic acids, and proteins, designed for cell/tissue samples have been established for basic biology and diagnostics. However, most such assays are destructive, and thus limited in following the dynamics of the underlying processes. Hence, the challenge remains, of monitoring molecular dynamics within live systems over time.

Nanoneedles are arrays of vertical, high-aspect-ratio nanostructures, and thanks to the development of microfabrication technology, both the geometry, structure and flexibility of nanoneedles can be well-controlled and fine-tuned at nanoscale resolution, which serves as versatile platforms for transmembrane delivery and intracellular interrogation. Facilitated by nanobiopsy, which is a non-destructive, controllable and label-free method for capturing and retaining intracellular molecules after interfacing the tissue samples, nanoneedles thus can probe individual biomarkers or small biomarker panels. Moreover, through the repeated sampling of the same cell or regions of tissue, nanoneedles also can provide information on the temporal evolution of their different molecular profiles.

My project aims to develop a pipeline for the non-destructive and longitudinal molecular sampling of living systems using nanoneedles. We have fabricated types of nanoneedles with both opaque and a tunable transparency substrate, explored methodologies for functionalizing nanoneedles for cell access and molecular retention, established the automatic nanobiopsy platform to interface the nanoneedles with tissues in situ, and strategies to retrieve the immobilized intracellular molecules for ex-situ analysis without impacting the tissue. We have tested the nanobiopsy platform in frozen tissue and extended the approach to generate molecular replicas from fixed and fresh live tissues. We have developed staining assays to assess the lipophilic components and nucleic acids in the tissue replicas, and identified the optimal conditions for capturing molecules from the mouse brain.

9:15 AM *SB02.07.03
Longitudinal Single Cell Analysis Enabled by Nanopipettes Paolo Actis, Fabio Marcuccio, Chalmers Chau and Lucy Stead; University Of Leeds, United Kingdom

Physiological and pathological processes within the human body are controlled by complex cell-cell interactions within the context of a dynamic microenvironment. The ability to dynamically measure phenotypes (i.e. gene expression, protein activities, ion fluctuations, signaling) at the single cell level is key to understanding cellular behaviour in a complex environment.
I will present the integration of nanopipettes with scanning probe microscopy techniques to enable the extraction of genetic material from living cells. I will discuss the longitudinal profiling of brain cancer cells to characterize the transcriptional reprogramming at the single cell level after chemotherapy and radiotherapy.

9:45 AM SB02.07.04
NV-Centers Nanodiamonds to Study Oxidative Stress in the Male Germ Line Arturo Elias Llumbet[1,2], Aldona Mzyk[1], Claudia Reyes San Martín[1], Thamir Hamoh[1] and Romana Schirhagl[1]; [1]UMC Groningen, Netherlands; [2]University of Chile, Chile

Nanodiamonds with structural Nitrogen-Vacancy (NV) defects can translate magnetic noise in their surroundings into easily detectable fluorescent signals. This makes them ideal sensors for short-lived free radicals produced in biological systems. Free radicals are a crucial group of Reactive Oxygen Species (ROS) whose quantification offers pivotal insights into oxidative stress-related conditions such as cancer, aging, drug response, and infertility. We use NV-centers nanodiamonds for the magnetometric detection of free radicals at a single-cell level with subcellular resolution. We have successfully applied diamond magnetometry in all the conditions mentioned above. Now, we are focused on the connection between oxidative stress, aging, and male infertility. Various socioeconomic factors have contributed to the established trend in western countries of delaying fatherhood, which is linked to reproductive problems such as subfertility, congenital anomalies, and neuropsychiatric disorders in the offspring. Studies conducted on sperm samples offer a perspective limited to the outcome of age- and oxidative stress-related mechanisms that affect spermatogenesis, completely ignoring what happens to the precursor germ cells of spermatozoa. Germ cells reside inside the seminiferous tubules of the testicles and experience complex differentiation processes that are sensitive to free radicals and other ROS. Using the D-Galactose mouse model of accelerated aging, we studied free radical production in different types of germ cells and also in Sertoli cells, the nurse cells for spermatogenesis. We think that the single-cell reporting capacity of diamond magnetometry applied for the first time to the complex scenario of the male germ line is attractive for the field of Reproductive Medicine and highlights the versatility of nanodiamonds as nanoscale biosensors.

“Brain” on a Chip—Toward a Precision Neuroelectronic Interfaces Hongkun Park; Harvard Univ, United States

Deciphering the brain's functional connectome requires new experimental tools that are sensitive enough to quantify the strength of individual synaptic connections yet also highly scalable to simultaneously measure and control a large number of mammalian neurons with single-cell resolution. In this presentation, I will describe our efforts to combine the advances in nanoscience and semiconductor technology to develop new electronic interfaces that can perform high-fidelity recording and stimulation of thousands of networked mammalian neurons in parallel. The same interface can also be used for multi-parametric functional imaging of other living cells and tissues, enabling fully electronic high-throughput live-cell assays for phenotypic screening. This technology should benefit a broad range of functional interrogations of cell networks and may lead to improved brain-machine interfaces.

11:00 AM SB02.08.02
Seeing the Sound—A Non-Invasive Acoustic Neural Interface Facilitated by Mechanoluminescent Nanomaterials Xiang Wu, Fan Yang and Guosong Hong; Stanford University, United States

Understanding the complex neural circuitry and its correlation to specific behaviors requires spatially and temporally precise modulation of neuron subtypes in certain brain regions. For decades, neural stimulation has predominantly been achieved by traditional electrical stimulation electrodes. More recently, optogenetics, which utilizes visible light to achieve neural modulation by genetically expressing microbial opsins in mammalian cells, has gained great popularity due to its rapid and precise control of neural activities. However, owing to the limited tissue penetration of visible light, invasive craniotomy and intracranial implantation of tethered optical fibers are usually required for *in vivo* optogenetic modulation.

Here, we report a new method termed ‘sono-optogenetics’, which provides non-invasive optogenetic neuromodulation in the brain without any scalp incision, craniotomy, or brain implant. Sono-optogenetics delivers nanoscopic light sources—mechanoluminescent nanoparticles—via the endogenous blood circulation, and provides millisecond-timescale switching of 470 nm light emission for optogenetic neuromodulation via brain-penetrant focused ultrasound. Furthermore, the mechanoluminescent nanoparticles could be recharged by an external photoexcitation light in superficial blood vessels during circulation, enabling repetitive through-scalp optogenetic stimulation and inducing behavioral responses in live mice. Unlike the conventional ‘outside-in’ approaches of optogenetics with fiber implantation, our method, which combines non-invasive ultrasound excitation and intravenous delivery of mechanoluminescent nanoparticles, provides an ‘inside-out’ approach to deliver nanoscopic light emitters via the intrinsic circulatory system and switch them on and off at any time and location of interest in the brain. **This work was published in PNAS (Wu, X. et al. Sono-optogenetics facilitated by a circulation-delivered rechargeable light source for minimally invasive optogenetics. *Proc. Natl Acad. Sci. USA* 116, 26332–26342 (2019)) and was awarded the Science and PINS Prize for Neuromodulation in 2020.**

To further optimize this acoustic neural interface and extend its utility, we developed a biomineral-inspired suppressed dissolution approach to synthesize multicolor mechanoluminescent nanoparticles with diameters down to 20 nm and bright emissions that cover the entire visible spectrum, including $Sr_2MgSi_2O_7$:Eu, Dy (470 nm), ZnS:Cu, Al (534 nm), ZnS:Mn (578 nm), and $CaTiO_3$:Pr (610 nm). We were able to, for the first time, visualize the ultrasound-mediated localized light emission produced by the nanoscopic light source in the vascular systems of multiple mouse organs, including kidney, liver, and brain. Specifically, upon non-invasive transcranial focused ultrasound stimulation, the mechanolumiescence generated inside the brain was sufficient to activate channelrhodopsin-2 (ChR2)-expressing neurons in live mice. **This work was recently published in JACS (Yang, F. and Wu, X. et al. Palette of rechargeable mechanoluminescent fluids produced by a biomineral-inspired suppressed dissolution approach. *J. Am. Chem. Soc.* 144, 18406–18418 (2022)).**

In summary, sono-optogenetics not only represents a non-invasive acoustic neural interface for neuromodulation, but also provides a unique tool of generating localized visible light inside highly scattering biological tissues for many optical biotechniques, such as fluorescence imaging, light-controlled gene-editing, and photodynamic therapy.

Pushing Limits of Neural Electrodes for Intracortical Recording and Stimulation Chong Xie; Rice University, United States

I will present our efforts in ultraflexible neural electrods and recent progress in scaling-up their channel count and density. I will also discuss using these electrodes for recording and stimulation in animal models.

11:45 AM SB02.08.04
Achieving Cell Optostimulation with Membrane-Targeted Molecules Arianna Magni[1,2], Matteo Moschetta[1], Giuseppe M. Paternò[2,1], Chiara Bertarelli[2,1], Luca Beverina[3], Fabio Benfenati[1] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Università degli Studi di Milano-Bicocca, Italy

In the last years, different non-genetic approaches have been proposed to obtain the light-driven modulation of cellular activity. A variety of different photoactive materials can be exploited as photo transducers, converting the light stimulus into a mechanical, thermal, electrical, or chemical stimulus that can be recognized by cells and tissues.

We are interested in using small organic molecules as photoswitches. Molecules have been designed and synthesized to satisfy the following requirements: (i) absorb light in the visible or near-infrared window of the spectrum; (ii) spontaneously and efficiently partition into the lipid bilayers owing to their amphiphilicity, (iii) exhibit low toxicity in dark condition and preferentially also under illumination.

The observation and the evaluation of the photoinduced effects of the different molecules on both HEK-293 cells, primary neurons, and bacteria strains, together with the photophysical characterization of the aforementioned molecules, lead to the identification of different light-driven mechanisms that allow us to control and manipulate the cell activity.

The photoinduced effects observed on cells are found to be related, for instance, to (i) the thinning or thickening of the membrane due to conformational changes in the molecules, (ii) the increase of the membrane permeabilization, and the formation of pore-like structures likely due to the lipid peroxidation following the photosensitization of singlet oxygen within the cell membrane, (iii) the rearrangement of the charges adsorbed to the membrane due to variations in the molecular dipole moment.

Mechanical Memory in Cells Migrating Through Nanostructured Confining Microenvironments Andrew Holle[1,2]; [1]Mechanobiology Institute, Singapore; [2]National University of Singapore, Singapore

The mechanical architecture of extracellular matrix (ECM) presents variable levels of stiffness and confinement to nearly all the cells in the body. Migrating cells are exposed to this confinement during diverse biological processes such as embryonic development, cancer metastasis, and immune cell homing, all of which involve cellular relocation from one mechanical niche to another. During this process, cells are also exposed to nanoscale cues in the form of matrix topography, which can be aligned, orthogonal, or random to the direction of migration. While many studies have explored the cellular response to externally-applied compression, it remains unclear why cells actively decide to enter highly confined spaces. We propose that cells retain mechanical memory of their microenvironmental stiffness, and that this memory plays an active role in their migratory potential. Multiple cell types that show non-permanent responses to substrate stiffness (e.g. cancer cells, fibroblasts) were cultured on soft (1 kPa) or stiff (34 kPa) polyacrylamide hydrogel substrates or glass. Cells were exposed to either 3 or 7 days of mechanical dosing prior to transfer to glass coverslips or into microchannel chips. Microchannel chips were fabricated via a two-step photolithography process that results in microchannels with heights of 10 µm, lengths of 150 µm, and widths between 3 and 10 µm. Nanostructuring of microchannel imprints on silicon wafers was performed to provide parallel, orthogonal, or random nanoscale cues. Cells were then assayed for their ability to spread and migrate on 2D surfaces, as well as interact with and enter confinement in diverse microchannel environments. Mechanically-dosed MDA-MB-231 cancer cells did not show any changes in cell or nuclear morphology after dosing on soft, stiff, or glass substrates. Migration speed and the ability to enter confinement also was unaffected by mechanical dosing. On the other hand, HFF-1 fibroblasts were able to retain a significant mechanical memory of their dosing. HFF cells were found to spread on glass significantly slower when they had been preconditioned on 1 kPa substrates compared to either 34 kPa substrates or glass. This effect was primarily in the initial spreading phase, as cells reached equivalent levels of spread area after four hours. Fibroblasts dosed on soft substrates were also found to migrate significantly faster than those on stiff or glass substrates. Interestingly, the amount of time cells were dosed enhanced this difference in migration speed. While dosing did not affect the overall number of cells interacting with confining microchannels, fibroblasts dosed on soft substrates were able to permeate through both moderate (10 µm) and extreme (3 µm) confinement faster than cells dosed on stiff or glass substrates. As a wide variety of cells must navigate diverse microenvironments, our results suggest that the stiffness of the 'home' niche may convey important mechanical advantages to cells migrating through confining interstitial spaces in vivo, and that this can influence subsequent migration on or through nanostructured surfaces. Future work on the precise cellular transcriptome and machinery found in dosed fibroblasts but not dosed cancer cells will likely reveal clinically relevant information for targeting metastasizing cancer cells.

4:00 PM SB02.10.03
Tunable Superhydrophobic Microwell Array Devices for High-Throughput Culture of 3D Cancer Models Maria Lopez Cavestany[1], Kalana Jayawardana[1], Olivia Wright[1], Noah Reckhorn[1], Tin Nguyen[1], Alberto Esteban Linares[1], Dmitry Koktysh[1], Daryl Briggs[2], Charles P. Collier[2], Dale Hensley[2], Deyu Li[1] and Michael King[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

3D cancer models offer higher physiological relevance than 2D cancer models as they are able to recapitulate tumor architecture with higher fidelity. Products to produce cancer spheroids, such as the Aggrewell800, are available commercially but rely on user coating with an anti-adherence solution, have difficulty forming tight spheroids in some cell lines, and provide only two microwell sizes. Cancer cells are known to cluster in circulation, conferring higher shear and treatment resistance, in addition to increased metastatic potential compared to single cells. Current methods in the literature to produce *in vitro* models of circulating tumor cell clusters or microemboli (CTM) are inconsistent and lack the ability to control cluster size. The goal of our study was to utilize microfabrication techniques to design a chip with tunable microwell array and a superhydrophobic surface at the bottom to achieve a device that can produce a range of 3D cancer models. Two different superhydrophobic array devices (SHArD) have been implemented to reliably culture a spheroid model (SHArD-S) and a CTM model (SHArD-C) *in vitro.*

Superhydrophobic surfaces were fabricated by spin coating a ZnO nanoparticle solution in MQ water onto a 3" Si wafer. Wafers were annealed and then baked at 90C for 4 hr while submerged in a zinc nitrate hexahydrate and HMTA bath to grow nanorods. ZnO nanorod thin film was characterized via SEM to be highly uniform and reproducible. The nanorods were randomly oriented on the wafer surface and had an average length of 500µm. Width ranged from 40nm to 100nm, corresponding to the size of the initial nanoparticle powder. Ultrathick SU8 lithography was performed for the SHArD-S to obtain a microwell wall height of about 400µm with an aspect ratio of 3. Lines were spaced 800µm apart resulting in square sections of 650x650µm^2. For the SHArD-C, the adhesion promoter OmniCoat was spin coated onto the wafer surface. SU8 lithography was done to create a 75µm thick grid, resulting in 100 x 100µm^2 microwells. The final step for both devices was to deposit a layer of non-adherent polymer via C_4F_8 plasma polymerization in an Oxford PlasmaPro100. Coating was confirmed to be homogenous and maintain surface nanoroughness via SEM and water contact angle (WCA) measurements. The static WCA of the nanorods coated with the non-adherent polymer was 167°. The dynamic WCA were 165.2° and 168.6° for the advancing WCA and receding WCA, respectively. Microfabrication processes and characterization were carried out at the VINSE cleanroom and the CNMS cleanroom at Oak Ridge National Laboratories.

For spheroid formation, the colorectal cancer cell line HCT116 was plated for 4 days with in the microwells at 2.5k, 5k, and 7.5k cells per microwell in the SHArD-S and the Aggrewell800 for comparison. Spheroids were observed via confocal microscopy by staining with DAPI to quantify compactness. Spheroids cultured in the SHArD-S were significantly less round and more compact than those cultured in the Aggrewell800, more closely resembling tumors in the body. Additionally, spheroids were exposed to physiologically relevant fluid shear stress (FSS) of 188 s^{-1} using a cone-and-plate viscometer to assess cell:cell adhesion stability. Spheroids grown in the Aggrewell 800 plates displayed a large decrease in cross-sectional area after FSS, while those grown in the SHArD-S showed no significant change in cross-sectional area. For CTM formation, HCT116 cells were plated for 48hrs in the SHArD-C at 3, 5, and 7 cells per microwell. Brightfield microscopy showed that CTM size was easily controlled by varying plating density of the cells within each microwell. CTMs grown in the SHArD-C did not disaggregate when exposed to FSS in a cone-and-plate viscometer. We thus provide a novel method to reliably produce highly tunable 3D cancer models from cancer CTMs to cancer spheroids, allowing one to simulate cell:cell interactions throughout the metastatic cascade.

Three-Dimensional Transistor Arrays for Cellular Recording Sheng Xu; University of California, San Diego, United States

Recording cellular electrical activities is critical for understanding pathologies and better therapeutic outcomes. This field is currently limited by the tools available for recording the cells. Existing techniques are either lack of accuracy or unable to scale up to record multiple cells simultaneously. In this presentation, I will show a vertically aligned needle-shaped field effect transistor array. I will go through its fabrication strategies, discuss the electrical characterizations, and demonstrate its use in interfacing cultured cells and organoids. Using the transistor array, we were able to directly record signal transport within one cell and among a cellular network, with high spatial and temporal resolutions. Those results hold implications for a wide range of fundamental studies and clinical applications.

9:00 AM SB02.11.02
Direct Recording of Action Potentials of Cardiomyocytes Through Solution Processed Planar Electrolyte-Gated Field-Effect Transistors Mario Caironi[1], Adrica Kyndiah[1], Michele Dipalo[1], Alireza Molazemhosseini[1], Fabrizio A. Viola[1], Francesco Modena[1], Giuseppina Iachetta[1], Nicolas F. Zorn[2], Felix J. Berger[2], Jana Zaumseil[2] and Francesco De Angelis[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Universität Heidelberg, Germany

Minimally invasive recording of intracellular action potentials in electrogenic cells is in high demand. Most of present electrical probing tools are either invasive or require complex manufacturing processes. With the aim of enabling a cost-effective, non-invasive probing platform based on devices that can be easily fabricated and processed from solution with large-area printing techniques, we propose planar Electrolyte Gated Field-Effect Transistors (EGFETs) based on solution-processed carbon nanotubes. Remarkably, despite the planar geometry of the device, we could demonstrate the spontaneous recording of intracellular action potentials of human induced pluripotent stem cells derived cardiomyocytes. The simplicity of the device combined with the high signal to noise ratio opens up new opportunities for low-cost, reliable, and flexible biosensors and arrays for high quality parallel recording of cellular action potentials.

Probing Retinal Electrophysiological Activities with Graphene Electrodes-Based Microfluidic Perforated Microelectrode Arrays Alberto Esteban Linares[1], Xiaosi Zhang[1], Hannah Lee[2], Michael L. Risner[2], Sharon M. Weiss[1,1], Yaqiong Xu[1,1], Edward Levine[2,1] and Deyu Li[1]; [1]Vanderbilt University, United States; [2]Vanderbilt University Medical Center, United States

Microelectrode arrays (MEAs) have revolutionized electrophysiological studies of the central nervous system (CNS) by simultaneously recording electrical activities from a population of neurons. Studying retina, a key component of the CNS, with traditional MEAs is challenging due to the strong curvature of the tissue, which prevents intimate contacts between the retina and electrodes, resulting in poor signal-to-noise ratios (SNR). Perforated MEAs (pMEAs) alleviate this issue by patterning the electrode array on a perforated flexible polyimide substrate placed on a fluidic chamber. Negative pressure can be applied from underneath the substrate to gently pull the retina towards the electrode layer to increase the contacts between the tissue and electrodes, therefore improving the SNR. In addition, it has been demonstrated that pMEAs enhance oxygenation of the bottom cell layer of the tissue as more fresh media perfuse through the tissue, allowing for long-term culture.
The large chamber height (1-2 mm) underneath the polyimide layer in commercial or reported custom-made pMEAs renders in-situ high-resolution optical imaging impossible. In addition, the chemical environment in pMEAs is traditionally regulated by bath perfusion, which limits the control of the microenvironment and hinders the possibility of local chemical stimulation. Developing platforms that combine these capabilities could be highly beneficial to unlock crucial information of retinal neuronal circuitry, understand response to different drug stimulations, and develop therapeutic strategies for retinal diseases.
In this work we report on microfluidic pMEAs (μpMEAs) that combine the capability of locally delivering chemical stimulations and high-resolution optical imaging through transparent graphene electrodes to study the response of retinal ganglion cells (RGCs) to different chemical probes. We demonstrate the potential of μpMEAs by measuring different RGC responses to locally delivered high K^+ stimulation through a restricted delivery channel. Results show correlated response from RGCs detected by electrodes located on and off the delivery channel. This coherent response was demonstrated to be mediated by intracellular communications through gap junctions that connect neighboring RGCs. Importantly, transparent graphene probes allowed for high-resolution confocal imaging of neuronal processes on top of the sensing electrodes. We expect that the μpMEA platform could enable novel retinal electrophysiological assays.

Dimensionality and Dynamicity Matters in Bioelectronic Interfaces Francesca Santoro; Forschungszentrum Jülich/RWTH Aachen University, Germany

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. For instance, electroactive materials in contact with cells can have very different composition, surface topography and dimensionality. Dimensionality defines the possibility to have planar (2D), pseudo-3D (planar with nano-micropatterned surface)[1] and 3D conductive materials (i.e. scaffolds) in bioelectronics devices. Their success for both *in vivo* and *in vitro* applications lies in the effective coupling/adhesion of cells/tissues with the devices' surfaces. It is known how a large cleft between the cellular membrane and the electrode surface massively affects the quality of the recorded signals or ultimately the stimulation efficiency of a device. In fact, the shapes of these newly designed electrode recalls those features of neuronal cells to ultimately induce biomimetic recognition. Furthermore, conductive materials that exhibit dynamic properties might better recapitulate the native environment of tissue. However, engineering such new platforms still require materials synthesis, integration into microfabricated platforms and stable cell interfacing. Here, we propose a new class of conductive materials which resemble the biomimetic architecture of neurite and dendritic spines and also can undergo dynamic reshaping. The cell response can be monitoring and eventually is adapting to the substrate changes over time. These new electrodes can pave the way to adaptive microdevices of use in bioelectronic application such as electrophysiology and sensing.

11:00 AM SB02.11.06
Conductive Thiophene-Based Fibers Synthesized by Living Cells as Novel Bioelectronic Materials Ludovico Aloisio[1,2], Guglielmo Lanzani[3], Giuseppe M. Games Paternò[4], Francesca Di Maria[4] and Matteo Moschetta[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Politecnico di Milano / Istituto Italiano di Tecnologia, Italy; [4]Institute of Organic Synthesis and Photoreactivity (ISOF)-CNR, Italy

In recent years, it has been observed that living cells can be employed as active synthesis platforms for the assembly of intrinsically biocompatible bioelectronic materials. This process, which lies at the interface between living and non-living matter, is of fundamental interest since self-assembly *in vivo* could allow to circumvent brain-blood barrier and deliver large aggregates or even devices to the brain. Within this context, thiophene-based compounds represent workhorse materials for organic bioelectronics, owing to their biocompatibility and to the possibility to afford both electronic and ionic conduction.
Here, we report about the cell-mediated assembly of semiconductive nanofibers based on dithienothiophene-S,S-dioxide (DTTO) derivatives. We found that fibers originate inside cells and grow also "through" them, reaching and piercing the plasma membrane in one cell to penetrate the adjacent cell, without killing them. We extensively characterized the photophysics of DTTO molecules during the various steps of fibers production through steady state and time-resolved spectroscopy. We report the presence of DTTO aggregates inside the fibers, which represent the conductive domains of the nanostructured material and describe the interaction between DTTO molecules and the protein scaffold. By complementing the spectroscopic data with XRD characterization and electrical conductivity measurements, we discovered an extended polymorphism of DTTO in solid state. Our results suggest that the aggregation occurring in living cells is somehow unique of the biotic phase, and it involves at least part of the cell machinery. As fibers show electrical conductivity, they represent a way to directly stimulate cells or to induce artificial gap-junctions between cells, possibly affecting signal propagation as occurring in cardio-myocytes or in general to affect cell population behavior.
Further studies on the fibers' production process are in progress, with the aim to open the way to a wide range of new protein-based materials for bioelectronics and cell photostimulation.

11:15 AM SB02.11.08
3D Generation of Bio-Suited Advanced Atomic Force Microscopy Probes—Broader Venues for AFM Biological Applications Ayoub Glia[1], Muhammedin Deliorman[1] and Mohammad A. Qasaimeh[2]; [1]New York University Abu Dhabi, United Arab Emirates; [2]New York University, United States

Fabrication of Atomic Force Microscopy tips still commonly relies on 2D micromachining of brittle silicon-based materials, thus imposing limitations on the design of the 3D tip structures, and their functionality in a range of bio-suited applications. In our previous work, we deployed two photon polymerization technique for generating biocompatible polymer-based AFM tips (3DTIPs) with great flexibility in design and function. We have demonstrated that, when compared with conventional silicon tips, the 3DTIPs prove effective in obtaining high-resolution, high-speed AFM images with common AFM modes and under ambient and liquid conditions. In particular, the 3DTIPs provide wide tuning range and high dynamic mode scanning speeds due to their extremely low Hamaker constant and reduced quality factor, two important features for advancing AFM imaging. We have also demonstrated that, 3DTIPs are useful for biological experiments that require soft tip-sample interaction with minimal bio-contamination on the tips. In this work, to further advance the 3DTIPs technology, our focus is directed toward biological applications that are deemed impossible or challenging using the conventional silicon tips. For instance, the flexibility of tip designs in 3D facilitates generation of 3DTIPs with horizontally aligned probes. With these probes, various applications can then be exploited in a creative and useful way, such as laterally "moving" cells to a fixing structure, performing sideway cell indentation, and with high aspect ratio tips, cell puncturing/lysing. Furthermore, the softer nature, low Hamaker constant, and superior high-speed imaging capabilities of 3DTIPs give rise to other novel 3D tip designs that suite better for prolonged and "gentle" molecular-level probing of cell viscoelastic and adhesion properties, mapping cell membrane carbohydrates, and real-time quantification/sequencing of DNA at varying spatiotemporal resolutions. The vision of this work is to expand AFM functionality from a mere sensing/imaging tool, to one with manipulation capacities at the nanoscale. This is achieved by developing, in 3D, unique AFM probe designs capable of precise manipulation of bio-samples, from whole cells down to biomolecules. In sum, we foresee those multifunctional capabilities of the 3DTIPs could outperform conventional silicon tips in several biological applications, and open doors for novel functionalities.

Atomic Layer Deposition of Inorganic Charge Transport Layers for Metal Halide Perovskite Photovoltaics Mariadriana Creatore; Eindhoven University of Technology, Netherlands

In the past decade, major progress has taken place in the field of metal halide perovskite photovoltaics (PV), as witnessed by the recently achieved conversion efficiency of 25.7% [1] and the concrete opportunities to go beyond the thermodynamic conversion efficiency limit of single junction PV by means of perovskite/ crystalline silicon tandem PV. Among the most recent efforts towards further development of perovskite PV and subsequent commercialization, strategies ranging from perovskite surface passivation and compositional engineering to thin film encapsulation, contribute to suppress the perovskite absorber and device instability to moisture ingress. In parallel, research efforts are presently dedicated to the replacement of organic charge transport layers (CTLs) such as poly[bis(4-phenyl)(2,4,6-trimethylphenyl)amine (PTAA), [6,6]-phenyl-C61-butyric acid methyl ester (PCBM) or C60, by inorganic CTLs, in order to address other challenges towards device large area processing and commercialization, such as thermal and mechanical device stability, as well as device efficiency yield.
In this contribution, our recent research on atomic layer deposited (ALD) selective CTLs for metal halide perovskite PV [2] is reviewed by addressing two case studies, namely, SnO_2 thin films, selective towards electron transport, and NiO thin films, selective towards hole transport. ALD is selected as deposition technology because of its merit of ultimate control over film thickness and conformality.
ALD SnO_2 [3], based on cycles of tetrakis(dimethylamido)-tin and H_2O as precursor and co-reactant, respectively, is the state-of-the art in both p-i-n perovskite single junction as well as tandem perovskite/crystalline silicon and perovskite/CIGS PV. Its presence is key to the device thermal and mechanical stability, to prevent humidity ingress in the device and suppress damage to the fullerene (PCBM or C60) during the sputtering of the transparent front contact.
ALD NiO [4], based on cycles of bis(methylcyclopentadienyl)nickel and H_2O as precursor and co-reactant, respectively, is found to impart stability to the perovskite device under acceleration test at 85°C, with 80% retention of the initial conversion efficiency after 300 hours at 1 sun illumination. Moreover, when NiO thin (7 nm) films are combined with the state-of-the art hole transport layer in p-i-n devices, i.e., the phosphonic acid-based self-assembled monolayer (SAM), the photovoltaic device exhibits higher thermal stability in comparison to the SAM only-based device. Furthermore, the SAM homogeneity and surface coverage on NiO improve, as witnessed by transmission electron microscopy (TEM) and conductive atomic force microscopy. This result is explained in terms of chemisorption reactions between SAM phosphonic acid groups and NiO hydroxyl groups. The SAM homogeneity on NiO leads to higher shunt resistance in the device with respect to the one with SAM directly processed on ITO. Moreover, the combination of NiO and SAM results in a narrower distribution of device performance reaching more than 20% efficient champion device.

Correlation between Defect Type, Doping Level and Schottky Barrier in Hexagonal WS_2 Jungchun Kim[1], Gwang Hwi An[2], Dong Geun Park[1], Donghyun Kim[1], Seoyeon Choi[1], Kiseok Heo[1], Sanghyeok Kim[1], Inkyu Yoon[1], Hyun S. Lee[2] and Jae Woo Lee[1]; [1]Korea University, Korea (the Republic of); [2]Chungbuk National University, Korea (the Republic of)

One of the representative two-dimensional (2D) materials, transition metal dichalcogenides (TMDs) have been widely studied for next generation device application. To realize the high-performance device application of 2D TMDs, it is necessary to understand not only the metal/channel interface related to SBH and contact resistance (R_C) but also properties of channel material. Previous studies approach channel material doping and defect engineering at interface. However, it has not been reported how the defect types and doping concentration of TMDs control the device characteristics on same material.
We investigated the various characteristic analyses depending on two different defects region in a single flake of hexagonal WS_2 FETs. Through photoluminescence (PL) intensity mapping and Raman frequency mapping, it was confirmed that the sulfur vacancy (SV) and the tungsten vacancy (WV) had distinct regions in a single hexagonal WS_2.
Various electrical characteristics on the SV FET and the WV FET at 300 K were compared. In the I_d-V_g characteristics, the SV FET had lower threshold voltage (V_{th}) and approximately 6 times larger I_d at V_g =60 V than those of the WV FET. On/off ratio of the SV FET had 5 times larger than that of the WV FET. Difference in current was originated from conductivity of each defect region. Using each channel conductivity to extract doping concentration (n) of the SV and WV FETs, they had values of $1.29*10^{19}$ cm^{-3}, and $1.44*10^{18}$ cm^{-3}, respectively. Difference in the doping concentration may affect the effective SBH between the SV and WV FETs.
Through the low frequency noise characteristics, the magnitude of the power spectral density (PSD) of the SV FET was approximately 5 times higher than that of WV FET. Normalized PSD of the SV and WV FETs was well fitted by carrier number fluctuation with a correlated carrier mobility fluctuation (CNF+CMF) model. The trap density (N_t) and Coulomb scattering coefficient (α) of the SV and WV FETs were extracted by CNF+CMF model. The N_t of the SV and WV FET was similar with the values of $3.2*10^{20}$ cm^{-3}eV^{-1} and $4.0*10^{20}$ cm^{-3}eV^{-1}, respectively. However, the α related to Coulomb scattering impurity densities of the SV FET ($7.7*10^7$ VsC^{-1}) had 4 times higher than that of WV FET ($2.0*10^7$ VsC^{-1}). Because of the reduced channel dimensionality, α for the SV and WV FETs was determined by the carrier density n. Therefore, the SV FET with higher doping concentration had larger α than that of WV FET.
Temperature dependent activation energy (E_a) and SB characteristics for the SV and WV FETs were analyzed according to temperature (300 K – 420 K). In the Arrhenius plot for on current, the trend of E_a for SV and WV FETs was different from 360 K. In high temperature (360 K – 420 K), the E_a of the SV and WV FET was similar as 53 meV and 57 meV, respectively. Before 360 K, the E_a of WV FET had 115 meV, twice that of high temperature region, while the SV FET had a similar 71 meV. In other words, the SV FET was operated without a change in the carrier transport mechanism at the metal-channel interface. However, in the WV FET, the main carrier transport mechanism was changed at 360 K. The SV FET with a higher doping concentration

became sharper and narrower SBH than the WV FET. The current of the SV FET flowed well through tunneling at all temperatures. In contrast, most of current was dominant on the external energy because of relatively thicker and higher SBH in the WV FET.
In this study, we compared the various characteristics on SV FET and WV FET in a hexagonal WS_2 FET. Since the SV and the WV have different doping concentration within single material, it is highly look forward to studying the various electronic device application using hexagonal WS_2.

Elucidating the Surface Adsorption and Substitution Reaction Mechanism of a Heteroleptic $CpZr(NMe_2)_3$ Precursor in Atomic Layer Deposition
Choi Aerim and Il-Kwon Oh; Ajou University, Korea (the Republic of)

With the miniaturization of electronic devices, high-k dielectric materials replacing SiO_2 are being intensively studied to improve leakage current characteristics. Understanding the surface reactions and chemistry of precursor molecules during atomic layer deposition (ALD) has played an essential role. Chemical precursors and reactants contribute significantly to ALD thin film properties. So far, various Zr precursors for ZrO_2 thin films have been studied for the ALD process. Among them, the widely used precursor type is the heteroleptic precursor because the structure can improve the vapor pressure and tune the Lewis acidity of the precursor. However, the surface reaction of heteroleptic precursor molecules requires more attention to understand because the reaction pathway is different for each ligand exchange reaction.
In this study, we used a commercially used $CpZr(N(CH_3)_2)_3$ precursor for the high-k layer of dynamic random access memory (DRAM) by providing low impurities and good conformability with other reactants in H_2O and O_2 plasma. The surface reaction mechanism regarding the ZrO_2 growth and its dependence on impurity incorporation has been elucidated based on the results of quantum chemistry calculations. In addition, chemical composition, surface roughness and microstructural analysis by electron microscopy and X-ray techniques were introduced. The correlation between experimental observations and theoretical calculations was studied using density functional theory (DFT) ; 1) 1st half reaction in a cycle : When $CpZr(N(CH_3)_2)_3$ precursor reacting with OH groups on the substrate surface, it is highly likely to react with 2 $-N(CH_3)_2$ out of 4 ligands, 2) 2nd half reaction in a cycle: showed that the reaction pathway of Zr–Cp ligand exchange ligands is less favorable than that of $Zr–N(CH_3)_2$. In addition, defects and impurities appearing because the reaction between Cp ligands and H_2O molecules is less effective than alkylamide ligands degrade device performance. In contrast, we used O_2 plasma to dramatically remove all ligands, improving the leakage current and dielectric properties of ZrO_2 thin films. We believe that these findings on the surface reaction of heteroleptic ALD precursors will be helpful for future miniature semiconductor devices.

11:30 AM SB03.01.04
Broad-Range Tuning of Plasma Polymer Composition and Stability Using Plasma-Assisted Vapour Thermal Deposition Zdenek Krtous[1,2], Jaroslav Kousal[1], Pavel Solar[1], Jan Hanus[1], Lenka Hanykova[1], Ivan Krakovsky[1] and Suren Ali-Ogly[1]; [1]Charles University, Czechia; [2]Polytechnique Montréal, Canada

The Plasma-Assisted Vapour Thermal Deposition (PAVTD) is a plasma polymerization technique utilizing a classical polymer in powder or granular form ("precursor") which is heated and evaporated (and/or thermally fragmented) in the crucible under low pressure. The released fragments (effective a "monomer" produced in-situ) of an unusually high mass for PECVD/plasma polymerization (5-100 monomeric units) are then repolymerized in the RF plasma. The high molar mass of the monomer leads to an interesting competition between the fragmentation ("top-down" process) and repolymerization ("bottom-up" process). Influence of these processes on the chemical composition and structure i.e. density of crosslinking can be controlled by the intensity of the RF plasma, effectively bridging the gap between classical polymers and PECVD films [1]. The possibility to tailor the macromolecular structure of these films leads to the ability to control the water solubility of the films from the films washable in the range of seconds up to insoluble films [2]. Such films can be used as barrier layers for drug delivery systems.
Currently, the PAVTD method has several drawbacks compared with PECVD. Since the capacity of the crucible is limited, the deposition must be done as a batch process. The thermal release of the precursor fragments is highly temperature-sensitive. The resulting fluctuations in deposition rate make retaining good reproducibility of the process rather tricky. To overcome these technical limitations, a continuous process inspired by the Fused Deposition Modelling (FDM) 3D printing technology is investigated. The polymer precursor is continously fed into a crucible in a filament form, that is readily available for various polymeric materials like polylactic acid (PLA) or polyvinyl acohol (PVA). In comparison with a batch PAVTD, improved control of the release of material from the crucible leads to significantly better deposition rate stability even at order of magnitude higher deposition rates (over 1 nm/s).
The ability of PAVTD to tune the resulting film properties (similarity to original polymer or solubility) will be demonstrated both for batch and contiunous version of the process.

Open-Air Spray-Plasma Deposition of Low Water Vapor Transmission Rate Multilayer Moisture Barrier Characterized Using Calibrated Infrared Imaging Ziyi Pan and Reinhold H. Dauskardt; Stanford University, United States

Emerging optoelectronic devices often require moisture barriers to prevent water ingress. While a variety of methods exist to limit moisture ingress including glass/glass encapsulation and multilayer films produced in vacuum environments, they present disadvantages in terms of rigidity, weight, cost and method of application. A rapid, conformal, and low-cost barrier coating method that can be applied in open-air for moisture barrier protection presents an attractive opportunity. A compounding aspect of barrier evaluation is the need for a both accurate and high throughput methodology. Existing calcium test and permeation methods for evaluating the water vapor transmission rate through moisture barriers while accurate surfer from low-throughput and the need for complex fabrication process or vacuum permeation chambers.

In this work, we show the development of multilayer moisture barrier deposited in the open-air and demonstrate a rapid testing methodology to measure the barrier efficacy. A scalable, open-air plasma process has been developed to deposit alternating layers of inorganic SiO_2 thin film and conformal organosilicate film barriers to prevent moisture ingress. The inorganic layer effectively blocks moisture ingress and the organsilicate layer decouples any pinhole defects in the inorganic layer. For moisture barrier efficacy evaluation, we developed a new testing methodology for water vapor transmission rate (WVTR) testing relying on infrared imaging at water absorption bands. The technique uses calibration of image intensity with moisture content in the polymer substrate and determination of water content that permeated inside the barrier substrate from images taken at different times.

A multilayer alternating barrier films with 900nm achieved WVTR on the order of 10^{-4} g/m^2/day at an accelerated aging condition of 38°C and 90% R.H., with transparencies ranging from 99% to 78% depending on the number of layers.[1,2] An infrared imaging system was developed to measure the performance of ultrahigh moisture barriers to a lower limit of detection of 5 *10^{-5} g/m^2/day, on par with commercial permeation instrumentation.[3] The ability of the rapid deposition of high efficacy multilayer moisture barrier in open-air as well as the non-destructive and in-situ evaluation of its efficacy enabling device resistance to humid environments is crucial towards realizing longer operating lifetimes.

Modelling the Key Reaction Steps for Plasma-Enhanced and Thermal Atomic Layer Deposition of Cobalt Thin Film for the Next Generation Interconnect Ji Liu and Michael Nolan; Tyndall National Institute, Ireland

Cobalt (Co) is a potential material in semiconductor industry due to attractive electrical, mechanism and physical properties. The replacement of Cu with Co as conductive contacts or interconnects in integrated circuit (IC) devices serves as an illustrative example and is an ongoing process driven by large IC device manufacturers. Atomic layer deposition (ALD) is widely used in microelectronics and semiconductor industry to deposit thin films as part of device fabrication in nano- or subnano-dimensions. The key advantages of ALD are the conformality and precise thickness control at the atomic scale, which are difficult for physical or traditional chemical vapor deposition methods. Two types of ALD are usually applied, which are plasma-enhanced ALD (PE-ALD) and thermal ALD. In this study, we present our recent studies on modelling the chemistry and reaction mechanism of (1) PE-ALD of Co thin film[1] using $CoCp_2$ and N-plasma (NH_3 or mixture of N_2 and H_2), and (2) thermal ALD of Co[2] using $CoCl_2$(TMEDA) (TMEDA = N,N,N′,N′-tetramethylethylenediamine) and $Zn(DMP)_2$ (DMP = N,N-3-(dimethylamino)propyl).
For the PE-ALD of Co, we first addressed the surface reaction mechanism at the metal precursor pulse and plasma half-cycle on NH_x-terminated Co (001) and (100) surfaces, which corresponds to the steady growth region. The (001) surface of both metals, with a hexagonal structure, is the most stable and the (100) surface with a zigzag structure is less stable but has high reactivity. These two surfaces allow the study of the influence of the surface facet. We studied the surface saturation coverages of NH and NH_2 and the results are then analyzed with ab initio thermodynamics by calculating the Gibbs free energy. Both the ultra-high vacuum (UHV) condition and standard ALD operating condition are used to elucidate the effect of pressure and temperature on the termination of metal surfaces.
At the metal precursor step, the adsorption and reactions of metal precursor $CoCp_2$ on NH_x terminated metal surfaces were investigated with the inclusion of van der Waals corrections. The plausible reaction pathways include: precursor adsorption, hydrogen transfer, CpH formation and CpH desorption. The direct Cp dissociation mechanism is not considered on these NH_x-terminated metal surfaces due to experimentally observed minimal C impurities at the deposited metal thin films, which indicates that most of the Cp ligand is removed completely. The barrier for proton transfer was calculated using climbing image nudged elastic band (CI-NEB) method. Our results show that (100) surface has higher activity than (001) surface. Our study highlights the role of surface facets on the growth mechanism.
For the thermal ALD, our experimental collaborators found out that the deposited Co thin film is metallic and Zn-free. The self-limiting behavior for $CoCl_2$(TMEDA) at 155°C and a fixed $Zn(DMP)_2$ pulse length of 5s were observed after 6s with a GPC of 0.3Å. Our DFT calculations indicate that the reactions proceed via initial ligand exchange of DMP and Cl on Co(111) surface with $CoCl_2$ termination and Zn is removed via ZnCl(DMP) formation and desorption, resulting $Co(DMP)_2$ termination on the surface. The two DMP ligands are removed via C-C bond formation in a straightforward way. Our simulation results are in consistency with experimental findings and this work offers a facile ALD method to deposit Co metal thin film.

2:00 PM SB03.02.03

Optical and Electrical Stability of Single-Layer Indium Oxide Thin-Film Transistors Fabricated Using Atomic Layer Deposition with a Novel Indium Precursor (SBIP-03) Ju-Hun Lee[1,2], Seung-Youl Kang[1], ChangBong Yeon[3], Jong-Heon Yang[1], Jaesun Jung[3], Chi-Sun Hwang[1] and Jaehyun Moon[1,2]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]University of Science and Technology (UST), Korea (the Republic of); [3]Soulbrain Co.,Ltd, Korea (the Republic of)

Indium oxide (IO) thin-film transistors have been attracting attention due to their high-mobility electrical properties. For this reason, it has been widely studied as a promising channel material for next-generation display backplanes. However, driving TFTs are frequently exposed to harsh environments such as backlight and continuous electrical stress, which can hamper circuit operation. These tough conditions affect not only the performance degradation of TFTs but also the reduction in lifespan. In conjunction with exploring compositionally simplified oxide semiconductors, we examined the stability issues of TFTs having 5 nm thin indium oxide channel. Technical reports on TFTs stability having single layer binary oxide as a channel are rather lacking. In this work, we present a novel liquid precursor of (N, N-di-tert-butylacetimidamido)dimethyl indium, SBIP-03) for atomic layer deposition. The optical stability was examined using three primary colors Red (λ = 633 nm), Green (λ = 520 nm), and Blue (λ = 463 nm) under various exposure times. Also, the electrical stability characteristics were evaluated under negative bias stress (NBS) and positive bias stress (PBS) conditions for the channel length from 5 to 160 µm in the stress time range of 0 to 1000 s. Devices showed stable operation under red and green exposure. Under blue light exposure, the transfer curve was observed to shift – 0.2 V. Stable transfer and output characteristics were obtained regardless of NBS, PBS, and channel length.

Quantitative Analysis of Interfacial Defects in Oxide Films and Electrical Devices Using Nonlinear Optics Hyunmin Hong, Min Jung Kim, Dong-Joon Yi, Dong Yeob Shin, Kwangsik Jeong and Kwun-bum Chung; Dongguk University, Seoul, Korea, Korea (the Republic of)

Transparent oxide-based thin-film transistors (TFTs) have attracted much attention due to their excellent electrical and optical characteristics. In particular, amorphous indium gallium zinc oxide (a-IGZO) TFTs have shown a better threshold voltage (V_{TH}) and field-effect mobility (μ_{FE}) due to the lack of grain boundaries, making this type of transistor a very promising alternative to an amorphous silicon TFT (a-Si TFT). In fabricating the a-IGZO-based TFTs, IGZO is deposited widely using magnetron sputtering. This technique generally provides such benefits as high deposition rates and has low processing temperatures. Therefore, IGZO has great potential to replace the existing silicon-based semiconductors and organic-based semiconductors that are employed as an active layer of the TFT backplane in the flat panel display. However, despite these merits, magnetron sputtering occasionally results in lower TFT performances due to the increase in surface morphology roughness.

The interfacial charge trapping, scattering, and rough surfaces cause a decrease in the saturation mobility (μ_{sat}), on/off current ratio (I_{ON}/I_{OFF}), and stability. An additional supply of O_2 during deposition or annealing in an appropriate environment can provide the oxygen content needed to compensate for oxygen vacancies (V_O) in the film. Although some studies have already reported the effect of oxygen vacancies on the electrical properties of IGZO thin films, the effective mechanism has hardly been clearly presented for this phenomenon.

In this study, we investigated the device properties and defect states in Indium gallium zinc oxide (IGZO) as a function of the oxygen flow ratio and annealing temperature during deposition. To investigate the defects at the interface, light was incident without deformation or destruction of the device using an fs-laser, and the defect density was quantitatively analyzed through the intensity of nonlinear light. In addition, the correlation between the intensity of the nonlinear signal and the device characteristics was analyzed and consistency was verified using the existing qualitative/quantitative defect analysis method.

Linking Mechanical Damage to *In Situ* Electrical Resistance in Metallic Thin Films Under Cyclic Loading Megan J. Cordill; Erich Schmid Institute, Austria

With the increasing demand for flexible displays and wearable sensors, the mechanical limitations of these systems need to be systematically investigated and fully understood. Ductile films and lines are an integral part of flexible electronics because they allow current flow between semiconducting islands and other operating features. However, the charge carrying ductile films must be of an optimum thickness and microstructure for suppression of cracking under cyclic tensile loading conditions. Studies of strained films on polymer substrates tend to emphasize only the electrical properties and thickness effects more than the mechanical damage that forms. In-situ measurements of electrical resistance have been used extensively as a failure criterion in cyclically loaded conductive films without regard to the type or amount of mechanical damage. However, not much research has been performed on extracting additional information about the mechanical damage that is contained within electrical resistance data sets. It will be shown that an increase in peak width of the resistance ratio evidences a transition from cracks bridging to through-thickness crack formation for Au and Au/Cr films on Polyimide. Understanding what can be learned from the electrical resistance without the need for additional damage characterizations allows for more insight into the combined electrical and mechanical failure of flexible thin film systems. The new knowledge gained about how the electrical data delivers mechanical damage information will aid in providing specific failure criteria for flexible electronics. Without specific failure criteria the electro-mechanical reliability of flexible material systems cannot be properly evaluated.

3:30 PM SB03.02.06

Through Thickness Film Fracture to Create Substrate Cracks for Chemical Storage of Antimicrobial Peptides Jia-Huei Tien[1], Hector Espejo[2] and David F. Bahr[1]; [1]Purdue University, United States; [2]Western Colorado University, United States

In most applications brittle film cracking on ductile substrates is seen as a nuisance that needs to be eliminated, but under proper conditions these surface structures can be a location for storage or be a carrier for a functional agent, such as lubricants or antimicrobial compounds such as peptides. Pulsed laser induced film growth in metals such as stainless steels and titanium has been used to create networks of cracks which penetrate a few microns into the substrate. To use these surface features in the films to impart additional functionality to a device there must be a balance between having a high enough density of cracks which provide the storage medium, but not so many or so large of cracks to substantially degrade the device's mechanical performance. In this current study we characterize the residual stress in these systems to monitor crack initiation and propagation. Pulse laser irradiation is used to provide high temperature under atmospheric conditions for oxidation reactions on various stainless steels, creating non-stoichiometric oxides that are not formed at slower oxidation conditions. Residual stresses play an important role since the different thermal expansion coefficients between martensite and the oxide layer drives cracking behavior after cooling down to room temperature to provide stress relief. Residual stresses were analyzed using the cos-alpha x-ray diffraction technique, and by varying the incident angle of the x-rays we are able to provide non-destructive measurement of effective residual stress as a function of depth in these materials over the same range as the crack depth. With the thickness of oxidation film in 400nm, subsequential cracking is observed perpendicular to the oxidation layer for 4-8μm at cross-section with the average crack spacing on the order of 20 μm. This density of cracks allows the functional agents to the surface of the material, in this case we used nisin, a polycyclic antibacterial peptide, which is applied to kill gram-positive bacteria and other microorganisms, and will present results on the efficacy of the nisin in controlling Listeria monocytogenes.

3:45 PM *SB03.02.07

Fast and Scalable Open-Air Spray-Plasma Processing of Protective Barrier and Other Functional Coatings Reinhold H. Dauskardt; Stanford University, United States

Open-air spray-plasma processing provides opportunities for versatile scalable and low-cost coating deposition on large and/or complex shapes in air and at low temperature. The generally solvent-free process further allows for the simultaneous functionalization of, and deposition on, substrates in a single step. Recent advances in the use of plasma process gasses (primary and carrier) that include inexpensive N_2 and compressed air together with the possibility of combining plasmas with spray deposition have further expanded the utility of the deposition technique. I will discuss the composition and molecular design of such barrier and multi-functional coatings, new methods for processing using plasma processing in air on plastics, and metrologies to characterize the moisture barrier, adhesive and degradation processes that are important for reliable application over extended operating lifetimes.

Specifically, we review progress using a newly developed and installed open-air plasma system with a 10-cm-wide plasma head and gantry robot system with scan speeds of 1 to 1,000 mm/s allowing for rapid film deposition through both *open-air* spray-plasma and chemical vapor deposition. Importantly, the system includes the capability to co-deposit a wide variety of precursors with precise control over the delivered precursor concentration. We can deposit different multilayer transparent barriers, anti-reflective and hydrophobic coatings at scale. We have successfully achieved alternating organic/inorganic moisture barriers with high transparency and WVTR of ~10^{-4} g/m^2/day. Methods to characterize film adhesion and moisture barrier properties rapidly with an imaging IR system calibrated with calcium and moisture permeation testing is discussed.

The scalable spray-plasma capability provides rapid processing of protective and mechanically robust barriers and other functional films for innovating device technologies that are sensitive to environmental exposures.

SESSION SB03.03: Thin, Flexible Bioelectronic Interfaces

Session Chairs: Yei Hwan Jung and Kyungjin Kim
Wednesday Morning, April 12, 2023
Moscone West, Level 2, Room 2014

9:00 AM *SB03.03.01
Flexible Bio-Integrated Electronics for Unconventional Human-Machine Interfaces Ki Jun Yu; Yonsei University, Korea (the Republic of)

This work focused on semiconductor materials and processing of the bio-integrated devices for unconventional human-machine interfaces. Recent advances in this area include materials, processing devices, integrated systems, and their biomedical applications that are capable of conformal and seamless contacts with the human body. The unconventional approach of building electronic systems opens a new pathway for improving diagnosis and therapeutic effects. Also, electronics in biomedical fields expands a major research field in diverse domains from basic science, and engineering to computer science for practical applications. Here, in this conference, I am introducing a few wearable and implantable bio-integrated electronics based on various novel materials for new device architecture of human-machine interfaces to provide unprecedented functionalities in a biomedical field and society.

9:30 AM SB03.03.02
A Double-Sided Coil Patterned Ultra-Thin Silicon Substate ChangHee Son[1], Sangyeop Lee[2], Placid M. Ferreira[1] and Seok Kim[2]; [1]University of Illinois, United States; [2]Pohang University of Science and Technology, Korea (the Republic of)

Fabrication of devices on ultra-thin silicon(UTS) substrate has significantly advanced as the demand for flexible and compact devices rises. However, the majority of research only focuses on a conventional single-sided fabrication and does not implement a double-sided fabrication due to challenges in fabrication on a UTS substrate. Here we implement a pattern transfer technique that enables transferring the UTS freely between substrates and even flipping the UTS at any step between processes. As an example, we fabricated a double-sided coil patterned UTS substrate(DCUTS) and demonstrated its functionality as an actuator and vibrational energy harvester. A combination of experimental, computational, and theory-based simulation modeling results are presented. The results prove the possibility of adopting this technique in fabricating double-sided, namely, higher density devices or multi-functional devices through two different patternings on the front and back sides.

10:15 AM *SB03.03.03
Mechanics Challenges and Considerations for Sub-Micron Thin E-Tattoos Nanshu Lu; The University of Texas at Austin, United States

Compared with conventional wearable devices, skin-conformable ultrathin and ultrasoft e-tattoos offer unique advantages such as low contact impedance comparable with gel electrodes, effective electrical, thermal, optical and/or mass transfer across the skin-tattoo interface, minimal relative motion against the skin during human movement, mechanical imperceptibility, and unobstructive to human touch sensation. We have therefore built a theoretical framework to predict the skin-conformability of e-tattoos based on the tattoo stiffness and thickness, skin roughness, and skin-tattoo interfacial adhesion.[1, 2] The framework was used to guide the thickness design of our graphene e-tattoos (GET).[3, 4] While sub-micron-thin e-tattoos can achieve unprecedented skin conformability, their connection to rigid printed circuit boards (PCB) for data acquisition (DAQ), storage and/or wireless transmission suffer from orders of mismatch in thickness and stiffness. The significant strain concentration at such interfaces makes them notoriously vulnerable and has prevented the mobile and ambulatory use of skin-conformable e-tattoos. We herein propose a simple yet effective solution named “heterogenous serpentine ribbons (HSPR)”,[5] which refers to the strategic overlap between a sub-micron-thin serpentine ribbon and a thicker metallic serpentine ribbon. Compared with heterogeneous strain ribbons (HSTR), HSPR offers a fifty-fold strain reduction and correspondingly, fifty-fold enhancement of stretchability at such interfaces. To demonstrate the capability of HSPR, we have fabricated 300-nm-thin serpentine-shaped GET to form HSPR with 750-nm-thin gold-on-polyimide (Au/PI) serpentine ribbons. While graphene is in contact with the skin, Au is facing up to form the electrical contact with a rigid EDA watch through a soft conductive elastomer. The HSPR construct for GET allows long-term, continuous, unobstructive and ambulatory EDA sensing on human palm during our daily activities as well as during sleep. We believe that the HSPR could be a generic solution to robustly connect any sub-micron-thin e-tattoos to rigid circuits, which could significantly enhance the reliability and usability of ultrathin, skin-conformable e-tattoos.

10:45 AM SB03.03.04
High-Resolution Pd-Ni Hydrogen Gas Sensor Capable of Detection Ultra- High Purity Hydrogen Seung-Ik Han[1,2], Chiwan Park[1], Le Thai Duy[1], Rubaya Yeasmin[1] and Hyungtak Seo[1,1]; [1]Ajou University, Korea (the Republic of); [2]Ajou university, Korea (the Republic of)

Hydrogen (H_2) has different types of impurities depending on the production method, which determines the purity of hydrogen. For hydrogen to be used as a fuel for a hydrogen fuel cell vehicle, the purity of hydrogen is very important. Low-purity hydrogen containing several impurities adversely affects the catalyst of the fuel cell and greatly reduces the lifespan of the fuel cell system. Gas Chromatography (GC) used in the field is a method of periodically extracting and measuring hydrogen gas, so it is impossible to check in real-time. Therefore, a hydrogen sensor capable of measuring high-purity hydrogen of 90% or more is necessary.

For the hydrogen sensor of the Delta Resistance type, it is important to secure a resolution capable of discriminating the difference in resistance between the measured hydrogen concentrations when measuring the hydrogen concentration. In addition, palladium (Pd) used as a hydrogen detection material has structural instability in a high concentration of hydrogen when used alone.

In this study, a multi-layered alloy catalyst of Pd and Ni was prepared using nickel (Ni) as complementary material to Pd. The core technology of the ultra-high concentration hydrogen sensor is to control the distribution density of the alloyed Pd-Ni catalyst metal layer to secure the hydrogen concentration resolution characteristics. A structurally optimized hydrogen sensor was fabricated by implementing the digit form.

The hydrogen detection layer manufacturing method uses an E-beam evaporator to deposit Pd-Ni, a catalyst metal for H_2 dissociation reaction, on a SiO_2 substrate in the form of a Pd/Ni/Pd sandwich type multilayer thin film. The Pd-Ni sensor was measured at various ultra-high hydrogen concentrations of 90-100% containing impurity gas.

The manufactured hydrogen sensor secured 0.1-1% resolution at high hydrogen concentration and showed excellent performance in detecting hydrogen within 5 seconds. This is thought to be because Ni acted as a co-catalyst in the Pd-Ni double-layer catalyst, resulting in a change in hydrogen adsorption/desorption reaction energy, and the digit structure increased the base resistance.

11:00 AM *SB03.03.05
Ultra-thin, Low-Noise Organic Transistor Integrated Devices for Minimally Invasive Brain Activity Measurement System Tsuyoshi Sekitani; Osaka University, Japan

I will introduce process technologies for high mobility, low noise, and uniform characteristics of organic thin-film transistors that utilize the softness of organic materials, as well as a brain activity measurement system that utilizes these organic nanotechnologies.

In recent years, the flexibility and lightweight properties of organic electronics have attracted attention, and bio-applications, such as wearable applications, have been gaining momentum. In addition to high electrical characteristics, such applications require the simultaneous fulfillment of various properties such as uniformity of characteristics and biocompatibility that allow for large-scale integration. Organic transistors, in particular, have inherently non-uniform characteristics, and this trend will become more apparent over time.

In this study, we have realized organic thin-film transistors with high mobility (μ>1 cm^2/Vs) and low noise on polymer films less than 1 micrometer thick by using photosensitive materials and self-assembled monolayers as gate insulator films [1,2] and have successfully reduced the variation in threshold voltage (V_{th}) less than 4%. This implies a V_{th} variation of 10-70 mV for a drive voltage of 2V. [3].

By highly integrating this organic thin-film transistor with biocompatible materials [4], we have developed an ultra-thin-film measurement device that can minimally invasively measure minute cellular action potentials in living organisms [5-10]. In this presentation, we will introduce a scalp EEG measurement system that measures from outside the skull and a brain measurement system that measures from inside the brain in an extremely minimally invasive manner.

Furthermore, with the aim of expanding the application of ultra-thin film organic devices to a wider range of areas, we are currently conducting research and development of organic electrochemical transistors capable of controlling high currents [11].

These results were obtained in collaboration with Dr. Koki Taguchi, Associate Professor Takafumi Uemura, Associate Professor Teppei Araki, and other members of the SANKEN research group at Osaka University, and Dr. A. Petritz, Dr. B. Stadlober, and other research group members at JOANNEUM RESEARCH, Austria. This work was supported in part by JST Moon Shot Type R&D Project (JPMJMS2012), Grant-in-Aid for Scientific Research (22H00588), and Research Grant (S) from Tateishi Science and Technology Foundation.

SESSION SB03.04: Reliable and Chronic Neural Interfaces
Session Chairs: Yei Hwan Jung and Kyungjin Kim
Wednesday Afternoon, April 12, 2023
Moscone West, Level 2, Room 2014

1:30 PM *SB03.04.01
Polymer Implantable Electrode Interfaces to the Nervous System Ellis F. Meng; University of Southern California, United States

Microelectrode array technologies can be adapted to interface with different parts of the nervous system, whether lying on the surface or placed into tissues. While traditionally constructed from rigid materials, emerging polymer technologies compatible with microfabrication offer interfaces possessing greater mechanical flexibility and material transparency. The use of a softer substrate material may alleviate chronic tissue damage and prolong function while material transparency allows use with optical imaging and interface modalities. In addition, the design space enables a variety of form-factors and anatomical targets, including surface, shallow and deep-brain structures, retina, spinal cord, and peripheral nerves. However, access to this technology is limited as is the infrastructure to scale the manufacture and dissemination of polymer interfaces. The Polymer Implantable Electrode (PIE) Foundry is a new resource concept that provides rapid access to custom or generic microelectrode arrays to the research community and borrows from pathways for project space sharing from the integrated circuit manufacturing industry. Progress in advancing this new foundry concept including the dissemination of polymer microelectrode array technologies to neuroscience and neural engineering users will be discussed.

2:00 PM *SB03.04.02
Are We at an Inflection Point—Advanced Thin-Film Encapsulation Concepts Enabling Chronic Implantable Devices in Chronic Human Applications Florian Solzbacher; Univ of Utah, United States

Implantable Brain-Computer Interfaces appear to be heading towards an inflection point: In the past decade the number and frequency of major technological advances and first in human demonstrations of new capabilities have started increasing significantly. Many technical and scientific hurdles have been overcome or at least addressed. The first generations of commercially available products appear to be imminent. They have the potential to become tangible tools to restore lost function and are serious contenders to address a variety of neurological disorders. Much of this has been enabled by breakthroughs in encapsulation approaches leveraging thin film and wafer level approaches for even complex implantable systems. The real-life settings associated with in-home use of these technologies lead to reprioritization of existing--as well as the emergence of novel--practical and fundamental challenges and opportunities. How do we identify and prioritize user, clinician and caretaker needs? What is possible today and what is a realistic technological roadmap that meets those needs?

2:30 PM SB03.04.03
Improved Parylene-Based Barrier Layers Using Low Temperature CVD Technologies Sébastien Buchwalder[1,2], Florian Bourgeois[3], Andreas Hogg[3] and Juergen Burger[1]; [1]Sitem Center for Translational Medicine and Biomedical Entrepreneurship, Switzerland; [2]Graduate School for Cellular and Biomedical Sciences, Switzerland; [3]Coat-X SA, Switzerland

Implantable devices, demanding efficient protection against body fluids as well as maximal miniaturization, require a high degree of biological safety. An ultra-tight encapsulation solution which enables safe long-term implantation close to inflammatory tissue and which has a superior temperature stability for multiple sterilization cycles is highly desirable. In this work, it is shown how these needs can be addressed by an innovative thin film encapsulation technology made of alternating organic and inorganic layers.

Parylene, as organic thin film, is a well-established polymer material, exhibiting excellent electrical insulation and dielectric properties, being often the material of choice for biomedical applications. However, parylene barrier properties are not sufficient to ensure a protection for long-term implantation in the human body of several years. The inorganic materials are dense and hence offer extremely good barrier properties. However, inorganics alone suffer from pinhole and micro-crack defects, which induce a poor long-term hermeticity. On the other hand, the combination of parylene with inorganic thin films provides excellent barrier properties and improves the scratch resistance, limiting the water permeation through potential defects.

This study investigates the barrier performances of inorganic monolayers and parylene multilayers in combination with inorganic films deposited by low temperature chemical vapor deposition (CVD) processes. Parylene VT4 film, deposited by the standard Gorham process (low pressure CVD), was used for its excellent thermal stability and its superior capability to enter into small voids or channels of substrates compared to other parylene types. Silicon-based layers, deposited by plasma-enhanced CVD (PECVD) were examined as single layer, bilayers and combined with parylene film as multilayers. Three precursors and two plasma generation methods (inductively and capacitively coupled plasma) were tested and evaluated for inorganic PECVD layers. Similarly, atomic layer deposition (ALD), including thermal and plasma oxidation methods, was used to compare three metal-oxide layers. Water vapor transmission rate (WVTR) measurements were performed to quantify the barrier performances using electrolytic and diode laser spectroscopy detection methods. The most efficient single layers show a WVTR in the range of 10^{-3} g m^{-2} d^{-1}, at 38°C and 90% relative humidity conditions, while the results of WVTR measurements for parylene-inorganic (1dyad) combinations are in the range of 10^{-4} g m^{-2} d^{-1} at 38°C and 90% R.H. Multilayer stack (more than 1 dyad) will be assessed and WVTR value will be measured for different organic/inorganic layer combinations. Finally, thin film encapsulations will be evaluated on functional active device, (e.g., electronic circuit) immersed in saline solution in order to determine the barrier performances close to real implantable applications.

2:45 PM *SB03.04.04
Investigations on the Longevity of Metal-Polymer Interfaces in Electrode Arrays of Neural Implants Thomas Stieglitz, Jennifer Schulte, Ioana-Georgina Vasilas, Calogero Gueli, Danesh Ahouri Vajari and Paul Cvancara; University of Freiburg, Germany

Neural interfaces need to provide stable and reliable functional interfaces to the target structure in chronic implantations both in neuroscience experiments and especially in human clinical applications. Proper selection of substrate, insulation, and electrode materials is of paramount importance as well as the knowledge how process parameters in device manufacturing influence material longevity. Aspects such as size, thickness, and shape contribute significantly to structural biocompatibility and modulate post-implantation foreign body reaction. Our work focused on polyimide as the substrate and insulating material with integrated thin film metallization as the conductor in our flexible neural interface approach. Platinum, iridium oxide, glassy carbon, and PEDOT serve as interconnect lines and electrode coatings, respectively, depending on the intended electrode size and application. We have investigated different metal-polyimide compounds after in vitro stimulation but also devices after explantation. Optical imaging during electrical stimulation of platinum in vitro showed actuation of thin-films during Implantation as potential origin of adhesion loss. In addition, accelerated aging led to changes in grain structures in these platinum layers. Post explantation analysis of platinum recording arrays from studies up to two years in ferrets proved these initial observations and showed signs of hydrogen embrittlement. In addition, dimpling of arrays into brain tissue, secondary dura and bone growths showed limitations in structural biocompatibility in exemplary cases. Peripheral nerve electrodes from stimulation in human clinical studies over a period of up to six months has demonstrated the stability of iridium oxide sites and the integrity of the metal-polymer multilayer film using silicon carbide as an adhesion promoter. Analysis of explanted fragments, however, showed the necessity to be able to image the device-tissue interface in one stage without separating devices from biological material. The layer composition and tissue contact to the surface might help to better assess the interface compatibility and the influence of surface roughness and coatings on the foreign body reaction and device functionality and longevity. So far, results are encouraging to continue the translational research path from basic studies to the first human clinical trials, which are necessary to prove that new materials, technologies and devices are applicable in clinical applications and can eventually be translated into an approved medical device.

SESSION SB03.05: Thin-Film Barriers
Session Chairs: Kyungjin Kim and Lokendra Pal

Thursday Morning, April 13, 2023
Moscone West, Level 2, Room 2014

8:30 AM *SB03.05.01
Combined High Stretchability and Barrier in Hydrogen-Bonded Nanobrick Wall Thin Films Jaime C. Grunlan; Texas A&M University, United States

Hydrogen-bonded multilayer thin films are very stretchable, but their gas barrier properties are modest compared to more traditional ionically-bonded assemblies. In an effort to improve the gas barrier of poly(ethylene oxide) (PEO) – poly(acrylic acid) (PAA) multilayer films, without sacrificing stretchability, montmorillonite (MMT) clay platelets were combined with PAA and alternately deposited with PEO. A ten bilayer PEO/PAA+MMT film (432 nm thick), deposited on a 1 mm PU substrate, resulted in a 54X reduction in oxygen transmission rate after exposure to a 20% strain. This system is the best combination of stretchability and gas barrier ever reported. This same concept can be converted into a single polyelectrolyte complex solution to achieve relatively good barrier in a single step. If there's time, I'll briefly describe how these types of polyelectrolyte thin films can be used to prepare insulation layers with high dielectric breakdown strength.

9:00 AM SB03.05.02
Photocurable Hybrid-Nanocellulose Multilayer Coatings on Biobased Substrates for Food Packaging Applications Aigoul Schreier and Yves Leterrier; EPFL, Switzerland

With waste management concerns, researchers are now focusing on developing recyclable or biodegradable materials in an innovative way. To comply with the food industry requirements, current studies aim to develop materials with high barrier properties to oxygen and water vapor while considering their entire lifecycle. Microfibrillated cellulose (MFC) produced in the form of thin flexible films have attracted an increasing interest in packaging applications due to their excellent grease and oxygen barrier properties. However, the permeability of such materials degrades exponentially with increasing relative humidity (RH) due to disruption of the Hydrogen bonds and swelling of the MFC. The moisture sensitivity of MFC can be reduced through thermomechanical treatments, or by encapsulation with a hydrophobic matrix.
This work aims to develop high diffusion-barrier materials in the form of multilayer coatings composed of MFC and UV-curable organic-inorganic hybrids coated on paper and biobased polymer substrate. Two end of life strategies are considered. The first is based on easy recyclable materials in an already existing paper mill. The second focuses on the development of biodegradable composites within relevant degradable environment.
In the case of a recyclable packaging, MFC is coated as a diluted aqueous suspension and dried to form a dense film. The hybrid interlayers combine a cycloaliphatic epoxy oligomer, 3-glycidoxypropyl trimethylenesilane (GPTS) as a coupling agent and tetraethylorthosilicate (TEOS) to favor interfacial interactions with the hydroxyl-terminated MFC layers. Particular attention is paid to the photo-induced conversion of the hybrid network, to the MFC-hybrid interface and resulting oxygen and water vapor permeability. Multilayers based on pure epoxy and MFC layers on paper led to oxygen transmission rate (OTR) and water vapor transmission rate (WVTR) of 25 cm3/m2/day/bar (23°C, 85%RH) and 14 g/m2/day (23°C, 85%RH), respectively. The achieved water vapor barrier performance is mainly coming from the epoxy. Moreover, epoxy did not properly wet the MFC surface and the interfacial adhesion was low. Adding TEOS and GPTS improved both the wettability and adhesion properties of the resin onto the MFC surface. Indeed, the addition of those two compounds led to the formation of covalent bonds through condensation reactions between the hydrolyzed TEOS and MFC surface. The photopolymerization rate and gel-time of UV-curable resins increased with increasing TEOS and GPTS concentration. A systematic analysis of barrier and adhesion properties is performed to assess the effect of the number of MFC interlayers and the composition of the UV-curable hybrid. The assessment of the recyclability of these multilayer films within a standard paper recycling scheme highlights their capability to be recyclable into Category II grade.
Focus is also given to a fully biodegradable, MFC-based multilayer film alternative using a biobased epoxidized soya bean oil (ESBO) as an organic matrix and a polyhydroxyalkanoate/polylactic acid blend (PHA/PLA) as substrate. Preliminary biodegradability tests confirm the ability of a consortium of bacteria to use each material as a carbon source. The polarity contrast between the precursor (MFC suspension) and the PHA/PLA substrate leads to important delamination issues during film formation. To face this problem, a treatment of the polymer with an organosilane 3-aminopropyl)triethoxysilane (APTES) was performed showing great improvement. Permeability tests are ongoing to further investigate the performances of this new biodegradable MFC multilayer films.

9:15 AM *SB03.05.03
Advanced Renewable Cellulose Nanocrystal and Chitin Nanofiber Barrier Packaging Tequila Harris[1], Kwangjun Jung[1], Yue Ji[1], Tae J. Jeong[1], Carson Meredith[1] and Peter Ciesielski[2]; [1]Georgia Institute of Technology, United States; [2]National Renewable Energy Laboratory, United States

Plastic waste is one of the most prominent materials impacting the environment and human health due to the inability to recycle or the difficulty of recycling and the release of toxins in the form of microplastics. To this end, there is a critical need to develop highly functional bioderived materials for applications such as food packaging, which is the most significant contributor to unrecyclable or difficult-to-recycle plastic waste. Cellulose nanocrystals (CNCs) and chitin nanofibers (ChNFs) are two biologically sourced materials that can be used to create biodegradable and sustainable oxygen and moisture barrier materials that are comparable to widely available barrier layers such as polyethylene terephthalate (PET). In this talk, we will discuss how the functionality of CNC and ChNF barrier thin films can be enhanced through material synthesis and manufacture. Attention will be paid to the process-structure-property relationships of the barrier thin film. Here, we demonstrate the viability of dual layer slot die coating of CNC/ChNF bilayers onto cellulose acetate (CA) substrates when compared to spray coating. It was observed that the dual layer slot die coating on a roll-to-roll system that applies the bilayer in a single pass enables a significantly lower oxygen permeability versus spray coating. It has been found that spray coated bilayer thin films were on average 25% thinner than the dual layer slot die coated bilayer film. However, the thickness-normalized oxygen permeability (OP) of the dual layer slot die coated ChNF/CNC bilayer thin film on CA was 20 times better than that of the spray coated bilayer thin films. OP values for the slot die coated bilayer thin films under optimized drying conditions were as low as 1.2 cm3 µm m(-2) d(-1) kPa, corresponding to an oxygen transmission rate of 0.32 cm3 m(-2) d(-1) at 23 °C and 50% relative humidity. It is also noted that the adhesive properties of the dual layer coating are also improved when the barrier thin film is air dried. Challenges to industrial implementation and approaches to overcome these will also be analyzed.

9:45 AM SB03.05.04
Enhancing the Thermal Stability of the IGZO Transistors by Suppressing the Oxygen Diffusion into Metal Using Self-Assembled Monolayer for Nanoscale Devices Juyoung Yun, Hyuk Park, Seung-Mo Kim, Byoung Hun Lee and Yoonyoung Chung; Pohang University of Science and Technology, Korea (the Republic of)

Amorphous indium-gallium-zinc-oxide (a-IGZO) thin-film transistors (TFTs) are extensively applied in large-area displays, machine learning, and memory devices. Recently, it was reported that the increased electron density caused by the oxygen vacancy reduces the contact resistance between a-IGZO and source/drain (S/D) metal.[1] However, a large amount of oxygen vacancies in the S/D region diffuses into the channel region by thermal stress, which causes performance degradation, such as V_{th} negative shift and loss of switching characteristics, especially in the nanoscale transistor.

To suppress the excessive generation of oxygen vacancies, We introduced the ultra-thin barrier layer (< 1nm), which prevents oxygen diffusion. A self-assembled monolayer (SAM) with various alkyl-chain lengths (C2, C4, C6, C8, C10) was used as a diffusion barrier. We extracted the effective channel length of the IGZO TFT by the transfer line method (TLM) pattern. The device with a thick barrier showed a negligible change of the channel length at 250 degrees thermal stress for 2 hours, indicating that the diffusion of oxygen vacancies was suppressed. Transmission electron microscopy (TEM) images showed reduced interfacial oxide after SAM insertion. Despite inserting a diffusion barrier with excellent insulating properties, the contact resistance was decreased by 72 % compared to the bare device due to the thinned interfacial oxide. As a result, we achieved high thermal stability by inserting a diffusion barrier and, additionally, low contact resistance due to the thinned interfacial oxide, which contributes to the realization of nanoscale devices without any side effects in the channel region.

1:30 PM *SB03.06.01
PolyCannabinoids—Synthetic Polyesters from Natural Feedstock, Cannabidiol (CBD), Cannabigerol (CBG) and Adipic Acid, as Non-Phenolic Antioxidant Bioplastics Gregory Sotzing; University of Connecticut, United States

Polycannabinoids are a platform technology based upon the polymerization of natural feedstock monomers. Two examples of monomers include cannabidiol, CBD, and cannabigerol, CBG, two of the five main cannabinoids in cannabis. CBD isolate, the pure form of CBD extracted from hemp biomass was used as a diol monomer along with adipoyl chloride, the monomer used for Nylon, to produce a polyester CBD-adipate. Hydrolysis of polyCBD-Adipate occurs under basic condition to produce CBD, insoluble in water, along with the natural chemical adipic acid that dissolves in water. Side-by-side studies with polylactic acid (PLA) show polyCBD-Adipate to be noncytotoxic, and unlike PLA, polyCBD-Adipate shows anti-oxidant activity with ORAC assay. CBD having two rings in its structure is then compared to CBG having one ring. In line with expectations based upon the number of rings, polyCBG-adipate exhibits a glass transition temperature at -33°C whereas polyCBD-Adipate is at 37°C. Copolymerization of CBD, CBG and adipic acid allows for the glass transition to be tuned to any specific temperature within this -33 to 37°C range. The anti-oxidant capability of a bioplastic presents a tremendous opportunity to applications in which materials need to hold up to oxidative stress, potentially protecting species such as drugs and enzymes that are prone to oxidation.

2:00 PM SB03.06.02
Nanomanufacturing of Lignin Biopolymer for High-Performance Wearable Triboelectric Sensors Robert Ccorahua, Shivangi Agarwal and Wenzhuo Wu; Purdue University, United States

Lignin is the second largest biopolymer on earth after cellulose. It represents 40% of the weight of a plant. It is considered the biopolymer with the most difficult processability due to its complexity and dual non-polar and polar nature. Such challenges prevent lignin's limited manufacturability and further applications. Herein, we manufactured lignin films though multiple nanomanufacturing methods by implementing a new environmental-friendly processing method. We further evaluated the parameters of each technique for lignin manufacturing and correlated them with their structure and property as triboelectric films. Moreover, we demonstrated that, compared with other biopolymers, lignin exhibits outstanding triboelectric properties for self-powered wearable devices in human-machine interface applications. Our developed framework opens doors to new technologies that utilize abundant bioderived materials for economically feasible and ecologically friendly manufacturing of functional devices in energy, electronics, and sensor applications.

2:15 PM SB03.06.03
Bioresorbable Shape-Morphing Biomedical Thin-Film Microrobots Wangqu Liu, Arijit Ghosh, Ruili Zhang, Gayatri Pahapale, Zijian Zhong and David H. Gracias; Johns Hopkins University, United States

Shape-morphing microrobots that can adapt to physiological environments and transform their geometry or functionality offer the potential for autonomous deployable, intelligent systems to enable biomedical functions, such as drug delivery and microsurgery. However, safety concerns can limit the wide-scale adoption of such devices. After completing their tasks, there is a risk that such devices can be stuck or retained in the body, which may require additional surgical interventions to be removed. In this work, we report shape-morphing origami microrobots composed of bioresorbable materials such as Fe, MgO, and Mo, offering the possibility for dissolution in the body. We characterize the thin film stresses and deposition parameters to create bilayers that can fold with appropriate angles and dissolve at different times. We demonstrate the creation of foldable microstructures using a novel water-free shadow mask microfabrication process. We believe this study advances water-free thin film microfabrication processes for bioresorbable materials and the devices are an essential step towards the creation of safe, dissolvable shape change microrobots for biomedical applications.

Delayed Release from Hermetically-Sealed Aqueous Capsules by Modulating the Thin Waxy Shell Eylul Utlu, Leah K. Borden and Srinivasa R. Raghavan; University of Maryland, United States

Biopolymer hydrogel capsules are typically created through physical crosslinking of polymer chains. They are environmentally friendly and non-toxic, making them very useful in different industries. However, hydrogel capsules are often unsuitable for drug delivery since they cannot keep small molecules encapsulated for long times without leaking. In an effort to resolve this problem, our lab has designed capsules with a hydrogel core and a thin shell of paraffin wax around the core. [1] The wax shell keeps hydrophilic solutes hermetically sealed, i.e., there is no leakage for a long period of time (months). The barrier properties of the wax shell arise because it is an extremely hydrophobic material with a melting point well above room temperature (~ 60°C).

While a hermetic seal is useful, there is still a need for solutes encapsulated in the capsule to be released at the appropriate time. For this purpose, we have improved the above capsule design to allow for: (a) a hermetic seal for a period of time; followed by (b) a slow and sustained release of the solute thereafter. The key to our new design is to add a low-melting additive to paraffin wax. Using this design, we can store hydrophilic solutes (such as hormones and therapeutics) in the capsules for multiple days at room temperature without any release (i.e., the solute remains hermetically sealed over this period). After this period, the solute is released at a slow rate out of the capsule. The time delay before solute release can be tuned through several variables, including the concentration as well as the molecular nature of the additive. Since the thin waxy shell is completely biocompatible, this approach could have a potentially significant impact on the delivery of many hydrophilic solutes, including drugs, agrochemicals and cosmetic agents.

Skin-Covered Hydrogels—A Novel Zero-Order Drug Delivery System Morine Nader[1], Sai Nikhil Subraveti[2] and Srinivasa R. Raghavan[1]; [1]University of Maryland, United States; [2]Princeton University, United States

In most drug delivery devices today, drugs are released out of the device in an immediate or first-order manner, implying that the rate of release is high at the outset and decreases exponentially thereafter. As a result, undesirable side effects are often observed, and moreover, increased dosing frequencies are needed to achieve the necessary therapeutic effect. Zero-order drug delivery devices have the potential to overcome these issues by releasing drugs at a constant rate; thereby maintaining drug concentrations within the therapeutic window for an extended period. Till date, researchers have explored several ways to accomplish zero-order release; however, the majority of these are complex, time-consuming, and difficult to manufacture.

Here, we design a simple way to achieve zero-order release of various water-soluble solutes out of any given hydrogel. Our solution is to create a thin polymeric skin around the hydrogel using an inside-out strategy. We show that uniform polymeric skins with a tunable thickness of 10−100 µm can be easily achieved using our technique. For zero-order release to occur, the skin is made mostly from a hydrophobic monomer, but with small amounts of a hydrophilic monomer. This generates hydrophilic domains in the skin, and we will demonstrate that this combination leads to a zero-order response. Additionally, we show that it is possible to tune the release rate by varying the thickness of the skin and the concentration of the hydrophilic monomer.

5:00 PM SB03.07.01
Spectroscopic Study of Passivation Effect of Common Polymers on MoS_2 Christine McGinn and Christina A. Hacker; National Institute of Standards and Technology, United States

The unique electronic and optoelectronic properties of two-dimensional transition metal dichalcogenides (2D TMDs) can deteriorate as a result of surface defects and in recent years, several materials have emerged to passivate the surface and mitigate these defects.[1] Hexagonal boron nitride has seen widespread use because it is CMOS compatible, but it has been shown that polymers can have a significant passivating effect on 2D TMDS. [2,3] In addition to facile processing, polymers are typically transparent in the visible range, making them ideal for passivation of optoelectronic 2D TMD devices. A few works have shown an improvement in photodetection by polymer encapsulation. [4] Notably, the addition of ferroelectric polymers led to significant performance improvement in 2D TMD photodetectors, but the passivation effect of the polymer was not studied. [5] Only a few polymers have been studied for passivation, but the degree of passivation has not been quantified or qualified against other polymers. This work uses spectroscopic methods to investigate a representative group of polymers and their relative passivation effects on MoS_2 for improved passivation in 2D TMD devices.

This study consists of spectroscopic measurements of MoS_2 monolayers and three common polymers: parylene N (Pa-N), polymethyl methacrylate (PMMA), and polyvinylidene difluoride trifluoroethylene (PVDF-TrFE). These polymers were chosen as a representative set because they are commonly available and facile to deposit. Parylene is an extremely inert polymer used frequently in organic electronics and biomedical devices for encapsulation. [6] PMMA is a standard electron beam photoresist frequently used to encapsulate 2D TMD devices to prevent degradation. [7] PVDF-TrFE is an electroactive polymer commonly used in organic, flexible, and biomedical devices. [8] Approximately 300 nm of each polymer was deposited onto monolayer MoS_2 on a Si/SiO_2 substrate procured from 2D semiconductors. Spectroscopic measurements including Raman spectroscopy, Fourier Transform Infrared spectroscopy, and photoluminescence spectroscopy were performed on these samples to observe the effect of polymer passivation on the MoS_2 monolayer. FTIR and photoluminescence measurements suggest that Pa-N provides the most passivation of the three polymers tested. The Pa-N coated sample demonstrated the smallest full width half max of the photoluminescence peak and the largest increase in the MoS_2 FTIR signature of the polymers tested, which are both indications of successful passivation. [9] This result is unexpected as it is the most inert of the polymers tested. PMMA and PVDF-TrFE have functional groups containing oxygen and fluorine that would be expected to better fix sulfur vacancies or provide doping. Pa-N also has the lowest dielectric constant of the three so should not provide much dielectric screening. However, the photoluminescence spectrum of PMMA and PVDF-TrFE sample showed marginal to no improvement and the MoS_2 FTIR signature did not improve as much when compared to the Pa-N coated sample. Further studies including electron mobility measurements and depth profiling X-ray photoelectron spectroscopy will be presented to better understand this relationship.

Organic/Inorganic Hybrid Nanocluster for Improving Hardness of PC/PMMA Film Soojeong Jeong and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

Conventional glass had been used in transparent parts of displays, cars, and aircraft. These days, many fields are trying to replace glass with polycarbonate(PC) film for less weight, and safe when it is destroyed. Especially, PC film also has flexible properties, it can be used in various shapes. However, PC films are easily scratched because of their low hardness, resulting in poor visibility. In this study, we synthesize organic/inorganic hybrid acrylate polymer using oligosiloxane nanocluster to improve the hardness of PC/PMMA film over pencil hardness of 4H and overcome other issues. Moreover, the hybrid acrylate polymer has low adhesion with PC/PMMA film, we conducted surface modification of the film and controlling the ratio with organic polymer for great adhesion strength of the coating film. These coating materials also demonstrate hydrophobic, bendable and highly transparent properties due to the combination of epoxy siloxane nanoclusters and polyacrylate networks containing perfluoro groups. And finally, the PC/PMMA film with high hardness and flexibility is expected to replace the glass successfully and can be applied in flexible and curved displays.

5:00 PM SB03.07.04
Anomalous Ionic Gating Effect in Degenerate Semiconductors Won Hyung Lee, Junghyup Han, Yong Hyun Cho and Youn Sang Kim; Seoul National University, Korea (the Republic of)

The insulated-gate field effect, a key feature of semiconductor devices used as switches or rectifiers in power electronics, induces the accumulation or depletion of charge carriers to govern the electrical properties of active layers. In particular, as demands for the miniaturization of electronic devices increase, various attempts have been made to achieve higher carrier density and lower operating voltage in field effect transistors (FETs). Notwithstanding, FETs with silicon dioxide (SiO_2), a typical gate dielectric material, require a high gate voltage (>20 V) to form an active channel by accumulating charge carriers between semiconductor/dielectric layers, resulting in high power consumption. To address this, various high-κ materials, including electrolytes, are desirable as the insulated-gate layer due to their high areal capacitance regardless of the dielectric thickness. Interestingly, studies related to ionovoltaic phenomena show that the electric double layer (EDL)-induced electrolytic gating effect enables ultra-high charge carrier accumulation at the semiconductor channel/electrolyte interface compared to the dielectric (*e.g.*, SiO_2) gating effect. However, as elucidating the cause of these interesting phenomena remains a challenging task, numerous studies related to the electrolytic gating effect have focused on practical applications rather than interpretation of the fundamental principle. Indium tin oxide (ITO) is one of the most widely used transparent conducting oxides in optoelectronics because of its electrical conductivity and optical transparency, but its degenerate doping (more like a metal) limits utilization as a semiconductor device. Nevertheless, in the ITO-based channel layer with high initial electron density, hidden non-degenerate semiconductor characteristics can be realized using dramatic electrolytic (ionic) gating effects. In this work, we observe an anomalous ionic gate field effect (gating off) that conversely reduces the conductivity of ITO (*i.e.*, depletion), resulting in a deactivated channel layer. In brief, we newly introduce a groundbreaking gate-off effect opposite to the principle of activating channels by exceeding the threshold voltage, which is the dielectric gating effect commonly used in FETs. Therefore, to implement the same principle as closing an electric faucet by the ionic gating effect, we propose a combination of the degenerate semiconductor (*e.g.*, ITO) and 21 mol of lithium bis(trifluoromethanesulfonyl)imide (LiTFSI), a water-in-salt electrolyte with relatively wide operating voltage window. To clarify the causality of ionovoltaic-related anomalous gating effect, we quantitatively analyze an accumulated/depleted electron density in the ITO channel layer through a sophisticated Hall measurement with applied electrolyte-gated voltage, bridging the fundamental correlation between solid-liquid interfaces and semiconductor principles. Hence, although the dielectric gating effect ($I_{on}/I_{off} \sim 1$) cannot dominate the degenerate semiconductor properties due to its high conductivity, the ionic gating effect ($I_{on}/I_{off} \sim 10^3$) operating at low voltage (<2 V) induces EDL formation at the solid-liquid interface, strongly governing the inherent properties of metal-like ITO. The anomalous ionic gating effect observed here has the significance of being able to realize degenerate semiconductors, which have limitations in controlling electrical conductivity, in an on/off state. Furthermore, we believe that this study serves as a stepping stone for revealing the unestablished principle of interfacial phenomena-dependent application devices based on various emerging semiconductor materials such as graphene and other two-dimensional materials besides ITO.

5:00 PM SB03.07.05
Probing Ion-Molecular Interactions at Solid-Liquid Interface Through Ionic Diffusion-Driven Ionovoltaic Transducer Junghyup Han, Won Hyung Lee, Yong Hyun Cho and Youn Sang Kim; Seoul National University, Korea (the Republic of)

Recently, electrolyte-interfacing systems ranging from electrochemical devices such as batteries and capacitors to electronic devices like electrolyte-gated neuromorphic devices have been actively developed, and solid-liquid interactions are one of the fundamental principles in their systems. These interactions also played a critical role in water motion-driven electricity-generating phenomena which originated from ion dynamics at the interface. Specifically, ion adsorption at electrolyte-insulator-semiconductor (EIS) structure accumulates or depletes the charge carrier of the semiconductor by means of coulomb interactions, and then changes its density near the interface, which was demonstrated as ionovoltaic phenomena. However, more details about various specific interactions such as chemical adsorption of ions, ion specificity, and coulombic pairing remain unrevealed issues in academic fields. Herein, an ion–charge carrier interaction at EIS structure is interrogated with an ionovoltaic transducer, controlled by interfacial self-assembled molecules. An electricity-generating mechanism from interfacial ionic diffusion is elucidated in terms of the ion–charge carrier interaction, originating from a dipole potential effect of the self-assembled molecular layer (SAM). While the ion diffuses through the distilled water (DI water) at the EIS structure, the potential difference between the semiconductor under the DI water and the ionic solution evolves. The ionovoltaic signal inversion occurs by applying the surficial molecules with opposite dipoles which are trichloro(1H,1H,2H,2H-perfluoro-n-octyl)silane (PFOTS) and (3-Aminopropyl)triethoxysilane (APTES) and induce cation and anion adsorption, respectively. In addition, this effect is found to be modulated via chemical functionalization of the interfacial molecular layer and transition metal ion complexation therein. The catechol group (CA), which can form a coordination complex with ferric ions (Fe^{3+}) was chemically modified on the APTES-treated device, and the variation of ionovoltaic signal was observed when the device was exposed to the Fe^{3+} solution and CA formed complexation with Fe^{3+}. In the case of Al^{3+} and Cu^{2+} which have a low binding affinity with CA, there was no evident change in generated signal. Those results show the Fe^{3+} concentration dependence and selectivity. With the aid of surface analytic techniques and a liquid-interfacing Hall measurement, electrical behaviors of the device depending on the magnitude of the ion-ligand complexation are interrogated. Specific chemical adsorption of Fe^{3+} on CA affected the interfacial molecular structure and therefore the change in carrier density of the semiconductor was observed, thereby demonstrating the ion–charge carrier interplays spanning at electrolyte–SAM-semiconductor interface. Hence, this system can be applied to study molecular interactions, including chemical and physical influences, occurring at the solid–liquid interfacial region.

Modification Rigid Type of Biodegradable Polymers with Amorphous PHA and Current Development Sunjong Kim; CJ Biomaterials, Inc., United States

Society has a serious problem of plastic waste management due to littering by mankind. One of the best solutions to this waste problem is composting. There a number of compostable polymers available such as PLA(PolyLactic acid), PBS:Poly(butylene succinate), PBAT:Poly(butylene-adipate terephthalate), etc..
CJ Biomaterials is one of top solution company which can produce PHA's at a commercial level. Amorphous PHA (Phact A1000P) has unique mechanical properties that makes it a good it a good modifier for rigid polymers including compostable resin such as PLA, PBS, scPHA, etc. The addition of amorphous PHA to these already widely used polymers enhance the properties opening new applications and speeds the rate of degradation reducing the cycle time of industrial composting.
Here we focused on modification of PLA which is one of the most common commercialized compostable polymer. However, its rigidity and stiffness were a limitation of possible applications.
Currently, we prepared a bi-orientated film application for a food packaging area. We will share some results of mechanical properties of bi-axially oriented film which mainly had PLA component with PHA as a modifier. When adding 30% of amorphous PHA(aPHA) in a PLA matrix, it showed lower than 40% relative modulus. Additions of 5% of aPHA in PLA in rigid applications gives a 5x increase in Izod impact than reference(neat PLA).
CJ Biomaterials will share its own characteristics of aPHA to expand the use of PLA a flexible packaging.

9:00 AM DISCUSSION TIME

9:15 AM SB03.08.03
Low Thermal Curing Hybrid Sol-Gel Coatings for Scratch and Corrosion Resistance Applications Sudhakara N. Neppalli[1,2,3], Qasim M. Warraich[3], James Kennedy[2] and Brendan Duffy[3]; [1]Trinity College Dublin, Ireland; [2]KASTUS Technologies, Ireland; [3]Technological university dublin, Ireland

Sol-gel surface coatings on metals and metals plated substrates play a crucial role in protecting not only from the harsh environments but also provide wider applications such as hydrophobicity, easy cleaning, anti-microbial, scratch resistance etc. Majority of the sol-gel coatings presently available are designed to cure either at shorter timings at higher temperatures (≥ 100 ^{o}C) or longer timings (≥ 24 hrs.) at lower temperatures (≤ 100 ^{o}C). Limitation of high temperature curable sol-gels are not suitable for plastics and the longer curing conditions are not industrially/economically feasible.
In addressing the issue, we have developed new organic-inorganic hybrid (OIH) sol-gel formulations which is curable at lower temperatures and shorter time intervals. Additional advantage of the developed formulations is that the sol-gels can apply on metal plated plastics such as chrome plated acrylonitrile-butadiene-styrene (c-ABS) and cure at lower temperatures (≤ 80 ^{o}C). Developed sol-gels were applied on aluminium and c-ABS and analysed using dynamic light scattering, UV-Vis spectroscopy, rheometer, filmetrics, nano scratch, neutral salt spray (NSS), pendulum & pencil hardness and optical microscopy. These results shows that particle size distribution is around 2-5 nm and the hardness for the coatings was increased to 6H on c-ABS and 8H on aluminium substrate. NSS test reveals the longer time (800 hrs.) resistance from corrosion.

9:30 AM SB03.08.04
Soft and Stretchable Elastic Films Patterned with Liquid Metal for Energy Harvesting and Electromagnetic Interference Shielding Materials Yuwen Wei[1], Priyanuj Bhuyan[1], Suk Jin Kwon[2], Sihyun Kim[1], Byeongjin Park[2] and Sungjune Park[1]; [1]Jeonbuk National University, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)

Liquid metal (LM) based soft and stretchable electronics that can be used for multifunctional electronic materials by referring to the human body, such as e-skin, and soft robotics. The development of an e-skin that can be self-powered and can prevent electromagnetic interference (EMI) is essential for the proper function of soft robotics and wearable electronics. Here, we present a design strategy for creating an absorption-dominate flexible and stretchable EMI shielding and energy harvesting, which is composed of a liquid metal grid and elastic polymer. The thin films are sustainable energy sources to power a diverse range of devices by tapping and it also has an impressive EMI shielding function in operation to avoid interference from external electromagnetic signals. The elaborate multilayered film with a thickness of less than 500 µm has a high absorption shielding effectiveness (SE_A) of more than 60 dB as well as a low reflection shielding effectiveness (SE_R) of 1.7 dB over a broadband frequency (50 GHz to 100 GHz). Moreover, the shielding effectiveness in a specific frequency range can be controlled by creating liquid metal mesh patterns with designed geometries. Due to the flexibility and stretchability (more than 1,000%) of the elastic film with liquid metal electrode, the alteration of the mesh patterns can be achieved by stretching the film, thus enabling the adjustment of the EMI shielding interval. Unlike traditional EMI shielding materials, our proposed elastic films can provide high absorption with low reflection and they can be adapted to the resonant frequency by stretching to shield the various frequencies of electromagnetic waves from the device. In addition, the grid structure of LM patterns can enhance structural stability and maintain a high triboelectric performance (120 V) compared to the conventional method of tiling thin layers of LM. This outstanding performance can be demonstrated by activating LEDs and an electronic wristwatch by hand-tapping the films under various deformations (e.g., rollable, foldable, and stretchable). Overall, our findings exhibit potential for developing a novel class of multifunctional soft and stretchable wearable e-skin for energy harvesting and absorption-dominant EMI shielding materials for application in the 5G generation electronics.

Flexible Silicon-Nanomembrane-Based Bioelectronic Implants with Ultrathin Biofluid Barrier Materials as Chronic Neural Interfaces Enming Song; Fudan University, China

Flexible engineered systems that establish high-performance, long-lived electrical interfaces to the brain and other tissue parts, at a variety of scales ranging from individual-neuron resolution level to macroscopic area coverage, are of particular interest to the neuroscience and biomedical researches, capable of serving as active implants with the ability to operate in a safe, stable fashion over extended periods of time. Conventional material approaches of state-of-

art, fully-integrated electronic systems, such as deep brain stimulators, pacemakers and cochlear implants, generally feature stiff, thick (millimeter-scale) materials constructed by bulk metal, ceramics and wafers, such as hermetic housings of titanium (Ti) or cofired alumina-glass packages. These resulting systems directly contact or insert into adjacent surface of bio-tissues by passive, rigid electrodes with high modulus, where the materials used for these systems are fundamentally mismatched with the curved, compliant and time-dynamic tissues, with the potential of injury and associated foreign-body response that induces device degradation at biotic/electrode interfaces.
Here, the critical challenge is in the development of active materials and device designs, in a thin-film form, that can serve as stable, intimate sensing and/or actuating interfaces to the targeted biological tissues, simultaneously providing robust biofluid-barrier strategies with multi-decades lifetime. Requirements are for robust defect-free, biocompatible and impermeable biofluid-barrier materials that can be rendered in thin, flexible forms and integrated with targeted electronic platforms. In this context, our work focuses on active, soft electronic materials, ranging from high-performance silicon-nanomembrane (Si-NM)-based bioelectronics, to long-lasting stable implants, to actively multiplexed high-channel-count matrix array for spatiotemporal mapping, to their use as high-resolution neural interfaces with chronic stabilities. To begin with, this report summarizes recent advances in this field of science and engineering, with an emphasis on active and passive constituent materials, design architectures and integration methods that support necessary levels of biocompatibility, electronic functionality and reliability for use *in vivo*. Detailed discussion includes our achievements on recent published work, ranging from (1) microscale fabrication for over 32,000 Si-NM CMOS transistors as flexible interconnected network via transfer-printing technology, serving as electrophysiological recording channels; (2) development of thermally-grown silicon dioxide as ultrathin encapsulation strategy at sub-micron thickness (< 1 µm) with operational stability of projected lifetime over 60 years *in-vivo* in human brain; (3) establishment of implantable, biocompatible electrophysiology mapping techniques for neuromodulation with capabilities of bio-signal sensing/stimulation with a high signal-to-noise ratio (SNR) over 40 dB. As a consequence, our work highlights many thousands of active, high density/resolution device arrays over full-brain-scale areas, with robust, ultrathin encapsulation strategies that can establish long-lived electrical and optical interfaces to neural systems. These achievements will open up future opportunities of new engineering design for neural electronic interfaces of stretchability and biocompatibility for multifunctional electrical/optical neuromodulation for diagnosis/treatment of associated neurological disorders such as epilepsy.

8:30 AM *SB03.09.02
Dry Thin-Film Processing for New Generation Devices—From the Role of Nanoporosity in Barrier Layers to the (Un)Wanted Effect of the Harsh Plasma Environment Alberto Perrotta; National Research Council (CNR), Italy

Functional organic and inorganic thin films offer innovative solutions for a plethora of technological applications: organic and hybrid electronics, smart (bio) devices, membrane technology, photocatalysis, sensors and drug delivery systems. The applicability of such thin films strongly depends on the versatility of the synthetic method in tailoring the chemical-physical properties of the materials. In this perspective, porosity is one of the most (un)wanted properties in thin films fabrication. When the thin films are adopted as permeation barriers, (nano)pores could be detrimental in blocking the targeted species and the fabrication methodologies aim at producing pore-free thin films or being able to “heal” the layer barrier properties.
The research on the porosity and its impact will be presented for organic and inorganic (ultra) thin films obtained via (plasma-based) dry deposition methods such as atomic layer deposition (ALD), plasma enhanced-chemical vapor deposition (PE-CVD), initiated CVD (iCVD) and molecular layer deposition (MLD). The undesired porosity will be investigated specifically in the field of protective coatings applied to flexible electronics. Optical and analytical methods for the characterization of such (intrinsic) porosity will be presented, with an overview on the processing aspects leading to its formation and curing.
On a second aspect, thin film fabrication relying on plasma-based techniques is the method of choice for a growing pool of academic and industrial-based innovation technologies. Plasma enhanced methods allow the production of materials with a considerable lower thermal energy and often with a higher chemical-physical quality. However, materials and devices undergoing plasma-based treatments and thin film deposition have to sustain the harsh plasma environment, often representing the bottle-neck for the applicability of these methodologies. The effect of plasma and plasma polymer deposition on emerging materials for energy harvesting and storage will be investigated. The application of fluorocarbon and S-containing plasma polymers and its effects on the opto-chemical properties, morphology and reliability of halide-based hybrid perovskite materials and devices will be explored, with the final goal of enabling their use in the challenging photocatalysis in aqueous environment. Moreover, plasma processing as a tool to mitigate and passivate surface defects will be also explored for thin film perovskite-based photovoltaic devices. Different plasma chemistries, commonly used in thin film deposition and plasma treatments, i.e., Ar, H_2, N_2, O_2, were applied on the halide perovskite layers, showing the limits of applicability and new opportunities of such a wide used technology on emerging thin film materials. Finally, the effect of plasma processing on bioderived carbon electrodes for a new generation of green electronics for energy storage will be shown.

9:00 AM *SB03.09.03
Hydrogels as Self-Acting Substrates for Generation of Flexible Electronics Lucian Lucia, Sachin Agate and Lokendra Pal; NC State University, United States

We fabricated a hydrogel laminated substrate exhibiting UV light-tunability to induce morphological anisotropy within low swelling zones. Such substrates display remarkable localized depolymerization, resulting in a self-acting patterned swelling phenomenon transverse to the long axial plane. Introduction of aqueous inks therefore biases self-alignment within the post-photocured patterns due to mechanisms such as ink polymer displacement by swelling, physical trapping of high viscosity inks, and hydrophilic selectivity. Our photocuring method can generate patterns smaller than 300 µm and offers an unparalleled platform for surmounting limitations of current printing and ink systems.

9:30 AM SB03.09.04
Anti-Adhesive Bioresorbable Elastomer Coating That Reduce Intraperitoneal Adhesions in Abdominal Repair Procedures Shantanu P. Nikam[1,2], Yen-Hao Hsu[1,2], Jessica Marks[2], David Ruppert[2], Howard Levinson[2] and Matthew Becker[2,2]; [1]The University of Akron, United States; [2]Duke University, United States

Intraperitoneal adhesions (IAs) are a major complication arising from abdominal repair surgeries and affects thousands of patients (>100,000) per year in the US with total treatment cost estimated upward of $1 Billion.
IAs can cause small-bowel obstruction, fistula, infection, chronic pain and inflammation, which often require high-risk re-operation with prolonged hospitalization and sometimes leading to chronically debilitated patients.
Herein, we fabricated a composite mesh using a macroporous monofilament polypropylene mesh and a degradable elastomer coating designed to meet the requirements of this clinical application. The degradable elastomer was synthesized using an organo-base catalyzed thiol-yne addition polymerization. The polymer design affords independent control of degradation rate and mechanical properties. The elastomeric coating was further enhanced by the covalent tethering of antifouling zwitterionic molecules on its surface using ‘Click Chemistry’ which was confirmed by XPS measurements. Quartz crystal microbalance measurements showed the zwitterionic functionalized elastomer further reduced fibrinogen adsorption by 73% *in vitro* when compared to unfunctionalized elastomer controls. Mechanical testing demonstrated the elastomer forms a robust coating on the polypropylene mesh that does not exhibit micro-fractures, cracks or mechanical delamination under cyclic fatigue testing that exceeds peak abdominal loads (50 N/cm). The elastomer exhibited degradation with limited tissue response in a 10-week murine subcutaneous implantation model. We also evaluated the composite mesh in a 12-week study

in a rabbit hernia adhesion model. The zwitterionic composite mesh significantly reduced the extent and tenacity of IAs by 94% and 90% respectively with respect to uncoated polypropylene mesh. The resulting composite mesh device is an excellent candidate to reduce complications related to abdominal repair through suppressed fouling and adhesion formation, reduced tissue inflammation, and appropriate degradation rate.

9:45 AM *SB03.09.05
Exploration of Hemp Hurds Waste for Lignin-Containing Nanocellulose Based-Barrier Films for Sustainable Packaging Preeti Tyagi, Lucian Lucia and Lokendra Pal; NC State University, United States

Over the past two decades, cellulose nanofibers (CNFs) have been explored as a source material for various applications such as reinforcements in polymers, thin films, electronics, hydrogels and food packaging. CNFs are predominately sourced from plant fibers (both wood and non-wood) through several pretreatment and mechanical processes. Production of these nanomaterials is a challenge, mainly because of the cost of feedstock materials. These concerns have given rise to a new category of nanocellulose, lignin-containing cellulose nanofibers (LCNFs), which is cheaper as compared to bleached cellulose nanofibers (BCNFs). Also, LCNFs have been found to be less hydrophilic compared to BCNF, which can be an advantage for many packaging applications.
In this presentation, we will talk about how we used residual hemp (Cannabis sativa) hurds to obtain LCNFs using different pretreatments such as autohydrolysis, carbonate, and kraft pulping. The obtained LCNFs were characterized morphologically, for crystallinity, and chemical characteristics using SEM-EDX, XRD, and ToF-SIMS, respectively. LCNFs films were made and water barrier properties of the same were measured in terms of water contact angle, water vapor permeability (WVP), and water absorption. The results showed that LCNF-based films derived from hemp hurd residual fibers could contribute to a circular economy and sustainability.

Robust Encapsulation of Printed Flexible Electronics via Cold Atmospheric Plasma Assisted Silicon Dioxide Coating Rahim Rahimi and Venkat Kasi; Purdue University, United States

Flexible hybrid electronics (FHEs) are emerging devices that bridge the divide between conventional, rigid electronics, and fully printed devices. The FHEs have opened a series of unprecedented application possibilities with broad interest and potential for impact, especially in wearable and implantable healthcare applications. Many such devices are exposed to harsh environmental conditions (e.g., high humidity levels and mechanical stress/strain), requiring them to be encapsulated with insulating polymeric coatings. One important parameter that determines the lifetime and reliability of encapsulated devices is the adhesion between the polymer coating and the printed substrate. In high humidity conditions (e.g., underwater), improper bonding between layers will result in water condensation at the interface between the layers, leading to the failure of the device and electrical shortage. This issue can become more challenging for circuits with complex designs when encapsulant delamination happens in hidden areas that can hardly be noticeable during the initial stage of failure. The bonding between coatings and substrates can be improved by using adhesion-promoting intermediate layers such as SiO_2 deposited through atomic layer deposition (ALD) prior to encapsulating with the polymeric coating. In this process, the hydroxyl groups (-OH) on the glass surface will interact with the silanol groups in the polymer resin coating, resulting in strong Si – O – Si covalent bonds that form between the two materials. Although ALD technology provides precise control of layer thickness at the sub-nanometer scale and is successfully implemented in the packaging of OLED technologies, the process requires complex and time-consuming vacuum-assisted machinery with limitations on the substrate size or dimensions. To address this challenge, we will discuss the novel use of cold atmospheric plasma (CAP) as an alternative to ALD with great potential for scalability and implementation in additive and roll-to-roll manufacturing processes. The CAP deposition process can be used to deposit thin films in a continuous process and directly onto specific locations that are needed. In this process, a plasma head is used to chemically decompose volatile organosilicate precursors and as a source of active species involved in the SiO_2 film deposition.
In this talk, we will review the CAP processing conditions for depositing SiO_2 coatings using Tetraethoxysilane precursor, and it's used as an intermediate barrier layer between the printed circuit and polymeric dielectric layer to improve moisture barrier properties. The processing conditions on the deposited coating's chemical structure, morphology, and electrical properties have been carefully investigated under different CAP processing conditions. This investigation showed the intermediate SiO_2 coating provided a 1000-fold improvement in moisture-resistant barrier properties compared to samples without the intermediate layer. The FHEs prepared with the optimized packaging conditions also show excellent environmental and mechanical stability (even after 1,000 cycles of bending under water). As a proof of concept, the use of the technology was investigated as a reliable packaging approach for robust packaging of printed antennas in automotive applications. It is envisioned that the intermediate SiO_2 coating process can provide a new route in the scalable, more cost-effective, and robust packaging wide range of FHEs for emerging application areas in wearable healthcare, environmental, agricultural, and structural health monitoring applications.

CRISPR Cas13a-Graphene Field-Effect Transistors for Amplification-Free Detection of Nucleic Acids Huijie Li and Yi Zhang; University of Connecticut, United States

Molecular diagnostics, in particular nucleic acid testing, is critical in a wide range of fields relevant to the quality of human life, including a fundamental understanding of physiological processes, pathogen detection, and disease prognosis and diagnosis. Over the past few decades, quantitative polymerase chain reaction (qPCR) has remained as the gold-standard technique for nucleic acid testing. However, qPCR is limited by expensive instruments, the need for well-trained personnel operation, and long sample-to-results time. Recently, the discovery of clustered regularly interspaced short palindromic repeats (CRISPR)-Cas (CRISPR-associated) systems has opened a new path for nucleic acid detection. Leveraging the single-nucleotide target specificity of CRISPR-Cas systems as a result of complementarity between guide RNA and target nucleic acid sequence, scientists have developed a variety of CRISPR-based biosensing strategies for ultrasensitive and highly selective nucleic acid detection. However, the application of current CRISPR-based molecular diagnostics still requires lengthy and complicated target amplifications. In this talk, I will present our recent efforts on the development of a set of CRISPR-based molecular diagnostic platforms without the need for target pre-amplifications by coupling CRISPR assay with bioelectronics of graphene field-effect transistors and other electrochemical biosensors.

8:45 AM SB04.01.03
Satellite-Inspired Ingestible Electronic Platform for Sensing from the Duodenum Yiyuan Yang, Kewang Nan, Fangzhou Xia, Miguel Jimenez and Giovanni Traverso; Massachusetts Institute of Technology, United States

Long term monitoring of gastrointestinal function often requires hospital-based medical interventions which are generally limited to transient optical evaluation as well as short term monitoring of temperature, pH or impedance for generally hours and up to 48 hours. Long term monitoring of both the gastric and duodenal compartments stands to transform our capacity to monitor feeding activity as well as liver and pancreatic function. Here we report the development of a system which combines wireless communication with multi-mode sensing in the form of miniaturized flexible-board electronics with thin film sensors compatible with ingestion. The entire system can be administered either endoscopically or ingested and operate over an extended period. Once active, the device naturally conforms to the GI tract and has the capacity to transiently anchor itself at the level of the pylorus through which integrated sensors can be deployed to support the collection of electrophysiological signals. In vitro and in vivo evaluation support the device’s long-term stability as well as their applicability in measuring local temperature, pressure and impedance in GI tract that serve as important physiological indicators for GI diseases such as inflammation, gastroenteritis, mobility disorders, bloating, ulcers, intestinal ischemia, and bile reflux.

9:00 AM SB04.01.04
Smart Stickers for Non-Invasive Wireless Detection of Early Stage CAUTI Sarath Gopalakrishnan, Muhammad Masud Rana, Michael Anthony Curry Jr, Akshay Krishnakumar and Rahim Rahimi; Purdue University, United States

A urinary catheter is a flexible tube widely used when patients have difficulty urinating naturally and collect urine in a drainage bag. Patients prefer indwelling catheters to avoid multiple insertions of the catheters. However, in many cases, germs like bacteria can enter the body through the catheters and cause an infection in the bladder or kidney called a catheter-associated urinary tract infection (CAUTI). CAUTI affects 0.4 million people every year and causes patient distress, discomfort, pain, and activity restrictions and in some cases can lead to life-threatening conditions. Moreover, CAUTI incurs a medical burden of $340–450 million per year in the US. While many conventional tools such as invasive Cystoscopy, Non-invasive Ultrasound/CT scan have widely used been used for the detection of CAUTI, they are expensive, not real-time, and need manual intervention. A low-cost, non-invasive and contactless automatable sensor is critical in tackling CAUTI.

To address this need, here, we develop a non-invasive smart sticker platform that integrates low-cost smart stickers with a portable reader to detect early-stage UTI through continuous monitoring of urinary frequency and conductivity of urine. Inflammation of the bladder, urethra, or both causes a sensation of the need to urinate thereby increasing the urinary frequency above the healthy range of 5-8 times in 24 hours. UTI causes an increase in the bacterial count and biofilm formation in the flushed-out urine, effectively reducing the conductivity of the patient’s urine at the onset of infection. To capture the urinary frequency through level detection and bacterial infection through conductivity measurements, the smart stickers are designed as two parallel metallic strips manufactured using laser processing of metalized PET tape. This scalable manufacturing technique offers a platform for the rapid production of smart stickers using roll-to-roll processing. Using this platform, a long smart sticker of size 20 cm x 2 cm is manufactured for urine level monitoring to cover the urine bags of volume 2000 mL. Next, to achieve conductivity detection, a short sticker of size 4 cm x 2 cm is manufactured to ensure that the sticker is insensitive to level changes.

The achieve non-invasive measurements, the stickers are attached to the surface of the urine bag and interfaced with a portable reader with the help of a snap-on magnetic connector. The portable reader consists of a signal generator and a scalar reflectometer to form a portable network analyzer. When the urine level increases, the capacitance between the long stickers increases leading to a shift in the resonant frequency. When the conductivity of urine increases, the attenuation between the short stickers increases leading to a reduction in the amplitude of the resonant peak. The readings from the network analyzer are collected by an Arduino module and transmitted using a WiFi module.

A systematic characterization of the smart stickers is performed using artificial urine placed inside the urine bag. The level detector demonstrates a frequency shift from 530 MHz to 234 MHz when the urine level is changed from 500 mL to 2000 mL. Furthermore, the smart stickers provide constant potential voltage over 24 hours of measurement and show an excellent linear sensitivity of 3.1 mV/(mS/cm) from 10 mS/cm to 40 mS/cm in the urine sample. A proof-of-concept analysis is performed to simulate CAUTI by spiking the bacterial CFU in the urine and the readings demonstrated a 10% decrease in the conductivity when CFU levels surpassed the threshold of 10^5 CFU/ml. The smart stickers presented in this work could be the first step towards the development of low-cost and automated noninvasive smart sensor tags for early-stage CAUTI detection.

9:15 AM SB04.01.05
Fully-Printed Multiplexed Wearables for Real-Time Electrochemical Sensing of On-Skin Metabolites Le Yang; Institute of Materials Research and Engineering, Singapore

In an increasingly health-aware population and a move towards remote diagnostics, remote healthcare monitoring, cloud-based med-tech, etc, we tap on the ubiquitous and unlimited reservoir of on-skin biomarkers, including sweat metabolites, in developing a wearable, non-invasive, continuous and real-time sensor – a printed, multiplexed biosensor device. In this talk, we highlight three components of our biosensor. Firstly, we look at the overall framework, of how the device is fabricated by a fully printed process, and what the integrated sensor is capable of measuring.[1-4] Carbon-based electrodes are promising candidates for developing cheap, miniaturized, and disposable biosensors for effective wearable applications. From developing our own printable carbon-based ink, to screen-printing the electrodes, to functionalising each electrode into a specific biosensor, and finally to multiplexing and integration; we show how these devices can potentially add value to home-based biomarker monitoring. Secondly, we look at a variation of our flexible electrode, a graphite/carbon fiber (G/CF) hybrid resembling a super-efficient 3D highway network where ample expressways (CF) run through numerous small factories (locally distributed graphite flakes) for rapid goods pick-up and transportation (electron transfer).[5] Lastly, we zoom in on the top-most layer of the device, the Kirigami paper sweat channel, critical in enabling real-time fresh-sweat reading.[6,7]

PEDOT:PSS Based Soft, Healable and Highly Adhesive Films for Monitoring Human Health Fabio Cicoira; Ecole Polytechnique de Montreal, Canada

Flexible, soft, self-healing, and adhesive conductive materials with Young's modulus matching biological tissues (with a moduli of 0.5-500 KPa)[1] are highly desired for applications in bioelectronics. Here, we report self-healing, stretchable, highly adhesive and conductive films obtained by mixing tannic acid (PVA), ethylene glycol, and Poly (3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS).[2] Our films demonstrated remarkable self-healing and self-adhesiveness, compliance on skin, outstanding stretchability, high adhesion on skin , and low Young's modulus. Our films were used to fabricate electrophysiological epidermal patch electrodes, which exhibited high-quality recording of electrocardiography (ECG) and electromyography (EMG) signals, like commercial Ag/AgCl gel electrodes.

9:45 AM SB04.01.07
Pressure-Sensor-Integrated Smart Bandage for the Management of Diabetic Foot Ulcers Xueju Wang; University of Connecticut, United States

Diabetic foot ulcers (DFUs) have affected millions of people in the U.S. and posed heavy burdens to patients and the healthcare system due to their being slow to heal, high recurrence rate, and potential risk of amputation and even premature death. A mainstay of DFU therapy is mechanical offloading to mitigate pressure at the ulcer, which, however, is usually not effective due to patients' diminished sensation capabilities on the foot and low adherence to offloading recommendations. I will present our recent effort in developing a soft, flexible, wireless pressure-sensor-integrated smart bandage system for continuously monitoring the pressure on the foot and alerting the users to offload under exceeded pressure. The pressure sensor exhibits high linearity, negligible hysteresis, fast response time, and excellent water-proof properties relevant to this application. Wireless data transmission onto a smartphone via Bluetooth enables the display and interpretation of the measured pressure with the option of a preset pressure threshold, when exceeded, an alert will be generated for immediate notifications. Trials on healthy subjects demonstrate reliable monitoring performance and effectiveness in aiding offloading. The developed smart bandage system represents a significant advance in the prevention and management of DFUs and other pressure injuries as well as compression therapy corrections.

10:30 AM *SB04.01.08
High-Detectivity Wearable Organic Photodetectors for Self-Powered Pulse Rate and Oximetry Measurements Thuc-Quyen Nguyen; University of California, United States

Wide-range light detection from the visible to the near-infrared (NIR) region is central to many applications such as high-speed digital cameras, autonomous vehicles, IR sensing, and wearable electronics. Recently, organic photodetectors (OPDs) were shown to be a promising platform for these applications. However, the conventional OPDs are often limited by low responsivity, narrow absorption range, large dark/noise current under applied bias, and large-scale production of these devices require halogenated processing solvents that have a negative environmental impact. In this talk, I will discuss strategies to reduce dark current in NIR OPDs based on a bulk heterojunction (BHJ) comprised of a polymer donor and a non-fullerene acceptor and the molecular design rule for processing OPDs from a green solvent, 2-methyltetrahydrofuran (2-MeTHF). Our OPDs exhibit an excellent specific detectivity (D*) over a broad wavelength range (400 -900 nm) and is comparable to those of commercial silicon-based photodiodes. We demonstrate that the PM7-D5:Y12 OPDs can be used as wearable self-powered devices to monitor heart rate and blood oxygen saturation.

11:00 AM SB04.01.09
Discovering Giant Magnetoelasticity in Soft Matter for Bioelectronics Guorui G. Chen and Jun Chen; University of California, Los Angeles, United

States

Conventional magnetoelasticity, defined as the change in magnetic property in certain materials under mechanical stimulations, is usually observed in rigid alloys such as $Tb_xDy_{1-x}Fe_2$ (Terfenol-D) and Ga_xFe_{1-x} (Galfenol). However, interfacing electronic devices based on these rigid alloys with the human body might hurt the surrounding tissues and the resulting scars will damage or even disable the devices. Herein, we discovered the giant magnetoelasticity in soft matter and achieved a magnetomechanical coupling factor of up to 6.77×10^{-8} T/Pa without the need of an external magnetic field, which is up to five times larger than that of traditional rigid metal-based counterparts.[1] Meanwhile, the soft matter with the giant magnetoelasticity demonstrates a strain of up to 500% and a Young's modulus as low as 166.2 kPa, which is well comparable to the human tissue and skin. To elucidate the fundamentals of giant magnetoelasticity in soft matter, we established an analytical model based on the magnetic particle and dipole interaction, which is well consistent with the experimental observation.

Then we explored our discovery in bioelectronics by coupling it with magnetic induction to invent a textile magnetoelastic generator (MEG) for biomechanical-to-electrical signal conversion. The human body is particularly rich in biomechanical energy,[2] which can be explored to power bioelectronics for *in vivo* and *in vitro* diagnostics and therapeutics. Intimately interfacing the textile MEG with the skin, the relevant body movements could deform the device and strongly alter its magnetic flux density, thereby inducing a current in the textile coil with a density of 1.37 mA/cm^2. The collected electricity in the capacitor could drive a commercial thermometer for personalized sensing.

Meanwhile, the textile MEG can work as a self-powered sensor for *in situ* biomechanical signal analysis.[1,3] Textile-based bioelectronics can realize wide biomedical applications while maintaining their initial wearing comfort.[4-8] Thus, we seamlessly sewed the textile MEGs on the chest area of clothes for respiratory monitoring.[1] With a fundamentally new working mechanism, the textile MEG demonstrated an intrinsic waterproof property, an sensitivity of 0.27 mA/kPa, a signal-to-noise ratio of 61.8 dB, and a response time of 15 ms, which could continuously monitor the strength, frequency, and patterns of various respiratory activities on heavy perspiration skin without any encapsulation. Assisted by a machine learning algorithm, respiration abnormalities, such as cough and rapid breathing, can be recognized with an accuracy of up to 90.89%, hence allowing a personalized and timely detection of respiratory diseases. Thus, we believe that the discovery of giant magnetoelasticity can branch out into broader soft-matter systems, illuminating the future of biomedical society by developing human-body-centered bioelectronics for personalized healthcare.

11:15 AM SB04.01.10
Albumin-Based Antifouling Coating for CRISPR-Based Electrochemical Detection of SARS-CoV-2 Jeongchan Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

As modern history progresses, the emergence of new viruses and the global outbreak of related diseases pose a serious threat to public healthcare issues. Recently, coronavirus disease 2019 (COVID-19) has become a global pandemic. Currently, the gold standard for COVID-19 diagnosis is quantitative reverse transcription-polymerase chain reactions (qRT-PCRs). However, it is time-consuming and requires laboratory-based hospitals, making the countries with poor infrastructures struggle to control the spread of virus.

We here present a method to formulate a thick (>1 μm) antifouling coating with macro- and nano-scale pores for electrochemical diagnostic sensors with ultrahigh sensitivity using an emulsion ink. Traditional antifouling coatings such as poly(ethylene glycol) (PEG) and bovine serum albumin (BSA) have several limitations in biomedical applications: they physically adsorb onto the sensing surfaces, which cannot ensure full blocking of the active surfaces and they may detach from the surface, 2) they hinder electron transfer in the electrode surfaces, reducing the electrochemical signal. Oil-in-water emulsion can be utilized to form the multiscale porous antifouling coating at any thickness desired and the highly porous nature of the material greatly increases its surface area available for bioreceptor presentation and interactions with analytes. We designed CRISPR-based sensors for detection of SARS-CoV-2 RNA using an electrochemical (EC) enzymatic sandwich detection assay, which allows us to detect the SARS-CoV-2 without electrode surface inactivation. It is also desirable as an antifouling coating as it can be rapidly applied using nozzle-assisted printing in a form that is highly sensitive and robust, plus functional nanomaterials can be embedded within the layer.

11:30 AM SB04.01.11
A Flexible and Switch-Matrix Addressable Active Electrode Array Based on Complementary Organic Electrochemical Semiconductor Technology Ilke Uguz[1], David Ohayon[2], Sophie Griggs[3], Iain McCulloch[3], Sahika Inal[2] and Ken Shepard[1]; [1]Columbia University, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]University of Oxford, United Kingdom

While there has been considerable recent interest in flexible and conducting polymer (CP)-based implants for interfacing with the brain, nearly all of these studies have focused on passive electrode arrays with low channel counts. Active integration of CP-based electronics for large-scale recordings, on the other hand, is limited, as the current library of active organic electronics is restricted to organic electrochemical transistors (OECTs). OECT gating is traditionally achieved over a common gate electrode and electrolyte, which limits the control of individual components in a large array. In addition, when OECTs are used for active switching operations, ion uptake of CPs poses a major issue for *in vivo* neural applications where the high ionic transients (~μA) result in the undesired activation of nearby neurons and lead to high ionic-electronic cross-talk with the adjacent OECTs. Therefore, there is a significant need for generation of alternative CP-based circuit components to generate complex organic circuitries capable of operation with internal ions to avoid interference with the measured media. In this work, we introduce a new class of organic semiconductors which can be operated by controlling the electrophoretic drift of the internally trapped cations in the channel to generate unidirectional conductivity with electrical output analogous to silicon-based diodes. We tune these organic diodes to work in complementary regime with the existing OECT configuration and demonstrate that this circuit architecture can be used to generate a switch matrix for electrode selection on the neural interface with minimal crosstalk between adjacent pixels. We further show that this topology enables the generation of ultra-thin (50-μm x 8-μm), flexible neural implants with high channel counts (32) that acquire local field potentials with high signal-to-noise ratio. To the best of our knowledge, this work is the first demonstration of active organic electrochemical circuits integrated in the front-end pixel of a fully implantable shank. Owing to their ionic-electronic conductivity, solution-based processability, and integrability with flexible, biocompatible substrates, unlike most inorganic circuit elements, CP-based circuitries are ideal to use on the neural interface.

SESSION SB04.02: Device Design for Bioelectronic Sensing
Session Chairs: Tzahi Cohen-Karni and Luisa Torsi
Monday Afternoon, April 10, 2023
Moscone West, Level 3, Room 3004

1:30 PM *SB04.02.01
Real-Time Biosensor Technology H. Tom Soh; Stanford University, United States

A biosensor capable of continuously measuring specific molecules in vivo would provide a valuable window into patients' health status and their response to therapeutics. Unfortunately, continuous, real-time molecular measurement is currently limited to a handful of analytes (i.e. glucose and oxygen) and these sensors cannot be generalized to measure other analytes. In this talk, we will present a biosensor technology that can be generalized to measure a wide range of biomolecules in living subjects. To achieve this, we develop synthetic antibodies (aptamers) that change its structure upon binding to its target analyte and produce an electrochemical current or emit light. Our real-time biosensor requires no exogenous reagents and can be readily reconfigured to measure different target analytes by exchanging the aptamer probes in a modular manner. Using our real-time biosensor, we demonstrate the first closed loop feedback control of drug concentration in live animals and discuss potential applications of this technology. Finally, we will discuss methods for generating the aptamer probes which are at the heart of this biosensor technology.

2:00 PM SB04.02.02
***In Situ* Swelling of Cartilage Explants for Osteoarthritis Through Graphene Strain Sensing** Charles Dhong; University of Delaware, United States

Osteoarthritis (OA) is a widespread disease which involves the degeneration of cartilage. Healthy cartilage derives its function from a combination of mechanical integrity of the collagen matrix and the physiochemical contributors of negatively charged aggrecan contained inside the matrix. While mechanical integrity via cartilage stiffness is a commonly used biomarker—primarily due to the wide availability of indentation tests—there are few approaches which focus on restoring the aggrecan content, which manifest as the swelling behavior of cartilage in response to different osmotic environments. The challenge is that cartilage explants—which have high physiological relevance—are too large for sensitive instruments and swelling changes are too little for simple visual or mass-based techniques. Here, we developed a platform which uses embedded graphene strain sensors to measure the swelling behavior of equine cartilage explants in real time. By simulating OA-like degradation through a series of enzymes, we were able to identify distinctive swelling profiles of explants undergoing proteoglycan digestion versus broad spectrum matrix damage. This parallel and scalable platform would enable new approaches to OA regeneration based on restoring proteoglycan content.

2:15 PM SB04.02.03
***In Situ* Surface Engineering, Processing and Characterization of Flexible PLA-Based Biocompatible Composites Using Confined Micro-Plasma-Based Technique—For Applications as Embedded Wafers for Targeted Drug Delivery** Manan Sehgal[1], Prakhyat Gautam[1], Mai T. Yang[1], Edgar Perez-Lopez[2], Edbertho Leal-Quiros[2], Saquib Ahmed[3,3] and Sankha Banerjee[1,4]; [1]California State University, Fresno, United States; [2]University of California, Merced, United States; [3]Buffalo State College, United States; [4]University of California, Davis, United States

The following work focuses on the surface modification and processing of flexible PLA and PLA-Graphene composites using room temperature and confined micro plasma-based Townsend discharges in ambient conditions. The work includes in-situ-based processing using a proprietary plasma-integrated 3D printing system developed in the Energy Devices and Plasma Applications Laboratory at California State University, Fresno. The current-voltage characteristics of the plasma are varied based on the use of a quasi-static DC and a pulsed discharge with a variable voltage of 1 kV to 2.2 kV and with currents below 1mA. The micro plasma-based discharges integrated with the additive manufacturing process can tailor the surface characteristics of the composites by modification of their surface energies. The surface characterization of the 3D printed geometries is performed using profilometry, scanning electron microscopy, and electrical impedance spectroscopy. The surface energy and wettability characteristics are studied using contact angle characteristics. The micro plasma is characterized using high voltage probes, and visible spectroscopy. These 3D-printed geometries can be used as embedded wafers for targeted drug delivery.

2:30 PM SB04.02.04
A Very Large-Scale Integration of High Performance, Low Leakage Internal Ion-Gated Transistors (IGTs) for Wireless, Battery-Free Implantable Bioelectronics Claudia Cea, Zifang Zhao, Jennifer Gelinas and Dion Khodagholy; Columbia University, United States

Organic material-based conformable electronics are optimal candidates for components of bioelectronic circuits due to their inherent flexibility and soft nature. We have shown that internally ion-gated organic electrochemical transistors (IGTs) operate by leveraging ion reservoirs inside their channels to dramatically improve the operation speed and integration capacity of this ion driven transistor. In order to establish IGTs as versatile building blocks of bioelectronics, it is critical to establish fabrication strategies to enable IGT-based high-density integrated circuits for creation of fully implantable, wireless, and battery-free devices. Here, we report a scalable, self-contained, and integrable sub-micron internal ion-gated organic electrochemical transistor with vertical channel (v-IGT). Owing to the sub-micron channel size, v-IGTs can operate in the MHz range, surpassing any other electrochemical device while maintaining a high amplification. Furthermore, we analytically and experimentally derived the non-linear relationship between transistor speed and contact area as a function of gate and channel capacitance. The device is encapsulated using long-term implantable grade (parylene-C) material ensuring operational stability of over 1 year. We also developed a micron-scale perforation strategy to ensure intact hydration paths for transistor channels while maintaining effective isolation of densely packed adjacent transistors and minimizing potential for cross-talk and gate current leakage. The presence of this hydration via does not cause a detriment to the device characteristics due to the hydrophilicity and sufficient containment of ion reservoirs in the channel. We fabricated a conformable v-IGT-based array with 155k transistor/cm2, highlighting the viability and feasibility of IGTs as transistor architecture for a majority of flexible electronics applications. We further showcase their functionality by creating high-gain multi-stage amplifiers, oscillators, and multiplexers. Finally, we created a novel wireless, battery-free strategy for electrophysiological signal acquisition, processing and transmission that employs v-IGTs and ionic communication (IC). The wirelessly-powered v-IGTs were able to acquire and modulate neurophysiological data *in-vivo* and transmit them across the dermis, eliminating the need for any hard Si-based electronics in the implant.

2:45 PM SB04.02.05
Quantum-NanoElectroPore Platform for Single-Molecule Conductance and Raman Detection of Biomolecules Sanjana Mukherjee[1], Ching-Wei Tsao[1], Lucas Domulevicz[2], Josh Hihath[1] and Quan Qing[1]; [1]Arizona State University, United States; [2]University of California, Davis, United States

The great advancement in nanopore technology has enabled real-time sequencing without the need for sample amplification with long read length. However, the ionic-current-based readout has limitations in the specificity and resolution, leading to higher error rate. The growing interest in analyzing other biomolecules such as proteins using nanopore configurations also demands integration of additional readout mechanisms such as recognition tunneling and metal-gap enhanced Raman. However so far there is very little success in the integration of single-molecule delivery, and multi-mode detection of the same molecule. We recently developed a new strategy to fabricate a single-molecule sensing microchip platform, Quantum Tunneling NanoElectroPore (Q-NEP), which integrates inside a nanofluidic channel a pair of tunneling electrodes self-aligned with a nanopore, by combining standard top-down lithography on standard semiconductor substrates with *in situ* reversible electrochemical deposition with feedback control. We have demonstrated simultaneous detection of DNA translocation events from coincidental ionic and tunneling current signals, and successfully obtained quantized conductance from short thiolated oligonucleotides bridging the tunneling gap as they were delivered through the nanopore. In addition, metal-gap enhanced Raman signals are also obtained from L-cysteine molecules through the device. These results provide the first step for the integration of ionic, tunneling current and Raman multi-mode analysis of individual molecules on the Q-NEP platform, and reveal the promising potential for a unified microchip platform for multi-omics analysis with high resolution and specificity.

Single-Molecule Reliable Detections with a Large-Area Electronic Interface Luisa Torsi; University of Bari A. Moro, Italy

A large millimeter-wide electronic interface can detect at a single-molecule/entity limit-of-detection. The technology is called SiMoT - Single-Molecule with a large Transistor.[1] So far, antigens (Immunoglobulins, C-reactive proteins, spike 1, HIV p-24), antibodies (anti-immunoglobulins, anti-spike1), peptides, viruses (SARS-Cov-2), bacteria (Xylella fastidiosa), and even DNA strands (KRAS, miR-182) have been detected. Selectivity is assured by covering the gate electrode with a large number (10^{11}-10^{12}/cm^2) of recognition elements to affinity binding the target element.

SiMoT detects directly in a droplet (0.1 mL) of a real fluid such as saliva from COVID-19 patients, blood serum, pancreatic cysts juice, and olive saps from infected trees. Relevantly Brownian diffusion enables the entity to statistically hit the millimeter-wide interface in a few minutes.[2]Considering the footprint of a molecule on a millimeter-wide interface, it is like spotting a droplet of water falling on the surface of a 1 Km wide lake as depicted in the graphical abstract.

The applications span from a handheld intelligent single-molecule binary bioelectronic system for fast and reliable immunometric point-of-care testing of COVID-19 patients[3] and Xylella fastidiosa single bacterium detected in infected plants sap. The phenomenon enabling such outstanding performance level was discovered in 2018.[4] While still under investigation, it is supposed to involve an amplification that starts from the single affinity binding that triggers a propagating collaborative response.

Future actions include the deepening of our understanding of the sensing mechanism and the engagement in a campaign of thousands of clinical trials that will bring SiMoT beyond TRL5.

Flexible, Implantable, Pulse Oximetry Sensors for Continuous Monitoring of Arterial Blood Oxygen Levels Joseph Troughton[1], Pauline Brige[2] and Marc Ramuz[1]; [1]MINES Saint-Étienne, IMT, France; [2]Aix-Marseille Université, France

Pulse oximetry is the most widespread method of monitoring patient heart rate and blood oxygen levels in both clinical and non-clinical settings. These devices tend to be ridged, bulky, and therefore suitable only for short-term use. In addition, they suffer degraded performance due to movement and changes in ambient light levels, and can present variability from one individual to another. To facilitate long-term monitoring of physiological parameters, including heart rate and oxygen saturation, implanted devices are required. Implantation removes interference from external light sources, eliminates sensitivity to skin pigmentation, and allows enhanced performance during movement associated with greater sensitivity.
Here we demonstrate a low cost, ultra-flexible pulse oximetry probe. The hybrid flexible devices are fabricated on 5 µm thick Parylene C using laser ablation to define the circuit design, and integrate a small ridged photodetector and LEDs using a flexible adhesive. Finally, contact between the probe and the processing board is achieved using a flat flexible cable and anisotropic conductive film. Devices are demonstrated *in vivo* on a sedated porcine subject and calibrated against a standard peripheral SpO_2 meter while the subject's oxygen intake was varied. In addition to demonstrating the functionality of these implanted devices, we show that the implementation directly on the femoral artery of our devices records a more acute response to the variation in oxygen intake compared to the peripheral measurements.
These devices are low cost and based on biocompatible materials, and can be easily implanted during cardiovascular surgery. This offers a route towards long-term implantation of devices for continuous patient monitoring.

4:15 PM SB04.03.03
A Skin Compatible Meta Structured E-Skin Patch for Long-Term Monitoring of Bio-signals Juhee Kim[1,2], Wonseop Hwang[3], Hyunjung Yi[1] and In-Suk Choi[2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)

In this presentation, we introduce a skin-compatible meta-structured e-skin patch that only consists of commercial adhesive dressing and FPCB for continuously collecting electrocardiographic signals over five days. In terms of long-term monitoring, it is crucial for the on-skin sensors to stably monitor bio-signals without any skin discomfort. Our approach presents a practical and cost-effective way to manufacture a skin-compatible wearable sensor system, making use of conventional materials that were difficult to include due to their high elastic modulus.

To rationally design the metal structural pattern of a stretchable sensor patch suitable for skin movement, we measured and analyzed the deformation field around the chest by using digital image correlation method and finite element simulation. Among many possible patterns, we chose the Kagome-based structure for the adhesive dressing that can well accommodate the deformation of the skin as well as give breathability to the patch due to its high porosity. We further devise a tethering scheme of attaching the FPCB to the adhesive dressing. The results showed that our sensor patch system greatly improved skin comfort and was able to monitor ECG signals for five days without any discomfort.

4:30 PM SB04.03.04
Wearable Non-Invasive Biosensors for Health Monitoring at the Molecular Level Hnin Y. Nyein; The Hong Kong University of Science and Technology, Hong Kong

The rather reactive and centralized medical approaches in today's healthcare system prevent individuals from obtaining diagnosis and treatment in a timely and accessible manner. Presently, commercially available devices for remote health monitoring are majorly limited to body's vitals and glucose levels, limiting access to healthcare. In this talk, I will present the wearable biosensors which utilized sweat to extract individual's biomolecular information. These sensors integrate flexible electronics and solid-state electrochemical sensors in a single robust platform to achieve reliable analyte quantifications at the site of sweat collection. Specifically, the wearable ultralow-volume sweat sensors make sweat a viable mode of health monitoring at the molecular level across activities, whether active or sedentary, and across user groups, whether young or old, healthy or ill. By using the sensors, continuous sweat analysis can be used to study how the body's endogenous and stimulated sweating response relates to stress, metabolic conditions, and potentially neurological afflictions through multiplexed quantification of ions, metabolites, and drugs.

4:45 PM SB04.03.05
Printed Carbon-Based Biosensors for Diagnostic and Cell Cultures Probing Mario Caironi[1], Adrica Kyndiah[1], Fabrizio A. Viola[1], Francesco Modena[1], Cristiano Bortolotti[1], Giulia Z. Zemignani[1], Gabriele Tullii[1], Francesco Galeotti[2], Carlotta Ronchi[1], Luca Sala[3] and Maria Rosa Antognazza[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]Istituto Auxologico Italiano IRCCS, Italy

Printed carbon based electrolyte-gated transistors represent ideal ionic/electronic hybrid devices that bridge biology and electronics. These devices are being investigated for a wide range of applications, from drug delivery to neuromodulation and highly sensitive biosensing. Here we report our recent progress in printed devices based both on thin films of polymer semiconductors and randon-networks of carbon-nanotubes. In particular, we show how large-area printed arrays of electrolyte-gated polymer transistors can enable future diagnostic tools to target specific biomarkers at clinical level. At the same time we propose printed carbon-nanotubes as an alternative approach for highly stable biosensors operating in acqueous environment. Besides their use to target biomarkers, we also show how such printed carbon-based transistors can be employed to monitor cell cultures proliferation over consecutive days. Remarkably, we also demonstrate that, despite the planar geometry of the device, spontaneous recording of intracellular action potentials of cardiomyocytes can be detected. Such results show that printed carbon-based electrolyte-gated transistors have great potentials for many aspects of future large-area bioelectronics, including diagnostic and parallel probing of electrogenic cell cultures.

SESSION SB04.04: Bioelectronic Interfaces
Session Chairs: Sahika Inal and H. Tom Soh
Tuesday Morning, April 11, 2023
Moscone West, Level 3, Room 3004

10:30 AM *SB04.04.01
Toward Flexible Multimodality Sense (and actuate)—Materials and Platforms Tzahi Cohen-Karni; Carnegie Mellon University, United States

My team's efforts are focused on the development and engineering of nanomaterials-based flexible platforms to interrogate and affect the properties of tissue, with a specific goal to understand signal transduction (chemical or electrical) in tissue or complex 3D cellular assemblies. Highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces, i.e., bioelectrical platforms for chemical and physical sensing and actuation. We developed a breakthrough bioelectrical interface, a 3D self-rolled biosensor arrays (3D-SR-BAs) of either active field effect transistors or passive microelectrodes to measure both cardiac and neural spheroids electrophysiology in 3D. This approach enables electrophysiological investigation and monitoring of the complex signal transduction in 3D cellular assemblies toward an organ-on-an-electronic-chip (organ-on-e-chip) platform for tissue maturation investigations and development of drugs for disease treatment. Utilizing graphene, a two-dimensional (2D) atomically thin carbon allotrope, we can simultaneously record the intracellular electrical activity of multiple excitable cells with ultra-microelectrodes that can be as small as an axon (ca. 2μm). The outstanding electrochemical properties of the synthesized hybrid-nanomaterials allow us to develop highly efficient catalysts, and electrical sensors and actuators. We demonstrated sensors capable of exploring brain chemistry and sensors/actuators that are deployed in a large volumetric muscle loss animal model. Finally, using the unique optical properties of nanocarbons in the form of graphene-based hybrid-nanomaterials and 2D nanocarbides (MXene), we have formed remote, non-genetic bioelectrical interfaces with excitable cells and modulated cellular and network activity with low needed energy and high precision. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and potentially seamlessly merge nanomaterials-based platforms with cells, fusing nonliving and living systems together.

11:00 AM SB04.04.02
Printed Organic Electronic Devices for Plant Health Monitoring and Precision Agriculture Elliot Strand[1], Eloise Bihar[1], Sanggil Han[2], Catherine Crichton[1], George G. Malliaras[2], Robert Mcleod[1] and Gregory L. Whiting[1]; [1]University of Colorado, United States; [2]University of Cambridge, United Kingdom

Low-cost, flexible, and lightweight electronic biosensors offer an exciting pathway to future products for environmental and plant health monitoring. Organic electrochemical transistors (OECTs) are particularly favorable sensing platforms due to their high sensitivity, low power requirements, and use of soft, biocompatible materials. Furthermore, OECTs can be manufactured with scalable printing techniques, which makes them suitable for large-area electronics (LAE) applications. This presentation will describe the development of fully printed, flexible OECTs that can accurately detect a suite of analytes (e.g., nutrients, pH, temperature) that are relevant to plant health. For example, the devices were used to accurately detect macronutrient concentrations in whole plant sap and hydroponic fluids in real-time. The rheological and electronic properties of the OECTs were tuned by doping the semiconducting channel with sugar alcohols, super absorbing polymers and thickening agents. These additives boosted the transconductance and sensitivity of the transistors, which led to a super-Nernstian response to the target analyte. By utilizing ion selective membranes (ISMs), we fabricated OECT-based ion sensors that demonstrate selectivity to the target ion against similar ions over five orders of magnitude in concentration and a limit of detection (LOD) as low as 10 µM. The results confirm that lightweight, printed organic electronics are a suitable path to high-throughput, low-cost assessment of plant health, which could lead to massive efficiency gains in agriculture.

11:15 AM SB04.04.03
Flexible Graphene-Based mHealth and Wearable Sensors for Disease Monitoring and Management Jiaobing Tu, Rebeca M. Torrente Rodríguez and Wei Gao; California Institute of Technology, United States

With the emphasis of healthcare shifting towards prevention and early detection of diseases and monitoring of chronic conditions, there is a growing need for hassle-free telemedicine sensor technologies that can be seamlessly integrated into daily life. While significant progress has been made in the development of wearable sweat and salivary biosensors to meet this need for rapid, real-time collection of physiological information, the majority of current epidermal sensing systems are unable to detect trace-level disease-relevant biomarkers accurately in biofluids and cannot be mass produced. To meet this demand for low-cost, mass-producible mHealth devices for at-home settings, we developed several fully-integrated laser-engraved graphene-based biosensors for the detection of low-concentration sweat and salivary analytes including hormones (e.g. cortisol) and proteins (e.g. SARS-CoV-2 nucleocapsid protein and C-reactive protein). Several graphene surface engineering strategies are investigated for the sensitive and selective detection of targets. System-level engineering and microfluidic designs are explored to achieve on-demand sweat induction and harvesting under sedentary settings, automated sweat and reagent routing, and in situ signal correction and analysis for facile operation on the skin. The utility of these fully integrated flexible mHealth systems is evaluated through multiple human studies involving healthy and various patient subgroups towards stress assessment, rapid COVID-19 diagnosis and severity assessment, as well as the monitoring and management of various chronic conditions including chronic obstructive pulmonary disease, heart failure, and inflammatory bowel diseases. These fully integrated mHealth devices demonstrate an enabling technology that can be easily adapted to monitor a broad spectrum of disease-specific proteins, cytokines, and hormones, advancing future applications in personalized disease diagnosis, management, and prevention.

11:30 AM SB04.04.04
Wearable Electrochemical Biosensors for Real-Time Health Monitoring in Daily-Life Jayoung Kim; Yonsei University, Korea (the Republic of)

Wearable biosensors represent a promising opportunity to monitor human physiology through dynamic measurements of (bio)chemical markers in biofluids such as sweat, tears, saliva, and interstitial fluid in a continuous and non-invasive way. Such new platforms can thus offer real-time (bio)chemical information toward a more comprehensive view of a wearer's health, performance, or stress at the molecular level in daily-life. Continuous biomonitoring addresses the limitations of traditional invasive blood testing and provides the opportunity for early diagnostic and therapeutic interventions. My research is focused on developing wearable electrochemical biosensors towards non-invasive health monitoring opportunities and evaluating the potential impact of such wearable point-of-care devices on our daily life. The innovative biosensing technology was demonstrated by successful electrical/electrochemical signal transduction of biomolecular/biocatalytic reactions. It was further developed into various wearable form factors using printing technology, offering wearer conformity, flexibility, and stretchability. The wearable biosensors could measure a broad spectrum of biomarkers such as metabolites, electrolytes, hormones, and various small molecules in non-invasive biofluids, demonstrating clinical values through human studies. Furthermore, our recent outcomes will be discussed in this talk covering the discovery of new biomarkers and their underlying mechanisms utilizing various wearable form factors, such as mouthguards, contact lenses, and epidermal patches.

SESSION SB04.05: Flexible Bioelectronic Devices I

1:45 PM *SB04.05.01
Smart Skin Electrodes for Electrophysiological and Circulatory Monitoring of Freely Behaving Humans Yael Hanein; Tel Aviv University, Israel

Wearable devices are becoming ubiquitous. They are used extensively by consumers and are becoming more noticeable in the medical domain. But contemporary wearable devices are still relatively bulky and often have limited equivalence to medical gold standards. Skin patches with chemical, mechanical, and electrophysiological sensors offer new opportunities for future sensors. These devices can be designed to seamlessly interact with the user while also providing high quality and long-term data. In combination with miniaturized low power electronics and powerful data analysis algorithms these devices have the potential to provide continuous measures of various physiological parameters from freely behaving humans. In this presentation I will discuss some of our recent achievements in monitoring the electrophysiology (EEG, EOG, EMG and ECG) of freely behaving humans during rest, overnight sleep and during movement. I will also present recent progress towards simultaneous measurements of electrophysiology and blood pulsation at the arm, neck, and face.

2:15 PM SB04.05.02
Fully Implanted Battery Free Chronic Organ Interfaces Philipp Gutruf; University of Arizona, United States

Materials and fabrication concepts for the creation of soft electronics coupled with miniaturization of wireless energy harvesting schemes enable the construction of high-performance electronic and optoelectronic systems with sizes, shapes and physical properties matched its biological host[1]. Applications range from continuous monitors for health diagnosis to minimally invasive exploratory tools for neuroscience[2]. Translation of these approaches towards neuroscience tools to enable advanced insight into the central and peripheral nervous require means to enable full subdermal implantation and operation to enable naturalistic behavior which often is the readout of circuit level behavioral experiments that are critical to decipher function. This talk presents science and engineering approaches for the creation of soft devices with near field power transfer and data communication capabilities[3] and discusses application in devices for the stimulation and recording of organ systems such as the brain, the peripheral nervous, cardiovascular and the musculoskeletal system. We introduce a series of advances in subdermally implantable device technologies that enable digitally controllable subdermal platforms with multimodal optogenetic and electrical stimulation capabilities[4][5] with the ability to provide stimulus without the physical penetration of the blood brain barrier. Additional to these stimulation capabilities we demonstrate new capabilities in biointerfaces with the cardiovascular and musculoskeletal system[6] that enable recording of organ health as well as closed loop operation chronically in freely moving subjects. Because of the minimally invasive nature of these tools we show chronic neuromodulation capabilities over months in freely moving subjects enabling a digital disease models as well as platforms that can be rapidly translated to large animal models.

2:30 PM BREAK

3:00 PM *SB04.05.03
Paper-Based Devices for Flexible and Wearable Applications Seokheun Choi; Binghamton University, The State University of New York, United States

Paper-based devices have recently emerged as a simple and low-cost paradigm for flexible and wearable applications. Paper is a flexible and low-cost game-changing substrate for next-generation electronics because of its excellent mechanical and dielectric properties with chemical and thermal stability. The biodegradability of paper-based electronics has attracted much attention as the future of green electronics, reducing the dramatic increase in electronic waste. Concurrent with advances in paper-based electronics, remarkable efforts have been dedicated to paper-based microfluidics for next-generation point-of-care (POC) diagnostics, particularly in limited-resource and remote regions. Fluidic components, patterned in paper, allow for instrument-free liquid transport via capillary wicking and storage of biological and chemical reagents within their 3-D fiber network of paper. A merged system incorporating paper-based electronics and paper-based microfluidics will have the transformative potential to yield exceptionally powerful functions and performances. In this invited talk, he will present many innovative paper-based electronics and paper-based microfluidics that his research group recently developed especially for flexible and wearable applications. Details of the frontier of research to improve the performance of the devices will be discussed, followed by a critical perspective on strategic future directions.

3:30 PM SB04.05.04
Ion-Based Conformable Integrated Wireless Neural Implant Zifang Zhao[1], Claudia Cea[1], Jennifer Gelinas[1,2,2] and Dion Khodagholy[1]; [1]Columbia University, United States; [2]Columbia University Medical Center, United States

Understanding how neural activity evolves in a developing brain is of great scientific value and clinical importance. However, chronic *in-vivo* monitoring of neural activity in a fetal animal requires a minimally invasive, conformable, and miniaturized device. Here, we introduce a fully conformable, battery-free, implantable bioelectronics device integrating a neural probe, internal gated ion transistor(IGT), and ionic communication circuit(IC). We hypothesize that IGT could be wirelessly powered by a pair of IC electrodes sensing externally generated electrical potential energy within polarizable media, and IGT enables modulation of the IC current by electrophysiological signal that can be sensed externally. To validate this hypothesis, firstly, we have characterized IGT's performance under IC operation frequency. IGT shows no transconductance decrease when powered with 1MHz sine wave, compared with DC power. We have characterized the power efficiency and signal-to-noise ratio of this system. We demonstrated IC could effectively transmit mill-watt power to an implantable device and IGT could effectively modulate IC current with sub-millivolt gate signal. Finally, we fabricated a fully conformable, implantable device and implanted the device in baby mice. We demonstrated chronic recording of high-quality electrophysiological signals, including local field and action potentials over 30 days. In this work, we have demonstrated a fully conformable neural implant that establishes a safe, long-term pathway to the signal inside biological tissues.

3:45 PM SB04.05.05
Biocompatible Printed Adhesive Devices for Electrical Stimulation of Plants Eloise Bihar, Megan N. Renny, Elliot Strand, Catherine Crichton, Robert Mcleod and Gregory L. Whiting; University of Colorado-Boulder, United States

Understanding the chemical signals governing plant physiology is critical for environmental monitoring and protection. Electrostimulation of electrical networks in plants can be linked to ion transport and the activation of ion channels, and can trigger biological activities such as gene expression or plant movements. Electrical currents have also been used to enhance plant growth. Here, we present a new technique to fabricate biocompatible adhesive sensors that can be placed as wearable dressing, and stimulate or relay signals emitted by the plant. The customizable sensors are used to induce electrostimulation and can be controlled wirelessly for over 1 week. This work represents a stepping stone toward understanding the biological mechanisms of plants, and evaluating their defense response when subject to stress.

4:00 PM SB04.05.06
Soft MXene Filament Microelectrodes for High-Resolution, Localized Detection of Neural Transmitters and Electrical Signals Lingyi Bi[1], Kseniia Vorotilo[1], Natalia Noriega[2], Ruocun (John) Wang[1], Bhavik A. Patel[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]University of Brighton, United Kingdom

The development of soft neural interfaces opens opportunities for long-term studying and modulating brain functions and diseases with fewer side effects by minimizing the mechanical mismatch between artificial devices and soft tissues. However, few designs have enabled both electrical and chemical sensing – necessary for capturing the diverse neural signals *in vivo* – as simultaneous high conductivity and redox surfaces are required for such multifunctional electrodes. Here we report a novel method leveraging the unique combinations of electrical conductivity, functional surfaces, and solution processibility of MXenes, an emerging class of 2D nanomaterials, to produce a thin conformal MXene coating on nylon filaments (30-300 µm in diameter) at a fast speed (up to 15 mm/s). The highly aligned MXene coatings provide the microelectrodes with an electrical impedance as low as 3Ω at 1kHz. In addition, the MXene coating provides ample redox surfaces for the detection of neural transmitters such as dopamine and 5-hydroxytryptamine. These MXene filament microelectrodes offer a robust, miniaturized platform for the monitor and stimulation of neural activities at the cellular level, facilitating a greater understanding of health and disease.

4:15 PM *SB04.05.07
Wearable Microfluidic Electrochemical Biosensor for Automatic Molecular Monitoring Wei Gao; California Institute of Technology, United States

Wearable and flexible biosensors for the continuous monitoring of metabolites in sweat can detect a few analytes at sufficiently high concentrations, typically during vigorous exercise so as to generate sufficient quantity of the biofluid. I will introduce the design and performance of a wearable electrochemical biosensor platform for in situ analysis, in sweat during physical exercise and at rest, of trace levels of multiple metabolites, nutrients, and proteins. The biosensor consists of laser-engraved graphene electrodes that are functionalized with target-specific natural or synthetic receptors, and integrated with modules for iontophoresis-based sweat induction, microfluidic sweat sampling, signal processing and calibration, and wireless communication. The clinical value of our wearable systems is evaluated through human studies toward metabolic/nutritional assessment and disease management. These wearable technologies could open the door to a wide range of personalized monitoring, diagnostic, and therapeutic applications.

SESSION SB04.06: Poster Session: Flexible Bioelectronic Devices

Multimodal Neruonal Function Monitoring of hiPSC-Derived Organoids on *In Vitro* Platform Namyun Kim, MinJin Kang, Yamujin Jang, Nakwon Choi and Yi Jae Lee; Korea Institute of Science and Technology, Korea (the Republic of)

Neuron-on-a-Chip technology has been intensively studied in medical and pharmaceutical fields to understand and explore complex neurological systems in a controlled in vitro platform. This platform provides a biocompatible cell culture dish with multiple electrodes that can transmit bioelectrical signals and well for nourishing, guiding, and proliferating the neurons. Recently, many researchers studied and investigated three-dimensionally cultured organoids derived from human induced pluripotent stem cells (hiPSC) in in vitro systems. The organoids showed much similar behavior to in vivo systems than 2D cultured cells due to their capability of mimicking organ cell formation with cell-to-cell interaction. However, due to their self-organizing characteristics while development and proliferation, the design of the multielectrode array (MEA) and microfluidic channels should be considered an important factor in realizing practical preclinical models.
In this paper, we developed a MEA chip consisting of a total of 130 electrodes that each can act as an electrically stimulating or recording site and dumbbell-shaped microfluidic channel to investigate hiPSC-derived motor nerve organoids placed in two wells. To minimize the contact impedance of the electrodes, the opening area (9 um diameter) is covered with platinum black. The organoids were cultured for one month in vitro and organoid formation and axon growth were investigated. The results showed that the axons from the organoids extended ~3 times longer in narrow fluidic channel (300 um width) than inside the well (2 mm diameter). Developed MEA chip showed simultaneously detection of multiple neuronal activities with a low background noise level. Also, from the electrical stimulation tests, neuronal network activities including conduction behavior were measured and analyzed. Further improvements to the MEA chip including 3D shaped electrode array and microfluidic channel variation may provide a basis for an advanced preclinical model platform for regenerative medicine and human disease modeling in the future.

A Form Factor-Free Musculoskeletal Sensor Platform for Predicting Behavioral Intentions YunJeong Kim, Yulim Min, hanbit Jin, Chanhwa Hong, Saerom Seo, Chaehyun Lim and Hye Jin Kim; Electronics and Telecommunications Research Insitute, Korea (the Republic of)

As the aging of society proceeds and the healthcare market has been significantly growing, it is essential to develop a musculoskeletal biological signal monitoring platform. Although most semiconductors or MEMS sensors for acquiring biosignals have excellent sensitivity and accuracy, they have the limitation of form factor for long-term attachment to human bodies [1]. In this study, we demonstrated a formfactor-free musculoskeletal platform integrating four types of sensors on a stretchable substrate that is stretched up to 20 % through an in-situ process. The stretchable substrate fabricated with serpentine electrode structure showed almost no change in the resistance of the electrode when it was increased up to 20 % strain, a highly reliable biological signal can be eventually obtained. Also, the sensors of Mechanomyography (MMG), Forcemyography (FMG), Electromyography (EMG), and accelerometer are integrated with one stretchable substrate, and the correlation between the sensors is analyzed to monitor the biological activity with high accuracy. In particular, MMG sensors are required high sensitivity and SNR to detect extremely low amplitude vibration signals inside the skin. Most MMG sensors are used ceramic-based microphones of accelerometers which are highly sensitive and accurate. However, it is not conformally adhered to human skin due to the rigid type of ceramic-based devices, thereby there is a constraint of data reliability caused by motion artifacts. To enhance the reliability of data, a stretchable 10-um-thick MMG patch sensor was fabricated by screen printing based on flexible 0-3 nanocomposite piezoelectric materials. Moreover, the SNR of the signal was improved by more than 3.5 times with the bump structure to the sensor. The pressure sensitivity was 395 mV/N (0%) and 407 mV/N (20%), respectively, before and after a stretch of 20 %, which confirmed negligible hysteresis with a delta value ($\Delta< 3$). The MMG sensor can detect dynamic vibrations in the working frequency range from 1 Hz to 100 Hz. Finally, it was applied to recognize or predict motion intention by analyzing the correlation of biological activity through the four types of sensor signals acquired by isometric contraction and relaxation of flexor digitorum longus.

Polymerized Ionogels for Wearable Chemical Biosensors Detecting Biomarkers in Exhaled Breath Sang-Joon Park and Tae-Jun Ha; Kwangwoon University, Korea (the Republic of)

Wearable chemical biosensors detecting low concentration of biomarkers which can indicate health disorders such as asthma, cystic fibrosis, and bronchiectasis have attracted considerable attention in the field of bioelectronics [1]. To improve the sensing performance, various materials including nanostructured metal-oxide semiconductors and low-dimensional nanomaterials have been extensively investigated as promising active sensing channels owing to their high reproducibility and large surface-to-volume ratio [2]. However, the chemical biosensors based on these materials inevitably require high operating temperatures and complicated fabrication processes, which can limit the applicability of wearable electronics in the systel level [3]. Recently, polymerized ionogels exhibit great potential in ionotronic applications owing to their high chemical stability, mechanical flexibility, and ionic conductivity in addition to molecular interactions [4]. In this presentation, we will demonstrate polymerized ionogels consisting of ionic liquids (ILs) incorporated with 3 dimensional polymeric neworks which immobilize the ILs while maintaining distinctive their properties. We will also demonstrate chemiresistive-type wearable chemical biosensors based on polymerized ionogels, which can detect biomarkers of nitrogen oxide molecules in exhaled breath down to ppb-level and exhibit excellent operational stability under various environmental and mechanical conditions such as humidity, temperature, and physical deformation. We believe that this work can stimulate the field of ionotronic biosensors based on polymerized ionogels for human breath analysis underlying biomarkers.

Pinch Gripper with Multi-Sensor Capable of Detecting Embolism and Monitoring Pulse Wave in Blood Vessel Daseul Lim, Yeonwook Roh, Doohoe Lee, Insic Hong, Dohyeon Gong, Dongjin Kim, Dongwook Shin, Seongyeon Kim, Je-Sung Koh, Daeshik Kang and Seungyong Han; Ajou University, Korea (the Republic of)

During sugery, various diseases can occur dut to abnormal blood vessel. Thrombosis and air embolism occurs frequently. Diagnosis of thrombosis and air embolism is CT or Doppler examination is typically used. These diagnosis are difficult to detect immediately during surgery and cost a lot of time and money. In this paper, a device capable of pinch grip propose to stable hold blood vessel without damage. The device has a capacitance sensor and crack-based strain sensor to measure a pulse wave and detect substance in the blood vessel. An in vivo experiment using the carotid artery of a pig was conducted to demonstrate the potential of use in bio medical device. As a result, the strain sensor has same pulse wave as commercial BP monitoring system. At the same time, it was cofimed through the C-arm that the capacitance sensor detects air embolism. It was possible to predict the occurrence of a stroke. In the future, the pinch gripper can be used as a biomedical device for a innovative blood vessel monitoring system in surgery. Our device can prevent dagerous complications such as hypotension, stroke, and heart attack in transplant and long time surgery.

Micro Plasma-Based Surface Modification of Soft Biocompatible Polymers and Composites Towards the Modification of Surface Properties for Biomedical Applications—Development of Correlations Between Plasma Properties and Surface Characteristics Using Machine Learning Manan Sehgal[1], Prakhyat Gautam[1], Andres Raymundo[1], Edgar Perez-Lopez[2], David Ryman[1], Edbertho Leal-Quiros[2], Saquib Ahmed[3,3] and Sankha Banerjee[1,4]; [1]California State University, Fresno, United States; [2]University of California, Merced, United States; [3]Buffalo State College, United States; [4]University of California, Davis, United States

The use of 3D printing scaffolds and interfaces has become popular due to its optimal customization and process time. Polylactic Acid (PLA) is a commonly used biocompatible and biodegradable filament material in 3D printing. However, PLA is naturally hydrophobic. Cell growth and cell adhesion on biocompatible polymers are affected by the surface energy properties and the interface. This study is focused on mitigating these problems by incorporating plasma micro-discharge surface modification to tailor the surface roughness characteristics of soft PLA and soft PLA composites toward the development of biocompatible substrates for enhanced cell adhesion and growth. There is limited research exploring how changes in plasma parameters affect the wettability and surface energy characteristics of materials. The current work involves the development of correlations between plasma properties and surface characteristics using machine learning models. Consequently, this work will also review the changes of 3D printed PLA in wettability, surface roughness, and surface morphology as the input voltage of the plasma micro-discharge treatment (confined micro plasma-based Townsend discharges) is varied.

5:00 PM SB04.06.08

Study of the Efficacy of a Flexible Active Polymer-Based Non-Invasive Glucose Monitoring System—Towards the Development of Embedded Devices Using Refraction and Photoacoustic Characteristics David Ryman[1], Muhilan Manimaran[1], Edgar Perez-Lopez[2], The Nguyen[1], Saquib Ahmed[3,3] and Sankha Banerjee[1,4]; [1]California State University, Fresno, United States; [2]University of California, Merced, United States; [3]Buffalo State College, United States; [4]University of California, Davis, United States

The current work focuses on the development of a flexible non-invasive glucose monitoring device embedded in an active polymer matrix (e.g. PVDF-TrFE or PVDF-BaTiO3). The device consists of an embedded circuit with a pulsed laser and a continuous LED light in the near infrared range. This light source is incident on a glucose control solution to mimic a range of glucose concentrations in blood (in the range from 0 - 500 mg/dl). The glucose levels are detected by a perovskite-halide optoelectronic sensor (refraction) and are validated by a perovskite oxide transducer (photoacoustic) while using the active polymer matrix as a energy conversion media. Correlations between the output voltage and the glucose concentrations are developed using machine learning methods. The active properties of the polymer matrix is also characterized using electrical impedance spectroscopy.

From Disposable to Wearable Bioelectronics Using Paper-Derived Laser Induced Graphene Rodrigo Martins, Tomás Pinheiro, Ana Carolina Marques and Elvira Fortunato; CENIMAT\i3N Nova School of Science and Technology, Portugal

Laser-induced graphene (LIG) has established itself as a very attractive material for electrode fabrication, within several applications in bioelectronics. The straightforward, high throughput graphitization of several precursor materials using this laser conversion process allows for the simultaneous synthesis and

patterning of this 3D graphitic material with diverse electrode architectures, to target several biosensing applications, from biophysical to biochemical monitoring.
Recently, paper has appeared has a viable alternative to conventional petroleum-based plastic polymer precursors, such as polyimide. This is due to the possibility to photothermally convert aliphatic cellulose monomers into graphene lattices, using several cellulose substrate treatment strategies. Application of fire-retardant chemical modifications and external aromatic moieties improves the graphitization potential of cellulose, to reach LIG films with 5 ohm.sq^{-1} sheet resistance and conductivities as high as 67 S.cm^{-1}.
With these improved conductive properties of paper derived LIG, this precursor material can be easily employed for the fabrication of disposable biosensing units, where paper acts as both the support substrate and precursor material for conductive electrodes fabrication, without the need for more intricate printing techniques. Alternatively, strategies can be employed to separate converted and unconverted phases, through transfer methods, to make this material compatible with wearable applications.
In this presentation, we report the use of cellulose as a material in the toolbox of LIG precursors, aimed at the development of both disposable and wearable biosensing applications. Paper-based electrochemical sensors using this material are presented, aiming at disposable sensor development for different analytes. Glucose and pH electrochemical sensors were fabricated, showing the compatibility of the material with several sensing strategies, such as enzymatic and non-enzymatic sensing. To translate patterned electrodes for wearable applications, a straightforward transfer method is presented, using a water-induced peel-off method. This method is capable of efficiently separating unconverted cellulose and converted LIG phases, allowing for the transfer of LIG patterns onto flexible, conformable and elastomeric substrates with adhesive properties, for example medical grade adhesives. Using this method, electrochemical biosensors, strain sensors for biophysical monitoring and electrodes for electrophysiological signal monitoring are presented.
In conclusion, the concepts explored herein show the applicability of LIG towards the fabrication of robust point-of-care, disposable analytical devices, but also the its potential for integration in wearable sensing systems, aiming at more sustainable, accessible bioelectronic applications.

10:30 AM *SB05.01.01
Design and Biomedical Applications of AIE-Active Nanoaggregates Ben Zhong Tang; The Chinese University of Hong Kong, China

Nanomedicine is an emerging and fast-growing field in which the application of nanotechnology to healthcare offers numerous improvements to medical diagnosis, therapy, etc. The design and development of novel fluorescent nanomaterials for biomedical applications have become one of the most important aspects of nanomedicine and have attracted increasing research interest. Previous studies have mainly focused on fluorescent inorganic nanoparticles, such as fluorescent carbon dots, metallic nanoclusters, etc. The major issues for their practical biomedical applications, especially *in vivo* applications, are still challenging, mainly due to their notorious toxicity to living organisms. As alternative nanomaterials for various biomedical applications, fluorescent organic nanoparticles have emerged and gained significant interest because of their various interesting optical properties, facile fabrication, and excellent biocompatibility. However, the fluorescence of most conventional organic dyes is quenched in the aggregate state or at high concentration, which is named aggregation-caused quenching (ACQ). This ACQ effect seriously hampers their potential applications in nanomedicine, such as bioimaging, diagnosis, and therapy. By contrast, aggregation-induced emission luminogens (AIEgens) are weakly emissive when molecules are uniformly dispersed in solution but “light up” when forming (nano)aggregates. With the significant advantages of high emission efficiency in the aggregate state, low background noise in dilute solution, excellent photostability, and large Stokes’ shift, AIEgens and AIE nanoparticles are especially suitable for bioimaging, diagnosis and therapy. AIEgens with various skeletons are designed as superior agents for biological process monitoring and disease theranostics. Moreover, AIEgens and AIE nanoparticles can be conveniently incorporated into the present theranostic platforms by combining them with various imaging and therapeutics modalities, such as multiphoton imaging, photoacoustic imaging, photothermal imaging, chemotherapy, photodynamic therapy, photothermal therapy, gene therapy, etc.

11:00 AM SB05.01.02
Lanthanide-Doped Nanomaterials as Potential Bioprobes Eva Hemmer; University of Ottawa, Canada

The remarkable optomagnetic properties of the lanthanides (Ln) make Ln-based materials ideal for biomedical applications, including diagnostic (for instance, imaging or thermal sensing) and therapeutic (for instance, drug delivery and photodynamic therapy) approaches. This is due the unique electronic properties of the Ln (f-elements) allowing for upconversion and near-infrared emission under near-infrared excitation as well as high magnetic moments. Sodium lanthanide fluorides ($NaLnF_4$) are our favorite materials, and we developed a fast and reliable microwave-assisted synthetic approach allowing crystalline phase and size control in the sub 15 nm realm. Such control is crucial for the understanding of fundamental structure-property relationships and to optimize their optical and magnetic properties, when aiming for the design of next-generation optical probes or contrast agents for magnetic resonance imaging (MRI). For instance, $NaGdF_4$ nanoparticles (NPs) are gaining interest as alternative MRI contrast agent, while co-doping with emitting Ln^{3+} ions endows the NPs with luminescent properties for applications as optical probes. The hexagonal crystalline phase of $NaGdF_4$ is known as the more efficient host material for upconversion emission (i.e., the emission of one higher energy photon following excitation with two or more lower energy photons). In contrast, we observed that the cubic phase of $NaGdF_4$ shows superior performance as MRI contrast agent.
Having a fast and reliable synthetic route towards $NaLnF_4$ NPs on hand, we now explore various nanoparticle architectures and compositions with the goal to optimize their optomagnetic properties, ultimately resulting in the design of biocompatible multimodal bioprobes. This includes MRI contrast agents based on Gd- and Dy-containing NPs, and novel near-infrared emitters based on Ho or Pr for deep tissue optical bioimaging under near-infrared illumination, matching the biological transparency windows. In this presentation, we will also have a look at luminescent $NaLnF_4$ NPs with various surface-modifications and the suitability of hyperspectral imaging to study their nano-bio interactions.

11:15 AM SB05.01.03
Opening the Fourth Biological Window—Novel Lanthanide-Doped Near-Infrared Emitting Nanoparticles Abigale Puccini, Nan Liu and Eva Hemmer; University of Ottawa, Canada

Trivalent lanthanide (Ln^{3+})-based nanoparticles (NPs) are outstanding candidates for a wide range of sensing, imaging, diagnostic and therapeutic applications. Characterized by an incomplete 4f shell shielded by the outer $5s^2$ and $5p^6$ shells, the influence of the host lattice and surrounding environment on the optical properties of lanthanide ions is minimized. This results in long excited-state lifetimes and narrow absorption and emission bands that favour the use of excitation wavelengths in the near-infrared (NIR) region and leads to the emission of light in the ultraviolet (UV), visible, and NIR regions. By tailoring the choice of Ln^{3+} dopants, NIR-to-NIR wavelength conversion becomes possible, allowing for both the excitation and emission wavelengths to be compatible with the so-called biological transparency windows (NIR-I to NIR-III: 700 to 1870 nm). These optical properties make Ln^{3+}-based NPs favorable fluorescent probes for biological and biomedical applications. The use of NIR light is of particular interest for overcoming some of the limitations of conventionally used organic molecular fluorescent probes, which require excitation with UV light, including photobleaching, tissue autofluorescence, phototoxicity and limited tissue penetration depths. NIR light matching the biological transparency windows suffers from less scattering and absorption by water and biological tissues, which in turn improves spatial resolution and sensitivity and allows for deeper light penetration depths. Current and past research efforts have primarily focused on the development of fluorescent materials that emit at wavelengths longer than 1000 nm in the NIR-II (1000 to 1350 nm) and NIR-III (1550 to 1870 nm) region, under excitation with NIR-I light (700 to 950 nm). Recently, a fourth biological window (NIR-IV) has been suggested, centered at 2200 nm, but there still presents a significant lack of optical probes, specifically at the nanoscale.
To close this gap, here, we propose novel Ln^{3+}-doped NIR-IV emitting NPs to open the fourth biological window for exploration. Using the fast and reliable microwave-assisted thermal decomposition method, NIR-IV emitters praseodymium (Pr^{3+}) or holmium (Ho^{3+}) and sensitizing ytterbium (Yb^{3+}) and/or neodymium (Nd^{3+}) were doped into sodium rare earth fluoride ($NaREF_4$) host lattices to form sub-15 nm NPs. Co-doping with Yb^{3+} allows for 980 nm NIR excitation, while the absorption and scattering of the excitation light by biological tissues can be further reduced when using 808 nm excitation, which is achieved through co-doping with Nd^{3+}. This presentation will shed light on the influence of NP composition, surface chemistry, and aqueous versus non-aqueous media for NP dispersion on the optical properties, i.e., sought after NIR-IV emission. Seeking potential biomedical (and beyond) applications, we further assessed the performance of these NIR-IV emitters as nanothermometers. Optical thermal sensing allows to extract information on the local temperature of a given system at the nanoscale, including thermal irregularities related to various diseases. Overall, the developed NPs are highly promising to open the fourth biological window for imaging and sensing, and thus, potential innovative biomedical applications.

11:30 AM SB05.01.04
A Biomineral-Inspired Approach of Synthesizing Multicolor Colloidal Persistent Luminescent Nanophosphors and Mechanoluminescent Fluids as Intravital Light Sources Fan Yang; Stanford University, United States

Light is used in a wide range of biotechnologies, such as fluorescence imaging and optogenetics, yet a critical challenge of applying light *in vivo* arises from the poor penetration of photons in biological tissue due to scattering and absorption. Therefore, delivering photons deep into the body from an external light source requires invasive procedures, such as craniotomy, to surgically remove overlying tissues. Besides conventionally used external light sources, trap-engineered materials with persistent luminescence (PerL, as known as afterglow) and mechanoluminescence (ML) represent an arising opportunity for light delivery in deep tissue owing to their ability to store photon energy in their host structures. However, materials with strong short-wavelength PerL and ML are usually bulk particles (> 10 µm) synthesized via solid-state reactions at > 1000 °C to facilitate uniform doping and desirable polymorphs. Their large sizes prevent the formation of stable colloids in aqueous environment and prohibit their biological applications.
To address this challenge, here we report a bioinspired demineralization (BID) approach to synthesize stable colloidal solutions of solid-state PerL and ML nanoparticles with tunable wavelengths and remarkable luminescence intensity. Specifically, the BID approach is inspired by the strategy of biomineralization in nature: Biominerals, such as apatite in the dental enamel, can be gradually dissolved to nanostructures in a mildly acidic environment yet are resistant to further dissolution. This unconventional dissolution process, unlike the self-accelerating dissolution of soluble salts, is facilitated by the formation and growth of pits on the surface. The low solubility and thus high interfacial tension of biominerals results in a large critical size of 10 to 100 nm, below which the growth of dissolution pit is kinetically suppressed. In the BID approach, we demonstrated that sparingly soluble solid-state PerL and ML particles, similar to biominerals, also exhibited kinetically suppressed dissolution. Specifically, we used a citrate buffer to mimic the undersaturated

environment and produce colloidal nanoparticles down to 20 nm from their solid-state precursors with emission wavelengths covering the entire visible spectrum, including $Sr_2MgSi_2O_7$:Eu,Dy (470 nm), $Sr_4Al_{14}O_{25}$:Eu,Dy (490 nm), ZnS:Cu,Al (534 nm), ZnS:Mn (578 nm), $CaTiO_3$:Pr (610 nm), and $Ca_{0.85}Sr_{0.15}S$:Eu,Tm (650 nm). Furthermore, these BID-produced nanoparticles can be stably suspended in aqueous solution, while preserving the optical properties of their solid-state precursors, including strong PerL or ML intensities.
Additionally, we demonstrated the utility of BID-produced colloids in biology via excitation-free imaging and ultrasound-mediated non-invasive optogenetics. On one hand, owing to their exceptionally bright luminescence, BID-produced PerL nanophosphors exhibited the highest signal-to-background ratio for *in vivo* imaging among reported materials, and yielded the first example of transcranial afterglow imaging of cerebral vessels in the mouse brain. Furthermore, the bright short-wavelength PerL nanophosphors acted as an intravital light source and provided internal excitation for genetically encoded fluorescent reporters in a mouse brain through the intact skull, thus enabling afterglow imaging of fluorescent proteins for the first time. On the other hand, the BID-produced ML fluids acted as an ultrasound-mediated light source in the body after systemic delivery. We were able to visualize the ultrasound-mediated light emission from the ML fluids in the vascular systems of multiple mouse organs (including brain, liver and kidney) for the first time, and used this light emission for non-invasive optogenetics stimulation in transgenic mice expressing light sensitive ion channel ChR2.
The manuscripts based on these results were recently published in *Sci. Adv.* (DOI: 10.1126/sciadv.abo6743) and *JACS* (DOI: 10.1021/jacs.2c06724).

11:45 AM SB05.01.05
Design and Study of Hybrid Multifunctional Nanoparticles for Cancer Diagnostic and Treatment Through Spectral Photo Counting Scanner CT and X-Rays Activated PDT Frederic Lerouge[1,2], Loic Cuau[2], Frederic Chaput[2], Szilvia Karpati[2], Stephane Parola[2], Sylvain Bohic[3], Ludwig Dubois[4], Ala Yaromina[4], Pia Akl[5], Salim Si-mohamed[5] and Philippe Douek[5]; [1]Université de Lyon, France; [2]Laboratoire de Chimie ENS Lyon, France; [3]INSERM, France; [4]Maastricht University, Netherlands; [5]CHU de Lyon, France

General context
Cancer is one of the major societal issues of the century . Even if several strategies of treatments exist, the conditions of life of the patient during and after the treatment are deteriorated by side effects of heavy therapies such as radiotherapy (use of X rays of High energy). The need to propose new strategies of therapies is therefore of great interest.
Introduction
We are aiming at a technology that will ensure efficient treatment of cancer with low side effects, allow to perform accurate diagnostic and give access to in situ monitoring of the treatment. Our goal is based on the association of two cutting-edge technologies: spectral photon counting scanner CT (SPCCT) which is a ground-breaking imaging modality and a new X-ray based treatment known as X-rays activated Photodynamic Therapy (X-PDT). The perfect match between these two technologies will be ensured with specifically designed nanoprobes probes acting both as contrast media and therapeutic agents(1).

The possibility to use new treatments such as XPDT is raising a great interest. PDT alone is a clinically approved cancer treatment but, the strong absorption of light by tissues limits its use to rather superficial tumors. X-PDT is a new technology involving the same mechanisms but spreading the potential of this treatment. The principle of XPDT is to irradiate with low energy X-Rays hybrid nanoprobes consisting in an inorganic core functionalized with organic moieties (Photosensitizers-PS). Upon excitation the inorganic particle will emits light (scintillation) which will be absorbed by the PS. The latter will reach an excited state, making it able to react with surrounding oxygen and leading to the production of reactive oxygen species able to kill tumor cells.(2)

Spectral Photon Counting Computed Tomography (SPCCT) is a new imaging modality, currently in development. The SPCCT scanner is an evolution of the conventional CT scanner, with a totally new type of detection chain designed to provide high count-rate capabilities while offering energy discrimination with high spatial resolution. Its main asset is the ability to map and quantify elements based on their K-edge. For that modality, the traditional iodine based contrast agents are not particularly suited due to iodine's K-edge being outside the clinical X-ray spectrum, the use of new types of contrast agents is therefore necessary. (3)
Results
Based on our previous works on the design and surface modification of lanthanide fluoride nanocrystals (4) we describe the design of hybrid terbium (III)-doped gadolinium fluoride nanoparticles (NPs) which act as contrast media for spectral CT scanner and show scintillation properties (emission of light under low energy X-rays excitation). These nanoparticles can be considered as interesting nanoplatforms for further development related to X-Rays based imaging and treatment.
This presentation will first aim to highlight the results obtained concerning the luminescent properties of NPs under UV and X-ray excitation and their properties as contrast agent for spectral CT scanner (5). It will also describe the different strategies of surface modification for biocompatiblity and their effects on the optical properties of NPs. The proof of concept of the use of the nanoparticles as contrast agent in vivo as well as their ability to emit light when submitted to X-rays will be demonstrated. Finally, the functionalization of NPs by a PS will be discussed and results about in cellulo studies and singlet oxygen generation will be described.

Designed Synthesis and Assembly of Inorganic Nanomaterials for Medical and Healthcare Applications Taeghwan Hyeon[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Over the last 20 years, our laboratory has focused on the designed chemical synthesis, assembly and medical applications of uniform-sized nanocrystals. We demonstrated that ceria nanoparticles and ceria–zirconia nanoparticles can work as therapeutic antioxidants to treat various nasty diseases, including ischemic stroke, Alzheimer's disease, sepsis, and Parkinson's disease, rheumatoid arthritis, and radioprotectants.[1] We developed a click reaction-assisted immune cell targeting (CRAIT) strategy to deliver drug-loaded nanoparticles deep into tumor interiors, reducing tumor burden in an aggressive 4T1 breast cancer model without any systemic toxicity.[2] We synthesized $MnFe_2O_4$-anchored mesoporous silica nanoparticles to overcome hypoxia, and consequently enhancing the therapeutic efficiency of photodynamic therapy.[3] We reported a heterogeneous chemodynamic therapy system based on copper-iron peroxide nanoparticles (CFp NPs) for tumor microenvironment-mediated synergistic cancer therapy.[4] We report a highly sensitive and selective K^+ nanosensor that can quantitatively monitor extracellular K^+ concentration changes in the brains of freely moving mice experiencing epileptic seizures.[5] We fabricated ultraflexible and/or stretchable soft-electronic and optoelectronic devices integrated with various functional nanomaterials and their applications to wearable and implantable medical and healthcare devices.[6] We introduced electromechanical cardioplasty using an epicardial mesh made of electrically conductive and elastic Ag/Au nanowire-rubber composite material to resemble the innate cardiac tissue and confer cardiac conduction system function.[7] We fabricated highly conductive and elastic nanomembrane for skin electronics.[8] We synthesized a flexible, sticky, and biodegradable electronic patch for controlled drug delivery for GBM treatment.[9] We developed a microneedle-based delivery method of theranostic NPs and high-energy photons to treat two types of brain tumors.[10] Recently, we synthesized an injectable hydrogel nanocomposite for intracortical drug delivery to treat deep-seated brain tumors.[11]

Synthesis of Silicon-Metal Hybrid Hollow Nanostructures and Their Bio-Application Jeonghun Choi, Insu Lee and Nitee Kumari; Pohang University of Science and Technology, Korea (the Republic of)

Silicon nanostructures have been attractive materials in various field due to their unique properties such as large surface area, photoluminescence, semi-conductor. Despite enormous interest, synthesis of nanoscale (<100 nm) silicon nanostructures is challenging. Herein, we present the synthesis method of silicon nanostructures under 100nm through magnesiothermic reduction by handles of silica nanoparticles composition. During pretreatment of silica nanoparticles under vacuum condition, metal (Pd, Pt, Ni)-silicide and void space in silica nanoparticles play a key role to keep structures after conversion. We identified the optical properties of the silicon nanostructures and it is looking forward to giving high performance to Bio-application.

Antioxidative and Anti-Inflammatory WS_2 Nanosheets for Effective Wound Treatment Yoonhee So, Sin Lee, Chanhee Choi, Lee Hyun ji and Jong-Ho Kim; Hanyang University, Korea (the Republic of)

Deep partial- and full-thickness burn injuries are complicated traumas accompanying the severe failure of antioxidation, anti-inflammation, and inherent defense mechanisms against external bacteria. Accordingly, it is required to suppress oxidative stress and promote the recovery of intrinsic defense systems in burn wound lesions, but previous topical antipyrotics have been designed to date only to prevent bacterial infections. For this reason, it is an essential task to develop new efficient topical materials that can improve the intrinsic antioxidative and cellular defense mechanisms for the effective curing of deep burn wounds. Herein, we developed ultrathin WS_2 nanosheets exfoliated and functionalized with PCL-*b*-PEG (2H-WS_2) in aqueous solution, exhibiting superior scavenging ability and sustainability for a wide range of reactive oxygen species (ROS) and reactive nitrogen species (RNS) in keratinocytes. The functionalized WS_2 nanosheets were found to scavenge intracellular ROS and RNS as well as extracellular reactive species, suppressing oxidative stress in the wound lesions of mice. At the same time, the representative antioxidases, including CAT and GPx, were largely up-regulated in the presence of 2H-WS_2 nanosheets in burn wounds, improving the inherent resistance to oxidative stress. The 2H-WS_2 nanosheets also attenudated inflammatory cytokine secretion along with the inhibition of the extrinsic pathway of apoptosis in wound lesions. Moreover, the 2H-WS_2 nanosheets stimulated the production of innate antimicrobial peptides in burn wounds, enhancing the intrinsic resistance of cellular systems to external bacteria. All these integrated effects triggered by 2H-WS_2 nanosheets resulted in the successful healing of deep burn wounds. 2H-WS_2 nanosheets can be extended for the therapy of other diseases induced by oxidative stress and inflammation.

Laser-Assisted Surface Alloying to Enhance Antibacterial Properties and Bone-Cell Mineralization of Titanium Implants Sotoudeh Sedaghat, Vidhya Selvamani and Rahim Rahimi; Purdue University, United States

Orthopedic implants are commonly used to improve the patient's quality of life. Titanium-based alloys are widely employed in surgical implants due to their cytocompatibility and appropriate mechanical properties. However, the most common perspective problem that orthopedists face is implant-associated infection (IAI), which can lead to serious impacts such as the need for complex revision procedures, patient suffering, and even death. These complications that arise from the poor antibacterial property of titanium implants can be addressed by introducing antibacterial components such as silver. While researchers show the application of silver particles as an efficient anti-infection agent for Ti-based orthopedic implants, most of the developed products suffer from complicated and long fabrication/modification techniques, multi-step processing, high cost, unintended alteration in mechanical properties, unstable antibacterial effect, and leaching of the silver ions. Here we offer a simple and fast two-step technique for surface modification of the Ti-based implants using laser-assisted alloying (LAA). In this work, a nanosecond Nd:Yag laser was applied via optimized laser power for alloying of the coated Ag-ink film on the Ti surface. Besides, this prompt laser processing developed a micro/nano roughness on the Ti surface which was beneficial for osseointegration and cell mineralization. The Ti-Ag LAA samples prepared using a range of laser powers (8, 16, 24, 32, and 40 W) were characterized via various techniques. The scanning electron microscopy (SEM) images showed a developed hierarchical micro/nanostructure on the LAA surfaces. Energy-dispersive X-ray mapping and X-ray diffraction (XRD) results demonstrated enhanced oxygen level and Ag-Ti alloying. The Rockwell hardness tests of the Ti-Ag showed preserved bulk hardness of the samples with an average hardness of about 31 ± 1 HRC. This observation revealed a superficial alloying of the laser-assisted method which is essential for the Ti-based implant modification. The optimized Ti-Ag LAA sample (prepared with 32 W laser power) showed over 6-fold enhancement in antibacterial effect compared to the pristine Ti sample. This antibacterial property was shown to be effective on both gram-negative (E. coli) and gram-positive (S. aureus) bacteria during the test period of 12 days. On the other hand, the cell mineralization test showed over 2-fold increase in cell mineralization of the Ti-Ag LAA as compared to the pristine Ti sample which is due to the developed micro/nano features that provide active sites for cell attachment and growth. Moreover, the antibacterial effect of the developed surface helps the natural body cells to succeed in the competition on the implant surface toward the bacterial cell. The long-lasting antibacterial properties of the prepared Ti-Ag LAA samples along with cytotoxicity as low as 5- 10 % originated from the properly anchored Ag inside the Ti structure originated from the efficient laser surface alloying.

Predictive Interactions of Chiral Nanoparticles and Proteins—From Catalysis to Vaccines Nicholas A. Kotov; University of Michigan, United States

Biomimetic nanoparticles (NPs) are known to serve as nanoscale adjuvants, enzyme mimics, and amyloid fibrillation inhibitors. Their further development requires better understanding of their interactions with proteins. The abundant knowledge about protein-protein interactions can serve as a guide for designing protein-NP assemblies, but the chemical and biological inputs used in computational packages for protein-protein interactions are not applicable to inorganic NPs. Analyzing chemical (CH), geometrical (GE), and graph-theoretical (GT) descriptors for protein complexes, we found that GE and GT descriptors that are uniformly applicable to biological and inorganic nanostructures can predict interaction sites in protein pairs with accuracy >80% and classification probability ~90%. We extended the protein-trained machine learning algorithms to inorganic biomimetic NPs and found a nearly exact match between experimental and predicted interaction sites with proteins. These findings can be extended to other organic and inorganic NPs to predict their assemblies with chemically dissimilar structures.[1]
The design principles of and predictictive capabilities of NP-protein interactions have been utilized for formation of complexes of plasmonic NPs with proteins. They enabled polarization-based drug discovery platforms for Alzheimer syndrome,[2] materials for chiral catalysis,[3] and chiral antiviral vaccines.[4]

4:00 PM SB05.03.02
Boron Nitride Nanosheets Can Induce Water Channels Across Lipid Bilayers Leading to Lysosomal Permeabilization Xuliang Qian[1], Matteo Andrea Lucherelli[2], Wenpeng Zhu[3], Paolo Samorì[4], Huajian Gao[1,5], Alberto Bianco[2] and Annette von dem Bussche[6]; [1]Nanyang Technological University, Singapore; [2]CNRS, Immunology, Immunopathology and Therapeutic Chemistry, France; [3]Sun Yat-sen University, China; [4]University of Strasbourg, France; [5]A*STAR, Singapore; [6]Brown University, United States

While the interaction between two-dimensional (2D) materials and cell membranes is of key importance to the development of nanomedicines and safe applications of nanotechnology, still very little is known about the biological interactions of many emerging 2D materials. Here we investigate how hexagonal boron nitride (hBN) interacts with the cell membrane by combining molecular dynamics (MD), liquid phase exfoliation and in vitro imaging methods. MD simulations reveal that a sharp hBN wedge could penetrate a lipid bilayer and simultaneously form a cross-membrane water channel along its exposed polar edges, while a round hBN sheet does not exhibit this behavior. We hypothesize that such water channels could facilitate cross-membrane transport, with important consequences including lysosomal membrane permeabilization (LMP), an emerging mechanism of cellular toxicity that involves the release of cathepsin B and generation of radical oxygen species leading to cell apoptosis. To test this hypothesis, we prepared two types of hBN nanosheets, the former with a rhomboidal, cornered morphology and the latter with a round morphology, and exposed human lung epithelial cells to both hBN nanosheets. The cornered hBN with exposed polar edges resulted in a dose dependent cytotoxic effect, whereas round hBN did not cause significant toxicity, thus confirming our hypothesis. The described water channel mechanism suggests various applications including the development of hBN-based drug delivery systems and safe design of future advanced hBN containing composites and devices.

Nanoparticle Interaction with Extracellular Matrix Stabilizes Cartilage Tissue Integrity Ula von Mentzer, Gizem Erensoy, Stefanny de Fatima Guedes Cunha, Sara Yousefialdashi and Alexandra Stubelius; Chalmers University of Technology, Sweden

Statement of Purpose: Arthritic disorders are a leading cause of disability worldwide[1]. Current treatments result in unsatisfactory outcomes due to the lack of specificity, fast clearance, and inability to penetrate biological barriers. Advancements in nanotherapeutics have shown that electrostatic interactions and nano-sized particles are able to target and penetrate dense, negative tissues such as the joint cartilage[2]. Previously, we have shown that nanoparticles (NPs) interact with proteins in the joint space, which dictate the NPs' interactions with cells and cartilage tissue[3]. As it is known that NPs must interact with the cartilage extracellular matrix (ECM) proteins prior to reaching their cellular target, this study aimed to demonstrate that the NPs' interactions with ECM can be used as a means to stabilize the tissue and reduce degradation.
Methods: A cationic NP panel that differed in size and charge was synthesized based on either poly(amidoamine) (PAMAM) dendrimers (DendritechR, Midland, MI, USA) or poly(lactic-co-glycolide) (PLGA; ResomerR, Essen, Germany) polymer particles (formulated by nanoprecipitation) decorated with either PEG or polyethylenimine (PEI)-PEG modifications. All particles were fluorescently labeled with FITC. NP size and charge were characterized by dynamic light scattering (DLS) as well as electron microscopy. To mimic the thickness of human cartilage, porcine articular cartilage explants were used in this study, and subjected to arthritis-relevant enzymes such as ADAMTS5 for 1 or 2 hours, followed by NP treatment of equivalent duration. Released ECM components including sulfated glycosaminoglycans (GAGs) were assessed by colorimetric assays and polyacrylamide gel electrophoresis (PAGE). NP tissue uptake was evaluated by confocal microscopy, while aggregate formation and tissue topography were determined by atomic force microscopy

(AFM). The interactions between the NPs and ECM proteins were evaluated by isothermal titration calorimetry (ITC) and quantitative proteomics.
Results: Physicochemical characterization of PAMAM particles revealed sizes of 7.2 nm and 11.0 nm and zeta potentials of +17.0 mV and +4.0 mV for non-PEGylated and PEGylated NPs respectively. Control PLGA-based NP size varied between 270 nm and 264 nm with their respective zeta potentials exhibiting +22.2 mV and +3.78 mV. By treating porcine explants with the different particles after enzymatic stimulation, we measured a reduction of GAG concentration in the supernatants after 2- and 4-hour treatments compared to the control. To investigate the level of engagement between the particles and the tissue, we tracked the fluorescently labeled NPs using confocal fluorescent microscopy. To further analyze the specific interactions with the ECM proteins and individual NPs, proteomic analysis revealed several highly abundant integrity-associated proteins that could account for the NP-matrix stabilization interactions including proteoglycans such as biglycan and fibromodulin, as well as collagen-binding proteins such as matrilins that are essential for tissue integrity.
Significance: Soluble GAG concentration was inversely correlated to particle cationic charge, suggesting an effect based on electrostatic interactions with the anionic ECM components. NPs are usually studied as carriers for drug delivery applications, yet their physicochemical effects on the ECM are rarely reported. This study aims to be the first to demonstrate that interactions between cationic NPs and ECM components such as anionic GAGs can result in cartilage tissue stabilization in the catalytic proinflammatory arthritic environment.

4:30 PM SB05.03.05
Assessing Toxicity of Fullerene Nanostructures Using Human Proteins by Combined Computational Chemistry and Cheminformatics Approach
Mariam Zamani[1,1], Stephen Szwiec[1,1], Gerardo Casanola-Martin[1], Natalja Fjodorova[2], Marjana Novič[2], Katja Venko[2], Melek Türker[3], Gulcin Tugcu[4], Safiye S. Erdem[5], All Toropova[6], Andrey A. Toropov[6] and Bakhtiyor Rasulev[1,1]; [1]North Dakota State University, United States; [2]National Institute of Chemistry, Slovenia; [3]Bogazici University, Turkey; [4]Yeditepe University, Turkey; [5]Marmara University, Turkey; [6]Istituto Di Ricerche Farmacologiche Mario Negri IRCCS, Italy

In recent years nanomaterials have found a widespread application in material science, pharmaceutical, biomedical and medical fields. Various nanomaterials are applied, as well as in development, as high effective drugs or as drug delivery agents for targeted treatment, including cancer, viruses and etc. Here we show how the combination of computational chemistry, data mining and cheminformatics approaches can help in assessment of toxicity and virtual screening of fullerene nanostructures for combined drug-like and toxicity properties. We demonstrate how the combination of inverse molecular docking, quantum chemistry and machine learning methods can be applied to investigate these nanostructures. A high-throughput virtual screening was applied to both large set of fullerene nanostructures and known biological targets (human proteins), to assess binding scores and to investigate the potential interactions with biological targets. We show several case studies, including analysis of aquatic toxicity of fullerene derivatives, since it is crucial to understand their fate in the environment, particularly their effects on aquatic organisms. Regression models were built and artificial neural network algorithms were applied for property prediction and screening FDs for structural features responsible for binding activity and then highlighted the most active fulleren derivatives that may have the greatest impact on aquatic organisms.
The outcome of this study has the potential to reveal which structural features of fullerene nanostructures have the main impact on toxicity, to be able to decide what fullerene derivatives should be prioritized first. This will help to decrease the need for animal testing and make decisions on applications in advance of manufacturing.

SESSION SB05.04: Poster Session I: NanoBio Interactions I

5:00 PM SB05.04.01
Anti-Bacterial Surface Based on Nanostructurs and Biocompatible Materials for Surgical Titanium Plate *In Vivo* Jeong-Won Lee[1], Chang-Hun Lee[2] and Sung Jae Kim[3]; [1]Chosun University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [3]hallym University, Korea (the Republic of)

In the modern era, the anti-bacterial efficacy of surgical implants in the body is attracting great attention. The method is to modify the surface of the implant to reduce the adhesion of bacteria to limit the formation of a biofilm or, on the other hand, to coat the implant with a functional material that kills the surrounding bacteria. However, most of these research results are difficult to mass-produce, or there are hurdles in practical application as materials that have not yet received FDA approval in the human body. In the case of the SLIPS surface, which has recently attracted attention, its excellent effect has been demonstrated by applying a physical barrier that bacteria cannot settle. However, in the case of an actual infection model, not only the problem of biofilm formation on the surface, but also the occurrence of infection around the implant, so simply a physical barrier on the surface cannot prevent the deterioration of the affected area. Additionally, fluoroalkyl silane used in the SLIPS method applied to implants is a material that has not yet been approved. Therefore, for practical application, the use of materials available to the human body, prevention of biofilm formation on the surface, and prevention of bacterial infection in the vicinity should be provided.
In this study, we used TiAl6V4 implant, which is currently the most used material in the medical industry, and manufactured an innovative coating that overcomes both infection models using only materials approved for the human body. In addition, SLIPS surfaces with proven superior function was fabricated, and comparison and efficacy were demonstrated through in vivo experiments.
TiAl6V4 plates were immersed in NaOH solution with 0.5 mol concentration at 180°C in the oven for formation of nanostructure. The formation of 20 nm scale structures of titanium dioxide (TiO_2) is a process of dissolution and precipitation reactions. Next, a mixture of Poloxamer 407, Octanoic acid, and EGCG was coated on the nano Ti surface. Poloxamer 407 and EGCG are mixed and placed in an oven at 100°C for about 30 minutes to liquefy. Since the mixed solution of Poloxamer407 and EGCG has a very high viscosity and is difficult to use for coating, Octinoic acid is used to dilute it.
The usefulness of titanium implant with nano-structure having a sustained-release coating of Poloxamer/Octanoic Acid both was verified in vitro and in vivo. In particular, we made a rabbit surgery model similar to fracture surgery performed in humans. We confirmed the usefulness of our coating by inducing Pseudomonas aeruginosa infection and biofilm formation. Our results confirmed that the poloxamer/octanoic acid coating material lowered the infection rate and had a low toxicity. We propose that a titanium implant with a nano surface structure having a poloxamer/octanoic acid coating could be a novel alternative for surgical metal processing.

5:00 PM SB05.04.02
Fabrication of Antiviral/Antimicrobial Metal Nanoparticle-Embedded Polyelectrolyte Coatings for PPE Substrates Elayaraja Kolanthai, Andrew Sanford, Craig J. Neal, Udit Kumar, Candace Fox, Griffith Parks and Sudipta Seal; University of Central Florida, United States

The emergence of the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) brought a global pandemic as a result of the virus's ease of spreading and its potential to incubate in asymptomatic hosts. Coronavirus disease (COVID-19) can be developed when infected by the virus, resulting in potentially lethal respiratory distress. A human gets infected when exposed to infectious respiratory fluids. Therefore, the use s of personal protection equipment (PPE), such as masks, can protect from the direct route of infection. PPE are critical to the well-being of essential healthcare workers and the general public, reducing the spread of the virus. Given the magnitude of SARS-CoV-2 transmissibility, novel precautionary efforts are necessary to kill or halt the virus's spread even in the current pandemic or for future unknown emerging virus diseases. Recent involvements in nanotechnology have effectuated need-based virus-resistance face masks/shields developed through the addition of nanomaterial coatings or impregnating nanomaterials in the masks/shields to combat the virus and augment protection levels. We hypothesized that modifying existing PPE materials with engineered antiviral/antimicrobial nanoparticles could produce substantial improvement in the material's efficacy in preventing transmission. The layer-by-layer (LbL) coating technique is a user-friendly and low-cost method chosen for PPE surface modification without using any acid or heat treatment. A wet chemistry method was used to synthesize the antiviral nanoparticles (<100 nm, silver, and gold). Synthesized nanoparticles added to cationic (chitosan, CHI) and anionic (poly(acrylic acid), PAA) polymer solution and co-solution were used to produce LbL coatings. Initially, PPE materials were applied to polyethyleneimine (PEI) or sulfuric acid treatment based on turning charge on the surface. The wet surface of face mask and face shield were immersed in the nanoparticles/CHI solution for 15 min followed by immersion in PAA for 15 min using the LbL coating technique. The fabricated thin films were characterized by XPS and SEM. Biological studies were performed using *E. coli* as a model bacterium to assess the fabricated coatings' antimicrobial activity. Coated PPEs exhibited considerable bacterial inhibition. Antiviral assays were performed with calicivirus as a model virus, and similar trends in antimicrobial results were obtained. According to these findings, silver and gold nanoparticle-based PPE coatings fabricated via LBL appear promising for COVID-19 prevention.

5:00 PM SB05.04.03
Versatile Phenol-Incorporated Nanoframes for *In Situ* Antibacterial Activity Based on Oxidative and Physical Damages Pei Liu and Paul K. Chu; City University of Hong Kong, Hong Kong

Gold nanoparticles (GNPs) with oxidase and peroxidase properties are great candidates for antibiotic-mimicking materials due to reactive oxygen species (ROS) production. However, the bioenzymic properties are not long-lasting due to the short lifespan of ROS and have only been observed from GNPs with a size of less than 20 nm, thus making the synthesis laborious and inefficient. Herein, GNPs with controllable size and effective ROS utilization are synthesized by an environmentally green process using natural phenols extracted from plants as the reducing and capping reagent. Functional metallic ions are chelated by taking advantage of the coordinating properties of phenols to form the versatile nanoframe (pGNP-Fe) that can self-assemble onto bacteria due to the inherent attraction rendered by phenols, and the physical pressure causes bacterial membrane damage. During internalization in bacteria, the cascade process resulting from the enzyme-like properties generates cytotoxic reactive ROS via oxidization, and the Fenton reaction enhances the antibacterial efficiency. This dual physical/chemical antibacterial process obviates the need for external antibiotics and antibacterial agents, which may otherwise pose toxicity in vivo. The fabrication strategy and materials properties described here provide insights into the design of antibioticmimicking materials based on enzymatic and physical effects.

5:00 PM SB05.04.06
Development of Antimicrobial ZnO Nano-Spine Thin Film on Commercial Air Filter Dae Hoon Park, Younghun Kim, Gunhee Lee, Inyong Park, Sang Bok Kim and Bangwoo Han; Korea Institute of Machinery and Materials, Korea (the Republic of)

COVID-19 is a disease caused by the novel coronavirus SARS-CoV-2. According to the U.S. Centers for Disease Control and Prevention (CDC), SARS-CoV-2 is transmitted by exposure to infectious respiratory fluids caused by infected individuals talking, coughing, or sneezing, thus, spreading the virions in airborne droplets (~370 virions in 1 μm and ~360,000 virions in 10 μm) and in aerosol forms, which are called 'bioaerosols'. Bioaerosols are one of the particulate matters (PMs) carrying living organisms from biological sources which include fungi, bacteria, and viruses. To reduce the exposure of biological PMs in indoor air condition, an air filter could be applied in air conditioning system in order to collect the bioaerosols on the surface of the filter membrane. However, previous studies report that viruses remain infectious on various surfaces such as polymeric fibrous filters for a few days. That triggered a tremendous effort to develop antimicrobial fiber-based filters for prevention of infectious virus transmission by fomites. Herein, we present antimicrobial thin film of zinc oxide (ZnO) nano-spines on commecial fiber-based filters and its potential for infection prevention. By developing a novel technique of dry aerosol coating process, (Zn) nano-seed was well-covered on the commercial filter fiber. After hydrothermal treatment, high aspect-ratio ZnO nano-spines were densely exhibited on the filter surface, which have significant antimicrobial effect to airborne pathogens due to. their spiky morphology. This novel thin film hold potential for airborne microbial disinfection, and the design of microbicidal materials with wide applicability to commercial air filter.

5:00 PM SB05.04.07
Harnessing the Bio-Nano Interactions of Natural Clay for Advanced Antimicrobial Solutions Ofer -. Prinz Setter[1], Alva -. Gilboa[1], Iser Snoyman[1], Ghazal Shalash[1] and Ester Segal[1,2]; [1]Technion - Israel Institute of Technology, Israel; [2]The Russel Berrie Nanotechnology Institute, Israel

Biological cells have evolved alongside of natural mineral clay (layered aluminosilicates) leading to intriguing interactions from beneficial to bio-adverse. Specifically, bacteria were shown to adhere to clay particles and even incorporate them into their biofilm[1]. We endeavor to direct these interactions to neutralize a specific pathogenic bacterial srain in a heterogenous culture, maintaining the non-pathogenic populations unharmed and mitigating the global surge in antibiotic resistance. To that end, we utilize Halloysite nanotubes (HNTs), which are 600-900 nm long and 50 nm wide, and exhibit a hollow lumen with an inner diameter of 15 nm. This intrinsic mesoporous morphology of HNTs combined with their adsorptive silica surface renders the clay ideal for carrying various antimicrobial cargoes. The desired specific antibacterial effect is based on the selective binding of the clay to the target bacteria which is realized by antibodies we immobilize onto the HNTs' surface[2]. Next, we investigate the loading of the antibody-functionalized HNTs with two separate antimicrobial payloads: (1) the potent antibiotic ciprofloxacin (CIP) to be gradually released near the target bacteria[3], or (2) plasmonic gold nanorods (AuNR) to be activated by near-infrared irradiation for a local photothermal effect.

The selective binding of the Ab-functionalized HNTs to their target bacteria is confirmed by fluorescence and electron microscopy along with high-throughput imaging flow cytometry[4]. Consequently, CIP-loaded Ab-HNTs exert a two-fold higher potency against the target bacteria, whereas in the same heterogeneous culture, the inhibition of non-target bacteria is decreased by 50-90%. Regarding the AuNR-Ab-HNTs hybrids, upon irradiation with a near-infrared laser, a superior antibacterial activity is observed in comparison to free AuNR, despite the 5-fold higher increase in bulk temperature induced by the latter[4]. In addition, the biocompatibility of the multifunctional clay is studied towards a physiologically relevant co-culture of human colon epithelial cells (Caco-2 / HT29) and the localization of the particles after administration is investigated.

In this presentation, I will discuss our findings as well as the preceding considerations involved from the bioconjugation step to the loading of the clay for obtaining the desired bio-nano interactions. We believe this work signifies the potential in comprehending the interface between biological cells and natural nanomaterials, which are abundant and easily obtainable, to utilize the latter for novel biomedical applications.

Neoteric Silver-Ceria as a Rapid, Residual Antibacterial Agent for Abiotic Surfaces Abinaya Sindu Pugazhendhi[1], Craig J. Neal[1], Udit Kumar[1], Fei Wei[1], Elayaraja Kolanthai[1], Andrew Andy[1], Candace Fox[1], Christina Drake[2], Griffith Parks[1], Sudipta Seal[1] and Melanie J. Coathup[1]; [1]University of Central Florida, United States; [2]Kismet Technologies, United States

Introduction: High rates of mortality and morbidity due to hospital acquired infectious (HAI) disease remains a serious problem in the healthcare sector. The application of nanotechnology as a novel antimicrobial agent has proven effective and is of high interest. Among them, cerium- and cerium oxide-based (ceria) nanoparticles (CNPs) have received much attention owing to their unique surface kinetics *via* auto-catalytic cycling between two oxidative states ($Ce^{4+} \rightarrow Ce^{3+} \rightarrow Ce^{4+}$). CNPs have been shown to be less toxic to mammalian cell lines but effective in eradicating bacteria through the formation of reactive oxygen species (ROS). Nano-based silver is also known for its efficient antimicrobial action. The aim of this study was to investigate the antibacterial activity of silver-doped ceria nanoparticles (AgCNPs) on three bacterial genera both in a liquid and dry form and its potential role as a novel, self-disinfecting and residual coating for high-touch abiotic surfaces. We hypothesize that through heightened generation of ROS, AgCNPs interact with the bacterial membrane leading to oxidative stress and bacterial death.
Materials and Method: AgCNP was synthesized using a base-mediated forced hydrolysis method and material characterization performed. The minimum inhibitory concentration (MIC) of AgCNPs and CNPs was determined for *Pseudomonas aeruginosa* (PA), *Staphylococcus aureus* (SA), and methicillin resistant *Staphylococcus aureus* (MRSA). Experiments were conducted with AgCNP and CNP at concentrations of 100 µg/mL (PA), 300 µg/mL (SA and MRSA), $AgNO_3$ (20 µg/mL) and gentamicin (20 µg/mL). Cell viability, a time-scale assay using TEM, intracellular ROS, DNA, and membrane damage were analysed. The ability of each agent to generate superoxide ($O_2^{\bullet-}$) and hydroxyl ($OH^\bullet$) radicals, RNS, and H_2O_2 was determined. To test each agent's residual antibacterial activity, solid surface (individual and multiple species) re-challenge tests were carried out with four cumulative doses (~10^8 cells/mL) of bacteria. Biofilm from each bacterial species was allowed to form followed by treatment with each agent for three days at intervals of 24 h. Biofilm thickness and bacterial viability was assessed. All experiments were carried out in triplicate and a Mann-Whitney U test was used for statistical analysis where p values < 0.05 were considered significant.
Results: AgCNP consisted of particles composed of 53.7% Ce^{3+}:Ce^{4+}(%Ce^{3+}) and 14.6% [Ag]/[Ag+Ce]. Treatment with AgCNP resulted in significant PA cell death (100%) after 60 mins ($p < 0.0001$) and SA and MRSA death after 180 mins (both $p < 0.0001$). AgCNP significantly induced ROS generation when given to all three bacteria (PA (~20-fold), SA (~7.4fold) and MRSA (~21fold)) when compared to control (all $p < 0.0001$). TEM analysis showed AgCNPs localized onto the bacterial membrane resulting in a significant and fatal increase in cell size (PA ($p<0.01$), SA and MRSA ($p<0.05$)). Results also revealed a significant increase in DNA damage following AgCNP treatment in all groups when compared to control (all $p < 0.0001$). Further, AgCNP induced a significantly increased amount of $O_2^{\bullet-}$, $OH^\bullet$, H_2O_2 and RNS compared to all other agents. An AgCNP-coated glass slide surface re-challenge test showed 100% inhibition of PA, SA and MRSA both individually and as a multispecies inoculation. Finally, AgCNPs were able to disrupt pre-formed biofilm in all three species and significantly eradicated shielded bacteria within (all $p < 0.0001$). AgCNPs outperformed CNPs, $AgNO_3$ and gentamicin.
Discussion and Significance: This study showed that AgCNPs, whether in a liquid or dry form, were able to eradicate *S. aureus*, MRSA, and *P. aeruginosa*. AgCNPs displayed synergistic and augmented antibacterial activity when compared to Ag or CNPs alone. We have demonstrated that AgCNP coatings may offer a new type of continuous disinfectant that leaves behind a continually disinfecting film with excellent antibacterial efficacy.

Investigating the Effect of Surface Chemistry of Mesoporous Silica Nanoparticles (MSNs) on MRI Performance Connor Wells[1,2], Danielle Winning[3], Dermot F. Brougham[3], James Wilton-Ely[2] and Gemma-Louise Davies[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University College Dublin, Ireland

Magnetic resonance imaging (MRI) is a leading non-invasive medical imaging technique due to its well established spatially resolved images. To aid this diagnostic tool further, contrast agents have been designed to improve the quality of the images, with nanostructured MRI contrast agents showing exceptional promise in image enhancement at extremely low doses.[1] Relaxivity is the term used to assess the effectiveness of an MRI contrast agent on signal enhancement. Taking advantage of their generally high surface areas, nanostructured contrast agents often host large numbers of paramagnetic centres thereby increasing sensitivity through increased local concentration. Importantly, their bulky size improves relaxivity by contributing to slower rotational correlation time, resulting in longer T_1 relaxation times.[2] There is also increasing evidence that nanoscale design features, such as pore size and surface chemistry can influence water mobility and hence affect the ultimate capability of these nanostructures as MRI contrast agents.[2,3] Surface modifications can not only impact water diffusion, but also directly affect the local tumbling rate of a chelated paramagnetic centre.[4,5] However, understanding the structure-property relationship of designed nanostructured contrast agents is still relatively poor and therefore a more thorough investigation is required in order to improve their potency.
The objective of this work is to explore how nearby surface modifications could influence the relaxation of Gd^{3+}-chelates loaded in mesoporous silica nanoparticles (MSNs). We seek to gain a better grasp of how a gadolinium complex interacts with neighbouring functional groups, such as hydrophilic thiols or bulky phenyls, across a range of molar percentages present in the pores, to probe water diffusion and effects on local tumbling, and understand the resulting impact on relaxivity. As well as full structural characterisation, single-field and fast-field cycling relaxometry (SFR and FFC-NMRD, respectively) have been used to analyse the water diffusion/exchange behaviour within these composites. It was found that modifying the molar percentages of either functional group did not significantly affect the colloidal stability of the particles, nor their particle size, as determined by TEM. Functionalised particles displayed differing behaviour when analysed using SFR; the relaxivity of phenyl-functionalised MSNs did not exhibit a linear trend with an increasing number of phenyl groups present, indeed showing no influence from the bulky ligand, whereas the thiol-MSNs gave lower

relaxivities as the thiol molar percentage increased. This is potentially due to the hydrophilic nature of the thiols and thus their interactions with water affecting the exchange rate. FFC-NMRD analysis revealed that both sets of functional groups influenced the paramagnetic Gd^{3+}-chelate compared to non-functionalised MSNs. This work provides valuable insights into the importance of nanomaterial design features, in particular the location and nature of functional groups in MRI contrast agent design. An improved understanding of the interplay between these factors should prove useful in the development of such agents for diagnostics and sensing.

Application of Porous Nanomaterials in Filtration of Biological Systems Alexandra Ten Bosch; Centre National de la Recherche Scientifique, France

Nanofiltration is shown to provide a way to test and measure nano-bio interactions between the nanofilter material and biological nanoparticles (NP). Nanofiltration is used in biotechnological and biopharmaceutical industries for separation and purification of biological molecules such as viruses, monoclonal antibodies, vaccines, blood plasma and therapeutic proteins. Other applications can be found in water purification, air filtration, biomaterial processing.. Membrane fouling limits use of nanofiltration in large low value applications such as wastewater treatment and has encouraged the development of better membranes. Nanofibers of polymers produced by electrospinning yield filters with higher flux and better mechanical stability. Ceramic membranes such as nanoporous zeolites improve selectivity. Recently Carbon nanotubes (CNT) and other nanotube materials have been explored and show promising properties. The interaction between nanofilter material and permeating biological nanoparticles determines the efficiency of the filtration process.
A theory for the efficiency and permeability of a nanomembrane is presented. The dynamic equations for flux and concentration profiles, derived from a kinetic theory of non-equilibrium statistical mechanics, are solved analytically. The penetration of the nanoparticles is determined by the ratio of the flux at the exit of the membrane to the flux at the entrance.
The theory is applied to two specific examples.
●Filtration of virus-like particles in air by a nanofibrous membrane with and without charge on fiber surfaces. The model treats the virus as a spherical particle of net surface charge and the polymer fiber as a neutral or charged line or plane. For like net charges on fiber and virus the electrostatic interaction between the NP and the fibers is shown to decrease penetration and impact NP aggregation, pertinant for the smallest NP sizes.

●Filtration of a polydisperse virus sample in water by a cylindrical CNT of radius H. The model demonstates a transition with increasing effective interaction from "hydrophobic" rejection of water molecules (diameter σ) for weak van der Waals forces with the carbon walls to notable penetrration with large flux and density, localized for $\sigma/H = 1$ at the center of the tube. Interactions between water molecules play an important role. The virus interacts with the pore material principally by a Lennard Jones type interaction. Viruses with effective diameter greater than H are inhibited from entering the CNT by steric effects and pure water exits the CNT pore.

Molecular Investigation of The Interaction Between a Gold Nanoparticle and a Polymer in Aqueous Solution Roberta Cappabianca, Paolo De Angelis, Annalisa Cardellini, Eliodoro Chiavazzo and Pietro Asinari; Politecnico di Torino, Italy

Several experimental and theoretical challenges limit a more rational design of nanoparticles (NPs) with a specific target application, i.e., the preparation of NPs with different structures/properties for various final uses. The characterization of different nanoparticle suspensions in liquids has drawn significant attention in a wide range of engineering applications. Recently, many computational approaches concerning the interactions between soft materials and inorganic nanoparticles proved to be promising in guiding the experimental preparation of nano suspensions [1-3]. Due to their optical and electronic properties, gold nanoparticles (AuNPs) are interesting for several applications, ranging from energy (e.g., solar steam generation [4,5]) to medicine (e.g., cancer theranostics [6,7]). Regarding the latter, AuNPs often encounter biocompatibility and biodegradability issues that can be overcome by encapsulating them in a poly (lactic-co-glycolic acid) (PLGA) matrix. Understanding the self-assembly dynamics of PLGA on the AuNP surface is crucial to guide and optimize the design of AuNPs coated with a PLGA corona. In this work, we combine different computational techniques to understand the interactions of an AuNP with PLGAs, aiming at assessing the most efficient and effective AuNP shape for biological applications. Specifically, we first perform classical molecular dynamics simulations while tuning the PLGA concentration in an aqueous solution; second, relying on a recently developed unsupervised machine learning (ML) algorithm, we evaluate the time evolution and behavior of PLGA clusterization. Finally, we employ the umbrella sampling approach to explore the AuNP-PLGA free energy landscape; this, combined with a detailed analysis of the surface still accessible to the solvent, allow us to gain insight into the anisotropic adsorption behavior of PLGAs onto AuNP. Our results highlight that the shallow morphology, besides surface chemistry, can influence the adsorption phenomena: in particular, the tested AuNP topology present the Au {1 1 1} crystal planes as privileged adsorption sites. This modeling-based investigation offers a comprehensive methodological approach for the rational and functional design of PLGA-coated gold nanoparticles [8].

Poly(acrylic acid)-Based Nanocomposite Hydrogel Prepared by Gamma-Irradiation Crosslinking for Sweat Urea Detection Nichaphat Passornraprasit[1], Tatiya Siripongpreda[2,1], Sumalee Ninlapruk[3], Nadnudda Rodthongkum[4,5,1] and Pranut Potiyaraj[4,5,1]; [1]Chulalongkorn University, Thailand; [2]Nanoscience and Technology Interdisciplinary Program, Thailand; [3]Office of Atoms for Peace, Thailand; [4]Metallurgy and Materials Science Research Institute (MMRI), Thailand; [5]Center of Excellence in Responsive Wearable Materials, Thailand

Nanocomposite hydrogel is fabricated via γ-irradiation crosslinking of PAA, graphene oxide (GO), and cellulose nanofiber (CNF) to serve as a sensing substrate for non-invasive dual detection of urea in sweat. In this work, CNF helps to improve the mechanical properties of the hydrogel whereas GO plays a key role in enhancing the detection signal of urea in laser desorption/ionization mass spectrometry (LDI-MS) and increases the hydrogel functionalities. The hydrogel possesses high water-sorption capacity and transparency suitable to accommodate coloring reagents and enzymes for the colorimetric sensor. The sensor exhibited vivid color change towards the increase of urea concentration in a linear range of 40–80 mM covering for chronic kidney disease (CKD) indication. Furthermore, the hydrogel can be directly applied as a substrate for the direct quantitation of urea by LDI-MS. In LDI-MS, it verifies that GO/CNF/PAA hydrogel can act as a direct matrix for promoting urea ionization, and these results corresponded well with the colorimetric sensor. Hence, this hydrogel patch might be a potential material to be applied in the non-invasive dual detection of CKD in medical diagnosis.

5:00 PM SB05.04.19
Design of Mesoporous Silica Nanoparticles for Crossing the Blood-Brain-Barrier by Modulating Surface Properties Zih-An Chen[1], Si-Han Wu[2], Chung-Yuan Mou[1] and Peilin Chen[3]; [1]National Taiwan University, Taiwan; [2]Taipei Medical University, Taiwan; [3]Academia Sinica, Taiwan

Mesoporous silica nanoparticles (MSNs) have been demonstrated as an excellent platform for drug delivery carriers in cancer treatment where tumor targeting is normally achieved via the enhanced permeability and retention (EPR) effect. However, it remains challenging for MSNs to deliver chemical drugs, nuclear acids, or proteins to reach brain tumors due to the presence of the blood−brain barrier (BBB). Here, we propose a simple strategy to modify MSNs to target brain tumors. Our strategy was to optimize the size of PEG on the surfaces of MSNs to overcome BBB. We first tested different sizes of PEG coating on the MSNS in the in vitro BBB model, where the smaller size of MSNs with near neutral charged ($RMSN_{25}$-PEG-TA) possesses higher transport efficiency to cross the BBB-mimicking endothelial cell layer. To evaluate the circulation of MSNs, we utilized two-photon microscopy. We observed that the MSNs stayed long enough in the circulation system (over 24 h) and could be accumulated outside of the cerebrovascular in mouse brains. We also examined the EPR effect with various functionalized MSNs. A particular modification in MSNs led to their abundant accumulation in tumor tissue. In a drug delivery study, we explored the potential of using MSNs to deliver drugs (DOX@MSN) into the glioma tumor. It has been observed that the functionalized MSNs with DOX significantly suppress the growth of orthotopic glioma tumors and improved DOX's severe side effects in vivo study. The biosafety result showed that the given dose of the functionalized MSNs appeared safe and decreased severe side effects caused by DOX in the animal models.

Tannic Acid-TiO_2 Heterojunction within Mesoporous Silica Particles for Reduced Photo-Induced Toxicity and Enhanced Sunscreening Effects Saehan Choi, Jeonga Kim, Rafia T. Rahman and Yoon Sung Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Wide bandgap semiconductor nanoparticles, such as zinc oxide (ZnO) and titanium dioxide (TiO_2) nanoparticles, have been widely used as ultraviolet (UV) blocking materials due to efficient UV absorption and excellent stability. However, the high chemical potentials of the photo-induced electrons and holes unavoidably generate reactive oxygen species (ROS) that can induce adverse chemical and biological damage. Synthetic polymer encapsulation has been commonly used to suppress photo-induced ROS generation, but recent studies continue to warn against the use of synthetic polymers in cosmetic and personal care products. Here we present a new method to effectively minimize the photo-induced toxicity of TiO_2 using tannic acid, a bio-inspired adhesive antioxidant polyphenol molecule, that can strongly bind to TiO_2 nanocrystal surface via ligand-to-metal charge transfer (LMCT). SiO_2-TiO_2 particles were prepared through the *in situ* TiO_2 nanocrystal synthesis within mesoporous SiO_2 particles to minimize the photochemical reactivity of TiO_2. TA was spontaneously deposited on the TiO_2 surface by Ti-catechol and Ti-pyrogallol coordination to synthesize SiO_2-TiO_2-TA hybrid particles. TiO_2 nanoparticles penetrated the cellular membrane by endocytic internalization and accumulate around the endoplasmic reticulum and nucleus. Accordingly, fibroblasts treated with TiO_2 nanoparticles exhibited lower cell viability under UV or HEV light irradiation due to highly reactive ROS generation. However, SiO_2-TiO_2-TA hybrid particles did not penetrate the cell membrane but efficiently protected the fibroblasts against UV and HEV damage through the effective scavenging of photo-generated ROS. Additionally, the LMCT from the TA HOMO to the TiO_2 conduction band allowed a new absorption pathway, enhancing the UV-to-HEV blocking performance, which significantly increased the sunscreen performance of an emulsion formulation containing SiO_2-TiO_2-TA hybrid particles. This work demonstrated a new promising strategy of plastic-free sunscreen agents with enhanced sunblock performance and suppressed photochemically induced toxicity.

Towards the Development and Optimisation of Designer Nanocomposites for Biomedical Applications Sam Ackerley[1], Leslie P. Hughes[2], Duncan L. Browne[1] and Gemma-Louise Davies[1]; [1]University College London, United Kingdom; [2]AstraZeneca, United Kingdom

Flow chemistry is a fast-advancing field involving the continuous combining of reactants which are fed into a reaction chamber, followed by the continuous output of product. When compared to batch methods, flow chemistry boasts better mixing, more efficient heat transfer and the ability to undergo self-optimisation.[1] Typically synthesised in batch, nanoparticles which display superior properties (e.g. chemical, thermal, optical) to their molecular counterparts are becoming increasingly in demand, however their large-scale synthesis, necessary for industry, is currently limited. One significant benefit to flow is the ease of scale-up whilst still retaining the desired particle properties. A range of nanoparticles from metal oxides to polymers have been produced *via* flow techniques, for example microfluidics.[2] Moreover, in flow the user has much greater control over the experimental parameters, i.e. reaction time can be fine-tuned much more easily than in batch which is useful for reactions which occur in a matter of seconds.

Continuous stirred tank reactors (CSTR) are commonplace in many large process reactions such as pharmaceutical manufacturing where they are predominantly used to synthesise organic compounds on the molecular level. Whilst CSTRs are generally involved in batch reactions they can be utilised in continuous flow processes too. The fReactor™ represents a versatile piece of flow equipment consisting of five connected CSTR modules, each of which form a discrete reaction zone. Each module has multiple ports making telescoping of reactions possible. Offering alternative routes of synthesis, this equipment can be used to conduct both single and multiphasic reactions. Additionally, the fReactor allows for the exploitation of traditional chemical and physical principles but provides that critical level of control not seen in batch, owing to its small size and modular design. Thus, bridging the gap between batch and classical flow/microfluidics.

Using the fReactor, this work describes the optimisation of poly(lactic-co-glycolic) acid (PLGA) nanoparticle synthesis by nanoprecipitation. This polymer presents itself as an ideal candidate for encapsulating active pharmaceutical ingredients owing to its biocompatible and biodegradable nature, coupled with its FDA approval for use *in vivo.*[3] Initial optimisation experiments allowed the formation of spherical nanoparticles ~200 nm with polydispersity indices of 0.05, a significant improvement over the polydispersity observed when prepared using traditional bath methods. Furthermore, we describe a methodological design which was carried out as a systematic study to assess several parameters including type of PLGA, solvent, flow rate, residence time, agitation speed, use of surfactants, and encapsulation ability. Notably we found that as agitation speed within the fReactor was decreased in regular intervals from 1500 to 500 rpm during the synthesis, nanoparticles size increased linearly ($R^2 = 0.98$). However, for speeds lower than 500 rpm this control was lost and an increase in particle polydispersity was observed. A full comparison against PLGA prepared through batch nanoprecipitation demonstrated that this flow technique has the ability to tune particle properties readily, through greater control over process parameters and produced nanoparticles with a smaller size distribution.

We have further demonstrated the broad utility of this cascade of small volume CSTRs by optimising the synthesise of superparamagnetic iron oxide nanoparticles (8 nm diameter) and mesoporous silica nanoparticles with tuneable pore diameters, which can be used as medical imaging agents and drug delivery carriers, respectively. All particles made in the fReactor were comparable to the equivalent batch materials.

Graphene Oxide Nanoplatforms to Enhance Cisplatin-Based Drug Delivery Silvia Panseri[1], Arianna Rossi[1,2], Ludmila Zarska[3], Darren Beirne[4], Giada Bassi[1,5], Andrea Ruffini[1], Monica Montesi[1], Diego Montagner[4] and Vaclav Ranc[3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]University of Messina, Italy; [3]Palacký University Olomouc, Czechia; [4]Maynooth University, Ireland; [5]University of Chieti-Pescara, Italy

INTRODUCTION

Glioblastoma is a very aggressive type of cancer with a very poor life expectancy for patients and breast cancer often metastasizes into the liver, lungs, brain, and, in 70% of cases, to bones[1,2]. Chemotherapy is largely used to treat cancer and it is based on the use of molecules targeting the high cancer cell proliferation metabolism[3]. Platinum (Pt) and three of its isoforms (cisplatin, carboplatin, and oxaliplatin) are some of the most successful metal-based drugs to cure breast cancer and glioblastoma[4,5]. Despite Pt-based chemotherapeutics being effective, their side effects (high degradation before entering the cells, the off-target organs toxicity, and cell resistance) remain great drawbacks[6-9]. In this work, it was developed a Graphene Oxide (GO) nanoplatform functionalized with Pt as a promising smart delivery system that could increase the Pt cellular uptake reducing the Pt amount needed for cancer treatment and consequently the side effects.

EXPERIMENTAL METHODS

GO nanoplatforms were treated with 8-arm polyethylene glycol-amine (PEG) that permits to load Pt on the platform (GO-PEG-Pt) and an extensive *in vitro* screening was performed on two breast cancer cell lines with aggressive nature that lead to metastatic behavior (MDA-MB 231 and MDA-MB 468) and two glioblastoma cell lines (U87 and U118). The bioactivity of GO-PEG-Pt compared to Pt-free (15 µM, 30 µM, and 60 µM) was analyzed looking at the effect on cellular uptake (ICP-OES), viability (MTT Assay), morphology (DAPI and actin staining), and migration up to 72 hours (Scratch Assay).

RESULTS AND DISCUSSION

The cell viability was significantly lower in MDA-MB 468 and U118 cells at 30 µM for GO-PEG-Pt group compared to Pt-free (<75%), and even the cell morphology seemed to be compromised. These results were highly related to the cellular uptake of GO-PEG-Pt which is significantly higher compared to Pt-free after 24 hours. This data confirmed that our nanoplatform promotes drug delivery directly inside the cells. In addition, GO-PEG-Pt mostly affected the cell migration compared to Pt-free, in particular, MDA-MB 231 showed a migration reduction of 60%, and this could be a great advantage in reducing the metastasis process.

CONCLUSION

This study demonstrated that the combination of Pt onto PEG-functionalized nano-sized GO provided numerous advantages for tumor therapy such as minimizing toxicity, enhancing the cellular uptake, and consequently we could reduce the side effects because a lower amount of Pt is necessary.

Mannose-conjugated Ferritin Nanocages for Targeted MRI of Atherosclerosis Tanvi S. Kaku and Sierin Lim; Nanyang Technological University, Singapore

Atherosclerosis is characterized by the recruitment of monocytes to the subendothelial space which then mature into macrophages in the presence of macrophage colony stimulating factors and under the influence of their microenvironment to either M1 or M2 phenotypes. Early detection of atherosclerosis is challenged by a phenomenon known as positive arterial remodelling. This phenomenon is characterized by outward expansion of arterial walls in response to development of plaques, thus retaining the lumen diameter and demonstrating no stenosis. It is one of the major causes for missing out the detection of atherosclerosis by techniques that rely on lumenography. This leads to the need for imaging agents capable of targeting and imaging plaque components. The current study aims at targeting one such plaque component, the M2 macrophages, that are prevalent in higher numbers during early-stage atherosclerosis and to image these macrophages using magnetic resonance imaging (MRI) to aid early detection and facilitate timely therapeutic intervention of atherosclerosis. The study employs ferritin, an iron storage protein, with its natural ligand, iron, for MRI contrast. M2 macrophages are known to express mannose receptors on their surface, and we thus aim at using mannose conjugated ferritin nanocages for targeted MRI of the M2 macrophages in the atherosclerotic plaques. Mannose-conjugation is hypothesized to increase accumulation of ferritin nanocages in M2 macrophages and therefore improve contrast by virtue of targeting.

Enhanced Immobilization of Glucose Oxidase by Ferrocene-Branched Chitosan for Non-Invasive Glucose Sensing with High Selectivity and Sensitivity Yi-Ting Lai[1], Tzuhsiung Yang[2] and Nyan-Hwa Tai[2]; [1]Ming Chi University of Technology, Taiwan; [2]National Tsing Hua University, Taiwan

Diabetes, one of the leading causes of death worldwide, is responsible for one-seventh of deaths in the global population each year. Non-invasive methods for sensing and screening glucose level are highly desirable due to the more comfortableness, simplicity, and no risk of infection. However, the insufficient accuracy and ease of interference limit the non-invasive sensing technique from practical medical applications. Here, we develop a non-invasive glucose biosensor for measuring glucose in saliva based on ferrocene-chitosan (Fc-Chit) modified carbon nanotubes (CNTs) electrode through a simple drop-casting method. Quantum chemical calculations as well as comprehensive experiments were conducted to optimize the electro-mediated Fc-Chit, demonstrating sturdy immobilization of glucose oxidase (GOx) on the electrode and leading to a better electron transfer process. Superior glucose sensing sensitivity of 119.97 μA/mMcm^2 in phosphate buffer saline (PBS) solution and 108.21 μA/mMcm^2 in artificial saliva, respectively, can be achieved in a wide sensing range of 20–800 µM. In addition, the electrode shows high stability (remaining 95.0% after three weeks) and high selectivity toward glucose in the presence of various interferences, including uric acid (UA), ascorbic acid (AA), and lactic acid (LA), which is attributed to the specific sites enabling GOx to be sturdily immobilized on the electrode. The results show that the proposed non-invasive glucose biosensor can serve as a technological solution for regular and accurate screening of blood glucose levels by saliva tests.

5:00 PM SB05.04.26
Albumin-Albumin/Lactosylated Core-Shell Nanovectors—Therapy to Treat Hepatocellular Carcinoma for Controlled Delivery of Doxorubicin Neyelli G. Teran-Saavedra, Jose A. Sarabia-Sainz and Alexel J. Burgara-Estrella; Universidad de Sonora, Mexico

Doxorubicin (Dox) is the most widely used chemotherapeutic agent and is considered a highly powerful and broad-spectrum for cancer treatment. However, its application is compromised by the cumulative side effect of dose-dependent cardiotoxicity. Because of this, targeted drug delivery systems (DDS) are currently being explored in an attempt to reduce Dox systemic side effects. In this study, DDS targeting hepatocellular carcinoma (HCC) has been designed, specifically to the asialoglycoprotein receptor (ASGPR). Dox-loaded albumin-albumin/lactosylated (core-shell) nanoparticles (tBSA/BSALac NPs) with low (LC) and high (HC) crosslink using glutaraldehyde were synthesized. Nanoparticles presented spherical shapes with a size distribution of 257 ± 14 nm and 254 ± 14 nm, as well as an estimated surface charge of −28.0 ± 0.1 mV and −26.0 ± 0.2 mV, respectively. The encapsulation efficiency of Dox for the two types of nanoparticles was higher than 80%. The in vitro drug release results showed a sustained and controlled release profile. Additionally, the nanoparticles were revealed to be biocompatible with red blood cells (RBCs) and human liver cancer cells (HepG2 cells). In cytotoxicity assays, Dox-loaded nanoparticles decrease cell viability more efficiently than free Dox. Specific biorecognition assays confirmed the interaction between nanoparticles and HepG2 cells, especially with ASGPRs. Both types of nanoparticles may be possible DDS specifically targeting HCC, thus reducing side effects, mainly cardiotoxicity. Therefore, improving the quality of life of patients during chemotherapy.

5:00 PM SB05.04.27
Pyrene-Perfluoroalkyl (PP)-Incorporated Liposomes for Improving the Oxygen-Enriched Photodynamic Therapy (Oxy-PDT) Kwang Min Kim, Manoj Manna, Mohammed Inayathullah, Kyle D. Brewer, Bhavika Mam, Kelly B. Mahaney and Jayakumar Rajadas; Stanford University, United States

The Oxygen-enriched Photodynamic Therapy (Oxy-PDT) is one of the emerging tumor-treating approaches, where the perfluorocarbon as a high-capacity oxygen carrier is conjugated to the photosensitizer that converts the carried triplet oxygens into reactive singlet oxygens, which kill cancer cells. However, the efficacy of Oxy-PDT in the biological system remains challenging because it is difficult to obtain cytosolic delivery of the Oxy-PDT agent into cells due to its low cell permeability. To overcome the issue, we synthesized the perfluoroalkyl-pyrene (PP) as the Oxy-PDT agent, which was further incorporated into lipid bilayers (DSPC and DPPC) for enhancing the delivery of the agent into cancer cells. Our results showed that the PP formed a well-ordered structure within a hydrophobic region of the DSPC-DPPC bilayers (Fluoroscence spectroscopy, DLS). We also confirmed that the PP incorporated into the liposomal bilayers successfully exhibited an excimer emission at 450 nm in aqueous solutions (Fluoroscence spectroscopy, DLS) and produced singlet oxygens ($^1O_2$) (UV-Vis absorption spectroscopy). Then, we applied our new Oxy-PDT to the human patient-derived cancer cells (i.e., glioma, a type of brain cancer) to evaluate the therapeutic efficacy. Using the immunocytochemistry and confocal microscopy, we demonstrated that the PP-liposomes were localized only within cancer cells and significantly decreased the number of cancer cells when irradiated with light. In this study, we are introducing a new class of small organic molecules for biomedical applications. We expect that our approach incorporating oxygen carriers, photosensitizers, and liposomes in one system would make a significant contribution to the study of the Oxy-PDT modality by improving the localization and timing of cancer killing agent delivery.

SESSION SB05.05: Nano in Tissue Engineering

Polymer Blended Membranes Bi-Functionalized with ZnO-NPs via Electrospinning for Periodontal Bone Tissue Regeneration—Antibacterial Effect and Osteogenic Differentiation Stimulation Gina Prado-Prone[1], Phaedra Silva-Bermudez[2], Sandra E. Rodil[3], Maria L. Focarete[4], Jorge A. García-Macedo[5] and Argelia Almaguer-Flores[1]; [1]Universidad Nacional Autónoma de Mexico, Mexico; [2]Instituto Nacional de Rehabilitación LGII, Mexico; [3]Universidad Nacional Autonoma de México, Mexico; [4]University of Bolognia, Italy; [5]Universidad Naciona Autónoma de México, Mexico

Periodontitis is a highly prevalent infectious disease that causes the progressive destruction of teeth-supporting tissues: alveolar bone, cementum, and periodontal ligament. If left untreated it can lead to tooth mobility and eventually tooth loss, impairing oral function, aesthetics, and the patient’s overall quality of life. Bone Tissue Regeneration (BTR) is a surgical therapy to restore the alveolar bone around the tooth for reducing its mobility or, if the tooth was already lost, for future implant placement. This periodontal therapy involves the use of a resorbable membrane that selectively excludes the relatively rapid epithelial and fibroblastic down growth into the bone defect, allowing the repopulation of the defect sites with slower migrating endogenous bone cells and stem cells to regenerate the affected tissues. Two of the major reasons for clinical BTR failure are the bacterial colonization of the membrane-defect area and the fast biodegradation of the membrane, causing postoperative infections and a premature rupture of the membrane, limiting the regeneration process.

In this work, we present the development of biodegradable polymer-blended membranes functionalized with ZnO-NPs via electrospinning to prevent local bacterial colonization and, simultaneously, favor bone growth.

The developed membranes were synthesized based on a homogeneous polymer blend of polycaprolactone and gelatin (PCL-G) and modified, via electrospinning, with different concentrations (1, 3, and 6 wt.%) of ZnO nanoparticles (ZnO-NPs). The chemical composition, micro-morphology, hydrophilic character, biodegradation rate, and thermal and mechanical properties of the membranes were analyzed under conditions similar to the physiological environment. The antibacterial effect of the PCL-G membranes modified with ZnO-NPs was evaluated using five bacterial strains, two important periodontal pathogens: *A. actinomycetemcomitans* serotype b and *P. gingivalis*; and three aerobic pathogens causing prevalent nosocomial infections: *S. aureus*, *E. coli*, and *S. epidermidis*. We also investigated whether the developed membranes could stimulate osteogenic differentiation, and consequently bone regeneration. For this, the expression of osteoblast markers (osteocalcin and osteoprotegerin) and calcium deposition in human bone marrow-derived mesenchymal stem cells (BM-MSC) after exposure to the membranes, were analyzed.

The developed membranes presented appropriate physicochemical properties to be potentially used in clinical treatments, mainly, the mechanical properties and biodegradation rates were satisfactory. All the PCL-G membranes modified with 1, 3, and 6 wt.% of ZnO-NPs showed a significant reduction in the planktonic and biofilm formation of the five clinically relevant tested. However, only the membranes modified with the lowest concentration of ZnO-NPs (1 wt.%) stimulated the production of osteoblast markers and calcium deposits in human BM-MSC and were biocompatible with human bone cells and gingival fibroblasts cells.

These results suggest that the PCL-G membranes with 1 wt.% of ZnO-NPs are high-potential candidates for BTR treatments, as they were the most effective in terms of better antibacterial effectiveness at biocompatible NPs-concentration while creating a favorable cellular microenvironment for bone growth.

9:00 AM SB05.05.02

Nano-Biofabrication Approaches Towards Human Eardrum Reconstruction Shivesh Anand[1], Cemre Günday[2], Nazende Günday Türeli[2], Thomas Stoppe[3], Marcus Neudert[3], Serena Danti[4], Lorenzo Moroni[1] and Carlos Mota[1]; [1]Maastricht University, Netherlands; [2]MyBiotech GmbH, Germany; [3]Technische Universität Dresden, Germany; [4]University of Pisa, Italy

Introduction: The human eardrum or tympanic membrane (TM), is a thin, conical tissue of the middle ear that captures sound waves and transforms them into mechanical motion. Successful transmission of these nano-vibrations to the inner ear is attributed to its precise three-dimensional (3D) design [1]. In this work, we investigated the integration of tissue engineering with different nanotechnologies for an accurate modelling and reconstruction of the human TM. Hierarchical scaffolds were biofabricated in this regard, and validated based on their mechanical, acoustical, and biological response [2]. Subsequently, antibiotic-loaded nanoparticles along with anti-inflammatory nanofillers were incorporated to prevent infections or immune reaction post implantation [3, 4].

Methods: A Python script was developed for modelling the anatomical architecture of the human eardrum. Computational simulations were performed on COMSOL Multiphysics to identify dominant structural attributes within the generated TM models. The selected geometries were fabricated using a combination of poly(ethylene oxide terephthalate)/poly(butylene terephthalate) (PEOT/PBT) with chitin nanofibrils (CN). A hybrid biofabrication approach combining electrospinning and additive manufacturing was implemented in this regard. 3D patterns with varying radial and circumferential arrangements were deposited on the nanofibrous electrospun membranes to replicate the collagen fibrils of the native tissue. A co-electrospinning setup was introduced for the incorporation of ciprofloxacin-loaded poly(lactic-co-glycolic acid) (PLGA) nanoparticles within these eardrum scaffolds. The mechano-acoustical response of the fabricated constructs was evaluated by applying the techniques of macroscopic indentation and laser Doppler vibrometry. Finally, human mesenchymal stromal cells (hMSCs) were cultured to assess their differentiation towards TM fibroblasts.

Results: Biomimetic eardrum scaffolds were fabricated using PEOT/PBT/CN nanocomposites. A three-fold reduction in the diameter of electrospun nanofibers was obtained upon the introduction of CN within the polymeric matrix. The co-electrospinning setup was successful in depositing and adhering PLGA nanoparticles onto the nanofibrous membranes. *In silico* investigation of the chosen TM models suggested a geometrical dependency of their mechanical and acoustical responses, which was further corroborated by the experimental measurements. In general, radially aligned constructs were noted to show a more comparable mechano-acoustical behavior with respect to the native tissue. *In vitro* studies performed with hMSCs revealed a favorable influence of 3D hierarchy on cellular alignment and extracellular collagen production. Moreover, a pronounced downregulation of pro-inflammatory cytokines was achieved with the inclusion of CN. Lastly, the ciprofloxacin-loaded TM scaffolds demonstrated the desired biocompatibility and drug release kinetics.

Conclusions and Outlook: The optimized nano-biofabrication strategies allowed the creation of biomimetic constructs within the anatomical dimensions of native eardrum. The addition of CN as a nanofiller within the PEOT/PBT matrix produced significant improvements in their mechanical and immunomodulatory capabilities. Besides, a tunable release of ciprofloxacin was achieved from the fabricated scaffolds. Finally, advanced 3D bioreactor platforms are currently under investigation to differentiate the cultured hMSCs toward TM-specific cells.

Acknowledgments: This project was funded by EuroNanoMed III under Horizon 2020 Research and Innovation Framework Programme of the European Commission and the Netherlands Organization for Scientific Research (NWO).

Micro-Injection of Amphiphilic Nanoparticles into a Droplet Interface Bilayer Reveals Particle-Induced Reductions in Membrane Capacitance
Farzin Mashali, Colin Basham and Stephen A. Sarles; The University of Tennessee, Knoxville, United States

With their ability to passively enter cells, amphiphilic gold nanoparticles (AmNPs) functionalized with a striped pattern of hydrophilic sulfonate and hydrophobic octanethiol ligands show promise for enhanced drug delivery. However, the specific mechanisms of their passage through cellular membranes remain unclear, in part due to a lack of appropriate experimental tools. Ongoing work in the Sarles group at UTK seeks to reveal these interactions by leveraging the droplet interface bilayer (DIB) technique for model membrane formation and electrophysiological characterization. The advantages of the DIB method for assembling a lipid bilayer include the ability to independently control droplet and lipid leaflet compositions and membrane area. The DIB technique also permits the use of electrophysiology measurements to monitor changes in bilayer structure and transport properties, both of which may aid in the disclosure of NP-membrane interactions.
Herein, we utilize micro-injection to incorporate AmNPs into one droplet of a droplet interface bilayer *after* bilayer formation occurs and use electrophysiological measurements as well as brightfield imaging to assess NP-induced changes in bilayer properties. Post-bilayer-formation direct micro-injection of NPs allows for maintaining stable membranes needed to study NP-membrane interactions and permits before-and-after comparisons to be made on the same membrane. In this study, DPhPC model membranes are formed between 300 nL droplets in hexadecane. A pulled micropipette connected to a pneumatic injector is used to inject AmNPs without disrupting the membrane. Before injecting AmNPs, the electrical resistance and capacitance of the membrane are electrically tested using wire-type electrodes to establish baseline bilayer characteristics and, thereby, quantify NP-induced changes to the membrane after injection. This procedure reveals that AmNPs with 15 mol% OT ligands decrease the area-normalized capacitance of the bilayer by up to 20%, where the amount of reduction depends on the final AmNP concentration. When combined with other electrical measurements, this trend indicates that AmNPs spontaneously embed into the hydrophobic center of the bilayer, increasing its average thickness and reducing its capacitance per unit area. In contrast, no discernible changes in the bilayer's specific capacitance were observed after adding hydrophilic NPs lacking hydrophobic ligands. This implies that the hydrophobic ligands are responsible for the insertion of AmNPs into the bilayer. Moreover, AmNPs with 30 mol% hydrophobic ligands showed larger decreases in specific capacitance that occurred at a lower AmNP concentration) compared to 15 mol% OT AmNPs. Finally, we observed that AmNPs lowered the membrane resistance, resulting in increases in average ion current through the bilayer under an applied voltage. These changes also coincided with transient, discrete current spikes with durations of 3 and 12 ms. Unlike many works which leveraged qualitative experimental measures, our findings demonstrate how direct microinjection and electrophysiology measurements that specifically incorporate capacitance monitoring can be used to study NP-membrane interactions.

9:30 AM SB05.06.03
The Role of Fluid Dynamics and Particle Physicochemical Properties in Characterizing the Nano-Cellular Interface Within a Multi-Cellular *In Vitro* Model Kristen Krupa, Maggie Jewett, Hayley Jesse and Audrey Brackenridge; University of Dayton, United States

Due to their unique physicochemical properties nanomaterial (NM)-based technologies are growing exponentially in scope and economic importance. Additionally, due to their electric and antibacterial attributes silver NMs (AgNMs) are integrated into electronic, sensing, and consumer applications. This surge has resulted in significant degrees of NM waste and increased rates of human exposure. This has created a vital need to fully understand the potential biological consequences of NM exposure, characterize resulting NM-biological interfaces, and determine subsequent toxicological effects. NM safety assessments are currently being carried out in both cell-based in vitro and animal-based in vivo models, with limited correlation between the two models due to the fact that NM behavior is dependent upon environmental and exposure factors. Therefore, there exists a need for the development of an enhanced cellular model that preserves the advantages of in vitro systems while incorporating in vivo influences to produce an efficient, realistic, and relevant means for NM exposure and evaluation.

As such, the goal of this study was to design, optimize, and implement an enhanced in vitro microenvironment model to create a rapid, more realistic mechanism to evaluate the safety and nano-cellular interface of experimental NM constructs. Using perfusion plates, this model was comprised of three cellular compartments, dynamic flow to represent the cardiovascular system, and a combination of tissue-based and immune cell lines. The set-up selected for this study includes 1) initial NM exposure into an alveolar model, followed by 2) transport into liver then 3) skin compartments: representing initial inhalation, movement into the liver for waste removal, and relocation to the skin. AgNMs were incorporated into for this study, which are renowned for their ability to induce stress, genetic modifications, immune activation, and cytotoxicity. Furthermore, to effectively correlate NM deposition and physicochemical properties to bioresponses, two different AgNM sizes and surface chemistries were evaluated.

The results of this work demonstrated that the nano-cellular interface varied as a function of several influences, predominantly the presence of fluid dynamics and both primary size and surface chemistry of the AgNPs. One unique aspect of this study was the development of kinetic profiles of the nano-bio interactions within each, interconnected cellular compartment. Polymer coated AgNMs proved to be more adept in traveling between cellular compartments than their citrate coated counterparts, with a more evenly distributed. Looking at the toxicological profile following AgNM exposure, the cellular immune response was substantially decreased under dynamic conditions, as assessed via pro-inflammatory cytokine secretion rate. The degree of nano-bio interactions was directly linked to observed cellular outcomes, including intracellular stress and activation of signal transduction pathways; both of which were dependent upon exposure conditions and AgNM physicochemical properties. In conclusion, the enhanced in vitro model, which successfully incorporated multiple cellular components and fluid dynamics, resulted in a modified nano-cellular interface from a static, mono-cellular control. The evaluation of kinetic deposition rates, which varied with NM surface chemistry and primary particle size, were correlated to observed nanotoxicological outcomes. This work demonstrates that by including physiologically relevant modifications, in vitro models can be an effective tool in predicting nano-bio interactions, particle fate, and safety assessments within a biological system.

Futureproofing Formulations, Fast! Claire Thompson; Agility Life Sciences, United Kingdom

The vast majority of new drug candidates are "badly behaved", either poorly soluble, poorly permeable, or both. The pandemic has increased the expectation from patients and investors that we develop medicines more quickly. So, how can we accelerate timelines while also giving drug candidates the best chance of success in preclinical and clinical studies? We will discuss case studies demonstrating how nano-enabled approaches can enable you to formulate fast while also futureproofing your products.

11:00 AM SB05.07.02
Lidocaine and Cyclodextrin Complexes as a Bio-Textile Patch for Fast-Releasing Topical Administration of Lidocaine Ankit Kirtania, Asli Celebioglu and Tamer Uyar; Cornell University, United States

Bio-textiles are primarily engineered for specific biomedical end-uses like textile-based drug-delivery carriers for appropriated *in-vivo* target sites while maintaining somatic harmony. The use of nanotechnology for fabricating such bio-textiles via electrospinning gained importance because of controllable nanoscale diameters, the encapsulation amount of active agents, and overall efficacy in targeted delivery overcoming first-pass metabolism barriers. Fine-tuning such parameters positively affects the morphology interface, imparts enhanced physiochemical properties, and facilitates bio-nano-interface construction. Responsive polymeric base materials as encapsulation agents for electrospun nanofibers for active agents like medicaments are preferred for their biocompatibility and homeostasis during interaction with bio-compounds. The large surface area and highly porous structure of the nanoparticles allow easier disintegration upon subjection to proximal physiological fluids. The protein corona expedites the stable transition of the nanoparticles to the target delivery site via endocytosis or direct penetration. The amorphized state of the active agent within the nanofibrous matrix allows easier adsorption into target organs. Apart from polymeric bases, cyclodextrins are a safe choice for nanofiber matrices to confine active agents via inclusion complexation (IC) within the hydrophobic truncated cone for drug delivery systems by amorphization of the crystalline active agents and enhancing its solubility, bioavailability, and stability. Cyclodextrins are more water soluble than polymers and become a better choice as an encapsulation agent because solubilizing polymers need toxic solvents sometimes. Cyclodextrin help in the fast or slow, or controlled release of the encased active agents leading to drug delivery in a similar fashion as the polymeric nanofibers. Cyclodextrin and active agent inclusion complexes can be electrospun into nanofibers in the form of strips or onto textile substrates to form bio-textiles. In this study, Lidocaine (Lid), a crystalline and poorly water-soluble amino-amide drug, was encapsulated within Hydroxypropylated Beta Cyclodextrin (HPβCyD) nanofiber matrices to enhance its topical bioavailability and solubility. Aqueous solutions of Lid/HPβCyD-IC in different molar ratios were electrospun into nanofibrous (NFs) strips and checked for their physiochemical properties to ascertain IC formation and understand the efficacy of encapsulation and amorphization of Lid in HPβCyD nano matrix through 1H-NMR, FTIR, XRD, DSC, and TGA. The Lid/HPβCyD-IC NFs were deposited on a non-woven cotton patch to create a bio-textile patch for topical administration. The *in-vitro* release performance was examined, and the findings corroborated the fast-release corollary.

11:15 AM SB05.07.03
Structure Optimized Lipid-Based Intradermal Delivery—Needle-Free Transdermal Drug Delivery Hyunro Kim[1], Jaeyi Choi[1], Jisung Shim[2], Jaegeun Noh[3], Byeong Ju Kwon[4], Sung Uk Kuh[4], Youngdo Jeong[1], Kwanhyi Lee[1] and Hojun Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University School of Medicine, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of); [4]Yonsei University College of Medicine, Korea (the Republic of)

Transdermal drug delivery (TDD) exhibits high drug efficacy and minimized side effects over oral administration because it bypasses first hepatic metabolism and gastrointestinal tract. However, the outermost layer of the skin, the stratum corneum (SC; composed of thousands of lipid layers), is recognized as the major barrier in TDD.
With the recent FDA approval case, Microneedle (MN) is recognized as an effective solution for TDD. MN, however, also has an issue with remaining physical damage up to the dermis, where abundant immune cells reside. Therefore, MN can cause external infection and induce the hypersensitivity that can be fatal for children.
Here we devised a needle-free TDD based on lipid as a chemical penetration enhancer. Specifically, we designed structure of lipid nanoparticles with different fusogenicity (liposome < cubosome < hexosome). With structure engineered lipid nanoparticles, Structure Optimized Lipid-based Intradermal Delivery (SOLID) patch was fabricated. Our *in vitro* test revealed that cubosome- and hexosome-SOLID patch outperforms that of liposome in SC penetration. To understand behind principle of outstanding performance, we conducted *in situ* synchrotron SAXS study and found out both cubo- and hexo-some show much faster kinetics in SC lipid layer disruption over liposome. Our study indicates that structure engineering of lipid nanoparticle can be an effective approach for the development of needle-free TDD. We believe needle-free TDD can be an effective strategy for not only drug delivery, but many other applications including mRNA intradermal vaccine to prevent pandemic.

11:30 AM SB05.07.05
Nanoneedle-Decorated Bioresorbable Vascular Scaffold (BVS) Technology Priya Vashisth, Cong Wang and Ciro Chiappini; Kings College London, United Kingdom

Numerous advances and innovative therapies have been developed for interventional cardiology over the recent years, since the first introduction of balloon angioplasty. Among these, bioresorbable vascular scaffolds (BVS) represent a breakthrough technology, heralded as potential candidates to treat atherosclerosis (a cardiovascular disease related to the build-up of hypercholesteremic plaque in the dysfunctional arteries). Compared to permanent metal stents, BVS brings the promise of complete bio-sorption after regaining the normal blood flow through arteries, restoration of natural vasomotion, and the possibility of restenting at the same site (if needed) without the interference of previous treatments. However, this breakthrough technology is facing a serious issue of late-stent-thrombosis. The underlying causes of failure of this technology could be summarized as (1) delayed endothelialization, (2) recoiling after the implantation, and (3) ineffective, and uncontrolled release of cytotoxic drug which not only stops the proliferation of vascular smooth muscle cells but also affects the normal functioning of endothelial cells.
In this study, to address these key shortcomings, we introduce a unique platform for effective drug delivery only to the lesion site, through the integration of nanoneedles (NNs) within a poly L lactic acid (PLA) BVS.
The planar surface (metal or polymeric) of stents usually result in the non-specific burst release of the cytotoxic limus drug towards the vessel wall as well as to the lumen, leading to less efficient drug delivery and disruption of normal functions/tight junctions of endothelial cells. In contrast, the NNs can penetrate the vascular tissue in a minimally invasive way and precisely target and modulate the release of drugs, thus selectively treating the atherosclerotic vessel wall and minimizing systemic dispersion. As a proof of concept, here we demonstrated the interfacing of NNs with primary human vascular smooth muscle cells (HVSMCs: the cells of interest and the primary cause of in-stent-restenosis) and the capacity of NNs to deliver the GFP-mRNA to these cells. The biocompatibility of the fabricated NNs platform has been evaluated using human vascular endothelial cells (HUVECs). Results demonstrated no significant impact on cell viability, adhesion, spreading, proliferation, and most importantly on the formation of the tight junction between the endothelial cells.
Furthermore, we evaluated the bio-interfacing of NNs with vessel wall tissue compared to the plane PLA surface to estimate the impact on recoiling. The cells are known to grab and pull on individual nanoneedles, yielding significantly enhanced adhesion which can thus enhance the apposition to the vessel wall and minimize the issue of BVS recoiling The *ex vivo* interfacing experiments, performed using porcine artery wall and analyzed using histological assessment of the interfaced tissue specified an overall effect of nanoneedles on underlying and surrounding tissue.

The developed degradable platform can be potentially used to deliver the drugs to the target site with minimal side effects and also can help to solve the recoiling issue that exists with BVS technology. With directional and respective modifications, this platform can also be used to treat other peripheral blockage conditions where we need to open up the lumen and at the same time need to deliver the drug/s efficiently to cure the condition.

SESSION SB05.08: Theranostics
Session Chairs: Gemma-Louise Davies and Claire Thompson
Wednesday Afternoon, April 12, 2023
Moscone West, Level 2, Room 2016

1:30 PM *SB05.08.01
Polymer-Based Nanoscale Theranostic Formulations Ziwei Zhang, Connor Wells, Gemma-Louise Davies and Gareth Williams; University College London, United Kingdom

Most conventional chemotherapeutics have narrow therapeutic windows, and thus their delivery remains challenging and often raises safety and efficacy concerns. Theranostic platforms, with simultaneous encapsulation of therapeutic and diagnostic agents, have been proposed as next-generation formulations which can overcome this issue. We have shown in recent studies that co-encapsulation of superparamagnetic iron oxide nanoparticles (potent magnetic resonance imaging [MRI] contrast agents) and chemotherapeutic active ingredients into nanoscale fibers and nano-microscale particles produces formulations from which drug release can be directly quantified from the MRI signal. We have generated systems appropriate for both oral and implant delivery. This presentation will summarize our recent findings in this research, exploring the effect of formulation composition and morphology on the functional performance.

2:00 PM SB05.08.02
***In Vitro* and *In Vivo* Analysis of Pancreatic Cancer Chemotherapeutics Encapsulated in Metal-Organic Frameworks (MOFs)** Francesca Melle[1,2], Jon Ostolaza[1], Sergio Mercado[1], Xu Chen[1] and David Fairen-Jimenez[1]; [1]University of Cambridge, United Kingdom; [2]AstraZeneca, United Kingdom

Pancreatic cancer is one of the most lethal and aggressive tumors with a 5-year survival rate of 5%. Due to the complex and surgically inaccessible anatomical position of the pancreas, most cases are treated using chemotherapeutics. However, these drugs have several limitations such as low targeting specificity, high instability, severe side effects from the use of high doses, inability to bypass cell membranes, and poor pharmacokinetics. One strategy to improve the efficacy of chemotherapy drugs is their encapsulation into nanoparticle systems. Among different nanoparticle systems, metal-organic frameworks (MOFs) represent a promising opportunity for the treatment of cancer. MOFs are a new class of biocompatible nanoporous materials with exceptionally high surface area (>8,000 m^2/g) and drug loading capabilities (>70% drug weight), surpassing that of alternative drug delivery systems. Their chemical flexibility allows them to host virtually any therapeutic payload, including small molecules and macromolecules, and to be functionalized with different surface molecules (e.g., PEG), offering a platform with the potential to ultimately become a universal "plug-and-play" system.

In this work, the drug loading efficiency of the most common chemotherapeutic drugs for pancreatic cancer (gemcitabine, paclitaxel, and SN38) was assessed using a MOF named PCN222. PCN222 was first synthesized and characterized by DLS and SEM to confirm a size between 120-150 nm that ensures its ability to interact at a cellular level. PXRD and N_2 adsorption were used to confirm the crystallinity and the porosity of the material. The three drugs were then loaded independently into PCN222 followed by surface functionalization with PEG chains to increase both stability and biocompatibility of the drug-MOF complex. The drug loading efficiency was measured using UV-vis and HPLC while PEGylation and drug content were confirmed by ζ-potential, DLS, FT-IR, and TGA. Following the material characterization, the three drug-loaded PCN222 were tested for *in vitro* toxicity in pancreatic cancer cell lines (BxPC-3, Mia-Paca-2, and PANC-1) using live-imaging cell analysis and MTS end-point viability assays. Cell internalization was further studied using confocal microscopy. Subsequently, the most effective formulation was evaluated *in* vivo using a subcutaneous xenograft mouse model of human PDACs of BxPC-3.

The viability analysis showed that different pancreatic cancer cells tolerated high concentrations of the empty PCN222, highlighting its biocompatibility *in vitro*. The PEG coating improved the stability and the sustained drug-release capability of loaded PCN222 *in vitro*. In addition, PCN222 showed a high cell internalization efficacy in BxPC-3, Mia-PaCa2, and PANC-1 cells. The *in vivo* studies using human pancreatic cancer xenograft mouse models showed that the delivery of chemotherapeutics loaded in PCN222 led to enhanced antitumor efficacy when compared to the free drug.

PCN222 is a promising drug delivery system able to increase the efficacy and safety of current standard-of-care chemotherapeutics such as gemcitabine, paclitaxel, and SN38, paving the way toward the clinical translation of MOFs in pancreatic cancer and other hard-to-treat cancers.

2:15 PM SB05.08.03
7-Dehydrocholesterol Lipsome Nanoparticle as a Targeting Radiation-Induced Ferroptosis Radiosensitizer for Non-Small Cell Lung Cancer
Jianwen Li, Wei Yang, Shuyue Zhan and Jin Xie; University of Georgia, United States

Therapeutics that can be activated by radiation in situ to enhance the efficacy of radiotherapy are highly desirable. Herein, 7-Dehydrocholesterol (7-DHC), a biosynthetic precursor of cholesterol, is engineered in a liposome nanoparticle as a targeting delivered radiation-induced radiosensitizer (RIRS) towards non-small cell lung cancer (NSCLC). The studies show that 7-DHC can be activated and react with radiation-induced reactive oxygen species (ROS) and in turn promote lipid peroxidation, subsequently induce ferroptosis. For efficient delivery, 7-DHC is encapsulated into a liposome nanoparticle, and been tested in tumor bearing mice, results showed a significantly enhanced the efficacy of radiotherapy. After treatment, 7-DHC is converted to cholesterol, causing no detectable side effects or hypercalcemia. This new method represents a nature-inspired, safe RIRS with great potential in clinical translation.

2:30 PM SB05.08.04
Ultrasound-Triggered Piezocatalytic Cancer Therapy Using Piezoelectric Nanomaterials Quan Truong Hoang[1], Ravichandran Vasanthan[1], Thuy Giang Nguyen Cao[1], Min Soo Son[1], Hyeon Ju Kang[1], Ji Hee Kang[2], Young Tag Ko[2], Tae Il Lee[2] and Min Suk Shim[1]; [1]Incheon National University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

Piezoelectric nanomaterials, which are capable of generating reactive oxygen species (ROS) via piezocatalytic redox reactions under mechanical stress have emerged as promising nanoplatforms for efficient cancer treatment. Herein, piezoelectric nanoparticles such as ZnO nanorods and metal sulfide nanoparticles were functionalized with poly(ethylene glycol) (PEG) and loaded with chemodrugs for ultrasound (US)-triggered combination chemo-piezocatalytic cancer therapy. The drug-loaded piezoelectric nanoparticles can efficiently induce piezoelectric polarization for the generation of ROS under US irradiation. In addition, the drug-loaded piezoelectric nanoparticles not only generated ROS under US irradiation but also improved the intracellular delivery of chemodrugs. In vivo study showed that drug-loaded piezoelectric nanoparticles effectively accumulated in the tumors and significantly suppressed the tumor growth under US irradiation without systemic toxicity. This study demonstrates the feasibility of piezoelectric nanoparticles as US-triggered piezocatalytic agents that can selectively and effectively eradicate tumors via chemo-piezocatalytic combination therapy.

2:45 PM SB05.08.05

Development of Thermo-Responsive Theranostic Mesoporous Silica Nanoparticles for Hepatocellular Carcinoma Marwa Rizk[1,2], Connor Wells[1], Gareth Williams[1] and Gemma-Louise Davies[1]; [1]University College London, United Kingdom; [2]Alexandria University, Egypt

Hepatocellular carcinoma (HCC) is commonly diagnosed in the late stages which restricts treatment options to the FDA approved drug sorafenib. However, sorafenib's low efficacy, poor solubility, and toxic side effects limit its performance to only 30% of patients. In addition, the lack of a proper diagnostic tool for either detecting the tumour in the early stages or to monitor the disease progression represents another barrier. [1-3]

This work aims to solve these problems by developing theranostic mesoporous silica nanoparticles (MSNs) that can enhance the therapeutic and diagnostic performance through combination therapy of doxorubicin.HCl and sorafenib tosylate as well as magnetic resonance imaging (MRI) contrast by loading of MRI-active gadolinium 1,4,7,10-tetraazacyclododecane-N,N',N'',N'''-tetraacetic acid (Gd^{3+}-DOTA) chelate. Therapeutic MSNs have been prepared and the effect of the pore size, internal pores' chemistry and solvent polarity (DMSO, DMF, ethanol, THF, acetone) on both drug loading and entrapment efficiency of sorafenib tosylate and doxorubicin.HCl has been studied. In term of diagnosis, MRI-active MSNs have been optimised by incorporating the MRI contrast agent (Gd^{3+}-DOTA) chelate to internal surfaces, at different locations where water gating can be exploited to provide an 'on/off' MRI signal switch for disease diagnostics. [4] In order to cap the pores, different molecular weights of UCST thermo-responsive polymers (poly(acrylamide-co-acrylonitrile)) were synthesized using reversible addition−fragmentation chain-transfer polymerization (RAFT); where design of experiment (DOE; central composite design) was applied to optimise the temperature at which the polymer will change its conformation from dehydrated to hydrated, allowing water access to the internally located paramagnetic species (turning 'on' the MRI contrast) and concurrent controlled drug release. [5,6]

Sorafenib tosylate loading capacity into MSNs has been highly affected by solvent polarity and pore size variation; where maximum drug loading was achieved upon using THF as a solvent and MSNs of narrow pore diameter of 3.5 nm. In the case of doxorubicin.HCl, the loading capacity was decreased 5 times upon scaling up, however other parameters showed no significant effect on its loading. The dual loaded optimised MSNs showed loading capacity and entrapment efficiency percentages of 29.1 % and 27.1 % for sorafenib tosylate and 17.4% and 9% for doxorubicin.HCl, respectively. MRI-active MSNs showed relaxivity values (r1) of 60.1 mM^{-1} s^{-1} at 0.47 T for internally located Gd^{3+} chelates on MSNs-Gd, compared to the commercially available Gd^{3+}-DOTA chelate (Dotarem®) of r1 3.4 mM^{-1} s^{-1} at 1 T. The molecular weight of the synthesised UCST thermo-responsive polymers (poly(acrylamide-co-acrylonitrile)) ranges between 84600- 164100 g/mol and their cloud points were characterised using dynamic light scattering (DLS) as well as turbidimetry, and found to range between 36.6–85.5 ^{o}C. As a final step, the behaviour of the optimised thermo-responsive polymer grafted onto the theranostic MSNs will be described, including studies on the efficacy and biosafety of the developed system on Hep-G2 cell lines.

(Cancer) Theranostics with (Intrinsically) Radiolabeled Nanomaterials Weibo Cai; University of Wisconsin--Madison, United States

Radiolabeled nanomaterials have gained tremendous interest over the last 2 decades, which can play diverse roles in imaging, image-guided drug delivery, as well as theranostics of a number of diseases such as cancer. Some recent examples of radiolabeled materials from our recent work will be briefly described in this talk.

Although chelator-based radiolabeling techniques (commonly used for labeling nanomaterials with radiometals such as ^{64}Cu/^{89}Zr) have been used for decades, concerns about the complexity of coordination chemistry, possible alteration of nanomaterial pharmacokinetics, and potential detachment of radioisotopes have driven the need for developing a simpler yet better technique for future radiolabeling, which may facilitate future clinical translation.

The emerging area of intrinsically radiolabeled nanomaterials can take advantage of the unique physical and chemical properties of well-selected inorganic or organic nanomaterials for radiolabeling, and more importantly, offer an easier, faster, and more specific radiolabeling possibility to facilitate future clinical translation. Generally speaking, the four major categories of intrinsically radiolabeled nanomaterials include: 1) hot-plus-cold precursors, 2) specific trapping, 3) cation exchange, and 4) proton beam activation.

Representative examples of these strategies will be briefly illustrated in this talk, with the main focus on our own work that involves the radiolabeling of a variety of nanomaterials via "specific trapping". The nanomaterials investigated in our laboratory include silica/carbon-based nanomaterials, COVID-19 nano-vaccines, multifunctional/multimodal hybrid nanomaterials, iron oxide nanoparticles, micelles, DNA nanostructures, etc. **[1-10]**.

Improving Surgical Treatment of Breast Cancer: Dual-Modality Nanocrystals for the Detection of Sentinel Lymph Nodes Loren Deblock[1], Benedicte Descamps[1], Glenn Vergauwen[1,2], Jens Debacker[1], Philippe Tummers[1,2], Isabel Van Driessche[1], Klaartje De Buysser[1], Jonathan De Roo[3] and Christian Vanhove[1]; [1]Ghent University, Belgium; [2]Ghent University Hospital, Belgium; [3]Universität Basel, Switzerland

Each year, more than two million women worldwide are diagnosed with breast cancer [1]. In the typical surgical treatment of this cancer the primary tumor is removed, together with the so called sentinel lymph nodes (SLNs), these are the lymph nodes that have the highest probability of being invaded by cancer cells. A combination of two methods has been established as the gold standard for the detection of SLNs. Metastable radioactive Technetium-99m (^{99m}Tc) labeled nanocolloids are either peritumoral or periareolar injected several hours before surgery and accumulate in the SLNs. A preoperative SPECT/CT is made to identify the exact anatomic location of the SLNs and during surgery, a handheld gamma counter is used as confirmation. SLN imaging is often supplemented by an intraoperative injection of a blue dye to visually guide the surgeon. Unfortunately, the current standard has several downsides; the radioactive nanocolloids have a short half-life (i.e. 6 hours), SPECT imaging has a spatial resolution in the mm-range and both the patient and the surgical team are exposed to ionizing radiation. In addition, the blue dye can only be detected at a depth of a few millimeters (increasing the risk of missing the SLN), is prone to leach from the lymphatic vessels, occasionally cause (severe) allergic reactions, and may cause a long-lasting blue stain remaining on the breast for several months. Therefore, there is a need for alternative imaging methods to identify SLNs.

As an improved alternative to the current clinical standard, we have developed dual-modality nanocrystals (NCs) for the detection of SLNs using X-ray Computed Tomography (CT) and near-inrared (NIR) fluorescence. By removing radioactivity from the equation, we could reduce overall patient radiation exposure and remove the need for high-cost SPECT scanners, and instead use more widely available and faster imaging techniques like CT or conventional radiography to identify SLNs. The second imaging modality, NIR-fluorescence, is part of the same imaging probe and as such does not suffer from undesired tissue extravasation like the currently used small molecule dyes do. To mimic the behavior of the currently used clinical nanocolloids, we synthesized high-density bio-inert nanocystals that are approximately the same size after surface functionalization (5 - 10 nm). Next, we functionalized the NCs with our recently developed catechol-derived ligands, providing colloidal stability in relevant biological buffers, such as phosphate buffered saline at concentrations up to 300 mg NCs/ml. In the following step, we further improved the surface chemistry of the NCs by synthesizing an azide-terminated catechol ligand and apply strain-promoted click chemistry to covalently link fluorophore molecules to the NCs to create a dual-modality imaging-probe. Following this, we performed an *in vivo* evaluation of the dual-modality NCs in mice, imaging the lymphatic system using CT and NIR-fluorescence. We found that the NCs drain to the SLN shortly after injection and provide high *in vivo* contrast enhancement and NIR-fluorescence. Contrast enhancement and fluorescence remain high over several hours, which could make the NCs useable for extended surgical procedures. We further confirmed our findings by performing a longitudinal statistical study between a test and control group. Finally, we directly compared the NCs in terms of lymphatic drainage, spatial resolution and image quality to ^{99m}Tc-Nanocoll, the most used radiographic compound for SLN identification in Europe, and found that the NCs show similar drainage behavior as the clinical standard while allowing for faster scan times at higher scan resolution.

Engineered Multifunctional Superparamagnetic Copper Iron Oxide Nanoparticles (SCIONs) for a Combined Magnetic Hyperthermia and Immune Therapy of Metastatic Cancers Yuxin Cai and Pengyu Chen; Auburn University, United States

Metastatic cancer has remained one of the most lethal diseases worldwide for decades because of its complex pathophysiology. Given the great efforts and investment devoted, the remaining high mortality of metastatic cancer patients is certainly frustrating. Yet in recent years, cancer immunotherapy has been considered a promising cancer treatment regulating the immune system and stimulating innate immune responses to fight tumor cells. There are several strategies that achieved a certain level of clinical success. Even so, restrained by the complex tumor microenvironment, these strategies are still limited by the insufficient activation of the immune system, poor infiltration to the tumor microenvironment, and the inability to track the distribution of the anticancer ingredients. Consequently, combining treatments for metastatic cancer to enhance the infiltration to the tumor microenvironment and immune response has been paid noteworthy attention. Considering the severe side effects caused by radiotherapy or chemotherapy and the limited penetrating ability of near-infrared light, magnetic hyperthermia therapy (MHT) becomes a promising treatment to induce and promote an immunological response in the tumor microenvironment safely and effectively. Such a remote-controlled therapeutic system affords triggered release for high local effectiveness of the anticancer process with excellent tissue penetration and minimal damage to healthy tissue.

Hyperthermia is a cancer therapy raising the local tumor temperature and maintains 41 - 45 °C for a period to kill the tumor cells while sensitizing them to other treatments. For iron oxide nanoparticle-based MHT, the heat will be generated by the MNPs while an alternating magnetic field (AMF) was applied. By harnessing the unique property of superparamagnetism, the MNPs will be well-dispersed in the tumor microenvironment while avoiding the high cost and long preparation time of the regular methods for targeted drug delivery including the cell-specific ligands and pH-responsive. Additionally, the particles manipulated by a magnetic field indicate that precise targeting delivery and MHT cancer treatment can be realized at the same time.

In this study, we designed and synthesized the superparamagnetic copper iron oxide nanoparticles (SCIONs) and engineered them into a monodisperse multifunctional anti-cancer SCION complex, programmed for targeting delivery, hyperthermia therapy, and immune therapy of metastatic cancer treatments. The porous structure of our SCIONs provides multiple Cu^{2+} sites. When loading sodium diethyldithiocarbamate trihydrate (DDC-Na), the $[Cu(DDC)_2]$ complex will be self-assembled on the surface, which has been wildly proven as an effective anticancer ingredient. Compared to common combined magnetic hyperthermia and immune therapy where the high-performance-hyperthermia magnetic nanoparticles and the programmed checkpoint blockade therapy ingredients were treated to the tumor environment separately, each SCION complex is a multifunctional tumor cell treatment.

In the pre-clinical study of 4T1 tumors (murine breast cancer cells) on BALB/c mice, the MHT and anti-cancer immune therapy collaborate simultaneously. The inherent mechanism and the process of the anti-cancer effect are proposed following. Firstly, the SCION complex generates a considerable amount of local heat to eliminate tumor cells when AMF is applied. Meanwhile, the anti-cancer ingredients will continuously function in the tumor microenvironment inducing tumor cell death and apoptosis. Then, combined MHT and $[Cu(DDC)_2]$ complex treatment ablation of tumor cells could generate tumor-associated antigens, The antigens were uptaken by dendritic cells (DCs), which would lead to the activation of immunological cell death (ICD). Furtherly, the anti-cancer ingredients loaded on the surface of the SCION complex keep functioning to inhibit epithelial-mesenchymal transition

(EMT) to prevent cancer metastasis from happening.

Mxene Nanocomposites Based 3D Printed Scaffold Sensors for Cancer Metastases Study Danling Wang, Mahek Sadip and Kalpana Katti; North Dakota State University, United States

Breast cancer (BrCa) is the most common cancer worldwide and approximately 70% BrCa patients eventually develop bone metastasis. 80-90% of breast cancer (BrCa) patients die because of the skeletal complications due to the bone metastases. Therefore, the presence of bone metastases plays an important role in cancer patient's prognosis, quality of life, and the planning of the treatment. To better understand cancer metastases, it is critical to find an effective method of detecting the status of bone metastases and investigating the dynamics of breast cancer metastasis to bone in a timely and cost-effective manner. Current techniques including imaging techniques such as CT, MRI, particular skeletal scintigraphy, have been developed and used as an initial work-up for the detection and management of bone metastases from breast carcinoma. These techniques are accurate but cause concerns about high dose of radiation exposure, comprehensive operation, and expensive cost. The development of 3D models for cancer metastasis using scaffolds provide a way to recapitulate native microenvironment for the metastasis to bone. However, imaging techniques and 3D models using scaffolds both can not real-time capture and evaluate the circulating process of cancer cells to cancer tumor at the bone site.

This presentation focuses on developing a new MXene based 3D printed scaffold sensors to 1) real-time capture and evaluate the circulating process of cancer cells to cancer tumor at the bone site; 2) control tumor formation; and 3) find solutions of improving new drug response and delay metastases. We will take a two-pronged approach: (1) the 3D bone mimetic scaffold seeded with cancer cells, placed in a bioreactor to mimic physiological flow conditions, with embedded sensors for real-time monitoring will capture the chemical and biological signals during tumor formation, (2) keeping the same conditions as in the previous approach, anti-cancer treatments will be introduced in the bioreactor, and real-time monitored as the treatment inhibits tumor formation. These experiments, along with characterization techniques such as gene and protein expressions, and imaging will supplement the sensor data to develop the roadmap of tumor formation and assist in developing the design rules. This work will be to initialize a new research area of developing new functionalized sensing techniques that can sense the impact on osteogenesis of bone in tumor proximity and monitor new drug response to limit tumor formation and cancer metastases. In particular, this work will expect to design multifunctional 3D scaffolds as novel biomaterials with sensing capability and tissue-engineering performances.

Virus Like Shape Nanoparticles for Tuberculous Meningitis Treatment Alessandra Pinna[1,2], Ieva Ragaisyte[1], William Morton[1], Maddalena Cerrone[2], Alize' Proust[2], Rocco D'Antuono[2], Katalin Wilkinson[2], Jakson Luk[2], Robert J. Wilkinson[2,1,3] and Alexandra Porter[1]; [1]Imperial College, United Kingdom; [2]Francis Crick Institute, United Kingdom; [3]University of Cape Town, South Africa

INTRODUCTION

Tuberculous meningitis (TBM) is the most severe form of tuberculosis infection with very high mortality and accounts for 2-5% of all tuberculosis cases among children and HIV-positive adults, causing permanent neurological consequences and disability.[1]

TBM arises from mycobacterium tuberculosis (*M.tb)* release into the brain, which triggers an inflammatory cascade. TBM treatment is currently based on the treatment of pulmonary tuberculosis with combinations of antibiotics including first-line antibiotics drugs, such as rifampicin (RIF). Therapy using these drugs has poor outcomes because suboptimal drug levels reach the brain due to poor blood brain barrier (BBB) penetration. There is an urgent clinical need for alternative vehicles to deliver antibiotics and anti-inflammatory drugs inside the brain to treat TBM locally. In this work a biodegradable and monodisperse mesoporous silica nanostars (MSNS) have been proposed as a carrier of RIF (antibiotic) and cerium oxide nanoparticles (nanoceria, anti-inflammatory) with the aim of using the system to treat TBM.

EXPERIMENTAL METHODS

MSNS were synthesized using a sol gel single-micelle epitaxial growth approach[2]. In a typical synthesis CTAB is used as mesoporous template, NaOH as catalyst, n-hexane as co-solvent and TEOS as silica source. Temperature, aging time and stirring rate effects on MSNS diameter and spike length were investigated. The drugs, RIF and nanoceria, were encapsulated into MSNS using a passive diffusion method and post-synthetic impregnation respectively. The MSNS physicochemical properties were determined by using transmission electron microscopy (TEM), dynamic light scattering (DLS), Brunner-Emmett-Teller (BET) analysis and X ray diffraction spectroscopy (XRD). Encapsulation of RIF and cerium oxide were confirmed using high performance liquid chromatography (HPLC) and inductively coupled plasma mass spectrometry (ICP-MS).

The toxicity and immunogenicity of MSNSs were evaluated in PBMC, astrocyte, pericyte and microglia cells by MTS and Luminex assays. An *in vitro* BBB model was used to assess the BBB permeability to MSNS in comparison to spherical mesoporous nanoparticles (MSNP).

RESULTS AND DISCUSSION

The synthetic approach used in the present work to produce virus like shape nanoparticles allows to tune the size and the spike length of MSNS. Two types of nanoparticles, MSNS-1 with size of 83 ± 9 nm (spike length: 9 ± 2nm) and MSNS-2 72 ± 11 nm (Spike length:18 ±4 nm) were chosen for further experiemnts. XRD analysis reveals their amorphous structure while the BET demonstrates a high surface area of ~200 m^2/g which allows a high drugs encapsulation. RIF was successfully incorporated in both type of MSNS at concentration of 70 mg/300mg MSNS-1 and 220mg/300mg of MSNS-2. Furthermore, XRD and ICP-MS analysis show the successful incorporation of nanoceria into MSNS. MSNS Cellular toxicity was measured and the 1 µg/ml of MSNS was set do not induce any cellular toxicity and any immunogenic effect in PBMC cells and in the four types of cells that make up the BBB (astrocytes, pericytes, endothelial cells, and microglia). Moreover, the capability of MSNS to cross the BBB was assessed in a unique 3D *in vitro* model showing MSNS better crossing the BBB respect to the spherical MSNP.

CONCLUSION

The present work shows we can tune the size and the morphology of MSNS, RIF and nanoceria drugs were successfully incorporated into MSNS without producing any modification in the silica structure. MSNS tdid not induce any cellular toxicity and immunogenic effect and are able to better cross the BBB respect to the spherical counterpart. The preliminary results pave the way to a new therapy for TBM.

Functionalized Carbon Nanotubes for the Electrochemical Quantification of Renin as a Marker of Tissue-Perfusion Ariadna Schuck, Hyo Eun Kim and Yong-Sang Kim; Sungkyunkwan University, Korea (the Republic of)

Renin is an enzyme with the function to produce angiotensin I in plasma triggering a cascade of reactions that regulate blood pressure homeostasis. It is a useful marker of tissue perfusion plasma renin activity (PRA), but it was not well exploited in terms of electroactivity in human blood while evaluating the renin-angiotensin-aldosterone system. To quantify the renin levels in human plasma samples, a novel screen-printed carbon electrode (SPCE) sensor modified with doped multi-walled carbon nanotubes (MWCNTs) and polyethylene glycol (PEG) is proposed and experimentally demonstrated. PEG is a biopolymer commonly used to coat the surface of nanostructures to reduce nonspecific interactions and minimize aggregation promoting colloidal stability. The functionalized MWCNTs were first evaluated with Fourier-transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM) images. The structural analysis proved that there were no further effects on the size and shape of the carbon nanostructures. The doping was confirmed with the three-electrode cyclic voltammetry (CV) technique where the peak currents were amplified by almost 6.5× after the functionalization step. Afterward, the Human Renin Antibody Pair is immobilized on the nanocomposite film for 1 hour before the performance of the electrochemical measurements with the samples containing the enzyme. Differential pulse voltammetry (DPV) measurements were performed to quantify the Renin (0 ~ 2,000 pg/mL) in human plasma samples (<20 µl) that are injected into the device. The variation of the current peaks presented high linearity (linear regression coefficient (R^2) of 0.9890) with the levels of renin enzyme. The validation was obtained while comparing the results of the SPCE device with the gold standard method, Enzyme-Linked Immunosorbent Assay (ELISA), using the Bland–Altman plot with a good agreement between the two methods within a 95% confidence interval. Further studies involve the combination with the other inflammation-related markers already evaluated with our multiplexed electrochemical sensing device.

5:00 PM SB05.09.02

Nanoplasmonic Immunoassay Based Integrated Microfluidic Device for *In Situ* PD-L1-Exosome Mediated Cell Communication Visualization and Analysis Chuanyu Wang, Chung-Hui Huang and Pengyu Chen; Auburn university, United States

Cellular communication is an essential process to maintain cellular bio-function. Communication between cancer cells and immune cells has been investigated for decades. One of immune checkpoint cancer therapies is developed after fully understanding the communication between programmed death ligand 1 (PD-L1) from cancer cells and programmed death 1 (PD-1) on T cells. Cancer cells can remotely deactivate T cells by secreting soluble PD-L1 proteins and secreting extracellular vesicles (EVs) with exosomal PD-L1. Commercial immunoassays, such as enzyme-linked immunosorbent assay (ELISA), have been utilized to measure concentrations of PD-L1, IL-2, and IFN-γ for the demonstration of cellular interaction between cancer cells and T cells. However, commercial immunoassays cannot detect a diffusion path of proteins. A diffusion map of proteins is also significant information to understand how cells secrete proteins. Here, a specially designed on-chip device consists of cell isolation chambers and a gold nanosphere-based nanoplasmonic digital immunoassay, rendering *in situ* remote cell communication to visualize a diffusion map and quantify a concentration of proteins. A machine-learning-based image process method was utilized to generate a signal map translating a PD-L1- exosome-mediated communication between breast cancer cells and T cells. This developed platform provides new methods for visualizing cell-cell remote communication that has high potential as a characterization method for monitoring cellular progression.

5:00 PM SB05.09.03

Fluorogenic Immuno-Sensor Using Inverse Opal Hydrogel with Target Specific Aptamer Modification Jaewook Lim, Hyo Lee and Seungjoo Haam; Yonsei University, Korea (the Republic of)

Over 10million people have disabilities due to nervous system disorders. Alzheimer's, a representative degenerative brain disease, is characterized by irreversible cognitive dysfunction and occurs when amyloid plaque accumulates even before symptoms occur. Therefore, it is more important to prevent it through early diagnosis than to treat the disease. One of the early diagnosis system is Liquid biopsy that diagnoses using blood, urine, spinal fluid, etc. The aqueous humor is body fluid which fills the space between the lens and the cornea of the eye. The aqueous humor contains biomolecules come from central nervous system. Diagnosis platform using aqueous humor can be a promising platform for early diagnosis of neurodegenerative diseases.

Here, we made fluorescence aptamer conjugated inverse opal hydrogel lens (FAIOL). Intraocular lens are implanted for vision correction or cataract surgery at eye chamber which is filled with aqueous humor. FAIOL is aptamer conjugated intraocular lens system. When the biomarker approaches at FAIOL, quencher modified aptamer combines biomarkers and dissociates from fluorescence modified complimentary DNA. To raise specificity of FAIOL, AFIOL is made by MMA (methyl methacrylate) which is well known hydrophobic monomer. And for sensitivity of FAIOL, we applied inverse opal system that makes fluorescence signal amplification by photonic band gap. FAIOL can be a target independent sensor such as protein sensor by, DNA sensor, or RNA sensor. Early diagnosis of various neurological diseases will be possible through FAIOL

5:00 PM SB05.09.05

Acoustic Anti-Cancer Therapy Using Nanoparticles Yong-Gyu Jeong[1], Hyo-Soo Lee[2] and Dongwoo Khang[1,1,1]; [1]Gachon University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Sonodynamic (SDT) has the advantage of localized anti-cancer treatment on the targeted tumor region and, can minimize the side effects for normal tissues. SDT is usually operated by ultrasound of 20 kHz or higher frequencies. However, biomedical research on audible soundwaves below 20kHz to control SDT were vailed. Herein, we report audible soundwaves that triggering the aggregation of the nanoparticles and, the aggregation behavior of the nanoparticles subsequently influenced the intracellular autophagy formation. Thus, the amplified autophagy by audible soundwave responsive nanodrug effectively increased apoptosis in cancer cells. In conclusion, obtained result clearly demonstrated the anti-cancer therapy using sub-audible ranges of frequency and suggested novel strategy for the treatment of anti-cancer therapy with noninvasive manner.

5:00 PM SB05.09.06

Cellular Uptake and Cytotoxicity of Varying Aspect Ratios of Gold Nanorods in HeLa Cells Yolanda Vasquez, Deshani Fernando and Shoukath Sulthana; Oklahoma State University, United States

Gold nanorods (GNRs) have received broad attention due to their tunable surface plasmon modes, which make them attractive candidates for applications in drug and gene delivery, biological imaging, and cancer treatments. In this study, we highlight the interactions of four different aspect ratios (ARs), 2.6, 3.2, 5.4 and 11.5, of GNRs with HeLa cells. Specifically, we study the uptake of the particles by HeLa cells while also considering the effects of other parameters such as the surface stabilizer, supernatant, and serum proteins present in the medium. From this work, it was determined that the cell viability depended on the chemical composition of the supernatant especially the amount of excess surfactant, hexadecyltrimethylammonium bromide (CTAB), used for the synthesis of GNRs; thus, the effect of aspect ratio of GNRs on endocytosis could not be directly discerned. For example, when exposed to GNRs of aspect ratio 11.5, HeLa cells showed higher cellular uptake compared to smaller aspect ratios, and also exhibited lower cytotoxicity due to the lower concentration of CTAB used in their synthesis. Gentler purification methods (sedimentation) appeared to be a factor in lowering the free CTAB concentration for experiments containing GNRs of aspect ratio 11.5. Overall, the synthesis protocols functionalization, purification processes, and the stability of GNRs in media have an effect on cellular uptake and viability. Our results suggest that the AR of GNRs may a role in endocytosis when mPEG, instead of CTAB, is used as a stabilizing ligand although an overall trend could not be unequivocally established. In future studies, sedimentation, contact time, and internalization kinetics need to be probed further using more biocompatible ligands and less inert ligands (mPEG) to determine the effect of AR on GNR internalization in HeLa cells.

5:00 PM SB05.09.07
Educational Stemsome Targeting and Destroying Pancreatic Tumor Jun-Young Park, Jun Young Park and Dongwoo Khang; Gachon University, Korea (the Republic of)

Currently, the survival rate of pancreatic tumors has not been improved despite development of therapeutic agents for other tumors, such as breast cancer, liver cancer, lung cancer, and stomach cancer. This is because ligand-antibody binding strategies cannot be applied for pancreatic tumors, and thus, targeting pancreatic cancer is not available yet. Due to the unique ability of stem cells for targeting the specific tumor environment, stem cell membranes (stemsome) with nano-encapsulated mediators can target tumor and can load active anticancer agents. In this study, a specific cancer targeting strategy for stemsomes prepared by extracting ectosomes from stem cells with improved pancreatic cancer targeting ability was demonstrated. Stem cell membranes with enhanced targeting ability to pancreatic tumor cells were encapsulated with doxorubicin-loaded PLGA nanoparticles, successfully targeted and reduced pancreatic deep tumor tissue. Considering that there are no known target proteins in pancreatic tumor cells, the proposed platform technology can utilize for targeting various malignant tumor possessing unknown surface target receptors on cancer cell membranes.

5:00 PM SB05.09.08
Tumor-Activatable Tissue-Adhesive Chitosan Nanodepots for Site-Directed Treatment of Cancer Yu Ri Jeon[1], Mou Seung Kim[1] and Yun Kee Jo[1,2]; [1]Department of Biomedical Convergence, School of Convergence, Kyungpook National University, Korea (the Republic of); [2]Cell and Matrix Research Institute, Kyungpook National University, Korea (the Republic of)

Even though chemotherapy is most commonly applied to treat cancer, the insufficient locoregional retention and systemic toxicity has remained to be solved. Naturally derived chitosan is a promising biomedical material due to its biocompatibility. However, pH and concentration-dependent solubility of chitosan has been restricted further applications to clinical settings. Here, we propose chitosan-based nanodepots containing Fe(III)-catechol complexes (Cat-CS NPs) as a tumor-activatable therapeutics delivery system to accomplish highly site-directed administration while minimizing adverse effects towards surrounding normal tissues, inspired by intriguing adhesion mechanism of marine mussels. The Cat-CS NPs fabricated through electrospray exhibited Spherical uniform size nanoparticles. Furthermore, they indicate improved adhesiveness on glass and porcine skin tissue model in aqueous conditions. The pH-dependent stoichiometry of Fe(III)-catechol coordination in the doxorubicin-loaded Cat-CS NPs (Cat-CS@DOX NPs) allows the triggered release of DOX in response to the acidic conditions around the tumor tissues. The Cat-CS@DOX NPs showed a significant inhibition of growth of cancer cell *in vitro* while exhibiting a good biocompatibility towards normal cells. In addition, they demonstrated superior adhesion ability to tissue substrates after local spray process *in vitro* and *in vivo*. Taken together, our polysaccharide-based sticky nanoparticles can be applied to open new avenues as a topical delivery system to adjuvant cancer therapy.

5:00 PM SB05.09.09
mRNA Encapsulated Ectosome-Liposome Hybrid for Anticancer Therapy Su Hyun Lim, Geunhye Kim and Dongwoo Khang; Gachon University, Korea (the Republic of)

Recently, artificial liposomes were developed as an effective carrier for the COVID-19 vaccine. However, liposomes are not sufficient to use for the treatment of diverse diseases due to the absence of the ability for targeting pathophysiological sites. In this regard, ectosomes, a type of nano vesicles composed of cell membrane can be endowed with target ability, is a promising drug delivery vector. In this study, macrophage derived ectosome shows greater cancer targeting efficacy. Macrophages can migrate to the cancer cells and additionally can release pro-inflammatory cytokines, such as TNF-a, IL-1b, and IL-6. Macrophage-derived ectosomes fused with liposomes, hybrid nano formation (ecto-liposome), enhanced the anticancer efficacy of delivery to malignant tumor tissues. Specifically, a mRNA, regulating signaling pathways involved in cancer, was encapsulated in ecto-liposome inhibited cancer cell growth and suppressed chance of metastasis. Obtained results in this study clearly suggested that the mRNA encapsulated ecto-liposome is highly effective and thus, represents a novel strategy for the treatment of anti-cancer therapy.

Mitochondria-Targetable Lysine-Based Biodegradable Nanogels Through Hydrophobic-Hydrophilic Conversion Hana Cho and Han Chang Kang; The Catholic University of Korea, Korea (the Republic of)

For several decades, to maximize the therapeutic efficacy of drugs, various drug delivery systems that target various cells or subcellular organelles (e.g., nucleus, mitochondria, lysosomes, endoplasmic reticulum, Golgi apparatus, etc.) have been developed. However, most targeted drug delivery systems use methods to directly conjugate the targeting moiety to the drug or to decorate the nanoparticle surface.

In this study, an ε-poly($_L$-lysine)-based mitochondrial targeted drug delivery system (i.e., REPL-NG) was developed by introducing hydrophobic and biodegradable disulfide bonds into a hydrophilic polymer without a mitochondrial targeting moiety. REPL exists in the form of nanogels in aqueous solution due to hydrophilic primary amines on the surface and hydrophobic disulfide bonds inside the core. Thus, hydrophobic drugs such as doxorubicin could be encapsulated into REPL-NG (i.e., DOX@REPL-NG) by hydrophobic interactions.

In HCT116 cell line, a human colorectal cancer cell line, DOX@REPL-NG was internalized by endocytosis and was able to escape the endo/lysosomes by the proton-buffering effect of the primary amine of REPL-NG. After internalization, DOX@REPL-NG favored mitochondria over the nucleus, and as a result, a greater amount of DOX was uptaken into mitochondria rather than the nucleus. In addition, in HCT116-xenografted nude mice, DOX@REPL-NG exhibited superior antitumor effect than free DOX-HCl by tumor accumulation and retention of DOX. In conclusion, DOX@REPL-NG could target mitochondria by modulating the hydrophobicity of lysine-based polymers without commonly used mitochondrial targeting moiety.

5:00 PM SB05.09.11
Advanced Delivery of Therapeutics Using Metal-Organic Frameworks (MOFs) in 3D *In Vitro* Respiratory and Cancer Cell Models Sergio Mercado, Francesca Melle, Jon Ostolaza and David Fairen-Jimenez; University of Cambridge, United Kingdom

Therapeutics used in the treatment of various types of cancer and respiratory diseases present significant drawbacks such as limited efficacy and severe off-target toxicity. These issues hinder their success and support the current need to develop enhanced formulations to improve the prognosis of patients.

Metal-organic frameworks (MOFs) have attracted much attention for biomedical applications since they can encapsulate and thus enhance the safety and efficacy of therapeutics. MOFs are a class of biocompatible nanoporous materials with exceptionally high surface area (>8,000 m^2/g) and drug loading capabilities (>70% drug weight).

In this work, molecular simulations were performed to find a MOF structure with a porosity compatible with different chemotherapeutics. PCN-222, a zirconium-based MOF with mesopore size (> 2 nm), was selected due to its high porosity and biocompatibility. Chemotherapeutics used to treat breast and lung cancer (fulvestrant and temozolomide, respectively) were then loaded into PCN-222. Subsequently, a PEG coating was applied to drug-loaded PCN-222 to improve stability and slow-release profile. The resulting PEGylated drug-loaded MOFs were characterized for drug loading capacity and physiochemical properties, including size, aqueous stability, crystalline structure, and porosity. Drug loaded-PCN-222 was tested using *in vitro* models of breast and lung cancer (MCF7 and A549 cells, respectively). The effects of this nanomaterial's characteristics (including size, composition, and surface characteristics) on toxicity were assessed by metabolic activity. Live-cell imaging and confocal microscopy were used to analyze internalization and cellular interactions of PCN-222.

PCN-222 characterization showed nanoparticles of 120-150 nm in a homogenous dispersion. Drug loading of fulvestrant and temozolomide into PCN-222 was successful for both chemotherapeutics, achieving a loading efficiency of more than 30%. The effect of this nanomaterial on cell toxicity was assessed by a metabolic activity assay and live cell imaging, showing that breast and lung cancer cells tolerated high concentrations of PCN-222. These results highlight the biocompatibility of PCN-222. The PEG coating improved intracellular stability and delayed drug-release capability. PCN-222 showed a high cell internalization efficacy in MCF7 and A549 cells, as seen by confocal microscopy.

PCN-222 showed biocompatibility, high loading capabilities, delayed drug-release, and efficacious cell internalization. Further works using *in vivo* mouse models are expected to confirm the previous *in vitro* data. Finally, PCN-222 is a promising nanocarrier able to increase the efficacy and safety of current standard-of-care chemotherapeutics and facilitate the progress of nanomaterials for medical applications.

5:00 PM SB05.09.12
Nano-Corona Anticancer Strategy Jun Young Park[1] and Dongwoo Khang[1,2,3]; [1]Gachon university, Korea (the Republic of); [2]Lee Gil Ya Cancer and Diabetes Institute, Korea (the Democratic People's Republic of); [3]gachon, Korea (the Republic of)

Nano-corona is induced by the interaction of nanoparticles with plasma proteins. Although the immune toxicity aroused by nano-corona has been intensively studied for the past decade, there were no reports on immunotherapy using nano-corona. It is widely believed that nano-corona invoke intrinsic and adaptive immune responses by conformation changes in the protein structures. In this study, the anti-cancer efficacy of nano-corona was analyzed in the tumor microenvironment in which the immune response was suppressed by cancer cells. Surprisingly, nano-corona significantly induced M1 differentiation from the M2 phenotype in the tumor microenvironment with a stimulated innate immune response. In addition, to examine the removal of the tumor tissue, combination therapies using nano-corona, photothermal therapy, and anti-cancer immune-therapy was conducted. Combinational therapies inhibited the growth of tumor tissues. Activation of NK cells and cytotoxic T cells that directly destroyed tumor cells and importantly, T_{reg} cells are reduced at the tumor microenvironment. Obtaimed results represent that the anti-tumor immune response enhanced by nanocorona. Importantly, the study suggested evidence that controlling of immune responses using nano-corona significantly influences the efficacy of anti-cancer therapy by switching immune regulation at the tumor environment.

5:00 PM SB05.09.13
Stabilization of a Synthetic Protein Nanoparticle by a Polycation for Gene Delivery Fjorela Xhyliu; University of Michigan, United States

Nanoparticles (NPs) have attracted significant attention in the field of gene therapy in recent years. Despite the many advances in NP-mediated non-viral gene delivery, the stability of the NPs, successful internalization of nucleic acids, and efficacy in delivery and transfection in cells remains an obstacle to their clinical translation. This work explores the surface-stabilization of a synthetic protein nanoparticle (PNP) with a polycation for improved NP stability and pDNA transfection *in vitro* and *in vivo*. Utilizing electrohydrodynamic (EHD) jetting, PNPs were used to encapsulate a large plasmid followed by stabilization by a polycation. The stabilization of the PNP in solution is enabled by the electrostatic interactions between the polycation and the protein. Electron microscopy, dynamic light scattering (DLS), and nanoparticle tracking analysis (NTA) confirm that the surface-stabilized PNPs (ssPNPs) have sub 200 nm diameters in their dry and hydrodynamic states. Additionally, it was determined that the ssPNP size and positive charge are stable in aqueous conditions for extended periods of time, without the addition of stabilizing agents. Utilizing NTA and UV-vis absorbance data, a method was established to determine the DNA amount per ssPNP, indicating an overall yield of 75-80%. In human HepG2 cells, more than 90% of cells take up the ssPNPs, partly due to the positive surface charge. Moreover, transfection of ca. 50% can be achieved while varying the amount of DNA and NP dosing, with negligible cytotoxicity. In a mouse glioblastoma model, ssPNPs demonstrated transfection effectiveness higher than JetPEI®, a commercially used product. This platform shows that using a polycation as a surface stabilizer allows for successful pDNA internalization, NP stability, and transfection efficacy. These findings demonstrate the capability of this new gene delivery system to overcome challenges that hinder the clinical translation of NPs, with the potential for the treatment of various cancers and diseases.

5:00 PM SB05.09.14
Mesenchymal Stem Cell Conjugated with Triamcinolone Loaded Gold Nanoparticles Attenuates Rheumatoid Arthritis Minjun Shin[1], Jun-Young Park[2], Youn Joo Kang[3] and Dongwoo Khang[1,2,1]; [1]Gachon University, Korea (the Republic of); [2]Lee Gil Ya Cancer and Diabetes Institute, Korea (the Republic of); [3]Eulji Hospital, Korea (the Republic of)

Unfortunately, conventional therapy for rheumatoid arthritis (RA), which is an autoimmune and inflammatory disease, was not enough to attenuate the RA patient with severe inflammatory symptoms. Mesenchymal stem cells (MSCs) are considered as a promising regenerative therapy for the treatment of RA due to their regenerative activity and ability to migrate toward damaged tissues, but the insufficient anti-inflammatory efficacy limited MSC application in various stages of RA patients. In this aspect, the combination of nano-drugs and MSCs can increase the anti-inflammatory response at the inflamed joints, and the severe stages of RA can be recovered. In this study, the inflammation-mediated education process without genetic engineering enhanced the migration ability of MSCs to inflamed joints. Star-shaped gold NPs (AuStar: AuS) were synthesized with the conjugation of Triamcinolone (TA), a glucocorticoid widely used for inflammatory disease. AuS-TA stably conjugated on the surface of MSCs, and inflammation-educated MSCs with conjugation of triamcinolone-loaded gold nanostar (Edu-MSCs/AuS-TA) elicited remarkable attenuation of RA in collagen-induced arthritis (CIA) mouse model. Furthermore, photothermal therapy (PTT) with the irradiation of near-infrared (NIR) laser on inflamed joints showed the maximized efficacy of the anti-inflammatory response for the treatment of the severe stage of the CIA model. Specifically, Edu-MSCs/AuS-TA promoted the repolarization of macrophages from the M1 to the M2 phenotype and decreased the recruitment of neutrophils in joints. Additionally, Edu-MSCs/AuS-TA significantly decreased pain and increased general locomotor activity levels and cartilage regeneration.

Designed Biosilica and Collagen-Coated Carrier to Deliver Growth Factor for Bone Regeneration Mi-Ran Ki, Sung Ho Kim, Seok Beom Rho, Ki Ha Min, Gyu Do Lee and Seung Pil Pack; Korea University, Korea (the Republic of)

Since the silica surface is generally composed of hydroxyl groups and ether bonds, it is considered to have a negatively charged surface that readily adsorbs oppositely charged molecules. The heparin-binding domain (HBD), mainly composed of positively charged residues, is present in many growth factors (GFs). It plays an essential role in the binding with the anionic sulfate of heparin/heparan sulfate. Based on this, GFs containing HBD may have an affinity for the anionic silica surface. We hypothesized that the silica coating would increase the association for the growth factors. To identify this, hydroxyapatite, currently used as a bone graft material and BMP2 carrier, was coated with bio-silica on the surface using a silica-forming peptide. By atomic force microscopy, we measured the binding force between GF, BMP2, and the silica surface, demonstrating that the biosilica surface showed an 8-fold higher binding strength than the HA alone. While the loading efficiency was increased due to the strong binding force, there was a problem in that the release rate was low. For effective delivery of GF by increasing diffusion rate, collagen was introduced. HA was coated with collagen and biosilica layer by layer according to collagen concentration and the number of coating layers. In the final biosilica-coated surface, the diffusion rate of two successive coatings of collagen and biosilica was higher than the one-time coating. Meanwhile, triple layers lowered the loading efficiency (LE%) and diffusion rate than the former coating. Double successive coatings of collagen and biosilica with 0.01% collagen displayed the highest LE% and diffusion rate. Hence, this formulation was selected as an optimal carrier for GFs. The carrier above demonstrated increases in cell proliferation, alkaline phosphatase activity, osteogenic gene expression, and calcium mineral precipitation in the osteogenesis of MC3T3 E1 cells compared to those of HA and one-time biosilica-coated HA. Therefore, the biosilica/collagen-coated HA can be an effective carrier for GF-employed therapy in bone regeneration.

RANKL Reverse Signaling Derived Bone Regeneration by Osteoclast Membrane Vesicle-Functionalized PLGA Nanoparticle Jae Won Jang[1], Hyunji Kim[1], Dongtak Lee[2], Yonghwan Kim[1] and Hyo Gi Jung[1]; [1]Korea University, Korea (the Republic of); [2]Brigham and Women's Hospital, United States

Controlling the bone formation and resorption processes by osteoblast and osteoclast is crucial for bone regeneration. Previously, it was solely reported that osteoblast secretes receptor activator of nuclear factor kappa-B ligand (RANKL) to differentiate osteoclasts. However, it is recently reported that RANKL reverse signaling mechanism which induce the bone formation by osteoclastic exosomes possessing RANK. Bioinspired by the RANKL reverse signaling pathway, we fabricated artificial osteoclastic exosomes to induce enhanced bone formation. In detail, we extracted osteoclast-derived cell membrane vesicles (OCMVs) which were functionalized on PLGA nanoparticle core. We successfully confirmed the synthesis of the OCMVs by the analysis of dynamic light scattering, zeta potential, and TEM imaging. In addition, the presence of RANK on OCMVs was verified via confocal microscopy and western blot. Finally, we validated the enhanced bone regeneration process by OCMVs using alkaline phosphatase (ALP) assay. The results show that the degree of bone regeneration by OCMVs significantly increased compared to that of bone morphogenic protein-2 (BMP-2). Our findings suggest that OCMVs have a potential to be utilized in biomedical application of bone regeneration.

DNA Origami—Increasing Functionality in Biological Settings Veikko Linko[1,2]; [1]University of Tartu, Estonia; [2]Aalto University, Finland

Sub-nanometer-precise DNA origami structures may serve as versatile high-resolution templates for engineering inorganic materials [1] and as components for bridging molecular and macroscopic scales [2]. For biomedical applications, DNA origami could be integrated into robotic devices [3], gene-editing tools [4], delivery vehicles [5], and diagnostic platforms [6]. However, under physiological conditions these structures may suffer from poor stability due to low-cation-induced denaturation and enzymatic degradation. Here, I will present some of our very recent results in the following topics:
(1) Structural design governs the folding [7] and environment-dependent stability of DNA origami [8].
(2) Superstructure of DNA origami can be harnessed in rational design of drug release profiles [9].
(3) Customized static [10-12] and stimuli-responsive [13] coatings can be used for targeting, for protecting DNA origami from degradation, and for increasing the immunocompatibility of DNA-based delivery systems.

Highly Effective Porous Antimicrobial Coatings Saeed Behzadinasab, Myra D. Williams, Christopher Stoll, Joseph O. Falkinham III and William A. Ducker; Virginia Tech, United States

Antimicrobial surface coatings can be used to reduce the transmission of infectious diseases that are spread by contact. An effective coating should kill microbes in the time between users, which is minutes or less, and also continue to operate for an extended period. Fast killing is a transport problem, and our solution is a porous coating with the active material inside the pores. We use hydrophilic pores of dimensions 5-100 µm such that they infiltrate liquid droplets in seconds, and from there transport distances and times are short, defined by the pore size, rather than the droplet size. Our coating has two levels of structure: (A) a porous scaffold and (B) an antimicrobial coating within the pore structure containing the active ingredient. Two scaffolds are studied: stainless steel and poly(methylmethacrylate) (PMMA). The active ingredient is electrolessly-deposited copper. To enhance adhesion and growth of copper, a layer of polydopamine (PDA) is deposited on the scaffold prior to deposition of the copper. This porous copper coating kills 99.8% of *Pseudomonas aeruginosa* within three minutes, which is highly effective. Killing on this fast scale is appropriate for antimicrobial applications to prevent disease.

5:00 PM SB05.09.20
Mineralization Stimuli of Hydroxyapatite-Embedded Hierarchical Nanofibrous Scaffold Using Piezoelectric Protein for Tissue Engineering Ji

Yeon Lee[1], Chan Hee Park[2] and Cheol Sang Kim[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

The development of novel biomaterials that provide electrical potentials generated through bioactive scaffolds with respect to their appropriate effects on cell behaviors is essential for tissue engineering. In particular, piezoelectric biomaterials are attractive due to the possibility to produce electrical potentials for stimulation via cell motility. Despite their capacity to promote tissue regeneration through cell stimulation, synthetic piezoelectric biomaterials still face issues with poor biocompatibility and inflammatory response. Here, we designed a scaffold that supports cellular activity without eliciting any toxic effect on the host immune response by using a nature-derived piezoelectric protein and mimicked extracellular matrix microenvironment topologies using electrospinning to enhance cell adhesion. The scaffold enhanced piezoelectricity to overcome limited electrical signaling pathways of the nanofibrous membrane via alpha-helix to beta-sheet transition, and this led to elevated mechanical properties and wettability according to the morphological modification. In addition, the hierarchical structure of the scaffold induced a sequential release of hydroxyapatite and simvastatin by gradual biodegradation of the protein to accelerate homogenous growth in a higher local ion concentration during mineralization. Our scaffold is a promising candidate for tissue engineering and mechanoelectrical transduction platform due to its phased functionality in electrophysiological activity, biodegradability, and mineralization. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2021R1C1C2011542) and NRF-2017-Fostering Core Leaders of the Future Basic Science Program/Global Ph.D. Fellowship Program.

5:00 PM SB05.09.22

Carbohydrates-Modified Pt(IV) Pro-Drugs -Conjugated Graphene Oxide as a Novel Therapeutic Strategy to Target Osteosarcoma Giada Bassi[1,2], Ludmila Zarska[3], Eoin Moyinihan[4], Arianna Rossi[1,5], Andrea Ruffini[1], Silvia Panseri[1], Diego Montagner[4], Vaclav Ranc[3] and Monica Montesi[1]; [1]Institute of Science, Technology and Sustainability for Ceramics (ISSMC) National Research Council, Italy; [2]University of Chieti, Italy; [3]Regional Centre of Advanced Technologies and Materials, Palacký University, Czechia; [4]Maynooth University, Ireland; [5]University of Messina, Italy

INTRODUCTION

Osteosarcoma is the most common type of bone cancer diagnosed especially in children and young adults[1]. A combination of chemotherapy, radiotherapy and surgery is commonly used to treat this type of cancer[2,3]. In detail, chemotherapy is based on the use of molecules targeting the high cancer cell proliferation metabolism such as Platinum (Pt)-based drugs that binds nuclear DNA upon overpassing the cell membrane, causing its damage and the arrest of the cancer cell cycle at G2/M transition phase, leading to apoptosis[4-7]. Despite Pt chemotherapeutics are the most potent used anticancer drugs, their side effects (high degradation before entering the cells, the off-target organs toxicity, and cell resistance) remain great drawbacks[8-11].

EXPERIMENTAL METHODS

In this study, we synthetized Graphene oxide (GO)-based nanoplatforms as smart delivery systems of Platinum-based drug. In order to reduce GO cytotoxicity in health cells while promoting its cellular uptake in cancer cells, and to allow Pt loading on GO, 8-arm polyethylene glycol-amine (PEG) was used. The bioactivity of GO-PEG-Pt platforms were compared to Pt-free (15 µM, 30 µM, and 60 µM) on three osteosarcoma cell lines (MG63, U2 and SAOS-2). The in vitro analysis of cellular uptake (ICP-OES), viability (MTT assay), morphology (actin and DAPI staining) and migration (scratch test) was performed.

RESULTS AND DISCUSSION

A preliminary study showed that GO-PEG was not toxic for cells at any concentration tested compared to cells only. A significant cell viability reduction was detected at 30 µM GO-PEG-Pt for all cell lines compared to Pt-free, reaching 70% cell mortality in MG63 (p value ≤ 0.0001) and SAOS-2 (p value ≤ 0.001). Morphological analyses showed a round-shape cell morphology and cell number reduction in the presence of GO-PEG-Pt respect to Pt-free in a dose dependent trend. Cellular uptake of GO-PEG-Pt was significantly higher after 24h for SAOS (p value ≤ 0.05) and MG63 (p value ≤ 0.0001) cell lines than Pt-free. The cell migration was lower in Go-PEG-Pt than Pt-free in MG63 and U2 with overall more than 60% migration inhibition over time at 30 µM concentration.

CONCLUSION

The results confirmed that GO-PEG-Pt platforms work as promising anticancer delivery systems. In fact, all the three osteosarcoma cell lines showed higher susceptibility to GO-PEG-Pt in terms of lower metabolic activity and lower migration rates due to the higher GO-PEG-Pt uptake compared to Pt-free.

Understanding the Host-Guest Chemistry of CuMOF-Gliotoxin Complexes by X-Ray Absorption and X-Ray Photoelectron Spectroscopy Izuchika Nduka, Sara Namvar and Rosa Arrigo; University of Salford, United Kingdom

Introduction: Gliotoxin, a secondary metabolite isolated from the fungi, *Aspergillus fumigatus* has shown cytotoxic activity against neuroblastoma (1), a type of cancer accounting for 15% of all childhood cancer-related deaths (2). But as with all other chemotherapeutic agents, this compound is toxic to both tumour cells and healthy cells. To minimize toxicity towards the healthy cells, a biocompatible nanoparticulate system is needed. For this reason, our study has explored the use of nanosized metal organic frameworks (MOFs) – a class of organic-inorganic hybrid materials made up of metal nodes held together

by organic bi or tridentate linkers, as drug delivery systems with the goal of achieving controlled delivery of gliotoxin to neuroblastoma cells. Amongst the MOF systems we have investigated, Cu-MOFs with RAWYAS and GIFKUC phases showed interesting results and are the focus of this contribution. By means of microwave-assisted solvothermal method, we synthesized some Cu-based MOFs at 1 (MOF1Cu), 5 (MOF5Cu), and 30 (MOF30Cu) minutes, using copper (ii) nitrate trihydrate as the metal ion and 5-aminoisophthalic acid as the ligand, and studied their structural characteristics by means of scanning electron microscopy (SEM) and X-ray diffraction (XRD). We also explored their adsorption capacities using high performance liquid chromatography (HPLC) and investigated their cytotoxic effect against the SHSY-5Y neuroblastoma cell line by means of 3-(4,5-dimethylthiazol-2-yl)-2,5 diphenyltetrazolium bromide (MTT) assay. To rationalize our findings from the MTT assay, we sought to understand the nature of the intra-and inter-molecular interactions between gliotoxin and the synthesized Cu-MOFS by measuring the K-edges of Cu, C, N, O, and S of the MOF-gliotoxin complexes by means of soft and hard x-ray absorption spectroscopy (XAS) and x-ray photoelectron spectroscopy (XPS) in an ex-situ fashion.
Results: The MTT assay showed that upon immobilization of gliotoxin within the synthesized MOFs, its cytotoxic effect was increased. This enhanced cytotoxicity suggests that not only do the MOFs act as carrier systems, but they also provide a synergistic effect. The changes in the near edge x-ray absorption fine structure (NEXAFs) spectra on immobilization of gliotoxin within the synthesized Cu-MOFs showed that there is an interaction between the drug and the MOF systems. This is particularly evident in the N K edge spectrum of the MOF sample after immobilization of gliotoxin 1:5 ratio with a shift of the 1s→p* transition of the amino group of MOFs to higher energy. Moreover, the ratio between the 1s→p* and 1s→s* in the OK edge changes significantly upon immobilization of gliotoxin, indicating a significant structural modification of the MOFs. Also, marked changes can be seen in the S2p XPS spectra upon gliotoxin immobilization, which suggests a direct co-ordination between the sulphur of gliotoxin and the Cu metal sites of the MOFs. Based on these results, we posit that the interaction of the gliotoxin with the MOFs involves mainly the N site of the ligand. More investigations on the S L edge XAS will clarify any modification on the structure of the gliotoxin.
Conclusion: Taken together, our findings highlight an approach to enhancing the pharmacological activity of gliotoxin. As an outlook, we would further explore the nature of the host-guest chemistry between gliotoxin and the synthesized Cu-based MOFs from a computational viewpoint using molecular dynamic studies.

Lactosylated Graphene Oxide—An Strategy For Hepatocellular Carcinoma Targeted Therapy Kevin Ricardo Díaz Gálvez, Alexel J. Burgara-Estrella and Jose A. Sarabia-Sainz; Universidad de Sonora, Mexico

We report the evaluation of lactosylated graphene oxide (GO-AL) as a potential drug carrier targeted at an asialoglycoprotein receptor (ASGPR) from hepatic cancer cells. Structural-modification, safety evaluation, and functional analysis of GO-AL were performed. The structure and morphology of the composite were analyzed by atomic force microscopy (AFM), while Raman and FTIR spectroscopy were used to track the chemical modification. For the safe application of GO-AL, an evaluation of the cytotoxic effect, hemolytic properties, and specific interactions of the glycoconjugate were also studied. SEM and AFM analysis of the GO showed graphene sheets with a layer size of 2–3 nm, though a few of them reached 4 nm. The Raman spectra presented characteristic peaks of graphene oxide at 1608 cm^{-1} and 1350 cm^{-1}, corresponding to G and D bands, respectively. Besides, Si–O peaks for the APTES conjugates of GO were identified by FTIR spectroscopy. No cytotoxic or hemolytic effects were observed for GO samples, thus proving their biocompatibility. The cytotoxicity in cancer cells of GO, GO-A or GO-AL was evaluated at different concentration by MTT (0.25 to 100 ug/mL). The interaction of *Ricinus communis* lectin confirmed that GO-AL has a biorecognition capability and an exposed galactose structure. This biorecognition capability was accompanied by the determination of the specific absorption of lactosylated GO by HepG2 cells mediated through the asialoglycoprotein receptor. The successful conjugation, hemolytic safety, and specific recognition described here for lactosylated GO indicate its promise as an efficient drug-delivery vehicle to hepatic tissue.

5:00 PM SB05.09.26
Temperature-Controlled Gene Expression Using Thermoresponsive Polymer-DNA Conjugates Assala Al Samad and Michael Booth; UCL, United Kingdom

Nucleic acid technologies, including plasmids, ASO, siRNA and mRNA, are a suite of well-studied and emerging tools to study living systems and target genetic disorders *in vivo*. Controlling nucleic acid technologies by external stimulus has become a vital requirement in biotechnology and gene therapy. Among the external stimulus that can be used, temperature is an ideal candidate due to its reversibility and high tissue penetration, when combined with ultrasound[1]. Temperature control can be achieved by using thermoresponsive polymers. Thermoresponsive polymers are “Smart Materials” that can switch between globule and coil states when changing the temperature. They are divided into 2 categories; polymers with a lower critical solution temperature (LCST) aggregate when temperature is above a critical temperature, and polymers exhibiting an upper critical solution temperature (UCST) become soluble above their critical temperature. Poly(N-isopropylacrylamide) (PNIPAM), which exhibits a LCST of 32○C, has been previously coupled to DNA[2] and preliminary studies have shown it can be used to regulate gene expression when polymerized with antisense oligonucleotides (ASOs)[3]. ASOs are short ssDNA that can bind to complementary mRNA then allow their cleavage in the presence of RNAse H enzyme, and have been used to control protein production in cell-free and living systems. In this project, we are exploring the conjugation the LCST and UCST (co)polymers onto DNA template and ASOs to produce a platform for temperature control.
Here, different (co)polymers (PNIPAM and P(NIPAM-co-AAm)) with LCSTs in the range of 32-38○C were synthesized by reversible addition-fragmentation chain transfer (RAFT) polymerization and conjugated to functional DNA and ASO by click chemistry to produce defined polymer-nucleic acid species. These conjugates aggregated upon heating, as expected, and were used to control cell free protein synthesis (CFPS). In the first instance, we conjugated PNIPAM to a DNA template, encoding a fluorescent protein. The expression from DNA-PNIPAM was significantly decreased upon heating above the LCST, compared to the non-modified DNA template. We have also generated defined conjugates of ASOs with PNIPAM, unlike the previously example that employed free radical polymerisation[3]. In preliminary results, these ASO-PNIPAM conjugates were able to degrade mRNA below the LCST, but exciting, showed no degradation above the LCST.
These results demonstrate that it is possible to use thermoresponsive polymers to control both large (DNA template) and small (ASOs) nucleic acid technologies, using bioconjugation. Creating these bioconjugates, rather than the polydisperse nanoparticle aggregates, allows for the formation of a distinct, single molecular species, which simplifies synthesis, analysis, and pharmacokinetics. Our future aim is to attach LCST and UCST (co)polymers, which can be activated by mild hyperthermia, to many nucleic acid technologies and demonstrate their ultrasound-targeted application in biology and medicine.
ACKNOWLEDGEMENTS

4D Printed Fiber-Reinforced Highly Stretchable Uterine Tissue Engineering Scaffolds with Controlled Release of Hormone Jizhuo Chen, Shangsi Chen and Min Wang; The University of Hong Kong, Hong Kong

Diseases of and injuries to the uterus can have significant effects on functions of the uterus, causing irregular menstruation, dysmenorrhea, or even infertility. These medical problems severely influence the quality of life of millions of females both physically and mentally. Conventional treatments for uterine diseases resort to drug therapy as a conservative treatment, hysteroscopic adhesiolysis as a surgical treatment, and so on. Although these treatments can mitigate the pain and partly restore functions of the uterus to some level, infertility due to uterus disease or injury poses a great challenge in the medical field. Tissue engineering (TE) now offers a promising approach to address the difficult problems in human body tissue/organ repair and regeneration, and it has been successfully used to regenerate body tissues such as skin, blood vessels, bone, tendon and ligament. However, tissue engineering strategies have been rarely adopted to treat uterine defects owing to various difficulties, including matching the highly elastic behavior of myometrium of the uterus. In this study, fiber-reinforced strong and highly stretchable tissue engineering scaffolds with controlled release of a hormone were made via 4D printing and their characteristics were subsequently studied. The fabrication of the new scaffolds involved the following steps: (1) 17β-estradiol (E2)-encapsulated polydopamine (PDA) nanospheres were synthesized; (2) a thermoplastic polyurethane (TPU) was dissolved in an organic solvent and different amounts of E2/PDA nanospheres were added to make E2/PDA/TPU mixtures which were subsequently electrospun into E2/PDA/TPU nanofibers; (3) different amounts of E2/PDA/TPU short fibers were blended homogenously with a poly(D,L-lactide-co-trimethylene carbonate) ("PLATMC", which is a shape memory polymer often used for 4D printing for different applications, including applications in the tissue engineering field) solution to make printing inks; (4) the inks were used in 4D printing to fabricate uterine scaffolds with designed structures. The optimal amounts of both E2/PDA in electrospun TPU fibers and E2/PDA/TPU in printing inks were determined through various experiments. Good printability was achieved through ink optimization. Tensile tests of 4D printed scaffolds showed that with the 30% wt. content of fibers in scaffolds, the Young's modulus and tensile strength of composite scaffolds were 2.5 and 3.6 times, respectively, those of 4D printed pure PLATMC scaffolds, with less than 20% sacrifice in ultimate elongation. *In vitro* E2 release experiments revealed that E2 was released gradually from PDA/TPU fibers during the 8-week test period without apparent burst release. The *in vitro* degradation study showed that PLATMC in composite scaffolds degraded initially causing with the exposure of fibers, and E2/PDA was then released gradually with time. In *in vitro* biological study, rat bone marrow mesenchymal stem cells (rBMSCs) seeded on composite scaffolds were found to attach and proliferate well with the cell survival rate reaching 99.5% at day 2 of culture. All of these results show that the 4D printed highly stretchable scaffolds with controlled release of E2 have high potential for uterine tissue regeneration.

Aptamer-Functionalized Metal-Organic Frameworks as an Efficient Delivery Vehicle of Antimicrobial Peptides Jon Ostolaza, Anna Scheeder, Ioanna Mela, Clemens Kaminski and David Fairen-Jimenez; University of Cambridge, United Kingdom

Infections caused by bacteria are among the most serious physiological conditions that threaten human health. The swift emergence of resistant bacteria is jeopardizing the efficacy of most antibiotics, highlighting the importance of finding non-invasive theragnostic systems to treat bacterial infections. Currently, different antimicrobial systems used in the field include metal-ion nanoparticles (NPs) (*e.g.*, Ag NPs), semiconductor photocatalytic materials (*e.g.*, TiO_2), and antibacterial-nanocarrier composites. However, these systems face several shortcomings such as very low efficiency, short-term effect, and fast release of the antimicrobial agent. To overcome these issues, metal-organic frameworks (MOFs) have emerged as a promising theragnostic system. MOFs are nanoporous crystalline materials made by the self-assembly of metal clusters and organic linkers. They have shown high biocompatibility, high drug loading capacity, slow release of their cargo, and a surface that is easy to functionalize. Despite the potential of these materials as nanocarriers, hardly any research has been carried out using MOFs for antimicrobial delivery.

In this work, a novel MOF named PCN-222 was functionalized with aptamers (apt@PCN-222), short oligonucleotide sequences that selectively bind to bacteria, to deliver doxorubicin and antimicrobial peptides (apt@dox@PCN-222) to bacterial targets. PCN-222 is a photoluminescent Zr-based nanomaterial that has shown great potential for bio-applications due to its large porosity, high stability, and biocompatibility. Growth assays for Gram-positive (*Bacillus subtilis*) and Gram-negative (*Escherichia coli*) bacteria were used to determine bacteria growth with bare PCN-222, free doxorubicin, apt@PCN-222, and apt@dox@PCN-222. Different characterization techniques were used to assess the physico-chemical properties of the NPs. High resolution transmission electron microscopy (HR-TEM) was used to confirm the crystallinity NPs. Scanning electron microscopy (SEM) and dynamic light scattering (DLS) were carried out to determine the particle size of the NPs and their colloidal stability, respectively. Ultraviolet-visible spectroscopy (UV-vis) was used to determine the drug loading content and inductively coupled plasma mass spectrometry (ICP-MS) was utilized to quantify the binding of aptamers into the surface of PCN-222. Finally, the binding of apt@PCN-222 NPs to the different types of bacteria was assessed by structured illumination microscopy (SIM).

Crystalline PCN-222 NPs with a size of 145 ± 7 nm and a BET area of 1980 m^2/g were successfully synthesized. Doxorubicin was successfully encapsulated into PCN-222, obtaining a drug loading greater than 40%. This result confirms the expected high porosity of this NP. Enhanced binding of PCN-222 to the bacteria was corroborated by measuring the overlapping region by SIM since GFP-expressing *E. coli* are green and the PCN-222 NPs are red. The increase in binding levels was obtained by exploiting the synergistic effect of two binding mechanisms: electrical binding due to the positive charge of PCN-222 and selective binding by the addition of aptamers to the surface of the MOF. The phosphate ions present in PBS destroyed the porous matrix of PCN-222, thus releasing the doxorubicin in a slower manner than the current antibacterial-nanocarrier composites. The slow release of the drug, together with the selective binding of the apt@PCN-222 conjugate to the bacteria resulted in an increased reduction of bacteria growth when compared to free doxorubicin.

PCN-222 has shown promising physico-chemical properties for the effective delivery of antimicrobial agents to bacteria. Further studies will examine the effect of using larger aptamers or cationic polymers to increase its targeting effects. This study represents the first systematic attempt to target bacteria using aptamer-functionalised PCN-222, promoting the use of nanomaterials against antibiotic resistance.

Ultrasmall Gold Nanoparticles Decorated with Biomolecules for Specific Interaction with Cells and Proteins Matthias Epple[1], Nataniel Bialas[1], Marc

Heggen[2], Kai Klein[1], Sebastian Kollenda[1], Kathrin Kostka[1], Benedikt Kruse[1], Kateryna Loza[1], Viktoriya Sokolova[1] and Natalie Wolff[1]; [1]University of Duisburg-Essen, Germany; [2]Ernst-Ruska Centre, Forschungszentrum Juelich, Germany

Ultrasmall gold nanoparticles (diameter 1-2 nm) are smaller than most proteins and therefore well suited to elucidate particle-protein interactions after suitable surface functionalization. siRNA and fluorescing dyes (e.g. FAM, Cy5, Alexa647) were attached by copper-catalyzed azide-alkyne cycloaddition (click chemistry) to azide-terminated gold nanoparticles. Peptides of different length were directly attached via cysteine, taking advantage of the strong gold-sulfur bond. The particles were characterized by high-resolution transmission electron microscopy, differential centrifugal sedimentation, and ultraviolet spectroscopy. Extensive NMR spectroscopic investigations of dispersed particles were possible due to the ultrasmall nature of the particles. By combining the results of all these analytical techniques, a full image of the particles was gained, including the number of ligands (typically 5-10 per nanoparticle) and the details of the ligand-gold bond.
The nanoparticles were surface-decorated with biomolecules and synthetic receptor molecules to interact with the surface of model proteins as probed by NMR spectroscopy, isothermal titration calorimetry, and fluorescence polarisation. Such particles are easily taken up by cells as demonstrated in classical two-dimensional cell cultures and in three-dimensional organoids. Notably, the particles were able to enter the cell nucleus and also to cross the blood-brain barrier in brain organoids that exhibit a functional blood-brain barrier in vitro. We also demonstrated how they were taken up by bacteria.
In conclusion, covalently functionalized ultrasmall gold nanoparticles have a strong potential for specific interaction with proteins, for imaging and as drug carrier into cells and organoids.

Biomolecular Corona and Mechanisms Involved in Tumor-Targeting and Renal Clearance of Mesoporous Silica Nanoparticles Si-Han Wu; Taipei Medical University, Taiwan

Mesoporous Silica Nanoparticles (MSNs) have been considered promising for in vivo biomedical applications, such as targeted therapy and diagnostic imaging. However, once nanoparticles are exposed to the biological system, biomolecular corona formed around the nanoparticles can result in unexpected outcomes in terms of therapeutic efficiency, biodistribution, and pharmacokinetics. Therefore, understanding the composition and functionality of protein corona is crucial for nanomedicine development. Nowadays, cancer nanomedicines are widely applied to overcome the low tumor-targeting efficiency of the conventional drug, but the elimination processes of nanoparticles are still unclear. Kidneys, with a filtration threshold of 6 nm for metal-based nanoparticles or proteins defined by the previous investigation, are the major excretion organs in metabolism to remove excess waste in the body.
In this study, we employed LC-MS/MS, SDS-PAGE, DLS, and Zeta potential measurements to identify the protein corona after the *in vitro* incubation of 25 nm cationic PEGylated MSNs with human plasma and intravenous injection of nanoparticles into the mice. Additional bioinformatics analyses using ClueGo and Ingenuity Pathway Analysis (IPA) revealed altered regulation in crucial pathways. The biodistribution of MSNs in 4T1 breast tumor-bearing BALB/c mice was investigated using immunofluorescence microscopy and a non-invasive *in vivo* imaging system (IVIS). Our results demonstrated that superior tumor-targeting efficiency could be achieved more simply by reducing protein adsorption but not manipulating protein type on the surface of MSNs. On the other hand, immunofluorescence and TEM visualization showed the localization of PEGylated MSNs in the glomerular basement membrane and mesangial cells. Notably, intact 25 nm cationic PEGylated MSNs were observed in the collective urine. A comprehensive evaluation revealed that the biomolecular mechanisms involved in the excretion of MSNs are through the proximal tubular epithelial cells by caveolae-mediated albumin transcytosis.

9:15 AM SB05.10.05
Synthesis of Silver-Modified Nanoceria Formulations Through Solution-Based Nanoengineering and Their Unique Efficacies Towards (Non-) Enveloped Virus Species Craig J. Neal[1], Candace Fox[1], Elayaraja Kolanthai[1], Yifei Fu[1], Udit Kumar[1], Christina Drake[2], Griffith Parks[1] and Sudipta Seal[1]; [1]University of Central Florida, United States; [2]Kismet Technologies, United States

The utility of noble metal species in catalysis has been further broadened by investigations into their complex substrate interactions (catalyst-substrate/support effects). Such studies highlight the impact of chemical environment on material character as emergent phenomena (*e.g.* varied plasmon character, unique reaction selectivity (reactivity)). In the presented study, noble metal silver's limited solubility in and surface-phase formation on redox-active cerium oxide nanoparticles is overcome by manipulating the unique chemistry of ionic silver in aqueous solution. In particular, the oxidation of silver and, thereby, the final nanomaterial synthesis products, are *nanoengineered* by top-down chemical etching process to remove contaminant silver (oxide) phases post-synthesis (utilizing Tollen's reagent, $[Ag(NH_3)_2]^+$, formation from silver (oxide)) (*AgCNP1*) or selective-oxidation of Ce^{3+} over silver by hydrogen peroxide ($H_2O_2+Ag^0,Ag_2O \rightarrow Ag^++H_2O+$(radical oxygen species)), bottom-up process, to preclude silver (oxide) particle phase formation (*AgCNP2*). Each synthesis produces surface/near-surface silver-phases of varied oxidation states (evidenced by x-ray photoelectron spectroscopy) due to the unique crystal environments evolved by each synthetic route (evidenced by transmission electron microscopy, x-ray diffraction, electroanalysis). Further, synthesis conditions and product silver phase character strongly impact cerium site reduction in each formulation (25.8 and 53.7 %Ce as Ce^{3+} for AgCNP1 and 2, respectively). Biomedically-relevant, reactive oxygen species modulating enzyme-mimetic catalysis assays (peroxide-degrading: catalase, superoxide radical scavenging: superoxide dismutase) were performed for each formulation, which correlate catalytic redox activity with extent of cerium reduction in the formulations. The complex nature of the silver surface phase character and silver/ceria-mediated surface catalysis activity of each formulation were further highlighted in studies demonstrating their unique efficacy towards inactivation of enveloped (OC43 *coronavirus*) and/or non-enveloped (RV14 *rhinovirus*) viruses. Specificity towards virus character is further studied through electroanalytical methods (electrochemical impedance spectroscopy, circuit modeling) and adsorption studies.

Inorganic/Organic Nanocomposite Particles (I/O-NP); A Platform Technology for Future Healthcare Applications Marco Giardiello; University of Liverpool, United Kingdom

Nanomedicine represents one of the fastest growing fields of research in recent years, encompassing both therapeutic and diagnostic medicine. Global impacts across several wide-ranging disease conditions have been achieved, for example Doxil/Caelyx and Myocet for cancer chemotherapy, Macugen for macular degeneration, Fosrenol for renal disease and Endorem for magnetic resonance imaging. Critically, all advances in nanomedicine are driven by material development on the nanoscale, with many applications established through fundamental research and design of novel nanomaterials. Thus, in order to discover next generation technologies, next generation nanomaterials must be developed.
The success of current clinical nanomedicine is borne out of advances in both inorganic and organic nanomaterials. The Inorganic/Organic Nanocomposite Particles (I/O-NP) platform technology is composed of organic, polymeric nanoparticles that incorporate and functionalise various inorganic nanoparticles. The aim is to harness the versatility of both inorganic nanoparticle (I-NP) and organic nanoparticle (O-NP) technologies to develop a highly versatile platform with multiple opportunities in varied healthcare applications possible through variation in nanocomposite structure and composition. Through advanced materials design and collaborative research approaches, the scientific objective is to apply the versatility of the I/O-NP platform across several emerging healthcare applications, both diagnostic and therapeutic. Herein an overview of synthetic approaches towards composite material developments aimed at several healthcare applications will be presented:
1. Superparamagnetic Iron Oxide Nanoparticle based tracers for Magnetic Particle Imaging (MPI)

2. Gold nanoparticle based radiosensitisers for Proton Beam Therapy
3. Lanthanide Upconversion Nanoparticles as Optical Imaging Probes
4. Polymeric nanocomposites as theranostic agents for Magnetic Resonance Imaging (MRI)

Ultrasmall Silica Nanoparticle-Intrinsic Therapeutic Solutions for Modulating the Tumor-Immune Microenvironment in Cancer Michelle Bradbury[1], Ulrich Wiesner[2] and Michael Overholtzer[1]; [1]Memorial Sloan Kettering Cancer Center, United States; [2]Cornell University, United States

Considerable strides continue to be made in the design of nanoparticles as highly specialized therapeutics for improving treatment outcomes and overcoming limitations that may be observed with standard pharmacologic agents. Novel emerging paradigms that lead to durable response rates in combination with other classes of therapeutics are also critically needed. One promising strategy exploits the unique self-therapeutic capabilities that may be exhibited by the nanomaterials themselves, which do not require attachment of a cytotoxic drug. These capabilities are governed by the physico-chemical properties of these materials, which can disrupt signal transduction pathways, cell cross-talk or invasion, induce cell death programs, or mediate other biological properties within the melanoma tumor microenvironment (TME), thereby providing unprecedented opportunities for combating disease. We find that an ultrasmall fluorescent core-shell silica nanoparticle, Cornell prime dots (C’ dots), exhibits multiple distinctly separable intrinsic therapeutic properties, including their ability to (1) specifically induce regulated cancer cell death programs, such as the iron-dependent process, ferroptosis; (2) selectively modulate expression profiles with activation of multiple gene classes and proinflammatory cytokines, in addition to their ability to (3) directly activate immune cell populations towards an anti-tumor pro-inflammatory phenotype in syngeneic models. Our future work will continue to explore the nature/type of interactions among TME populations exposed to C' dots, probing mechanisms by which these particles engage pro-inflammatory anti-tumor and cytotoxic responses. Such information, in turn, can be used to develop novel treatment paradigms for clinical cancer care.

11:00 AM DISCUSSION TIME

11:30 AM SB05.11.04
Engineering Immunotherapeutic Exosomes from Dendritic Cells Stimulated by Intracellular Self-Assembled Peptide Networks for Cancer Vaccine Min A. Kang[1], Aloka Paragodaarachchi[1], Takamasa Kawano[2], Kiyotaka Shiba[2], Stefania Gallucci[3] and Hiroshi Matsui[1,4]; [1]Hunter College-CUNY, United States; [2]Japanese Foundation of Cancer Research, Japan; [3]University of Massachusetts Amherst, United States; [4]Cornell University, United States

Here we inrtoduce a new approach for generating immunotherapeutic nanoparticles of dendritic cell (DC)-derived exosomes (DC-Exos) on a large-scale for the clinical translation. Exosomes denote a family of nanoparticles (30–120 nm in a diameter) secreted by most cell types. Secreted exosomes consist of a surrounding lipid bilayer containing various proteins, lipids, and nucleic acids in donor cells. The use of DC-derived exosomes was recognized to address the technical challenges associated with DC-based immunotherapy, leading to multiple clinical trials. However, the workload required to upscale the production of DC-Exos is currently not suitable for their major clinical use. Our lab has been showing that a peptide (NapFFK(NBD)Yp) self-assembles in fiber networks in the cytoplasm of donor cells, catalyzed by alkaline phosphatases (ALPs), and such peptide self-assembly can increase the secretion of exosomes in various cancer cells, reaching in some cases a 10-fold increase. We observed that the peptide self-assembly was triggered by ALP in DCs, in which the expression of required enzyme was induced by specific growth factors, and this assembly stimulated mass production of DC-Exos; the production of exosomes from bone marrow-derived DCs was amplified 7-folds by the self-assembled peptide without inducing major toxicity. We also showed the potential that the self-assembled peptide could activate DCs to become strong stimulators of the immune response by triggering pro-inflammatory recognition mechanisms *via* proteomic analysis and flow cytometry. With proteomics, the heatmap of protein expression of exosomes with the peptide treatment indicates the packaging of exosomes is not affected by self-assembled peptides in parental cells, an important condition for their clinical applications. The proteomics could also suggest possible biogenesis and mechanism of amplified generation of exosomes.
The outcome could advance scientific knowledge for precision medicine as proposed exosomes can be applied as intercellular vectors for personal RNA-based therapy (both miRNAs and siRNAs) with capability of individualized-specific targeting of cancers and suppression of immunogenic response. It will also lay the foundations for future studies implementing DC-Exos as delivery systems in mRNA vaccine, cardiovascular diseases-related RNA therapeutics that can be regulated through exosomes.

11:45 AM SB05.11.05
Virus-Mimetic Vaccine Based on Self-Assembled Antigen-Polymer Conjugates Eliciting Effective Immunity Against Influenza Virus Geunseon Park[1], Woonsung Na[2], Jong-Woo Lim[3], Chaewon Park[1], Hyun-Ouk Kim[4], Daesub Song[3] and Seungjoo Haam[1]; [1]Yonsei University, Korea (the Republic of); [2]Chonnam National University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of); [4]Kangwon University, Korea (the Republic of)

Vaccines have been providing humankind with the ability to defend against infectious diseases. However, existing vaccines face obstacles such as a risk of adverse effects and limited immunogenicity. In the present work, we developed a self-assembled vaccine (SAV) platform based on antigen conjugated with an amphiphilic block copolymer, mPEG-b-PLA-NHS. To improve subunit vaccine immunity, SAV was designed to be nanoscale for effective antigen transport and to display repetitive antigens on its surface to trigger immune cells via multivalent recognition. SAV demonstrated improved cellular uptake by dendritic cells (DCs), hence promoting an efficient activation of the adaptive immune system. In vivo study revealed that SAV induced high levels of IgG, IgG1, and IgG2, indicating effective B cell activation and T cell-mediated immunological response. In addition, we confirmed that SAV containing hemagglutinin (HA) effectively prevented mice from mortality due to influenza virus infection. These results imply that the self-assembled nanosystem constituted of antigen-polymer conjugate can serve as an effective and versatile vaccine platform.

SESSION SB05.12: Considering the Neural-Nanoparticle Interface

A NIR-II Bio-Interface for Non-Invasive Deep-Brain Stimulation Xiang Wu and Guosong Hong; Stanford University, United States

Neuromodulation techniques, such as electrical deep-brain stimulation and optogenetics, are capable of selective activation or inhibition of certain subgroup of neurons, thus providing unprecedented opportunities for the dissection of complex neural circuitry and the treatment of neurological disorders such as Parkinson's disease. The electric field or visible light used in the current predominant neuromodulation approaches, however, is strongly attenuated by the brain tissue, thus necessitating invasive implantation of stimulation electrode or optical fiber. Such invasive brain implants inevitably cause acute brain damage, chronic immune response, and physical tethering that interferes with the animal's natural behavior. Therefore, it is desirable to develop new methods that can modulate neural activities with an implant-free and tether-free interface.
To address these challenges, we designed a nanomaterial-based bio-interface in one of the biological transparence windows, the second near-infrared window (NIR-II, 1000-1700 nm), for remote and non-invasive deep-brain stimulation. NIR-II light exhibits reduced scattering than visible light and lower water absorption than longer wavelength NIR light, and is thus the optimal wavelength for deep-brain neuromodulation. Although no existing opsin responses to NIR-II photons, we got inspiration from the findings of Nobel laureate David Julius that rattlesnakes sense infrared irradiation through its thermal effect using transient receptor potential (TRP) channels. We hypothesized that TRP channels can also be used as NIR-II receptors in mammalian neurons. However, to activate deep-brain TRP channels, a high laser power is required, which inevitably leads to a high temperature increase on the brain surface, and as a result, altering the neural behaviors and even causing brain damage. To overcome this challenge, we designed nanotransducers named MINDS (macromolecular infrared nanotransducers for deep-brain stimulation) that strongly interact with NIR-II light. Specifically, MINDS consist of a NIR-II absorbing semiconducting polymer core with a photothermal conversion efficiency of 71% in the NIR-II window, and an FDA-approved amphiphilic polymer shell to facilitate water solubility and biocompatibility. As a result, through-scalp wide-field NIR-II illumination creates a local hotspot around MINDS up to a depth of 5-mm in the brain, while largely sparing the brain surface from heating. Consequently, MINDS act as an NIR-II sensitizer to remotely activate deep-brain TRP-expressing dopaminergic neurons in freely behaving mice without any brain implant or physical tethering, producing significant behavioral changes in a conditioned place preference test.
The utility of this NIR-II neuromodulation technique sits between optogenetics and chemogenetics: it eliminates the chronic brain implants and fiber tethering required for optogenetics and features a more precise temporal control of activation and inactivation than chemogenetics. Therefore, the NIR-II neuromodulation approach reported here allows timely behavioral modulation of freely moving subjects with minimal chronic gliosis in the neural tissue and no interference to natural animal behaviors. With complete elimination of any brain implant and head tethering, our approach could afford wide applications in dissecting the complex neural circuits of normally behaving animals in a natural interaction environment, such as in the IntelliCage, in the future. **This work was recently published in *Nat. Biomed. Eng.* (Wu, X. *et al.* Tether-free photothermal deep-brain stimulation in freely behaving mice via wide-field illumination in the near-infrared-II window. *Nat. Biomed. Eng.* 6, 754-770 (2022)).**

1:45 PM SB05.12.03
On the Coupling Mechanism Occurring at the Neuron-Nanoparticle Interface Greta Chiaravalli[1,2], Jasnoor Jasnoor[2,3], Tiziana Ravasenga[2,3], Elisabetta Colombo[2,3], Simona Francia[2,3], Stefano Di Marco[2,3], Fabio Benfenati[2,3], Riccardo Sacco[1] and Guglielmo Lanzani[1,2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Ospedale Policlinico San Martino, Italy

The injection of organic photo-responsive nanoparticles (NPs) of poly(3-hexyltiophene) (P3HT) into rat models of retinitis pigmentosa was proposed as a "*liquid retina device*" to treat degenerative blindness, inducing a light evoked retinal neuron response (Maya-Vetencourt et al., 2020; Francia et al., 2022). Although the efficiency of organic polymer-based retinal devices in vivo has been proven, the interpretation of the working mechanisms that grant photostimulation at the polymer/neuron interface is still a matter of debate.

In our work, we focus on understanding the mechanisms which may play a role at the bio-hybrid interface, decoupling them into: (i) a photochemical effect, which in our case consists in the photocathodic behavior of P3HT in watery oxygenated environment; (ii) an electrostatic effect, due to light induced capacitive charging of the NP, known as Photo-Dember effect. With mathematical modeling and electrochemical studies, we are able to identify the relative importance of each mechanism as a function of light intensity impinging onto the substrate, cleft size and cleft resistive properties.

The photo-chemical mechanism, connected to the production of O_2^- in the cleft, appears to be relevant solely when light intensity increases above the physiological ranges and under conditions of strict proximity to the neuron membrane (<50 nm). The capacitive effect induced by the electrostatic charging of the nanoparticle is instead appreciable only in the presence of a highly resistive medium, where ionic screening can be assumed as negligible (Debye Length>>cleft thickness): if this condition is verified by the system, even physiological light intensities (0.2 W/m^2) are able to induce appreciable depolarization of the neurons. The highly resistive medium in the model is accounted for by the presence of adhesion proteins in the cleft. Therefore, the formation of *"proteic islands"* is suggested by the model as a fundamental ingredient to ensure the coupling among neuron and nanoparticle at reduced light intensity.

A preliminary confirmation of our simulation results comes from ex vivo experiments on retinal explants that received P3HT-NPs in the subretinal space either acutely after the explantation or that were taken from rats which had been subretinally injected in vivo with P3HT-NPs one month before. The recordings of retinal ganglion cell firing on acutely injected explants displayed a significantly reduced response with respect to the retinas which experiences a prolonged in vivo contact with the NPs before explantation.
The combined use of modeling and physiological experiments suggests that, in vivo, NPs are engulfed by the neuronal membrane with a highly resistive medium which ensures an efficient electrostatic coupling. While at the high light intensities used in in vitro experiments both phenomena may take place, at the lower light intensities used in vivo the sole electrostatic effect is responsible for the photostimulation. The results also suggest that in vitro experiments do not faithfully reproduce the in vivo condition and that a prolonged in vivo contact between NPs and the neurons, occurring in vivo, is necessary to fully elicit the physiological effects.

2:00 PM SB05.12.04
Ultrasound Triggered Liposome Light Source for Noninvasive Optogenetics Huiliang Wang; The University of Texas at Austin, United States

Optogenetics has revolutionized neuroscience understanding by allowing spatiotemporal control over cell-type specific neurons in neural circuits. However, visible light cannot be directly delivered to deep brain tissue, due to the severe dissipation and scattering of photons. As a result, invasive craniotomy is usually required to implant optical fibers in the brain for in vivo optogenetic stimulation, resulting in permanent damage and chronic gliosis in brain tissue. To achieve non-invasive optogenetics with high temporal resolution and excellent biocompatibility, we have developed focused ultrasound triggered liposome-based light sources (Lipo@IR780/L012 nanoparticles) for deep brain photon delivery. Synchronized and stable blue light emission was generated under ultrasound irradiation due to the activation of chemiluminescent L012 via nearby reactive oxygen species generated by IR780. In vitro tests revealed that Lipo@IR780/L012 nanoparticles could be triggered by ultrasound for light emission at different frequencies and hence activate opsin-expressing spiking HEK cells under the ultrasound irradiation. In vivo optogenetic stimulation further demonstrated that motor cortex neurons could be noninvasively and reversibly activated under the repetitive ultrasound stimulation after i.v. injection of Lipo@IR780/L012 nanoparticles to achieve limb motions control.

Nanoparticle-Based Surface Localized Nucleic Acid Amplification for Rapid and Ultrasensitive Electrochemical Detection Jeong Ook Soh[1], Young Keun Kim[2] and Ju Hun Lee[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Of various methods that have been developed for the diagnosis of diseases, molecular diagnostic approaches have proven to be of great significance and thus have been developed to a great extent. Of these approaches, nanoparticle-based systems for nucleic acid detection have gained much attention due to the remarkable features of the nanoparticle platform (large surface area, electrochemical catalysis, biocompatibility, etc.). These methods produced notable results for detection of disease-related genetic material, which suggested the potential to overcome the critical drawbacks of conventional PCR-based diagnosis. However, the acquisition of both high sensitivity and short detection runtime in a single method remain a challenge as methods with high sensitivity demand lengthy procedures while faster methods require higher concentrations of genetic material for detection. In response to this matter, we propose an innovative nanoparticle-based system composed of a nucleic acid amplification method paired with electrochemical assay for rapid and ultrasensitive detection of genetic biomarkers. Termed “nanoparticle surface localized amplification (nSLAM)”, the method uses DNA functionalized Fe_3O_4−Au core−shell nanoparticles as a platform for nucleic acid amplification and accumulation. The surface-anchored DNA act as primers that bind and amplify target DNA directly on the nanoparticle surfaces using conventional PCR procedures. The surface-accumulated amplicons are subsequently subjected to electrochemical detection, which induces significantly amplified current signals that identify the presence of the target material. The nanoparticles function as dispersible nanometer-sized electrodes that significantly improve the biochemical contact efficiency between the primers and target gene of interest, further enabling amplification and collection of extremely low concentrations of target material. Furthermore, multiple measurements of electrochemical detection induce rearrangement of the dispersible nanoparticles, substantially enhancing the current signals for both ultrasensitive and rapid detection of target genes. The detection performance was tested using the COVID-19 model, which produced a remarkable sensitivity of ~1 RNA copy/µL using 35 PCR cycles. This ultrasensitivity enabled the reduction of amplification cycles to as low as 4 cycles (~7 min runtime) using 1 fM COVID-19 cDNA, which demonstrated the system’s capacity for rapid detection. These results suggest the potential for the system to overcome critical drawbacks of conventional COVID-19 molecular diagnosis by speeding up the detection process to enable expeditious treatment-related measures taken by medical personnel during emergency situations. The nSLAM system was also tested using the estrogen receptor 1 (ESR1) gene model, a ctDNA biomarker from metastatic breast cancer, which resulted in a successful detection of as low as ~1 aM concentration using 40 PCR cycles and reduction to 10 PCR cycles (~18 min runtime) for 1 fM ESR1 detection. The detection results provide a solution to the crucial shortcomings of detecting ctDNA for liquid biopsy, as the short half-life and extremely low abundance of ctDNA in blood are supplemented by the rapid and ultrasensitive detection properties of the system. The system is a promising platform that can be used to detect cancer- and infectious disease-related genetic material in an ultrasensitive and rapid manner. The system also demonstrates great versatility that can be tailored to specific diseases by designing and substituting the primers used for amplification. We plan to further develop the system as a multiplex platform for simultaneous detection of various diseases.

3:45 PM SB05.13.04
Hybrid Bio-Electronic Memristive Neuromodulation Interface for Real-Time Adaptive Coupling Between Neuronal Populations Catarina Dias[1], Domingos Castro[2], Miguel Aroso[2], Joao Ventura[1] and Paulo Aguiar[2]; [1]University of Porto - Faculty of Sciences, Portugal; [2]i3S, Portugal

Significant efforts are being made to develop nanoscale electronic devices integrated into neuromorphic circuits capable of emulating the dynamics of natural synapses. The coupling between neuronal populations via artificial synapses bears great potential for therapeutic strategies focused on the monitoring and control of neuronal electrical activity. Such hybrid systems, effectively coupling biological and electrical components, are important milestones for the development of a new generation of neuroprosthetic devices aimed to address a number of challenging neurologic disorders [1]. Consequently, therapeutic strategies based on the direct modulation of neuronal electrical activity have been producing remarkable results, with successful examples ranging from cochlear implants to deep brain stimulation. Developments in these implantable devices are hindered, however, by important challenges such as power requirements, size factor, signal transduction, and adaptability/computational capabilities. Memristors, neuromorphic nanoscale electronic components able to emulate natural synapses, have gained attention as a core component is these hybrid systems, mainly because of their neuromorphic properties, small size and low power signature [2]. They are nanoscale two-terminal electrical components whose present conduction state depends on the electrical stimulus that has been previously applied to them. The dynamics of a memristor’s response to stimulation is analogous to that of synapses, presenting learned transitions from low to high conductivity states, and vice versa. Importantly, the timescale of these transitions can be made analogous to the plasticity timescale of learning mechanisms in the brain, such as synaptic short-term plasticity (STP), which acts on the range from seconds to minutes. Relevant proofs of concept have already been presented in the literature [3], but we argue that crucial aspects have not yet been demonstrated on how these memristor-based hybrid systems can effectively operate in a meaningful way. Here we show, for the first time, how biological *in vitro* hippocampal neuronal populations can be dynamically coupled with a memristive device acting as a synapstor, forming a hybrid bio-electronic system [4]. We demonstrate that the conductance state of a memristor can be changed by the electrical activity of biological neurons and mediate a dynamic connection between isolated spiking neuronal populations. Our system connects biological neurons to microelectrodes, amplifier, memristor, stimulator, microelectrodes, and back to biological neurons, in an effective real-time configuration that does not use software nor simulations. Using our system, we can have neuronal population B being effectively activated if, and only if, there is a consistent firing pattern of activity in population A (network bursting activity). Importantly, we demonstrate that our artificial synapse is capable of short-term plasticity, dynamically changing its conductance level in both directions. Our results pave the way for further implementation of elements able to perform more complex modulatory operations in neuronal populations. We envision very similar systems being used for the automatic detection and suppression of seizures in epileptic patients.

Extended Functionality of Spherical Nucleic Acid for Biosensing Applications Eunhye Park and Jwa-Min Nam; Seoul National University, Korea (the Republic of)

Spherical nucleic acids (SNAs) are composed of inorganic core materials in cooperation with nucleic acids shell as soft material. The nucleic acid can be densely conjugated to the surface of the core material depending on the type of the core material. Polyvalent SNAs help in biosensing development because they provide a higher opportunity to recognize target strands. However, despite the widely applicable potential of DNA sequences on SNA, the function of nucleic acids has been limited in very simple operations. For example, colorimetric detection using gold nanoparticle assemblies triggered by target analytes is a common method in nanostructured biosensing applications. Previously, nucleic acid sequences worked simply to capture target strands or form DNA-mediated hybridization for core material assemblies.
To extend the functionality of the SNA nanoprobe, DNA nanotechnology can be combined with the SNA nanostructure. Accordingly, the way to exploit SNA for biosensors is to define a new role of nucleic acids layer on it. Nucleic acids can perform well-defined functions such as signal conversion or target amplification itself as far as the sequence-specific operating role is concerned. Target sequence conversions are useful when the target strands require high selectivity. For example, single nucleotide polymorphisms (SNPs) are challenging as target nucleic acids because there is only one single base mismatch between the analytes to distinguish specific targets, and the concentration of SNPs in biological samples is low. Consequently, converting sequences in high-density SNA nanoprobes allows similar target sequences to be transmitted to noticeably different sequences via encoding strand amplification. According to the experimental results, one target strand was encoded about 1000 strands in a distinctly different sequence. To distinguish four multiple targets of SNPs i.e., wild and mutant types, toehold-mediated strands displacement reaction on hydrogel microstructure has been designed as following detection process. Target sequence converting SNAs are enzyme-free amplification of targets and increased selectivity.
Furthermore, massively target strands hybridized SNA nanoprobe can be employed for the target amplification probe itself. To increase the target strand amplification efficiency, the nanoparticle-mediated cycle reaction has been developed under enzyme-free conditions with naked-eye detection. In each cycle, target amplifying SNA can exponentially increase the number of target DNA strands by up to 174^n folds during n cycles. The cycles can be repeated as enough strands are amplified. SNA-based target amplification showed four times higher detection efficiency than polymerase chain reaction (PCR), which is widely used for nucleic acid amplification with 2^n folds for n cycles. In addition, it was possible to detect the target strands up to 100 zM of target strands with a convenient detection process.

8:00 AM *SB05.15/SB06.14.01
Engineering Peptide-Based Synthetic Condensates Lorraine Leon; University of Central Florida, United States

Biological condensates (membraneless organelles) are liquid droplets consisting of proteins and nucleic acids that form within cells via liquid-liquid phase separation. These droplets are dynamic, have been shown to coalesce within cells, and can form and dissipate in response to biological and environmental signals. Many condensates have multiphase structure where different cellular components are sequestered into different layers, each with their own function. Here we discuss designing synthetic condensates to understand the role of diverse molecular interactions within proteins on biological phase separation, investigate the encapsulation of small molecules and enzymes, and establish design rules for multiphase formation. The synthetic condensates are formed via complex coacervation of oppositely charged polypeptides. Complex coacervation is a liquid-liquid phase separation that occurs via enthalpic charge interactions and entropic effects from the release of counterions and hydration water. We have created a library of different polypeptide sequences that incorporate various charge patterns, hydrophobic amino acids, and aromatic amino acids in the sequence. In addition, our sequences incorporate different chiral patterns of amino acids that bias the formation of liquid complex coacervates by preventing hydrogen bonding between the polypeptides know to form solid polyelectrolyte complexes. With this library we aim to explore the effects on the stability, encapsulation selectivity, and materials properties of the coacervate phase. Moreover, we mix coacervate phases with different interfacial tensions to create multiphase droplets.

8:30 AM SB05.15/SB06.14.02
Apoptosis Cell Classification Using Phase Contrast Images Yuki Kikuchi, Yuki Okuhashi, Hiroaki Ishihata, Misato Kashiba and Satoshi Sasaki; Tokyo Univ of Technology, Japan

Materials that cause apoptosis of cancer cells should potentially be candidates for future anti-cancer drug. Apoptosis cell classification using AI will be an effective method to evaluate the effect. Characteristics of apoptosis cells are effectively identified from the fluorescence-stained images. The effectiveness will increase if the classification could be performed without stains.
γ secretase inhibitor (GSI) is reported to cause apoptosis of K562, a human chronic myelogenous leukemia cell line. We found that AI-based classification results of phase-contrast images of the cells were quite similar to those of fluorescence images. Factors that AI identified, but naked eyes could not identify, were examined. Biochemical change inside cells were studied in connection with morphological characteristics.

8:45 AM SB05.15/SB06.14.03
Recognition Functionality Mapping at a Single Molecular Level by Frequency-Modulation AFM Imaging Ryosuke Izumi, Masayuki Morimoto and Hitoshi Asakawa; Kanazawa University, Japan

Molecular recognition is an essential function in developing advanced materials, including biomaterials. The precise design of molecular recognition functionalities, such as selectivity, affinity, and stimuli-responsibility, is the most important challenge in this research field. There are many studies on the design of molecular recognition elements using macrocyclic molecules, metal-organic complexes, and biomolecules. The designed recognition elements can capture guest molecules based on specific interactions. In addition, developing characterization tools is equally important to understand molecular-recognition functionalities and apply the advanced materials to various fields. Depending on their application, the designed recognition elements are often fixed on material surfaces. We easily imagine that the functionalities of the fixed recognition elements are influenced by their orientation and distribution on the material surfaces. However, a molecular scale understanding of the functionalities of the fixed recognition elements is still challenging due to the lack of analytical methods. Although the functionalities, such as the amount of capturing guest molecules, can be investigated with conventional analytical techniques, understanding the functionalities of each recognition element at a single molecular scale is difficult due to the averaging over numerous elements in conventional methods.

To overcome the limitation of conventional analytical methods, a method based on frequency modulation atomic force microscopy (FM-AFM). The FM-AFM technique is known to have the capability to visualize subnanometer-scale structures of various molecules and materials in liquid. The subnanometer resolution of the FM-AFM technique in liquid is based on the high sensitivity for interaction forces acting on the tip apex (the detectable theoretical limit is four pN). Moreover, conservative and non-conservative (dissipative) forces are measured separately in FM-AFM imaging. The characteristics of the FM-AFM technique suggest establishing a novel analytical method to investigate the recognition functionalities at a single molecular level based on the FM-AFM.

In this study, molecular-scale investigation of recognition events was demonstrated by FM-AFM imaging with a guest molecule-modified tip. Metal-salen complexes were fixed on a Si substrate as a model of molecular recognition elements. Amino-terminated AFM tips were prepared in this study because the metal-salen complexes have reported the capture of amino-containing molecules through the formation of coordination bonds. The FM-AFM experiments were performed with the amino-terminated AFM tips and the metal-salen complex fixed substrate. As a result, the fixed metal-salen complexes were visualized in the height images constructed by the measured signal of conservative forces. In contrast, energy dissipation images showed that dissipative interactions occurred in only a part of the fixed metal-salen complexes visualized in the height images. The results indicate that only a part of the fixed metal-salen complexes can recognize the amino group at the tip apex. The difference in the recognition function between the fixed metal-salen complexes is most likely caused by their orientation and dynamics. Our results demonstrate that the proposed analytical method based on the FM-AFM techniques with guest molecule-modified tips has the potential to investigate the recognition functionalities of the fixed recognition elements at the single molecular level, indicating future contributions to the development of advanced materials with recognition functions.

8:50 AM SB05.15/SB06.14.04
Development of Injectable Silk Hydrogel for Nanoprodrugs Control Release Mengheng Yang, Anh T. Dao, Ryuju Suzuki, Yoshitaka Koseki and Hitoshi Kasai; Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Japan

In traditional drug delivery systems, nanoparticles tend to accumulate at tumor sites due to the enhanced permeability and retention (EPR) effect, resulting in therapeutic efficacy. However, in the process of transporting through the blood, there is inevitable diffusion of drug to the normal tissue, causing side effects and reducing efficacy at the tumor site. An approach for such problems is to selectively release the drug at the tumor site through localized drug administration.

Silk protein hydrogels are inherently suitable for biological applications due to their permeability, high water content, and structural properties compatible with cell membranes. Its biodegradability can also be modified and subsequently utilized to control the drug release behavior, making silk hydrogel a potential drug-loading material. In vivo, hydrogels can be broken down by proteases. By changing the properties of the hydrogel, the degradation rate of the silk hydrogel can be tuned, therefore achieving controllability over the drug release. The study of injectable silk protein hydrogels as drug delivery systems has achieved good results in research for breast and liver cancers, but the research focus of controlling water-insoluble drug loading and drug release properties of hydrogels has not yet been realized. The aim of this study is to fabricate silk protein hydrogels that could be used as nano-prodrug carriers.

To this end, systematic changes in silk hydrogel preparation conditions were screened, and the obtained hydrogels were then used to load and release various types of drugs. Changes in dissolution conditions and gel parameters such as temperature, sonication time, shaking, stirring time, etc., during the preparation of hydrogels are considered to be factors that affect the performance of hydrogels. The properties of silk protein hydrogels were analyzed by gel fraction, swelling ratio, degradation rate, FT-IR, XRD, rheometer and so on.

In this report, calcium chloride solution was used to dissolve fibroin to obtain hydrogels with gelation times ranging from 1 to 4 days. By changing the gelation conditions, hydrogels with different properties were obtained. In addition, the loading of nano-prodrugs (NPDs) has been preliminary investigated. The in vitro drug release behavior of drug-loaded hydrogels will be studied. We expect to create an injectable hydrogel in which degradability can be controlled in vivo. This means that drug release can be manually controlled.

8:55 AM *SB05.15/SB06.14.07
Cyclic Peptide/Polymer Conjugates for Therapeutic Applications Sebastien Perrier; University of Warwick, United Kingdom

We describe the synthesis, characterisation and therapeutic applications of bioconjugate based on cyclic peptides covalently attached to well-controlled polymeric chains. The conjugates assemble into short nanotubes (20 to 200nm) through the stacking of the cyclic peptide motives, with functionality imparted by the polymeric chains. The resulting constructs show remarkable properties in terms of cell penetration, and *in vivo* biodistribution.

9:25 AM SB05.15/SB06.14.06
Graphene-Conductive Ink Coated Laser Engraved Kapton Electrochemical Biosensor for the Detection of Dopamine and Interleukin 6 Dipannita Ghosh[1], Md Ashiqur Rahman[2], Javier Becerril[2], Melanie Suarez[2], Robert Freeman[2], Ali Ashraf[2] and Nazmul Islam[1]; [1]The University of Texas at Rio Grande Valley, United States; [2]University of Texas at Rio Grande Valley, United States

A novel electrochemical biosensor platform based on graphene conductive polyaniline ink and laser-engraved Kapton sensor has been developed for the detection of dopamine and IL-6. Dopamine is an important catecholamine neurotransmitter, and the abnormal concentration of dopamine has been linked to several neurological diseases. IL-6 acts as an important biomarker for prostate cancer detection. We have developed graphene-conductive Polyaniline ink (G-PANI) and laser-engraved Kapton sensor in this work. For the fabrication of the laser engraved sensor, CAD design has been utilized and the parameter of the laser system has been modified. We have used silver ink as contact pads and Autolab Potentiostat for the electrochemical analysis. Due to the superior electrical conductivity, graphene is an appealing sensing material. Conductive Polymers coupled with graphene exhibit better conductivity, tunable surface properties, superior biocompatibility, and stability. Polyaniline incorporated in graphene improves solubility in aqueous solutions and shows improved conductivity and stability. Doping with acids enhances and improves the electroactive behavior of Polyaniline, and so we have created a homogenous mixture of phytic acid, polyaniline, and graphene with a planetary mixer. The SEM images depict that the surface of G-PANI is smoother with the nanoporous structure with around 1 μm diameter. To evaluate the effectiveness of the developed electrode in detecting dopamine and IL-6, we have investigated electrochemical techniques (Cyclic voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS)) with Fe^{2+}/Fe^{3+} redox pair. The Nyquist plots obtained from EIS are almost perfect semicircles (a characteristic of non-diffusion-limited electrochemical processes), with the diameter substantially dependent on charge transfer resistance(R_{ct}). The diameter of the Nyquist semicircle decreases with the increase of conductivity of the electrode surface and a shift to lower R_{ct} values. From the obtained equivalent circuit, G-PANI ink has a very low Rct value (13.5Ω), compared to the unmodified one (58.7 kΩ). We have analyzed the sensitivity of our proposed inks by using Cyclic Voltammetry with 3 μM dopamine in a basic medium (pH 7.4) with a scan rate of 0.08 V s^{-1}. The anodic peak current of the cyclic voltammograms (CVs) is 22.17 times higher than the unmodified laser-engraved Kapton sensor. The limit of detection (LOD) of the unmodified and modified sensor has been calculated over the range from 0.5 µM to 5µM dopamine. The G-PANI modified sensor has a much lower LOD (0.4084 µM) compared to the unmodified one (1.441 µM). The calibration curve shows a linear relationship (R^2 =0.99832 for G-PANI modified Kapton sensor) between the anodic peak current (I_{PA}) and dopamine concentrations. The sensor has been mildly oxidized by ozonolysis for about 30 sec to introduce -COO- groups for the immobilization. The equivalent circuit obtained from the EIS spectra has a higher Rct (1.87 kΩ) after ozonolysis, due to the inhibition of the electron transfer between the modified electrode and the negatively charged redox species. After IL-6 antibody immobilization, R_{ct} increased (12.5 kΩ) because IL-6 antibody film acts as a kinetic barrier for the electron transfer of the redox marker. Under optimal analysis settings, the analytical performance of the G-PANI modified Kapton sensor is tested in the presence of varying amounts of IL- 6 antigens utilizing EIS methods (frequency range 10 kHz to 10^6 kHz). The limit of detection for IL-6 antigen detection was 62.1283 pg/ml. In the future, we will be working on developing flexible paper-based electrochemical sensors for environmental estrogen detection.

Designing Bioinspired Materials for Therapeutics and Biosensin Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our work in the design of self-assembled, functionalised peptide and protein nanoparticles, hydrogels and bio-interfaces for applications in healthcare. These hybrid materials are of growing importance with potential applications including drug delivery and disease detection. We are developing high-throughput synthesis techniques to diversify peptide libraries and quickly survey properties of interest such as fluorescence and supramolecular behaviour [1]. Using molecular dynamics simulation, we can rationalise the different self-assembly behaviours across length scales and to understand the interplay of membrane-curvature and nanotopography at the biointerfaces to aid in the development of cell-active substrates [2]. With the design of peptide-polymer hybrid hydrogels, we are incorporating tailorable mechanical properties to self-healing injectable scaffolds with exciting applications in regenerative medicine [3]. We are exploiting the sensing capabilities of functionalised nanoparticles to engineer nanoprobes for in vivo disease diagnostics that produce a colorimetric response ideal for naked eye read-out [4] and for CRISPR-based preamplification free detection of ncRNAs (CrisprZyme) [5]. I will talk about how we integrate our portfolio of nanoparticle-based sensing probes for diagnosing and monitoring infectious and non-communicable diseases with integration to smartphone technology for mHealth approaches [6]. This talk will also provide an overview of our recent advances in Raman spectroscopy-based characterisation techniques for tracking the functionalisation in single nanoparticles [7]. Finally, I will discuss how we are actively engaging in efforts towards the democratisation of healthcare innovations [8].

11:00 AM SB05.14/SB06.13.02
Culturing and Characterization of Primary Corneal Epithelial Cells on PGS Films for Cornea Tissue Engineering Sevilay Sahin[1,2], Ebru Demir[1,2], Kamal Asadipakdel[1,2] and Sibel Cetinel[1,2,3]; [1]Sabanci University Nanotechnology Research and Application Center, Turkey; [2]TUBITAK, Turkey; [3]Sabanci University, Turkey

The cornea is the transparent, avascular, watch-glass-shaped tissue at the outermost part of the eye. It is effective in good vision as it allows the light coming into the eye to be transmitted to the lens. The cornea consists of five distinct layers, which are the epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The epithelium layer is the outermost layer of the cornea and is in direct contact with the outer environment. It has important functions such as water intake from tear and protection of the cornea from external factors. The corneal epithelium layer consists of 5-7 layers of corneal epithelial cells connected by tight junctions. Thus, selectivity is ensured in the intake of water and minerals from outside. The limbal epithelial stem cells in the limbus layer, which are located next to the cornea differentiate, and form corneal epithelium. By this stem cell source, corneal epithelium layer can be regenerated. The corneal epithelium is located on a thin layer consisted of collagen fibrils called Bowman's membrane. Bowman's membrane is a cell-free corneal layer and does not regenerate. Due to reasons such as keratoplasty being the only treatment method for corneal diseases, limited donor for transplantation and high donor age, corneal tissue engineering studies are of great importance.
In this study, it was aimed to mimic the corneal epithelium layer. Accordingly, corneal epithelial cells immortalized after being isolated from the human donor cornea were cultured on PGS films. The most suitable PGS films produced by different length pre-polymers were selected and the ability of the cells to show their properties on Bowman's membrane was examined. According to the MTS assay results, PGS membrane with longer pre-polymer chains provided better corneal epithelial viability. In addition to this, cytokeratin-3, which is the main corneal epithelial marker, was expressed in higher amounts in the cells cultured on PGS membrane produced with longer pre-polymers. This study presents a recent innovation for cornea tissue engineering and makes a significant contribution to the literature.

This work is funded by 2232 International Fellowship for Outstanding Researchers Program of TUBITAK (Grant number 118C371). The funder had no role in study design, data collection or analysis, the decision to publish, or the preparation of this abstract.

11:05 AM *SB05.14/SB06.13.03
Plasmonic and Magnetic Nanoparticles for Biomedical Application Nguyen T. Thanh; Univ College London, United Kingdom

The development of new chemical methods for the next generation of nanoparticles with very high magnetic moment, fine tuning Au nanorods and novel hybrid and multifunctional nanostructure is presented.
Detailed mechanistic studies of their formation by sophisticated and advanced analysis of the nanostructure allows tuning of the physical properties at the nanoscale; these can subsequently be exploited for diagnosis and treatment of various diseases. The studies are conducted to provide insight for future material design approaches. It will also help to identify the critical process parameters that can be manipulated in order to obtain the suitable physical properties for the intended applications.

Commercializing Nano Implants—Real Human Clinical Evidence of Success in the Spine Tom Webster[1,2,3]; [1]Hebei University of Technology, China; [2]Saveetha University, India; [3]UFPI, Brazil

The incorporation of nanotechnology into medicine (termed nanomedicine) has often been criticized for a lack of human clinical translation. While numerous studies have shown the ability of nanomaterials to improve tissue growth (such as bone, cartilage, nervous system tissue, etc.), fight infection, limit inflammation, and kill tumors in in vitro or animal studies, it has been largely speculated that few nanomaterials have been commercialized into real products helping human health. This talk will show for the first time human data in which spinal implants were modified to possess nanotextures and have been implanted into humans over the past 5 years. Impressively, out of approximately 14,000 patients, there have been no cases of implant failure including no cases on implant infection. Mechanistic studies have demonstrated that nanotextured implants not only mimic the natural roughness of bone itself but also possess altered surface energy to adsorb endogenous proteins known to promote osteoblast (bone forming cell) functions while inihibiting bacteria functions. Such results represent some of the only results available demonstrating the successful use of nanotextured spinal implants in humans and further demonstrate that bacteria infection can be stopped through the use of nanotextures alone, and not antibiotics which are causing the emergence of harmful antibiotic resistance bacteria.

10:30 AM *SB05.16/SB06.15.01
The Coming of Age of De Novo Protein Design David Baker; University of Washington, United States

Proteins mediate the critical processes of life and beautifully solve the challenges faced during evolution. Our goal is to design a new generation of proteins that address current-day problems not faced during evolution. In contrast to traditional protein engineering efforts, which have focused on modifying naturally occurring proteins, we design new proteins from scratch to optimally solve the problem at hand. We now use two approaches. First, guided by Anfinsen's principle that proteins fold to their global free energy minimum, we use the physically based Rosetta method to compute sequences for which the desired target structure has the lowest energy. Second, we use deep learning methods to design sequences predicted to fold to the desired structures. In both cases, we produce synthetic genes encoding these novel protein sequences and characterize them experimentally. In this talk, I will describe recent achievements in de novo protein design, including the development of novel self-assembling protein nanomaterials. I will also highlight RFdiffusion, a powerful new guided diffusion model that generates proteins in a manner similar to the popular image-generating tool DALL-E.

11:00 AM SB05.16/SB06.15.02
Effect of Charge on Molecular Self-Assembly, Nanoscopic and Bulk Material Properties of Ultra-Short Peptides Mohamed A. Soliman[1], Abdulwahhab Khedr[1], Charlotte J. Edwards-Gayle[2], Jacek K. Wychowaniec[3] and Mohamed Elsawy[1]; [1]De Montfort University, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]AO Research Institute Davos, Switzerland

Bioinspired *de novo* self-assembling peptides have been widely used for the development of soft biomaterials for a wide variety of biomedical and pharmaceutical applications, such as cell scaffolding for tissue engineering[1], controlled and localised drug delivery[2], biosensing[3], and many others. The meticulous control of peptide-based nanomaterial properties over the length scale, by molecular design, remains the main challenge for tailoring biomaterials properties to meet the application needs. In our group, we have recently adopted a minimalistic molecular engineering approach for the development of Ultrashort Ionic-complementary Constrained Peptides (UICPs), which were rationally designed to self-assemble into amphiphilic β-sheet nanofibers with unique hydrogelation properties and surface activity.[4] We have previously demonstrated the crucial role played by aromatic stacking for the formation and thermodynamic stabilisation of UICP β-sheet structures. Herein, we will show how charge interactions can be manipulated for fine tuning molecular self-assembly, morphology and size of nanofibrous structures formation and viscoelasticity of UICP hydrogels.

A library of 18 peptide sequences (4-5 residues long) was developed to study the effect of the sequence net charge, charge density distribution, reversal of charge order and ionic self-complementarity on their propensity towards self-assembly and gelation. Interestingly, 12 of these peptides self-assembled into β-sheet nanofibrous structures forming hydrogels at pH 4.5-5, as confirmed by ATR-FTIR, SEM, TEM, SAXS and oscillatory rheology. Full control over β-sheet content (ranging from ~30-80%), fibre morphology (thin fibrils, thick straight fibre bundles, twisted helical nanofibres, flat nanoribbons and nanotubes) and sizes (~4-67 nm in diameter), as well as gelation (critical gelation concentrations ranging from ≤7.5 to ≥100 mM) and viscoelastic properties (storage moduli G' ~0.1-100 KPa) was achieved by the careful positioning of both Glu and Lys residues at both C- and N-termini, in the sequence core and on both the hydrophilic and hydrophobic faces of the peptide chain. In essence, this design approach enabled/disabled lateral growth along the β-sheet ladder via electrostatic attraction (counter charge, anion-pi and cation-pi)/repulsion, hence controlling fibre thickness, morphology, entanglement, and the resulting viscoelasticity of the system. Our UICPs platform thus provides the flexibility in peptide molecular design for the manufacturing of soft biomaterials with versatile properties that can be in future tailored to the relevant biomedical application.

Co-Assembling Ultra-Short Ionic Complementary Peptide Emulgels for Controlled Delivery of Combination Anticancer Therapy for Glioblastoma Abdulwahhab Khedr[1,2], Mohamed A. Soliman[1,3] and Mohamed Elsawy[1]; [1]De Montfort University, United Kingdom; [2]Zagazig University, Egypt; [3]Cairo University, Egypt

INTRODUCTION

Assembling peptides represent a versatile chemical toolbox for the development of soft shear thinning nanomaterials exploited for a variety of biomedical applications. Herein, we developed two *de novo* ultra-short ionic co-complementary peptide sequences (5 amino acids long, each) capable of co-assembly into β-sheet nanofibers, immediately forming hydrogels upon mixing the countercharge peptide solutions. These peptides were designed based on the tetrapeptide Phg4.[1] These are the cationic peptide KPhg4 and the anionic counterpart $E(Phg4)^{Rev}$, in which the charged residues are alternating with phenylglycine (Phg) and distributed in a pattern conferring a charge co-complementarity between both sequences. Both peptides were characterized for molecular assembly and hydrogelation at the physiological pH 7.4, both individually and in combination where co-assembly into nanofibres is induced through counter charge interaction. Also, these biomaterials were used for emulsifying pharmaceutical oils, forming O/W emulsion hydrogels (emulgels). These dual-phase systems were used for loading both hydrophilic and hydrophobic anticancer drugs for sustained localised drug delivery against human malignant glioblastoma U87 MG cells.

EXPERIMENTAL METHODS

1. Emulgel formation: Peptide solutions were mixed at different molar ratios, pH and total peptide concentrations and at different O:W ratios. **2. ATR-FTIR spectroscopy:** Characterisation of peptides' secondary structures. **3. Thioflavin T assay:** Quantification of β-sheet secondary structures and for co-assembly kinetics. **4. Oscillatory rheology:** Characterisation of gels viscoelastic properties. **5. Scanning electron microscopy (SEM):** Characterisation of the emulgel's network and vesicular structures. **6. Transmission electron microscopy (TEM):** Characterisation of nanostructures morphology. **7. *In vitro* drug release. 8. Cell culture and cell viability assay:** Cytotoxicity assay of emulgels and drug-loaded emulgels against U87 cells.

RESULTS & DISCUSSION

Individual peptides neither self-assembled into β-sheet structures nor formed hydrogels at the physiological pH over a wide range of peptide concentrations. Mixing counter charge peptide solutions at pH 7.4 spontaneously formed self-supported hydrogels over a wide range of peptides molar ratios (1:9-9:1) of total peptide concentrations 10-50 mg/mL. The highest abundance of β-sheets was observed for mixtures prepared at and around the equimolar ratio with fast rate of co-assembly (equilibrium within 1 hour after mixing). Also, these peptide mixtures showed a unique surface activity, forming O/W emulsions when mixed with oily phase at 5-50 mg/mL peptide concentration and different O:W ratios (2:8-8:2). Oscillatory rheology showed that gel stiffness is controllable by fine-tuning molar ratios of peptide components. SEM showed the formation of microspheres (15-60 µm diameter) within the gel nanofibrous network for all formulations, with fibres diameter estimated using TEM. Plain gels with a net positive charge (high cationic to anionic peptide molar ratio) showed significant cytotoxicity against U87 cells. In addition, the hydrophilic anticancer drug; vincristine sulfate, loaded into the emulgel aqueous phase showed sustained drug release profiles over 96 hours with improved cytotoxicity against U87 cells. These results suggest that the physico-mechanical properties, drug loading capacity and cytotoxicity of these systems are dependent on pH, peptides molar ratio, total peptide concentration and O:W ratio, which in turn will have a direct effect on emulgel's anticancer activity.

CONCLUSIONS

In conclusion, these emulgels showed that the mesoscopic and bulk mechanical properties and cytotoxicity can be tuned by molecular design, pH, peptide concentration, and molar ratio and O:W ratio control, to develop biomaterials that can satisfy the needs of combination anticancer therapy.

Self-Assembling Peptide Nanofiber Hydrogel as 3D Scaffolds for Corneal Stromal Cells Ebru Demir, Sevilay Sahin and Sibel Cetinel; Sabanci University, Turkey

The leading causes of corneal damage are keratoconus, Fuchs endothelial dystrophy, keratoconus, and corneal ulceration. Once corneal damage causes visual impairment or blindness, cornea transplantation is the best treatment option to restore vision. Corneal tissue engineering provides an alternative to corneal transplantation to overcome limited donor tissue availability and drawbacks of transplantation. However, the complex mechanical, structural, and optical properties of the cornea make tissue engineering a challenging application. The expected properties of a corneal tissue-engineered scaffold include water permeability, optical transparency, and mechanical strength along with biodegradability, biocompatibility, and porosity. Some of these properties such as superior optical transparency and biocompatibility can be provided by peptide-based hydrogels. In this study, two different self-assembled peptide hydrogels are investigated for corneal stromal tissue engineering. Both MAX8 and RADA16-I peptides convert into β-sheet-forming hydrogels at high ionic strength and physiological pH. <div>Additionally, MAX8 peptides are modified with three different peptide ligands to enhance cell adhesion and inhibit neovascularization in the scaffold during stromal regeneration. The peptide hydrogels demonstrated proper optical transparency between %90 and %100 and refractivity of 1,337 mimicking natural corneas while maintaining 3D structure for corneal stromal cell proliferation. Hydrogels made up of MAX8 exhibited 40 ±1 Pa, 35,68 Pa, and 78,20 Pa average crossover modulus with different biomarker ligands and RADA8 showed similar results. The gel recovery was also observed after 10 µN constant shear stresses were applied to both hydrogels. On the other hand, human stromal keratocytes continued expressing cell-specific markers, collagen-I and keratocan, in both hydrogel formulations indicating their potential applicability.

Antimicrobial Activity of β-Sheet Forming Ultra-Short *De Novo* Ionic-Complementary Peptides Towards Wound Infections Mohamed A. Soliman[1,2], Abdulwahhab Khedr[1,3], Raymond Allan[1], Katie Laird[1] and Mohamed Elsawy[1]; [1]De Montfort University, United Kingdom; [2]Faculty of Pharmacy, Cairo University, Egypt; [3]Faculty of Pharmacy, Zagazig University, Egypt

Bacterial resistance is currently compromising the antibiotics activity that saved millions of people in the last 8 decades[1]. Recently, peptide-based hydrogels were introduced as soft, versatile, shear-thinning and thixotropic materials that can be sprayed for topical applications. Thanks to their biocompatibility, biodegradability and physicochemical tunability, peptide hydrogels have a great potential to be used as sprayable antimicrobial biomaterials for treatment of infected wounds. They might also overcome the antibiotic resistance through multi-mechanisms of bacterial killing. So, this work aimed to utilise ultra-short *de novo* ionic-complementary peptide sequences (4 – 5 amino acids) for the development of antimicrobial bionanomaterials based on the peptide self-assembly into β-sheet nanofibers and building networks of hydrogel in response to pH change.

Based on this, Phg4 peptide, previously reported by our group[2] was compared to 2 other Phg4 derivatives (EPhg4 and KPhg4) to investigate the role of charge type and distribution on the self-assembly into β-sheet fibers and hydrogel and whether such modifications could impart antimicrobial activity for the hydrogel. Interestingly, the three peptides self-assembled into β-sheet fibrillar assemblies and entangled to form hydrogels in response to pH change, as revealed from molecular (FTIR) and mesoscopic (SEM and TEM) characterisation. Critical gelation concentration (CGC) was significantly affected by peptide modifications, where it decreased from 37 mM for Phg4 to 15 mM for EPhg4, while KPhg4 showed to have the highest CGC at 75 mM concentration. Oscillatory rheology revealed viscoelasticity of hydrogels formed by the three peptides and ability to recover from shear stress i.e. thixotropic materials implying their sprayability. Hydrogel stiffness varied for the three peptides, with a storage moduli G' of 10 and 93 KPa for Phg4 and EPhg4 at 75 mM, respectively, however KPhg4 appeared as viscous weak gel that did not show linear viscoelasticity.

To investigate the inherent antibacterial activity of the three developed hydrogels, time killing point assays were carried out against the 2 bacterial species commonly responsible for causing wound infections (Methicillin-resistant *S. aureus*, gram positive and *P. aeruginosa*, gram negative). Strikingly, all hydrogels exhibited *in vitro* bactericidal behaviour against planktonic *P. aeruginosa MPAO1* (10^5 CFU/mL) within 2 hours (hrs) besides their ability to prevent *P. aeruginosa* biofilm formation in a concentration dependent killing manner where the higher the peptide concentration, the shorter the time needed for eradication that ranged from 2--8hrs. On the other hand, hydrogels of the three peptides did not show any antimicrobial activity against *MRSA NCTC 10442*, which was also confirmed by observation of bacterial cell morphology using SEM and confocal laser scanning microscopy (CLSM). Phg4-based hydrogel (92 mM) was then selected for further investigations and showed antibacterial activity towards both planktonic and surface population of four different clinical *P. aeruginosa* strains obtained from University Hospital Southampton NHS Foundation Trust in addition to other ESKAPE pathogens (*A. baumannii* 18X50606 and *E. coli* NCTC 8003, *K. Pneumoniae* ATCC 700831).

In conclusion, these ultrashort constrained ionic complementary peptides based on their stable self-assembly could be considered as a promising approach for treating wound infections as well as tackling the bacterial resistance and might be used as biomimetic ECM scaffolds for tissue regeneration at the wound site.

Improving the Efficacy of Neovascular AMD Therapy with Long-Term Drug Delivery Systems Saliha Durak[1,2], Özlem Kutlu[1,2] and Sibel Cetinel[1,2]; [1]Nanotechnology Research and Application Center (SUNUM), Sabanci University, Turkey; [2]Faculty of Engineering and Natural Sciences, Sabanci University, Turkey

Neovascular age-related macular degeneration (nAMD) is a progressive condition that is common in individuals over 50 years of age and cannot be cured in 90% of patients, and is one of the most common causes of blindness affecting more than 200 million people worldwide. Current therapeutic approaches include periodic intravitreal injections of monoclonal antibody-based anti-VEGF (anti-Vascular Endothelial Growth Factor) drugs. In spite of successful progress in neovascular AMD therapy in recent years, anti-VEGF therapies have some limitations such as the high cost and limited half-lives of protein drugs, need for frequent intravitreal injections, intravitreal injection-related complications and inadequate response to some anti-VEGF drugs. Because of these drawbacks, new approaches need to be developed for long-lasting anti-VEGF drug delivery. Peptide drugs offer ease of production and storage,

extended drug shelf life and reduced costs. Currently, a drug using anti-VEGF peptides in the treatment of nAMD is not available and several anti-VEGF peptides in the literature are waiting to be evaluated for their efficacy in nAMD therapy. This project aimed to develop a composite drug delivery system consisting of poly(glycerol sebacate) (PGS) nanoparticles and cross-linked hyaluronic acid hydrogel that reduces the frequency of intravitreal administration by providing sustained release (up to 6 months) of anti-VEGF peptide drugs as a new generation treatment method.
In this study, PGS nanoparticles obtained by solvent evaporation method have high encapsulation efficiency (93,7%) and their size was around 200 nm. HA-DVS crosslinked hydrogel was synthesized by Oxa-Michael addition reaction and successful crosslinking was confirmed by FTIR spectroscopy. Drug delivery system was formed by incubating anti-VEGF peptide loaded PGS nanoparticle solutions with crosslinked HA-DVS hydrogel to have 25% (v/v). The *in-vitro* drug release from drug delivery system was less than 20% in the first month, consistent with the targeted long-term release profile. It was demonstrated by calculating cell viability that the anti-VEGF peptide loaded drug delivery system does not cause cytotoxic effects on human retinal pigmented epithelial (ARPE-19) cells for up to 72 hours. The inhibition effect of anti-VEGF peptide on angiogenesis was determined by calculating cell viability and examining tube formation by incubating human umbilical vein endothelial cells (HUVEC) with anti-VEGF peptide-loaded drug delivery system.
Developing new generation biomaterials for the storage and preservation of therapeutic peptides and improving their bioavailability with prolonged release will significantly improve the efficiency of long-term treatment strategies for neovascular AMD.

Versatile Use of Tyramine-Modified Self-Assembling β-Sheet Peptides and Hyaluronic Acid Hydrogels—From Design and 3D Printing to Immunomodulation Jacek K. Wychowaniec[1], Ezgi I. Bektas[1], Andrea J. Vernengo[1], Charlotte J. Edwards-Gayle[2], Marcia Mürner[1,3], David Eglin[4] and Matteo D'Este[1]; [1]AO Research Institute Davos (ARI) | AO Foundation, Switzerland; [2]Diamond Light Source, United Kingdom; [3]ETH Zürich, Switzerland; [4]Mines Saint-Étienne, France

Multifunctional biomaterials which exhibit well-defined physicochemical properties and encode spatiotemporally controlled biological signals have the potential to act as next generation advanced systems modulating cellular behaviour. Within tissue regeneration field one of the commonly arising themes is impaired regeneration associated with the compromised immune system.[1] One solution to tackle this issue is to design immunomodulatory biomaterials that temporally control the overall level of inflammation.[1] For example, it has been shown that molecular weight of hyaluronic acid (HA) directly influences the polarization state of macrophages.[2] Designing functional materials that incorporate immunomodulatory effects, biocompatibility and that allow stable long-term polarization of macrophages is therefore of high interest in tissue engineering and 3D bioprinting.[1]
Self-assembling β-sheet forming peptides and tyramine-modified HA (THA) are two examples of biopolymers that have been shown as vital biomaterials spanning advanced cell culture systems up to effective minimally complex microenvironments for the generation of organoids.[3, 4] The role of these materials interfacing immune cells is not yet fully uncovered, therefore here we designed a selection of hydrogels built from self-assembling β-sheet forming peptides[5] and THA,[6] that can be processed by 3D micro-extrusion printing. A selection of peptide sequences was based on the alternation of hydrophobic and hydrophilic amino acids: **DABACABACD** (**A**: hydrophobic residue: **F** phenylalanine or **Y** tyrosine, **B**/**C**: hydrophilic residue e.g.: **K** lysine or **E** glutamic acid). THA of two molecular weights (280 kDa and 1640 kDa) were synthesized as previously described.[6]
A parametric study was carried out on the designed selection of **DABACABACD** peptides to verify the effect of rational peptide sequence modification on final physicochemical properties of peptide alone and peptide-THA composite hydrogels. **D** residues were rationally varied between hydrophobic (**Y**) or hydrophilic (**E**) amino acids to modulate the interactions' ability of formed β-sheet edges and shell with other peptide fibres and THA. All parental peptides self-assembled into semi-flexible networks and hydrogels above critical gelation concentration in the region of 2.5-5 mM and display characteristic high β-sheet content. Self-assembly, rheological properties and printability of both peptide and peptide-THA hydrogels can be controlled by the choice of primary peptide sequence, fabrication technique and final crosslinking mechanisms including enzymatic (horseradish peroxidase, H_2O_2) and visible green light crosslinking using Eosin. For the first time we also demonstrate the polarization effects of the supplemented THA on macrophages differentiated from human peripheral blood mononuclear cells over 5 days. M1 and M2 polarization modulated by the supplementation with low and high molecular weight THA were unravelled by the semi-automated image analysis from confocal microscopy, gene expression analysis and ELISA.
In summary here we uncover the link between basic molecular interactions driving self-assembly of functional tyramine modified peptide-based and hyualuronic acid-based biomaterials and demonstrate their capabilities as extrudable platforms for immunomodulatory tissue engineering.

Peptide-Enabled Design of Therapeutic Supramolecular Polymers Honggang Cui; Johns Hopkins University, United States

The physicochemical, biological, and responsive features of supramolecular polymers (SPs) enable their unique applications in many biomedical settings. By leveraging the assembling and biological features of short peptides, we have developed a class of therapeutic supramolecular polymers that are formed by self-assembly of rationally designed peptide-drug conjugates. Depending upon the drug's intrinsic assembling potential and its water solubility, various peptide designs were adopted to promote the drug's association into discrete supramolecular polymers that could further entangle into hydrogels. Our results suggest that the critical micellization concentration of an individual SP has a significant impact on their biodistribution and pharmacological behavior for systemic delivery, which is reflected in the maximum tolerated dose, tumor accumulation, toxicity, and eventually the therapeutic efficacy in suppressing tumor growth. On the other hand, the drug-based supramolecular hydrogel can be used for the local delivery and sustainable release of immune-modulating agents, and this localized chemoimmunotherapy hydrogel offers great potential to augment antitumor immune response and to sensitize tumors to immunotherapies in a safe and effective manner.

3D Printed Hydrogels: Engineering the Properties and Performance via Side Chain Design of Block Co-Polypeptides Stars Ronnie V. Garcia, Elizabeth Murphy, Nairiti Sinha, Yoichi Okayama, Robert Murphy, Matthew E. Helgeson, Javier Read de Alaniz and Craig Hawker; University of California, Santa Barbara, United States

Polypeptide-based hydrogels are of increasing importance due to their intrinsic biodegradability and tunable functionality that make them desirable for biological applications. While mechanical stability and shear processing properties has been demonstrated in many extrusion-based applications, ranging from injectable therapeutic carriers to recent 3D printing of living materials, probing the relationship between polypeptide structure and self-assembly has not been well studied. Herein we describe the synthesis and properties of a library of amphiphilic block-co-polypeptide stars with various canonical and non-canonical amino acid building blocks. Structure-function relationships were characterized using various rheological and scattering techniques to elucidate design rules for 3D printing. Significantly, non-natural amino acid building blocks were observed to form more stable networks with superior material properties compared to their natural analogs. The rational design of these materials provides a novel strategy for accessing tunable material properties based on molecular design that further expand the palette of 3D printable biomaterials.

11:15 AM *SB06.01.03
Controlled Assembly of Sequence-Defined Peptoids into Hierarchical Materials Chun-Long Chen; Pacific Northwest National Laboratory, United States

As one of the most common and well-developed peptidomimetics, peptoids have recently received increasing attention for the design and synthesis of functional materials with hierarchical structures.[1] Due to the unique proteinase-resistance, chemical and thermal stabilities of peptoids, peptoid-based nanomaterials are promising candidates for applications in photonics,[2, 3] flexible electronics,[4] and biological systems.[2, 3, 5] Recently, by designing amphiphilic peptoids that contain aromatic hydrophobic domains, our team recently reported their self-assembly into highly crystalline membrane-mimetic 2D nanosheets[2, 6] and 1D nanotubes,[7] we demonstrated that these peptoid materials are highly stable and a wide range of functional groups can be precisely placed within these materials to achieve programmable functions. To gain a better understanding of their formation mechanisms of these biomimetic materials, herein, I will report our recent discovery of designing short peptoid oligomers for controlled assembly into twisted nanoribbons, helices, along with nanosheets and nanotubes. Mechanistic studies using X-ray diffraction, AFM, TEM combined with computational simulations indicate the asymmetric packing of amphiphilic peptoids is the main driving force that leads to the formation of twisted nanoribbons and nanohelices. Tuning hydrophilic side chain chemistry, the number of hydrophobic side chains, and the solution pH can significantly influence the peptoid assembly pathways and dynamics for the formation of hierarchical materials with designed morphologies.

11:45 AM SB06.04.03
Spontaneous Alignment of Self-Assembled Cationic and Amphiphilic β-Sheet Peptides Gal Yosefi, Hanna Rapaport and Ronit Bitton; Ben-Gurion University of the Negev, Israel

Many of the bio-functionalities in living systems rely upon the alignment of the tissue (e.g., bones, heart, and spinal cord); hence aligned materials are very attractive for biomedical applications such as scaffold creation for tissue engineering. Scaffolds composed of self-assembling peptides offer biocompatibility and the versatility necessary to create tailor-made materials. Yet, utilizing the material's ability to self-assemble to create an aligned material without the application of external stimuli is still a challenge.
Here we present a novel material based on amphiphilic and charged β-sheet peptide (Pro-Lys-(Phe-Lys)$_5$-Pro) that undergoes a spontaneous time-dependent isotropic–nematic phase transition in an aqueous solution without the need for any external force.
This natural, timely orientation of the peptide fibrils in an aqueous solution, confirmed by small angle x-ray scattering and cryo-transmission electron microscopy, creates a highly dynamic system, for which the degree of alignment and the time required to achieve a complete isotropic–nematic phase transition is found to be concentration dependent and can be predicted by a model based on Onsager's excluded volume theory. Remarkably, the nematic phases remain aligned over the course of several months without the application of any external stimuli and can be cross-linked to form aligned gels by mild shearing through a salty medium.
This spontaneously aligned peptide-based material offers a novel platform for various biomedical applications such as bio-sensors, tissue engineering scaffolds, or drug delivery vehicles.

SESSION SB06.02: Biomedical Applications of Peptide and Protein-Based Materials I

Peptide-Based Functional Coatings and Assemblies That Resist Bacteria, Viruses and Fungi Meital Reches; The Hebrew University, Israel

The lecture will present bio-inspired functional coatings and assemblies that are spontaneously formed by short peptides. These peptide-based coatings self-assemble on either biotic or abiotic surfaces under mild conditions without any need for a curing step. The coating can serve many functions. One application is preventing biofouling - the undesirable adhesion of biomolecules and organisms to surfaces. This process leads to numerous adverse phenomena including hospital-acquired infection, blockage of water desalination facilities, and food contamination. We showed that this coating prevents the first step of biofouling, which involves the adsorption of bioorganic molecules to the substrate. Moreover, the coating significantly reduces the attachment of various organisms to surfaces. Another function that these peptide-based coatings can mediate is the adhesion of mammalian cells to implants. This function is important for the integration of implants into the human body. Finally, we showed that these peptides self-assemble in solution into particles that can be incorporated into polymeric films by co-extrusion and act to reduce the number of bacteria, fungi, and viruses on the surface.

2:00 PM SB06.02.02
Ultrashort Peptides as Versatile Materials for Biomedical Applications—From Scaffolds for 3D Cell Culture to Strong Adhesives. Panagiotis Bilalis, Abdulelah Alrashoudi, Hepi Susapto, Manola Moretti, Salwa Alshehri, Sherin Abdelrahman and Charlotte A.E. Hauser; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Ultrashort amphiphilic peptides with a characteristic sequence motif and containing up to seven natural amino acids exhibit self-assembling dynamic behaviours under physiological conditions. Despite their small size, they can form α-helical, β-sheet and β-turn secondary structures in aqueous solutions. At higher concentrations, they form nanofibers, leading to hydrogels with a very high content of water (>99%w/w). These hydrogels are biocompatible, biodegradable, and generally non-immunogenic and can find applications as 3D cell culture substrates, bioinks for 3D bioprinting, hemostatic agents, drug delivery systems, materials for soft tissue repair and others. Inspired by nature and particularly by the mussel's foot proteins that consist of a high content of a modified amino acid, 3,4-dihydroxy-L-phenylalanine (L-DOPA) and by introducing L-DOPA to the ultrashort peptide sequence, we successfully developed hydrogels with adhesive properties for wet environments, while keeping the characteristics of self-assembly. Moving a step forward by introducing a polymerizable group to the peptide sequence, we were able to crosslink the peptide-derived supramolecular structures to covalent polymeric networks. Toward this direction, we synthesized a peptide with catechol moieties and more than one vinyl group to act as a crosslinker. An aqueous mixture of our polymerizable peptide, the crosslinker and a water-soluble photoinitiator can be polymerized instantly under a LED light source to give a strong adhesive. This peptide-based glue cannot only glue objects that weigh more than two kilos but, most importantly can be applied under water. This type of adhesive peptide materials can be used for wound healing, as surgical adhesive glues, and in today's ecological challenges like coral reef restoration.

2:15 PM SB06.03.03
3D Bioprinting of Graphene Oxide-Incorporated Hydrogels for Neural Tissue Regeneration Jiahui Lai and Min Wang; The University of Hong Kong, Hong Kong

Hydrogels, especially natural hydrogels, have often been used for 3D bioprinting due to their numerous advantages, including excellent biocompatibility, biodegradability and similarity to natural extracellular matrix. However, natural hydrogels have shortcomings for 3D bioprinting, such as poor printability and very weak mechanical strength of printed structures. The incorporation of an additive (e.g., cellulose nanofibers, nanoclay particles, etc.) is an effective strategy to improve the performance (including mechanical performance) of natural hydrogels and may expand their potential applications in tissue engineering. The nervous system in human bodies is important as it regulates physiological functions and controls body activities. The native neural tissue is relatively soft and is sensitive to electrical stimulation. Therefore, materials used for neural tissue engineering should be soft and preferably have certain electrical conductivity. Owing to its good electron mobility and high surface-to-volume ratio, graphene oxidase (GO) is a promising material for creating electroactive hydrogels. Gelatin is a natural hydrogel obtained by denaturalization of collagen. It has intrinsic Arg-Gly-Asp (RGD) motifs and accessible active groups, which is desirable for tissue regeneration applications. However, gelatin alone is rarely used for 3D bioprinting because it is in the liquid state at 37 °C and hence cannot maintain the shape of a printed structure during its use in the body. Gelatin methacryloyl (GelMA) is a photocrosslinkable hydrogel that is derived from gelatin with the methacryloyl modification. After crosslinking, GelMA can maintain the shape of the printed structure. In this study, a natural hydrogel-based bioink (GO/Gelatin/GelMA) was developed by combining GO, gelatin, and GelMA, with the aim of obtaining a hydrogel with photocrosslinking ability, relatively soft nature, and improved electroactive properties. The performance of GO/Gelatin/GelMA composite hydrogels with different GO contents [0 ~ 0.1% (w/v)] was investigated in terms of microstructure, mechanical properties, degradation behavior, and water absorption properties. It was found that a low concentration of GO in the composite hydrogel had little effect on the microstructure of hydrogels, improved the mechanical strength slightly (but still at a kPa level), reduced the degradation rate, and increased water absorption. The electrical conductivity of GO/Gelatin/GelMA composite hydrogels was enhanced with the increasing GO contents. The printability of GO/Gelatin/GelMA composite hydrogels was studied by printing out multi-layered grid structures using a pneumatic extrusion-type 3D printer. It was observed that GO/Gelatin/GelMA hydrogels formed smooth filaments after extrusion and could be printed into 10-layer grids with good shape fidelity. After crosslinking, the printed grid structures could maintain their shapes and be held by hand without collapsing. Finally, neural cells (i.e., astrocytes) were added into GO/Gelatin/GelMA hydrogels to form bioinks for 3D bioprinting. It was found that astrocytes maintained high cell viability after bioprinting and grew well after culturing of the scaffolds for several days. The GO-incorporated gelatin/GelMA hydrogels have shown good biocompatibility, biodegradability, good printability, balanced softness and improved electroactivity, suggesting their high potential for 3D bioprinting, as well as applications in neural tissue regeneration.

2:30 PM SB06.02.04
DNA Origami Directed Virus Capsid Polymorphism Mauri Kostiainen; Aalto University, Finland

Most known viruses protect their genome by encapsulating it inside a protein capsid. Viral capsids can adopt various geometries, most iconically characterized by icosahedral or helical symmetries. The assembly process of native capsids is highly cooperative and governed by the protein geometry, protein-protein as well as protein-nucleic acid interactions. Importantly, the absolute control over the size and shape of virus capsids would have imminent advantages in the development of new vaccines and delivery systems. However, tools to direct the assembly process in a programmable manner are exceedingly elusive or strictly limited to specific structures. Here, we introduce a modular approach by demonstrating DNA origami directed polymorphism of single protein subunit capsids. We achieve control over the capsid shape, size, and topology by employing user-defined DNA origami nanostructures as binding and assembly platforms for the capsid proteins. Binding assays and single-particle cryo-electron microscopy reconstruction show that the DNA origami nanoshapes are efficiently encapsulated within the capsid. Further, we observe that helical arrangement of hexameric capsomers is the preferred mode of packing, while a negative curvature of the origami structure is not well tolerated. The capsid proteins assemble on DNA origami in single or double layer configurations depending on the applied stoichiometry. In addition, the obtained viral capsid coatings are able to efficiently shield the encapsulated DNA origami from nuclease degradation and prevent the structures from aggregation. Therefore, these findings may in addition find direct implementations in DNA nanotechnology-based bioengineering by paving the way for the next-generation cargo protection and targeting strategies.

Protein-Engineered, Dynamic Hydrogel Bioinks for 3D Bioprinting Sarah C. Heilshorn and Lucia G. Brunel; Stanford University, United States

3D bioprinting has emerged as a promising tool for spatially patterning cells to fabricate models of human tissue. To date, most bioinks have been formulated with a focus on printability, while often overlooking the cell-interactive properties of the material. Here, we present a protein-engineered bioink material designed to have viscoelastic mechanical behavior, similar to living tissue. This viscoelastic bioink is composed of an engineered protein and a recombinant polysaccharide that are crosslinked through dynamic covalent bonds, a reversible bond type that allows for cellular remodeling over time. Viscoelastic materials are challenging to use as inks, as one must tune the kinetics of the dynamic crosslinks to allow for both extrudability and long-term stability of the printed structure. We overcome this challenge through the temporary use of small molecule catalysts and competitors that modulate the crosslinking kinetics and degree of network formation. These inks are used to print a model of breast cancer cell invasion, where the inclusion of dynamic crosslinks was required to allow cell invasion. Altogether, we demonstrate the power of protein-engineered, dynamic bioinks to recapitulate the native cellular microenvironment.

4:00 PM SB06.03.02
3D-Printing Biopolymer Gels with an Electric Field—A Simple Route that Avoids Nozzles, Heat and UV Light Wenhao Xu and Srinivasa R. Raghavan; University of Maryland, College Park, United States

3D-printing of hydrogels has attracted great interest in recent years. In particular, gels of biopolymers such as proteins (e.g., gelatin) or polysaccharides (e.g., alginate) are used to encapsulate cells, and these can serve as scaffolds for tissue engineering. The promise of 3D-bioprinting lies in custom-printing a body part, potentially using a patient's own cells. However, current 3D-bioprinting is a cumbersome operation that requires a large 'printer' and expensive 'inks'. The inks, i.e., suspensions of cells in a pre-polymer, are typically pumped through fine nozzles in the printer. As soon as drops of this suspension emerge out of the nozzle, they are converted into gels by heat or UV light. By rastering the nozzle in 3D, a solid gel is built from the ground up (in layer-by-layer fashion) in a desired shape. Issues with this approach include the fact that the use of high shear (in the nozzle) or UV light can damage sensitive cells. Moreover, conventional 3D-bioprinting is slow and requires hours to create a custom part.

Here, we introduce an alternative method for 3D-printing gels of biopolymers such as alginate. Our method uses moderate electric fields (DC voltages around 5 to 15 V) and a solution of the above biopolymer. The central idea is that the biopolymer is gelled at a precise location by applying the electric field through fine metal electrodes. By moving the electrode(s) in 3D space using an externally controlled XYZ stage, we can build a gel in a specific shape. A gel that is 2 to 3 cm tall can be formed in a matter of minutes with our technique. The gel is also highly robust and it can be lifted out of the solution and manipulated by hand within seconds after the printing is complete. Layered gels with different internal contents can be readily created by this technique. Thus, this electro-gelation strategy could serve as a rapid, inexpensive, and powerful alternative to conventional 3D-printing of hydrogels.

4:15 PM *SB06.03.04
Bioinspired 3D-Hydrogels for Bone-Tissue Regeneration Lihi Abramovich; Tel Aviv University, Israel

Bone is a highly regenerative tissue, thus in young individuals, most fractures are spontaneously healed. Yet, in cases of large bone defects, as observed after bone tumor resections, severe fractures, or inflammatory diseases, the template for orchestrated regeneration is lacking. Therefore, reconstruction of bone defects continues to be an enormous clinical challenge. Although autogenic, allogeneic, and xenogeneic bone materials have been widely applied to treat such defects, they possess potential limitations, including limited availability and donor site morbidity, potential immunogenicity, and risk for disease transmission. Biomimetic materials that can stimulate and accelerate bone formation represent a promising alternative. The implementation of such matrices for bone regeneration is hampered by several requirements, including a 3D porous architecture, biological activity, biocompatibility, and immunomodulation.

Here, we applied a co-assembly approach using hydrogel-forming peptides, resulting in a synergistic modulation of their mechanical properties to form extraordinarily rigid hydrogels which supported osteogenic differentiation based on cells-mechanosensing. Furthermore, we designed a multi-component scaffold composed of polysaccharides, short self-assembling peptides, and bone minerals. We demonstrate the formation of a rigid, yet injectable, and 3D printable hydrogel without the addition of cross-linking agents. The formed composite hydrogel displays a nanofibrous structure, which mimics the extracellular matrix and exhibits thixotropic behavior and a high storage modulus. This composite scaffold induces osteogenic differentiation and facilitates calcium mineralization.

This work provides a conceptual framework for the utilization of co-assembly strategies to push the limits of nanostructure physical properties obtained through self-assembly for the design of new biomaterials for tissue engineering applications.

4:45 PM SB06.03.05
3D-Printed Dipeptides with Programmed Crystallinity for Multilevel Anticounterfeiting Ji Tae Kim; The University of Hong Kong, Hong Kong

The self-assembly of peptides into ordered supramolecular structures is of great interest in the field of materials chemistry [1]. The existing self-assembly pathways, however, have not been able to achieve the spatial programmability in shape, position, and crystallinity required for micro-circuit integration, due to their dynamics with stochastic nature.

Here, we present an additive manufacturing method that enables hierarchical structuring of diphenylalanine (FF) dipeptides from molecular to sub-micrometer scales [2,3]. This method exploits a femtoliter ink meniscus to guide the self-assembly of FF in three dimensions, thereby enabling the printing of a freeform, crystalline FF microarchitecture. Importantly, the extent of crystallization can be controlled in situ by solvent engineering. We have demonstrated that one can turn the crystallization "on" and "off" at will during the printing process, enabling the spatio-selective programming of crystalline/amorphous phase distribution in a single printed body. This capability offers a single-step route to integrate dipeptide's functionalities – e.g., piezoelectricity, optical nonlinearity/anisotropy – into the body of complex structural parts. Successful demonstration of 3D digital polarization-encoded anticounterfeit micro-labels has proven the practicality of the developed method. In this talk, we will further discuss the prospects of our work for potential applications in bioelectronics and photonics.

A Target-Oriented Approach for Materials Design Joel Schneider; National Cancer Inst, United States

Many drugs bind their biological targets selectively and reversibly with characteristic binding constants and on/off-rates. These same targets can serve as depots for drug loading, and be used as building blocks for the construction of new drug delivery materials. For example, self-assembling a given biological target should afford a material with a tunable copy number of selective binding sites that can house and subsequently release drug at predictable rates. We demonstrate feasibility of this approach by preparing gel networks by self-assembling amphiphiles containing the drug target of the antibiotic vancomycin. This drug kills bacteria by reversibly binding to the dAla-dAla dipeptide found within bacteria, inhibiting cell wall biosynthesis. Gel networks formed by dAla-dAla assembly serve as selective depots for vancomycin and provide sustained release of drug over months *in vivo*. Biophysical experiments and release simulations using mathematical models of mass transport dynamics indicate that drug release is largely dependent on the on/off-rates defining the reversible binding event between drug and target. Lastly, we demonstrate that the gel can be reloaded multiple times by simple tail-vein injection after releasing its cargo.

9:15 AM SB06.04.02
Transcytotic Intercellular Gelation Enables Cell Spheroids Jiaqi Guo[1], Fengbin Wang[2], Yimeng Huang[1], Hongjian He[1], Weiyi Tan[1], Meihui Yi[1], Edward Egelman[2] and Bing Xu[1]; [1]Brandeis University, United States; [2]University of Virginia, United States

Cell spheroids bridge the discontinuity between *in vitro* systems and *in vivo* animal models, but inducing cell spheroids by nanomaterials remains an inefficient and poorly understood process. We used cryo-EM to determine the atomic structure of helical nanofibers self-assembled from D-peptides, and used fluorescent imaging to show that endo/exocytosis of enzyme-responsive D-peptide assemblies results in intercellular gels that enable cell spheroids. Specifically, D-phosphopeptides self-assemble to form nanoparticles to undergo endocytosis. The nanoparticles, being resistant to proteolysis and partially dephosphorylated, go through exocytosis to the cell surface and turn into helical nanofibers, which act as the artificial matrices of intercellular gels to induce cell spheroids from either suspended or adherent cells. No cell spheroids form without the endo- or exocytosis, the phosphate triggers, or the shape-switching of the peptide assemblies. This study, coupling transcytosis and morphological transformation of peptide assemblies to form intercellular gels in situ, mimics biogenesis to form intercellular matrices, and demonstrates a biomimetic approach for regenerative medicine and tissue engineering.

Contactless Magnetically Responsive Injectable Hydrogel to Guide Aligned Tissue Regeneration Arianna Rossi[1,2], Franco Furlani[1], Giada Bassi[1,3], Catarina Correia[4,5], Carla Cunha[4], Anna Piperno[2], Monica Montesi[1] and Silvia Panseri[1]; [1]National Research Council, Italy; [2]University of Messina, Italy; [3]University of G. D'Annunzio, Italy; [4]i3S - Instituto de Investigação e Inovação em Saúde, Portugal; [5]ISEP - Instituto Superior de Engenharia do Porto, Portugal

INTRODUCTION
Human tissues have well-defined architectures and mechanical properties that play a crucial role in their functionality. Specifically, cellular alignment is fundamental in several tissues and organs such as spinal cord, muscle, tendon, and cartilage. Several well-oriented scaffolds, able to reproduce the crucial tissue microarchitecture and to sustain regenerative process, have been produced by various tecniques (e.g. bioprinting, electospinning, freeze-drying), but very few have shown translational applications also due to the invasive surgery necessary to be implanted. Injectable hydrogels can be transplanted *via* minimally invasive injection, but usually without displaying any aligned structure. In the present work, we developed an injectable hydrogel with anisotropic architecture by applying a static magnetic field (SMF), based on gellan gum (GG), a biocompatible and biodegradable polysaccharide, hyaluronic acid (HA) and magnetic collagen fibers (MagC) for skeletal muscle regeneration.
METHODOLOGY
GG (1%) hydrosol added of sodium citrate (0.1%) and HA (0-0.6%) can be injected at 37°C. The gelation occurs in the presence of cations (e.g. PBS, cell culture media, biological fluids) in few minutes. MagC are prepared by mixing the 1mg/mL magnetic nanoparticles to collagen type I at pH 7.4 in different ratios (1:1, 1:3), then they are added to the hydrosol. Mechanical properties were investigated by rheometer and dynamic mechanical analysis. An extensive 3D in vitro cell culture was performed to study cell muscle behavior (viability, differentiation, elongation) and immunomodulation of human and murine macrophage response by ELISA and flow cytometry analysis. Then the hydrogels were subcutaneously implanted and aligned in Wistar-Han rats. At 1, 3 and 7 days, the hydrogels and the surrounding tissue were processed for histological and immunohistochemical analyses. Potential toxicity was evaluated by analysing the spleen, liver, kidney, and lymph nodes.
RESULTS
The hydrogel could be easily extruded by a 30G needle. MagC embedded into the hydrogels were easily aligned by a short (<10 min) application of an external SMF (400mT, distance of ≈4cm) and, once gelated, it showed mechanical properties comparable to muscle tissue (12-19 kPa), and stress relaxation behavior was similar to human tissues when 0.3% HA was added. Additionally, the hydrogel did not negatively affected muscle cells viability and morphology, it enhanced their elongation on the magnetic fibers, and modulated macrophage polarization. Even in vivo, the hydrogel was easily injected and aligned, and no local or systemic immune reaction was detected.
CONCLUSION
In the present work, we developed a contactless magnetically responsive injectable hydrogel to direct aligned musculoskeletal tissue regeneration. *In vitro* analysis pointed out the system biocompatibility that was confirmed during the *in vivo* test, in which also was highlighted its ability to achieve an aligned architecture by a remote SMF application during the gelation.
The versatility of the proposed system can be expected to find application to several different minimally-invasive or endoscopic surgical interventions on different body parts that might benefit from the injection of anisotropic and bioactive materials, such as the heart, cartilage, brain, spinal cord.

Nanoscale Infrared Spectroscopy Reveals Non-Specific Binding Mechanism of Edaravone—The Next Possible Drug to Cure Alzheimers Suman Paul[1], Tobias Gokus[1], Elina Berntsson[2], Sebastian Wärmländer[2] and Andreas Barth[2]; [1]Attocube Systems AG, Germany; [2]Stockholm University, Sweden

The research on Alzheimer is one of the most popular topics across the labs worldwide where much time is spent to test candidate drugs. Edaravone is one such inorganic salt insoluble in water sold under the brand name Radicava. In our research, Edaravone was incubated with Amyloid-β_{40} in four different ratios and samples were collected at different times. The results clearly demonstrated lesser fibrils when an increased amount of Edaravone was present. Further, we were able to study the interaction between Amyloid-β_{40} and Edaravone using neaspec's popular nano-FTIR method. We found that Edaravone uniformly and non-specifically binds to Amyloid-β fibrils.

Novel Functions in Peptide Supramolecular Materials Samuel I. Stupp; Northwestern University, United States

Over the past two decades our laboratory has investigated the supramolecular polymerization of molecularly modified peptides in water known as peptide amphiphiles. In media of high ionic strength, these systems form highly hydrated networks of nanoscale filaments with diverse architectures and peptide sequence dependent degrees of internal order. A very exciting platform of bioactive materials has emerged from these systems with unprecedented ability to signal cells and drive regeneration of tissues. The lecture will report on a recent breakthrough in this area identifying supramolecular motion in peptide materials as an important feature in their ability to signal cells. Another topic to be discussed is recent work on the integration of peptide supramolecular polymers with covalent polymers, which generates a wide variety of stimuli-responsive materials. These novel materials respond to light as well as magnetic and electric fields, and exhibit the ability to emulate behaviors expected from living creatures. These materials can mechanically actuate, exhibit locomotion on surfaces, swim in water, and exhibit phototactic movements. In these emerging robotic materials, the presence of supramolecular assemblies of peptides plays a key role. This lecture will also discuss a new emerging frontier in the area of peptide materials, namely the design of systems capable of self organizing into electro-active structures such as ferroelectric phases and of generating ionically conducting structures for devices.

11:00 AM SB06.04.07
Development of Bioadhesive Microcapsules as a New Cellular Treatment for the Diffuse Cartilage Lesions Desiré Venegas Bustos, Matilde Alonso and Jose Carlos Rodriguez Cabello; Bioforge, University of Valladolid, Spain

Introduction: Cartilage structures can be damaged causing two types of injuries: focal; the lesion is restricted to a concrete zone or diffuse; the lesion affects a broad area of the articular cartilage. This type of lesions appears due to the reduced self-healing capacity of articular cartilage. Diffuse damage is much more difficult to treat, usually restricted to palliative care or systemic anti-inflammatory treatments. This type of diffuse lesions have a high prevalence as the common type of degenerative processes.
More recently, cell-based approaches using autologous chondrocytes or mesenchymal stem cells (MSCs)[1] have been tested and it can even be found in some clinics. However, the efficacy of such cell-based treatment is controversial[2]. In general terms, the applied cells stay in the injection site only for short periods of time, so their regenerative potential is greatly reduced. The most promising approach is the combination of such cells with a biomaterial-based carrier that can play that role.
The general objective of the project, in order to resolve the previous task, is the development of bioadhesive and injectable cell microcarriers with the ability to regenerate the articular cartilage. This aim is materialized in the fabrication of multibiofunctional capsules that are able to promote the cell cargo with selective adhesion and location on the articular surface. To do so, special attention is paid to the cell-material interaction on both the inner and outer surface of the capsule by means of the inclusion of specific cell adhesion domains and sequences that promote the adhesiveness to collagen II and chondroitin sulfate.
The microcapsules are based on a novel kind of biomaterials, named Recombinamers that are polypeptide materials obtained by recombinant DNA technology. In particular, the core composition of the microcarrier is the Elastin-like Recombinamers (ELRs)[3].
Experimental methods: Recombinant DNA techniques have proven to be very powerful tools for the development of novel protein-based biomaterials. This class includes ELRs, which are protein-based polypeptides that comprise repetitive units of the Val−Pro−Gly−X−Gly (VPGXG)n pentapeptide, in which X (guest residue) could be any amino acid except
L-proline. ELRs are inspired by elastin, showing excellent biocompatibility, and they exhibit thermo-responsiveness in aqueous media.
The cloning and molecular biology for gene construction were performed using standard genetic-engineering methods. Production was carried out by recombinant techniques using Escherichia coli as the cell system. Purification was performed by several cooling and heating purification cycles (Inverse Transition Cycling) following centrifugation; the ELRs obtained in this manner were dialyzed against MilliQ water and lyophilized.
Results and discussion: Genetic engineering methods allowed the synthesis of the genetic construct capable of synthesizing the desired biomaterial. Biopolymer adhesion to the hyaline-cartilage matrix was demonstrated measuring the adhesion forces between our biomaterial and surfaces with collagen II and chondroitin-sulfate versus control surfaces and quartz-microbalance.
Tailored layer-by-layer (LbL) approaches allowed the encapsulation of cell spheroids of autologous chondrocytes and MSCs.
In vitro and ex vivo assays were performed using cartilage explants from patients surgically intervened, this type of analysis showed the derivatized ELR adhesion efficacy to the articular surface and the final liberation of cell spheroids encapsulated hoping to demonstrate the cartilage regeneration.
Conclusion: In conclusion, a novel protein-based biomaterial with adhesion to the hyaline-cartilage matrix was synthetized. Besides, cell spheroids were encapsulated by the polymer.
Hence, in this study could be possible overcome the limitations of the current treatments used in diffuse cartilage lesions and suppose an advance in regenerative medicine.

11:15 AM *SB06.04.09
Biomolecules for Non-Biological Things: Peptide 'Bundlemer' Design for Polymerizatoin and Hierarchical Solution Assembly Darrin J. Pochan; University of Delaware, United States

Self-assembly of molecules is an attractive materials construction strategy due to its simplicity in application. By considering peptidic molecules in the bottom-up materials self-assembly design process, one can take advantage of inherently biomolecular attributes; intramolecular folding events, secondary structure, and electrostatic interactions; in addition to more traditional self-assembling molecular attributes such as amphiphilicty and kinetic assembly pathway dependence, to define hierarchical material structure and consequent properties. A new solution assembled system comprised of theoretically designed coiled coil bundle motifs, also known as 'bundlemers', will be introduced. The molecules and nanostructures are not natural sequences and provide opportunity for arbitrary nanostructure creation with peptides. With control of the display of all amino acid side chains (both natural and non-natural) throughout the peptide bundles, desired physical and covalent (through appropriate 'click' chemistry) interactions have been designed to produce polymer nanostructures. One-dimensional nanostructures span exotically rigid rod molecules that produce a wide variety of liquid crystal phases to semi-flexible chains, the flexibility of which are controlled by the interbundle linking chemistry. The assemblies can be responsive to temperature since the individual bundle building blocks are physically stabilized coiled coil bundles that can be melted and reformed with temperature. Computational design is used to design bundlemers with different net charged character in order to manipulate their interactions in solution. Finally, rigid rod polymer chains can be processed into liquid crystals and fiber materials with a completely peptidic molecular foundation. Included in the discussion will be molecule design, hierarchical assembly pathway design and control, click chemistry reactions, and the characterization of nanostructure via electron microscopy, neutron and x-ray scattering, and rheological measurements, as well as inherent material properties (e.g. extreme stiffness, responsiveness to temperature and pH, stability in aqueous and organic solvents).

1:30 PM *SB06.05.02
Photocontrol of Peptide Self-Assembly and Catalytic Activity Alexander Kros; Leiden University, Netherlands

Coiled-coil peptides can be designed to self-assemble with high affinity and selectivity, leading to them being widely employed for the de novo design of synthetic biomaterials. Active control of coiled-coil peptide formation allows spatiotemporal control of their binding interactions, a property which has proven useful in synthetic materials and biological applications. Previous studies showed the ability of the hydrophobic core to adapt to different amino acids with different sizes and polarities. In particular, the use of light to reversibly control peptide structure has been investigated because of the high resolution and biocompatibility of this strategy. Previous efforts to reversibly photocontrol coiled-coil peptides relied on intramolecular cyclization to control peptide structure, or the intermolecular connection of two separate coiled coil strands with a photoswitchable linker. The incorporation of photoswitches in the binding interface of coiled coils has not yet been attempted, and provide a more direct route for control over their activity. Therefore the incorporation of photoswitchable azobenzene-based amino acids, which change structure and polarity through cis/trans isomerization, allow for photocontrol over coiled-coil assembly.

In a second example, we incorporated phenylazo-phenylalanine in betasheet formning peptides to obtain photocontrol in the mode of assembly. With the azobenzene units in a trans-form, betasheets were obtained while upon irradiation these were transformed in micellar structures. Introduction of histidines in the peptide design resulted in catalytic active betasheets, which could be reversibly switched upon irradiation of the azobenzen units. Both examples show that the introduction of azobenzene-derived amino acids in peptides yields photocontrol over the assembly and catalytic activity in various supramolecular assemblies.

2:00 PM SB06.05.03
Self-Sorting in Supramolecular Peptide Amphiphile Nanostructures Si Eun Lee, M H. Sangji, Liam C. Palmer and Samuel I. Stupp; Northwestern University, United States

Soft materials in nature, such as the extracellular matrix and the actin filaments and microtubules found in the cytoskeleton, are often composed of mixtures of molecules that co-assemble into functional multicomponent networks through precise control of supramolecular interactions. Creating synthetic materials with ordered structures which mimic complex natural fibrous networks that self-sort into individual populations offers a valuable approach to designing novel multi-functional tissue scaffolds for regenerative medicine. We recently reported that supramolecular twisted nanostructures formed from peptide amphiphile (PA) molecules exhibit different supramolecular chirality depending on the intermolecular hydrogen bonding, which is determined by the amino acid sequences used. Here, we demonstrate that PAs can be designed to self-sort into either separate nanostructures or co-assemble within the same nanostructures by mixing PAs of different peptide sequences that vary in their β-sheet strength but have the same electrostatics. We use atomic force microscopy (AFM) to reveal the nanoscale morphology of the assemblies, and confocal laser scanning microscopy (CLSM) to determine the distribution of fluorescently labelled PA monomers between nanostructures. By correlating the two imaging modalities on the same region of the samples, we show that the multicomponent PA mixtures can co-assemble or self-sort based on the supramolecular twist of the assemblies: when PAs that form left-handed nanostructures are mixed with PAs that form right-handed nanostructures, the two components self-sort. However, a PA that forms both left- and right-handed nanostructures can co-assemble with either PA to different extents. Our results demonstrate that the driving force for the self-sorting reported here is determined by the enthalpic penalty of the torsion required to change the twist of a peptide in a β-sheet and is controlled by the internal hydrogen bonding sequence.

2:15 PM SB06.05.04
Supramolecular Peptide Crystals with Hydrophilic and Hydrophobic Pores for Chemo-Mechanical and Mechano-Chemical Actuation Vignesh Athiyarath, Elma E. Naranjo, Xi Chen and Rein Ulijn; Advanced Science Research Center, United States

Water-responsive (WR) materials generate mechanical energy by drastically changing their dimensions with respect to changes in relative humidity.[1]
Peptides are versatile building blocks for supramolecular materials with tunable properties and functionalities. We recently started to explore supramolecular peptide crystals with aqueous pores as candidates for systematic understanding of water-bonding triggered actuation, and recently demonstrated the first examples.[2]
Based on these previous results, we hypothesized that, peptides self-assembling into hydrated crystals with flexible hydrophobic and hydrophilic pores can be developed as multifunctional chemo-mechanical actuators. We explore two main features: (i) development of addressable crystals that can access multiple phases with different porosity and mechanical properties through controlled environments; (ii) addressable porous crystals that control chemical reactions.
First, we demonstrate that WR crystals of peptides with aliphatic and aromatic side-chains can be utilized to develop crystals with tunable mechanical properties. A number of di- and tri-peptides with aromatic and aliphatic side chains were studied, giving rise to crystals with water pores that are interspersed with hydrophobic (aromatic or aliphatic) pores. We will provide our progress in establishing systematic understanding of how peptide sequence dictates crystal packing and porosity.
Second, we will discuss one example, dipeptide Leu-Ile, that shows remarkable multifunctional behavior. This peptide crystallizes from water at room temperature to form a 2.5 hydrate and under heating as 0.75 hydrate. Both the forms have hydrophilic and hydrophobic channels and are interconvertible, resulting in switchable porosity. Remarkably, we found that changes in heating and hydration allows us to access three additional polymorphs, with

different properties and porosities. All five forms are interconverted reversibly by controlling relative humidity or temperature accordingly. The changes in the H-bonding pattern of water channel in each structure influenced the porosity, mechanical and solid-state fluorescence properties. Thus, a single crystal of the dipeptide can be tuned reversibly for different mechanical strengths with the aid of relative humidity and temperature.

Due to the controlled mechanical actuation in response to water bonding, we reasoned that peptide crystals may be promising to control hydrolysis or condensation reactions. In order to study this aspect, WR crystals of the tripeptide His-Tyr-Phe, was investigated. These crystals have nanometer sized pores that allow for easy diffusion of various esters of *p*-nitrophenol. We observed that by applying changes in the relative humidity on these guest-included crystals, the crystals can be actuated (reversible pore closure) and esters can be hydrolyzed. LCMS measurements showed the presence of transesterification of ester-substrates with the tyrosyl -OH group of the peptide molecule, thus leaving the free nitrophenol. The mass corresponding to trans-esterified intermediate and *p*-nitrophenol were also observed in TOF-SIMS technique recorded in the solid-state. Thus, we show proof-of-concept of mechano-chemical actuation and reactivity of peptide crystals.

In summary, we demonstrate that short peptide crystals are highly versatile materials with tunable porosity and responsiveness to humidity and temperature. These materials can be designed for multifunctional chemo-mechanical actuation by choosing suitable sequence of amino acid components. These structures are based on short peptides and are therefore scalable and hold much promise as sustainable and biodegradable materials.

Plant-Based Amyloids from Food Waste for Removal of Heavy Metals from Contaminated Water Wei Long Soon[1], Mohammad Peydayesh[2], Raffaele Mezzenga[2] and Ali G. Miserez[1]; [1]Nanyang Technological University, Singapore; [2]ETH Zürich, Switzerland

Water pollution is one of the major global threats brought about by industrial, agricultural, and any other anthropogenic activity. Heavy metals represent a large group of water pollutants that can accumulate in the human body, causing cancer and mutagenic diseases. Technologies currently used to treat polluted wastewaters of heavy metals employ chemical, ion-exchange, and membrane purification methods. However, high pressure and power requirements of membrane-based technologies require large energy input, making drinking water expensive and thus less affordable in developing countries. In this study, plant amyloid-carbon membranes consisting of sunflower and peanut amyloid fibrils were fabricated through a green and sustainable process and were used to remove toxic heavy metal pollutants to drinkable standards with negligible energy consumption. Protein-rich sunflower and peanut meals serve as low-cost raw materials obtainable from industrial oil production, from which proteins were extracted, isolated, and self-assembled into functional amyloid fibrils for heavy metal removal. These amyloid fibrils were incorporated into a carbon matrix to produce hybrid amyloid-carbon membranes, and were used to filter Pt-, Cr-, and Pb-containing water to produce water of drinkable standards containing < 10 ppb heavy metals with minimal energy input. This process can easily be upscaled due to its simplicity and minimal use of chemical reagents, pointing towards the future of low-cost yet efficient water treatment technologies.

Complex Morphogenesis out of Self-Organizing Polypeptide Recombinamers with High Intrinsic Disorder—From Bioinks to Biomorphs Jose Carlos Rodriguez Cabello; University of Valladolid, Spain

Natural structures are the result of complex hierarchical self-assembling processes. The complexity in those arrives from many fronts. First, the self-assembling molecules are already very complex in composition. Second, most, if not all, the organized structures correspond to far-from-equilibrium states. Third, in many cases they involve the concurrent self-assembling processes of different macromolecules. Fourth, dynamic interactions, environmental responsiveness and adaptability are common properties in those systems. In addition to all that, self-assembly of biological molecules seems to be the result of an order-disorder interplay in which intrinsically disordered molecules, or notable domains in them, play an essential role. Therefore, if one wants to understand and mimic such extraordinary processes, it is necessary to design model systems in which complexity, intrinsic disorder, dynamic behavior, and far-from-equilibrium states are preeminent. This draws a totally different paradigm to the one existing for the more conventional approach in designing most of the present self-assembling systems.

Recombinant technology is a powerful tool to fabricate such complex, but well-defined, and multifunctional macromolecules. Its polypeptide nature permits to include in their molecular design any peptide domain existing on natural proteins that can be of interest. On the other hand, as recombinamers are based in a totally synthetic DNA, the combination of peptide domains is essentially not restricted by any factor and, practically any composition of interest can be produced. Those may include even peptide domains that are not found in natural prote ins but they could be of interest.

During those last years, different recombinamers have been designed and tested in our lab. Some of the molecular designs have proven to be, for example excellent 3D bioinks [1]. In those, superior printability is obtained by an adequate programing, at molecular level, of a sequence of self-organizing events with different strengths and dynamics while showing excellent bioactivity and biocompatibility. In other cases, the combination of competing and independent self-organizing interactions some of them generating out of equilibrium stable arrangements has lead to the generation of complex 3D structures after a process of spinodal decomposition of T-sensitive high MW recombinamers with LCST behavior.

Programmable Order-Disorder Transitions Triggering Supramolecular Assembly of Peptides Zachary Urbach, Adam Grosvirt-Dramen and Allon Hochbaum; University of California, Irvine, United States

Many critical biological processes rely on dynamic and biochemically responsive protein assemblies. But mimicking these features in synthetic materials is challenging due to the complexities of protein-protein supramolecular interactions and the specificity of ligand binding sites. To address this challenge, we have developed a platform for the programmable assembly of *de novo* peptides by balancing a disorder inducing sequence motif with structure-stabilizing, bioinspired intramolecular bonding. The assembly platform is based on coiled-coil interactions between peptide monomers and the subsequent supramolecular assembly of coiled-coil oligomer building blocks. pH and charge screening-dependent electrostatic repulsion within the peptide sequence provide a tunable driving force for disorder that disrupts specific peptide-peptide interaction interfaces, precluding assembly. Gating the assembly in this way provides control over the hierarchical assembly of complex supramolecular peptide nanostructures through control of a-helical secondary structure of the monomer. Combining this tunable disorder motif with structure-stabilizing and stimuli responsive disulfide bond staples results in a monomer sequence that assembles in response to either redox or enzymatic signals. The gating of supramolecular interactions in response to these stimuli represent key advances towards the interconversion of biological signals across bionic interfaces and the integration of synthetic biology with a synthetic materials toolkit.

Self-Assembled Peptides for Electronic and Piezoelectric Applications Sharon Gilead, Gal Finkelstein and Ehud Gazit; Tel Aviv University, Israel

In recent years, a key direction in the field of electronics and electro-optics involves the transition from inorganic to organic components, thus paving the way towards flexible and wearable electronic devices. Bio-inspired organic materials may be the next-generation of organic optoelectronic devices, based on self-organization principles, which allow facile synthesis, eco-friendliness, resistance to oxidation and no need for heavy metal doping. Recent advances in bioorganic nanotechnology have established the notion that very simple building blocks, such as dipeptides, can form regular nanostructures with distinct mechanical, optical, piezoelectric and electronic properties. In particular, members of the diphenylalanine (FF) peptide archetypical family have been shown to form various morphologies and ordered nanostructures such as tubes, rods, fibrils, spheres, plates and macroscopic hydrogels with nano-scale order. These unique self-assembled peptide materials may be useful in the emerging field of implantable medical devices, which requires biocompatible power solutions to enable continuous and wireless operation.
The abundant mechanical energy stored in our body, ranging from body motion, walking, breathing to internal movement of organs, heartbeats and blood pressure, can be converted into electrical energy by the piezoelectric effect to serve as an autonomic electrical source. Currently, the field of piezoelectric materials mainly relies on lead-based ceramic materials such as lead zirconate titanate (PZT). However, as lead is toxic and entirely non-biocompatible, there is an emerging need for alternative materials with strong piezoelectric performance, especially in the field of bio-applications. Piezoelectric bio-inspired materials have attracted significant attention in recent years as promising alternatives for currently used poisonous piezoelectric materials owing to their strong piezoelectricity along with their biocompatibility. Specifically, several studies have explored the piezoelectric properties of the FF peptide. Although significant progress has been made toward the functionalization of piezoelectric biomaterials, challenges in the formation of well-ordered nanostructures limit their application. Controlling the organization of such assemblies is a crucial milestone in engineering applicable piezoelectric materials since the magnitude of the piezoelectric response is dictated by the molecular organization at the nanoscale. Here, we demonstrate the functionalization of piezoelectric FF derivatives by nano-structural alignment. We have developed a custom-made measurement system for piezoelectric performance evaluation, calibrated using a commercially available piezoelectric material. Utilizing this system, we show the realization of self-assembled peptides as a promising piezoelectric alternative for bio-compatible energy solutions.

4:30 PM SB06.06.06
Dynamic Optical Systems Inspired by Cephalopods Nikhil Kaimal, Georgii Bogdanov, Aleeza Farrukh, Atrouli Chatterjee and Alon Gorodetsky; University of California Irvine, United States

Cephalopods (e.g., squids, octopuses, and cuttlefish) have captivated the imagination of both the general public and scientists alike due to their sophisticated nervous systems, complex behavioral patterns, and visually stunning coloration changes. By drawing inspiration from the structures and functionalities of tunable cephalopod skin cells, we have designed and engineered human cells that contain reconfigurable protein-based photonic architectures and, as a result, possess tunable transparency-changing and light scattering capabilities (1). In turn, we have visualized the refractive index distributions of analogous engineered cells with three-dimensional label-free holotomographic microscopy techniques, and as a consequence, we have developed a detailed understanding of the relationship between their global optical characteristics and subcellular ultrastructures (2). We have moreover extended these efforts to the predictive engineering of the refractive indices and light-scattering properties of multiple self-assembled protein-based platforms, both in vitro and in vivo (2,3). Finally, we have developed improved chemical and genetic strategies for manipulating the sizes, numbers, and refractive indices of our subcellular structures (4). Our combined findings may facilitate an improved understanding of cephalopod camouflage mechanisms and lead to the development of unique tools for applications in biophotonics and bioengineering.

The Pyroelectricity in M13 Bacteriophage Han Kim, Kento Okada, Inseok Chae, Butaek Lim, Seungwook Ji, Yoonji Kwon and Seung-Wuk Lee; University of California, Berkeley, United States

Pyroelectricity serves important biological functions to sense the temperature of living organisms. However, the molecular mechanisms of pyroelectricity in biomaterials are not fully understood. Here we exploit the M13 bacteriophage (phage) as a model system to investigate the structure-and-function relationship of biological pyroelectricity. M13 phage possesses intrinsically aligned dipole structures originating from α-helical structures of the major coat protein (pVIII) arranged in a five-fold helical symmetry without an inversion center. We genetically engineer the tail part of the phage with six-histidine to fabricate vertically standing unidirectionally polarized phage structures on gold substrates. Through additional major coat protein engineering with different numbers of negatively charged glutamate, we investigate the chemical structure-dependent pyroelectric properties of the phage. M13 phage exhibits a pyroelectric coefficient of $0.058\ \mu\mathrm{C}\ \mathrm{m}^{-2}\ \mathrm{K}^{-1}$ upon heating. We also genetically modify the phage to sense different chemical environments based on pyroelectric sensing modality. Computation modeling and circular dichroism spectroscopy analysis verify that the unfolding of the α-helices of pVIII proteins can induce the phage protein polarization changes upon heating. Our phage-based approach to investigating bio-pyroelectricity will enhance our understanding of the thermos-electric behaviors of biomaterials and develop novel biomaterials that can be used for biosensors and electric energy generators in the future.

SESSION SB06.07: Poster Session I: Design Rules for Peptide and Protein-Based Materials
Session Chairs: Aline Miller, Jose Carlos Rodriguez Cabello and Rein Ulijn
Wednesday Afternoon, April 12, 2023
Moscone West, Level 1, Exhibit Hall

5:00 PM SB06.07.01
***In Vivo* Self-Assembly of Chimeric Ferritin for Multi-Functional Nanoparticle** KoungHee Kim[1], Mi-Ran Ki[1,2], Ki Ha Min[1,2], Sung Ho Kim[1], Jin Woo Shin[1] and Seung Pil Pack[1]; [1]Korea university, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Protein-based nanoparticles are attractive materials as carriers or templates in various fields because of several advantages: high biocompatibility and stability, uniform size, easy surface modification, and low immunogenicity. In particular, ferritin, one of the valuable nanoparticles, is an iron storage protein with a hollow form of a diameter of inner 8nm and outer 12nm. In ferritin, 24 monomers are arranged with 4-3-2 axial symmetry to form eight three-fold channels (N-terminal interface) and six four-fold channels (C-terminal interface), the diameter of 3~5 Å, which can make material diffusion between the outside and the inside. This structure formation is self-assembly and reversible assembly so that various materials such as drugs, dye, or metals can load inside. In addition, it can manufacture mixed forms with diversely modified monomers or control the number of functional monomers for a degree of activity. However, methods of reversible assembly-disassembly are often harsh enough to cause damage or incomplete assembly by applying extreme pH. Although most studies induce disassembly in pH 2 or 11 conditions, some researchers reported that it could not form intact at reassembly. This study produced a chimeric form without damage by simultaneously expressing two monomers using a dual expression vector. This method can make the chimeric form more easily without an additional purification process and loss of protein yield during manufacture. In order to check the ratio of each monomer and the difference in function according to it, silica forming peptide (SFP)-fused human ferritin monomer was used. The double expression confirmed that ferritin and SFP fusion ferritin were expressed at a constant ratio and gathered to form chimeric ferritin. The chimeric protein showed different sizes and functional properties than ferritins (non or SFP-fused form) composed of single monomers. This study showed that the form with two different monomers could be expressed intact in vivo to confer different functionalities on ferritin. Also, intact fabrication of protein-based nanoparticles combined with various functional tags will be applied more actively in nanotechnology.

5:00 PM SB06.07.02
Bioinspired Stiffness-Controlled Protein Filaments Based on Understanding Hydrodynamics and Molecular Self-Assembly of Constitutive Proteins Young Hyun Noh[1,2], Yong Ho Kim[2,2,2] and Minkyu Kim[1,1,1]; [1]The University of Arizona, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Natural materials like collagen, microtubules, and muscle fibers feature ultralong, tough, and robust mechanical properties. This is induced by complex hierarchical structures formed by the self-assembly of stiffness-controlled filaments and fibrils. As a result, understanding dynamic mechanical properties and the self-assembly of filaments and fibrils has become the focus of studies aimed to better understand the hierarchical structures of natural fibers. Moreover, synthetic polymer-based filaments and fibrils with controlled stiffness have been developed for drug delivery and tissue engineering applications. Recently, protein-based filaments have received attention as synthetic counterparts for healthcare applications due to their biocompatibility and biodegradability. In addition, proteins have highly controllable monomers and diverse functionalities, and they can be genetically fused to yield versatile protein polymers that form exquisitely designed bioinspired filaments. It is reported that crosslinking self-assembled protein nanostructures allows for the preparation of the protein filaments, and modulating crosslinking density enables the control of the filament stiffness. However, methods to tailor the stiffness of protein filaments remains unclear due to the delicate processing required, including the complexity of the self-assembly processes involved with sophisticated molecular interactions.
Herein, we report bioinspired stiffness-controlled protein filaments via the molecular self-assembly of designed protein polymers with constitutive coil-like and rod-like proteins. Using molecular dynamics simulations, biosynthesis, and characterization methods, we found that the hydrodynamics of the coil-like protein component showed high flexibility such that curvature was generated in the filament structures, while the rod-like protein component enhanced the stiffness. This finding leads to the investigation of the fundamental relationship between chain topology for designed protein polymers and their composition, structure, length, symmetry, as well as their interdependence. Our work provides insights into the scientific principles of protein filaments toward constructing biomimicking hierarchically structured protein fibers, which can open new avenues for healthcare applications in drug delivery, tissue engineering, and regenerative medicines.

5:00 PM SB06.07.03
Injectable Hydrogels of Stimuli-Responsive and Surface-Adhesive Multi-Block Copolypeptides JaeHee Lee, Jae Sang Lee, Min Jeong Kang and Dong Woo Lim; Hanyang University, Korea (the Republic of)

Surface adhesive proteins biomimicked from mussel foot proteins (MFPs) have been of interest for tissue engineering and regenerative medicine. Especially, 3, 4-dihydroxyphenylalanine (DOPA) residues of MFPs play a major role in controlled adhesion on the various surfaces under wet conditions. In addition, stimuli-responsive multi-block copolypeptides composed of elastin- or resilin-based blocks are applied as injectable hydrogels for facile administration of various biomedical applications. In this study, ABA type tri-block copolypeptides composed of MFP and elastin-based polypeptide (EBP) with thermal responsiveness were genetically engineered, over-expressed in *E. coli* and non-chromatographically purified. Hydroxylation of Tyr residues of MFP middle block was executed by either mushroom tyrosinase or bacterial co-expression to finely control the degree of modification. Hydroxylated EBP-MFP-EBP (hEME) triblock copolypeptides showed different lower critical solution temperature (LCST) behaviors depending on concentration and hydroxylation as compared to those of unmodified ones. Especially, the hEME triblock copolypeptides under concentrated conditions showed thermally triggered hydrogelation within several minutes because of physical cross-linking of the aggregated EBP blocks above LCST and oxidation of DOPAs into dopaquinones with sodium periodate. Furthermore, the hEME triblock copolypeptide hydrogels exhibited controlled surface adhesion properties on the metal surface as well as porcine skin under wet conditions due to DOPA-mediated intermolecular cross-linking via oxidation. Moreover, to finely tune the surface adhesiveness on the various surface, concentration of sodium periodate, incubation time, and temperature were optimized so that the hEME triblock hydrogels showed maximum adhesive strength of approximately 0.7 MPa. In conclusion, the injectable hydrogels of stimuli-responsive block copolypeptides with surface adhesive properties would be potential as tissue adhesives or hemostasis biomaterials for tissue engineering and regenerative medicine.

5:00 PM SB06.07.04

Synthesis and NMR-Spectroscopic Investigation of Peptide-Coated Ultrasmall Gold Nanoparticles (1-2 nm) Lisa-Sofie Wagner[1], Kai Klein[1], Torsten Schaller[1], Felix Niemeyer[1], Christine Beuck[1], Kateryna Loza[1], Peter Bayer[1], Marc Heggen[2] and Matthias Epple[1]; [1]Universität Duisburg-Essen, Germany; [2]Forschungszentrum Juelich GmbH, Germany

Ultrasmall gold nanoparticles (diameter 1-2 nm) have become increasingly important in biomedicine in recent years. If they are functionalized with biomolecules, they can be used in cancer therapy or for targeted drug release. The nature and size of the biomolecule determined the interaction with the gold surface and the number of attached ligands, including their molecular footprint.
We have attached cysteine-terminated peptides of variable length to ultrasmall gold nanoparticles. Besides model peptides consisting of a terminal cysteine and a chain of alanine, bioactive peptides were attached. The nanoparticle size was determined by differential centrifugal sedimentation (DCS), diffusion ordered NMR spectroscopy (DOSY), and transmission electron microscopy (TEM). By taking advantage of the fact that NMR spectroscopy is possible for ultrasmall nanoparticles, we have extensively characterized the ligand shell on the nanoparticles, including the binding state, by NMR spectroscopy. We have also determined the number of ligands on each nanoparticle by NMR spectroscopy and determined the change of molecular footprint as a function of peptide size. The ligand exchange studies at different temperature and pH as followed by NMR indicated the stability of the nanoparticle-peptide assembly which is important for its biomedical application.

5:00 PM SB06.07.05
High-Strength Spider Silk Composite Fibers with Photocatalytic Functionality Yi Ting Chen[1], Li-Sheng Chiang[1], Bo-Chun Chen[1], I-Hsiang Tseng[2] and Ta-I Yang[1]; [1]Chung Yuan Christian Univ, Taiwan; [2]Feng Chia University, Taiwan

The dragline silk of the giant wood spider (Nephila pilipes) was utilized to develop titanium dioxide (TiO_2)/spider silk composite fibers for photocatalytic applications. The surface of the silk fibers was modified with TiO_2 nanoparticles using hydrothermal method. The reaction procedure was optimized in order to obtain TiO_2 nanoparticles well-attached on the surface of silk fibers without damaging their integrity. The developed spider silk composite fibers remain the high mechanical strength (0.9 GPa) and fracture strain of 20%. The methylene blue dye served as a model to evaluate the photocatalytic performance of the developed composite fibers. The experimental results show that the TiO2/spider silk composite fibers have great ability to degrade the methylene blue and also exhibited appreciable reusability. This study demonstrated the feasibility of using sustainable and mechanically robust spider silk fibers to obtain TiO_2 composite fibers for use in photocatalytic applications.

5:00 PM SB06.07.06
Probing Sequence-Dependent Orientation in VOC Binding Peptides During IPA Exposure Using Near-Edge X-Ray Absorption Fine Structure Spectroscopy Gustavo Sant'Anna[1], Nicholas Bedford[1], Daniel Sim[2] and Steve Kim[2]; [1]University of New South Wales, Australia; [2]Air Force Research Laboratory, United States

Human psychological stress and fatigue levels can be monitored in real-time through performance-related biomarkers such as volatile organic compounds (VOCs) present in the exhaled breath using peptide-based graphene field effect transistors (GFETs). Ultimately, the biotic/abiotic interface is responsible for VOC recognition and subsequent sensor. During VOC exposure, perturbations to the biotic/abiotic interface results in changes to the electronic structure of the graphene, triggering a measurable electronic response. Aromatic residues in the peptides are considered the strongest driving force for noncovalent peptide functionalization of the graphene surfaces. As such, π–π interactions are predicted to play an essential role in sensor performance and thus provide an opportunity for directed sequence design for sensor optimization.
In this work, we determined the overall orientation on various 7-mer VOC binding peptides with different aromatic content on the graphene surface using near-edge X-Ray absorption fine structure (NEXAFS) spectroscopy. Two set of peptides were studied, the first set of sequences was generated via AI and MD simulations for optimal IPA binding. The second set of peptides were modifications of the first set, where key aromatic binding residues were substituted with non-binding functionalities. Peptide orientation was determined on functionalized graphene surfaces before and after dosing with IPA within the NEXAFS chamber to monitor perturbations to peptide morphology under simulated sensors conditions. Overall, clear differences in orientation were determined with NEXAFS, showcasing clear sequence dependence on peptide surface morphology and their interactions with IPA during dosing. This understanding can assist with knowledge-driven development of new sequences for device optimization, which can be further extended beyond VOC GFETs and into various fields of biosensing.

5:00 PM SB06.07.08
Effects of Nanoconfined Water and Heavy Water on the Mechanical Properties of Supramolecular Crystals Janel J. Rivera-Cancel[1,2,3], Nicolas Giovambattista[1,2], Gustavo Lopez[2,4], Xi Chen[3,5] and Rein Ulijn[3,2]; [1]Brooklyn College, United States; [2]The City University of New York Graduate Center, United States; [3]Advanced Science Research Center, United States; [4]Lehman College of the City University of New York, United States; [5]The City College of New York, United States

Water responsive (WR) materials, which can undergo reversible changes in their conformation in response to a change in the relative humidity (RH), have recently gained attention due to the opportunities for them to be used as an energy source. For example, evaporation-driven engines can be powered by WR materials to directly harvest energy from the natural evaporation of water and convert it into mechanical work and electricity. However, little is known about the mechanisms involved in these WR materials or the role of water in these systems. In particular, the effects of deuterium oxide (D_2O) on the mechanical properties of WR materials and the interactions between water and biomolecules is still an open question. In this study, we compared the responsiveness of histidine-tyrosine-phenylalanine (HYF) peptide crystals to H_2O and D_2O and the role of nanoconfined water in the water-peptide interactions. We investigated the changes in the mechanical properties of HYF due to isotope substitution (H_2O and D_2O). We performed experiments using powder x-ray diffraction (PXRD), atomic force microscopy (AFM), and Fourier-transform infrared spectroscopy (FTIR) in a humidity-controlled environment with both, H_2O and D_2O vapor to study its RH responsiveness. We plan to complement our experiments by performing classical and path-integral molecular dynamics simulations.

5:00 PM SB06.07.10
Elastic Modulus of Engineered Polymeric Hydrogel Materials Modulated by Sequence-Controlled Protein Polymers Christopher Camp and Minkyu Kim; University of Arizona, United States

The mechanical properties of polymeric materials are affected by diverse factors such as the compositions and arrangements within individual polymers as well as the overall chain length. However, precise control of those parameters in polymers is not trivial while a heterogeneous distribution of polymer compositions and sizes are common. Such inconsistencies can cause issues with reproducibility of mechanical properties. As such, studies that focus on precise monomer arrangements are difficult without a well-controlled system with uniform chain length and reproducible polymer composition. We developed thermoresponsive artificial protein polymers that can be photo-crosslinked to construct hydrogels, and we used the polymeric hydrogel system as a tool to investigate how changing the arrangement of the monomers can affect the elastic modulus of crosslinked materials. The artificial protein polymer technology offers precise control of the sequences through genetic engineering, and biosynthesis techniques ensure homogeneous chain length.

We found that two protein homopolymers of different sizes showed no significant difference in their elastic modulus when the monomer repeats and crosslinking number were well-controlled in our system. Then, we rearranged the monomer sequences of the homopolymer to investigate a protein block copolymer such that within the block copolymer, the more hydrophobic monomers that can be used for crosslinking were moved closer together on one side with the overall chain length held constant. We found the elastic modulus was dramatically reduced compared to the homopolymer with the same total chemical composition due to the formation of self-assembled structures. The elastic modulus recovered in a protein polymer blend containing the block copolymer and the homopolymer with the same chain length. Therefore, we identified a polymer blend method to overcome some of the loss of the mechanical properties. Our findings can be used to advance the design and control the mechanical properties of polymeric materials for biomedical applications such as tissue engineering, regenerative medicine, and drug delivery.

5:00 PM SB06.07.11
Understanding the Role of Aromatic Architecture in Tuning Water-Responsive Behavior of Peptide Crystals Fahmeed K. Sheehan[1,2,3], Haozhen Wang[4], Darjan Podbevsek[2], Rein Ulijn[2,1,3] and Xi Chen[2,1,5]; [1]The Graduate Center at the City University of New York, United States; [2]The Advanced Science Research Center at the Graduate Center, United States; [3]Hunter College, United States; [4]Stanford University, United States; [5]The City College of New York, United States

Water-responsive (WR) materials that reversibly change structure in response to changes in humidity are increasingly recognized for their potential in energy-harvesting and actuation applications. These materials translate the chemical potential of water into a defined mechanical actuation. Examples in nature include pinecones which expand and release seeds when the local environment is dry. Peptides are versatile designed supramolecular materials[1] and we recently started to explore them as WR responsive materials. Specifically, we previously developed WR peptide crystals with aqueous pores and deformable aromatic regions to understand the fundamental actuation mechanism of WR materials and found that a strong H-bonding network to bind with water was crucial to water-responsiveness[2].

In here we systematically study the architecture and deformability of the aromatic regions and their influence on WR behavior. We selected three aromatic peptide crystals that each contain aromatic regions and aqueous pores, but distinct aromatic topologies: Phenylalanine (F), diphenylalanine (FF), and histidyl-tyrosyl-phenylalanine (HYF). Based on architecture alone, we expected FF, which is composed of a network of water pores connected through aromatic zippers, to be a strong WR material owing to its large aqueous pore and H-bonding network. Surprisingly, we found that the structural rigidity offered by its aromatic zipper structure prevented any shape change in response to changing humidity. On the other hand, F emerged as an extremely strong WR material with an energy density of 19.8 MJ/m^3, exceeding that of HYF at 6.5 MJ/m^3. Results from powder X-ray diffraction (PXRD) and Fourier-transform infrared spectroscopy (FTIR) confirm that F undergoes a crystal phase change between 60-70% relative humidity that results in its WR actuation. This contrasts with HYF which reversibly loses its lattice structure upon dehydration. Our observations suggest that FF, which is too rigid, cannot deform in response to humidity, whereas HYF, which is more flexible, does not respond efficiently. These findings show that water-responsiveness requires a fine balance between water-bonding and aromatic stacking domains, and they can inform the design of responsive aromatic peptide crystals and provide further insight into the WR mechanism of supramolecular materials.

5:00 PM SB06.07.13
Fabrication, Structural Characteristics and Properties of a New Wool Based Non-Woven Fabric Hye Gyeoung Lee and In Chul Um; Kyungpook National University, Korea (the Republic of)

Silk sericin has a good biocompatibility, wound healing effect, and high water retention. Owing to the unique properties, it has been extensively studied to apply it to cosmetic and biomedical fields. Recently, a silk natural nonwoven fabric was successfully fabricated by using the adhesion character of sericin. In this study, a sericin was coated to wool fiber to provide a binding character of wool fiber and to improve the biocompatibility of wool. Also, the sericin coated wool nonwoven fabric was fabricated by carding, wetting, and hot press processes and the effect of the sericin amount on the structural characteristics and properties of the fabrics was investigated. It was found by FE-SEM observation that more sericin was well coated in wool fibers of the nonwoven fabric with increase of sericin addition. As the addition amount of sericin increased until a certain point, the breaking strength of the nonwoven fabric was increased, and then kept unchanged with further increase of sericin addition. Regardless of sericin content, all sericin coated wool non-woven fabrics showed a good cell viability.

5:00 PM SB06.07.14
Effect of Sericin Content on the Structural Characteristics and Properties of Silk Non-Woven Fabric Ye Eun Kim, Yu Jeong Bae and In Chul Um; Kyungpook National University, Korea (the Republic of)

Silk is composed of two biopolymers (fibroin and sericin) and a biomaterial with excellent blood compatibility, biodegradable and low inflammatory reactions in a body. Recently, a new natural silk non-woven fabric was successfully fabricated with simple treatment (wet and hot press treatment) attracting researcher's attention in medical and cosmetic applications. Although the mass production of new natural silk non-woven fabric was successfully done using an electric winder system, it is still necessary to reduce the production cost for various applications. In the present study, new silk non-woven fabrics were fabricated with new methods. Furthermore, the effect of sericin content on structural characteristics and mechanical properties of silk non-woven fabrics was examined. The sericin content in silk was diversely controlled by altering the degumming condition. As the sericin content in silk increased, the porosity, thickness, crystallinity, and elongation of the silk non-woven fabric decreased. On the other hand, the moisture regain and maximum stress increased as the sericin content increased. In addition, regardless of the sericin content, all silk non-woven fabrics showed an excellent cell viability.

5:00 PM SB06.07.15
Fabrication, Structural Characteristics and Properties of Silk Non-Woven Fabrics from Different Silkworm Varieties Yeon Jin Kim and In Chul Um; Kyungpook National University, Korea (the Republic of)

Since silk has good blood compatibility, excellent cyto-compatibility and minimal inflammatory reaction in a body, silk has been studied to apply it to biomedical and cosmetic applications including bone substitute, wound dressing, and mask pack. Recently, silk non-woven fabric has attracted researcher's attention because the mass production is possible using conventional facilities and good mechanical properties can be obtained. It was reported that various properties of silk can be obtained by using various silkworm varieties. Although a few silk non-woven fabric was prepared using the silkworm varieties previously, the related study has not been extensively. Therefore, in this study, the effects of different silkworm variety on structure and properties of silk non-woven fabrics were examined. Kumokjam resuled in white silk nonwoven fabric, whereas other silkworm varieties leaded to yellow colored nonwoven fabric. The weight distribution of the silk cocoons was different depending on the silkworm variety affecting reeling distance of cocoon. Daehwangjam showed the highest cocoon weight (0.88 g) and N74 exhibited the lowest (0.35 g). Interestingly, the reel-ability of the silk cocoons was strongly affected by the silkworm variety indicating the productivity of silk nonwoven fabric was determined by the silkworm variety.

5:00 PM SB06.07.16
Preparation, Structure and Properties of Silk Non-Woven Fabric with Different Cocoon Layers Yun Yeong Choi and In Chul Um; Kyungpook National University, Korea (the Republic of)

Silk is a natural composite material composed of continuous silk filaments and has been used as textile material for a long time. Thanks to the unique properties of silk including blood compatibility and cyto-compatibility, it has been studied as biomedical and cosmetic materials. Recently, a natural silk non-woven fabric was successfully fabricated using electric winder and hot press increasing its applicability to biomedical and cosmetic applications. In the present study, new silk non-woven fabrics were fabricated using electric winder. Silk fiber in different silkworm cocoon layers were used in the fabrication and the effect of the layer on the structural characteristics and properties of silk non-woven fabric was examined. As the silk in the outer layer was used, the crystallinity index of silk non-woven fabric was decreased and the moisture regain was increased. In case of mechanical properties, the breaking strength, elongation at break, and work of rupture of silk non-woven fabric were increased with using the silk in outer layer. All silk non-woven fabrics showed excellent cell-viability.

5:00 PM SB06.07.17
Biopolymer Design that Translates Single-Molecule Protein Nanomechanics to Macroscale Mechanical Properties of Polymer-Network Materials Samuel Kim[1], Marcus V. Cathey[1], Brandon C. Bounds[1], Piotr Marszalek[2] and Minkyu Kim[1,3,1]; [1]University of Arizona, United States; [2]Duke University, United States; [3]The University of Arizona, United States

Natural materials are a great blueprint for the development of next-generation biomaterials because of their exceptional physical, chemical, and biological properties. To mimic the unique properties of natural materials, protein-based polymer networks are utilized to develop well-characterized functional proteins that can be engineered into artificial protein polymers. However, it is still unclear how these artificial proteins can be incorporated into polymer networks that can properly translate protein nanomechanics. To translate protein nanomechanics to bulk mechanical properties, strong and specific cross-linkers is necessary to form stable polymer networks with reduced topological defects. Our recent work has shown that streptavidin tetramers fulfill the requirements and can be used to form protein-based polymer networks, potentially allowing the translation of protein nanomechanics to bulk hydrogel materials.

In this study, we investigated a novel mechanism involving streptavidin cross-linkers to determine optimal design components for producing protein polymer networks that can translate the single-molecule behavior into bulk mechanical properties. To properly mimic the reversible deformability of red blood cells and develop functional biomaterials for cardiovascular tissue engineering applications, ankyrin, a cytoskeleton protein from red blood cells were designed as artificial protein building blocks for fabricating polymer networks that can translate ankyrin nanomechanics to macroscale functional biomaterials.

SESSION SB06.08: Biomedical Applications of Peptide and Protein-Based Materials III

Self-Assembling Peptide Hydrogel Materials—From Lab to Commercialization Aline F. Miller[1,2]; [1]Manchester BIOGEL, United Kingdom; [2]University of Manchester, United Kingdom

Progressive efforts are been made to develop increasingly complex soft materials, driven by both fundamental curiosity and by urgent unmet clinical needs of an increasingly aging population. Self-assembling peptides have captivated attention as a key building block for the design of soft matter as they are inherently biocompatible and allow the design of stable, versatile hydrogels for use in a variety of biomedical applications. Here, I will discuss our platform technology for the design of hydrogels exploiting the self-assembly of short (8-12 amino acids) β-sheet forming peptides, and emerging themes in understanding and controlling their self-assembly and processability to create unique nanostructures and with tunable functionality, at scale. I will go onto exemplify how they are being translated from the lab into the clinic and finding application as supports for tissue regeneration, drug discovery, scaffolds for organoid manufacture and as vehicles for targeted drug delivery through commercial venture.

8:45 AM SB06.08.02
Design of Artificial Protein Polymers for Healthcare Materials Minkyu Kim; The University of Arizona, United States

Natural materials can serve as great inspirational sources to develop next-generation polymeric materials for healthcare applications, attributed to their exceptional physical, chemical and biological properties including biocompatibility, biodegradability and potential nontoxicity. Typically, the unique properties of natural materials are related to their biopolymer components, particularly multi-functional proteins and peptides, and the structural organization of biopolymers in materials. To mimic the superior properties of natural materials, well-characterized functional protein and peptide building blocks can be engineered into artificial protein polymers, which can then be hierarchically assembled into nanostructured polymeric materials, in contrast to fundamentally constructing the entire complex natural system. Based on this bioinspired approach, my research group is focusing on the development of (i) erythrocyte-mimicking microparticles with constitutive polymer networks that contain proteins with exceptional mechanical properties for effective and long-term drug delivery, (ii) protein polymers as a material platform to promote the use of numerous antimicrobial peptides as next-generation antimicrobial therapeutics to treat various (emerging) infectious diseases, and (iii) a self-assembled protein coating on metallic biomaterials to mimic human skin-fingernail interface for an enhanced skin-implant interface. In this presentation, I will discuss our current progress in developing erythrocyte-mimicking microparticles and antimicrobial peptide-incorporated self-assembled materials, which we expect to advance a wide variety of healthcare applications, including but not limited to tissue engineering, drug delivery, and combating the antibiotic resistance crisis.

9:00 AM SB06.08.03

Genetic Fusion of Thermoresponsive Polypeptides Mediates 1D Assembly of Coiled Coil Bundlemers Sai Patkar, Yao Tang, Arriana Bisram, Darrin J. Pochan and Kristi Kiick; University of Delaware, United States

Design of stimuli-responsive nanofibrillar assemblies is of interest for generating controllable nanomaterial motion for actuation in simple machines. Protein-engineering approaches provide excellent opportunities for the design and production of extremely well-defined biomimetic materials capable of organizing different types of molecular building blocks at multiple size scales. In this study, we genetically fused thermoresponsive resilin-like polypeptides (RLPs) of various lengths to two differnt computationally designed coiled coil-forming peptides with distinct thermal stability, to develop strategies to control the assembly of the coiled coil peptides on the basis of the temperature-triggered phase separation of the RLP units. This library of RLP-functionalized coiled coils was recombinantly produced in bacterial expression hosts and purified via immobilized metal affinity chromatography. Their composition and purity were confirmed via gel electrophoresis, mass spectrometry, and amino acid analysis. Ultraviolet-Visible turbidimetry measurements at 350 nm were used to validate that the thermosensitive phase behavior of the RLPs was preserved in the genetically fused hybrid polypeptides. An increase in scattering intensity upon cooling below the transition temperature was indicative of an onset of assembly. Circular dichroism spectra showed strong helicity characteristic of the coiled coil state remaining stable in the hybrid polypeptides below their transition temperature. Cryogenic-transmission electron microscopy revealed that genetic fusion of RLPs to both coiled coil-forming peptides resulted in nanofibrillar assembly of coiled coil peptide bundlemers. Our study provides opportunities for the fabrication of thermoresponsive 1D assemblies which can be used as fundamental subunits in simple molecular machines.

9:15 AM SB06.08.04

3D Scaffold-Based Cellular Model Mimicking the Heterogeneity of Osteosarcoma Microenvironment Giada Bassi[1,2], Silvia Panseri[1], Arianna Rossi[1,3], Denis Cochonneau[4,5], Elisabetta Campodoni[1], Monica Sandri[1], Dominique Heymann[4,5] and Monica Montesi[1]; [1]Institute of Science, Technology and Sustainability for Ceramics (ISSMC)_ National Research Council, Italy; [2]University of Studies "G. D'Annunzio", Italy; [3]University of Studies of Messina, Italy; [4]Institut de Cancérologie de l'Ouest (ICO), Tumor Heterogeneity and Precision Medicine Lab, France; [5]CNRS, Nantes Université, France

INTRODUCTION

Capturing and reproducing the biological complexity of cancer *in vitro* is an exciting challenge for scientists. Osteosarcoma (OS) constituted the main entity among primary bone sarcomas with a poor prognosis due to chemoresistance and early metastasis. Following the tumor engineering approach, we developed a more predictive 3D scaffold-based *in vitro* model reproducing the OS microenvironment heterogeneity. Promising results were obtained by our group in 2020, confirming the higher predictivity of in vitro 3D bone-like scaffold-based models of enriched-CSCs compared to scaffold-free conditions[1]. Using a biomimetic hybrid scaffold, that recapitulates the bone extracellular matrix (ECM)[2], 3D cell cultures of OS enriched-Cancer Stem Cells (CSCs)[3] and co-culture of RGB human MNNG-HOS OS (HOS) cells with mesenchymal stem cells (MSCs) or HUVEC cells, will be developed and characterized.

EXPERIMENTAL METHODS

The MgHA/Coll scaffolds derive from a bio-inspired biomineralization process[2]. The enriched-CSCs were obtained by sarcosphere-forming culture[3] and RGB human MNNG-HOS OS (HOS) were kindly provided by Nantes University. The cell seeding conditions have been defined and the cell/biomaterial interaction was studied by looking at the scaffold colonization by fluorescence analysis, the cell viability and morphology (live&dead assay, histology), the expression of cell-specific markers (immunohistochemistry, Western blot analysis and qPCR), the Sarcosphere-Forming Efficiency, the Stem Cell Frequency, the migration and invasion ability (transwell inserts 8 µm pores), and looking in detail at the mechanism of cell-cell and cell-ECM crosstalk.

RESULTS AND DISCUSSION

The results demonstrate that cells can grow and colonize the surface of the scaffold; CSCs, seeded by injection onto the core of the scaffold, expressed a higher level of stemness marker compared to the 2D in vitro culture. The mimetic structure of the scaffold allows to creation a bioactive environment stimulating HOS-MSCs and HOS-HUVEC crosstalk.

CONCLUSION

Overall, the results demonstrate that the proposed 3D scaffold-based in vitro model creates a permissive and inductive microenvironment able to mimic more in detail the OS complexity.

Chondroinductive and Chondroprotective Biomaterials for Cartilage Engineering Julie C. Liu; Purdue University, United States

Despite the promise of cartilage engineering, decades of research have not yielded a long-term cartilage-engineered therapy. Traditionally, research has focused either on generating new cartilage or reducing inflammation that degrades cartilage. A significant gap exists in understanding how biomaterial properties contribute to cartilage regeneration within the inflammatory environment found in damaged joints. Our group is developing biomaterials that both promote new cartilage formation from mesenchymal stromal cells (i.e., chondroinductive) and protect cartilage matrix from degradation in a pro-inflammatory environment. To do so, we developed a hydrogel consisting of a blend of collagen I and II that harnesses the chondroinductive activity of collagen II and the superior gelation properties of collagen I gels. Incorporating collagen II into collagen I gels promotes the in vitro differentiation of mesenchymal stromal cells to cartilage and improves cartilage repair and regeneration in a rabbit defect model. Building on that work, we incorporated peptide-modified chondroitin sulfate to increase in vitro cartilage matrix formation. Furthermore, inclusion of hyaluronic acid within the scaffolds conferred protective properties to the cartilage matrix by decreasing the degradative enzymes (e.g., MMP-13) secreted by cells in the presence of pro-inflammatory cytokines.

Tailoring Multifunctional Peptide-Based Biomaterials Mibel Aguilar; Monash University, Australia

Peptide self-assembled systems offer significant advantages including biological compatibility, ease of synthesis, low toxicity and functionalisability. However, the control over essential features such as chemical, structural and metabolic stability, the scale and relatively slow rate of self-assembly remain significant challenges. We have designed helical *N*-acetyl-β^3-peptides that spontaneously undergo supramolecular self-assembly to form a new class of biomaterials [1-4]. The unique helical structure of the peptide monomer offers the opportunity to introduce a wide variety of functions to the new fibres based on straightforward modification of the side chains of the component amino acids. These materials are also resistant to proteolytic degradation further adding to their potential as novel biomaterials. We have exploited this high symmetry to design lateral supramolecular self-assembly motifs to link the fibres in a controlled manner. The bioactivity of the resulting materials can be tailored to control cell adherence and function or targeted delivery of bioactive compounds, opening up a new generation of metabolically stable and biocompatible biomaterials [5-7].

Truncated Coiled-Coil Peptides as a Building Block for Hierarchical Material Synthesis Joshua Meisenhelter[1], Matthew Langenstein[1], Jeffery G. Saven[2], Darrin J. Pochan[1] and Chris Kloxin[1,1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

Proteins are capable of incredibly complex tasks enabled by their structure and exact display of chemical functional groups. Non-native materials applications of proteins are often limited owing to their sensitivity to denaturation upon chemical modification. Unlike most proteins, shorter peptide sequences are able to undergo denaturing and refolding cycles. This work investigated use of a peptide-based material that possesses the exact display of chemistry and self-assembling properties of proteins but is readily modified without negatively impacting the hierarchical structure. In previous work, 29-amino acid sequence peptides were computationally designed to form four-peptide coiled-coil assemblies or bundlemers. The bundlemers were stable over a range of temperatures and pH as an individual unit and were modified with maleimide and thiol functional groups to polymerize through a thiol-Michael reaction to form rigid-rods. Here, we investigate the effect of truncating the 29-amino acid coiled-coil sequence to 15-amino acids. Circular dichroism revealed that the 15-amino acid sequence only forms random-coils; however, subsequent bioconjugation of two 15-amino acid peptides at their N-termini resulted in extraordinarily long rigid-rods (2nm wide by multiple microns long), as observed by cryo-TEM. The observed polymerization is hypothesized to follow a chain-growth assembly mechanism that relies on the transient formation of unstable 15-amino acid coiled-coils that initiate/nucleate stable rigid-rod formation via overhanging 15 amino-acid random-coils. This pathway is unique from the previous 29-amino acid sequences, which form through a step-growth assembly pathway. The newly developed 15-amino acid peptide sequence accesses new assembly pathways for the creation of extraordinarily rigid polymers for broad applications ranging from nanowires to ultra-strong and ultra-light fibers.

11:15 AM *SB06.09.04
Soft Computing Guided Discovery of Short Peptides and Peptide Assemblies Daniela Kalafatovic; University of Rijeka, Croatia

The discovery of new active peptides (i.e., antimicrobial, antiviral, catalytic) is challenging, as they are part of a very large search space and the correlation between the peptide sequence and the desired activities and/or functions is not yet fully understood. To avoid expensive and time-consuming guesswork and experimental failure, our strategy is to apply soft computing techniques to accelerate peptide discovery. Soft computing is a set of probabilistic algorithms, which are robust to imprecision and tolerant to uncertainty, that enable us to grapple with analytically intractable problems and make up for the lack of theoretical knowledge. In our project we apply a wide range of soft computing models to predict peptide activity, construct novel peptides and cover the chemical search space (Kalafatovic et al., J. Cheminform, 2019). More in detail, we tackle the problems of (1) sensitivity of highly accurate predictive models, (2) building predictive models with low amount of available data, (3) interpretability of neural network-based classifiers, (4) ability to generate new peptide sequences, and (5) coverage-based parallel exploration of chemical space.
Focusing on therapeutic peptides, we addressed the issue of sensitivity of highly accurate predictive models (Erjavac et al., AI Life Sciences, 2022) and proposed the sequential properties representation scheme to improve their predictive power (Otovic et al., J. Chem. Inf. Model, 2022). This provided the foundations to employ deep learning models improved by transfer learning for the prediction of underrepresented categories or poorly researched peptide functions, such as their predisposition towards self-assembly or catalysis. To gain insight into the decision process of black-box neural network models we employ the Grad-Cam technique, which enables us to pinpoint the properties and residues important for the prediction results and analyze their behavior. We envision that these strategies will maximize the chance of successful identification of functional peptides, partly reducing the environmental impact of failed experimental attempts.

SESSION SB06.10: Clinical and Translational Aspects of Peptide and Protein-Based Materials

Volumetric Imaging and Analysis of Tissues for Clinical Research through *De Novo* Formation of Citrate-Based Fluorophores Jinyoung Pac[1], Dong-Jun Koo[1], Bohyun Kim[2], Ji-Ung Park[3,1], Sung-Yon Kim[1,1] and Yan Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Konkuk University Medical Center, Korea (the Republic of); [3]Seoul National University Boramae Hospital, Korea (the Republic of)

Two-dimensional (2D) slide-based histopathology is the current paradigm in diagnosis and prognosis. However, loss of volumetric information accompanied by slide preparation provides limited information about the spatial progression of diseases that may lead to an incorrect diagnosis. Recent technological advances, especially tissue-clearing techniques, have enabled three-dimensional (3D) imaging of pathological samples to overcome these limitations. However, affinity-based labeling strategies such as small molecule dyes and fluorescently-labeled antibodies show limited compatibility with tissue-clearing techniques. Moreover, the nonspecific binding of small fluorescent probes and slow penetration of antibodies into large-scale tissues due to their high molecular weight hinder the uniform staining of biological samples and may produce misleading results. Until now, effective labeling and imaging techniques for thick tissues have not been achieved despite the demand for accurate volumetric analyses of pathological samples.
Here, we present an imaging technique, 3DNFC ("3D tissue imaging through *de Novo* Formation of Citrate-based fluorophores"), for 3D reconstruction of thick tissues through the integration of tissue clearing techniques and citrate-based fluorogenic reaction. 3DNFC provides the anatomical morphology of tissues by generating fluorophores on non-fluorescent amino-terminal cysteine and visualizes the 3D structure of the tissues. Furthermore, 3DNFC can unbiasedly analyze various features from pathological tissues in their natural context based on the 3D reconstructed images. We believe that 3DNFC overcomes many limitations of conventional histopathology and may be a suitable 3D analog for the microscopic examination of pathological samples.

1:45 PM SB06.10.02
Development of Wet Adhesive Hydrogels to Correct Tracheomalacia Ece Uslu[1], Vijay Kumar Rana[1], Sokratis Anagnostopoulos[1], Peyman Karami[1], François Gorostidi[2], Kishore Sandu[2], Nikolaos Stergiopulos[1] and Dominique Pioletti[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]University Hospital, CHUV, Switzerland

Tracheomalacia (TM) is a congenital disease seen commonly in infants. It is characterized as collapse, or narrowing of airway lumen during respiration, resulting from softness or weakness of cartilage rings and/or abnormality in tracheal muscle. The main clinical approach to solve TM is to correct the geometry of the malacic trachea and to prevent the airway collapse. Surgical interventions and stenting are commonly used treatment methods for TM. However, they have certain limitations. For example, surgical interventions are time consuming and require extensive surgical skills. On the other hand, stenting can cause stenosis, migration, erosion, and the rigidity of stents could prevent natural and dynamic neck movements in infants. Moreover, extraluminal stents needs to be fixed outside of the trachea with pexy sutures which causes trauma to the surrounding tissues. Therefore, current treatment options are not well-suited and there is no well-established method to treat TM effectively.

To overcome these limitations, a numerical model was developed to prove the hypothesis that airway collapse can be hindered by correcting the geometry of malacic trachea with the external mechanical support of an adhesive hydrogel patch. This *in silico* model showed that the application of an adhesive hydrogel patch helped to preserve the physiological shape of the trachea by constraining the tracheal membrane folding. Based on this study, we formulated a new adhesive hydrogel employing hydroxyethyl acrylamide (HEAam) and Polyethylene glycol dimethacrylate (PEGDM). We found that HEAam-based hydrogels provided robust wet adhesion on the tracheal surface thanks to the two-step polymerization approach, bonding firmly to the tissue surface much better than currently known adhesive hydrogels. We further used micro-CT and *ex vivo* measurements to prove the potential of the hydrogel patch to restrain the luminal collapse when it is wrapped to a malacic trachea extraluminally. Finally, we examined the durability and stability of the hydrogel with and without corporation of PEG-NHS in enzymatic and oxidative mediums. We observed that PEG-NHS increased adhesion performance, and decrease swelling and degradation behavior, which are key aspects to consider for biomaterials in long term. Therefore, this study, to be confirmed by in vivo studies, can overcome the current limitations and open the possibility of a new treatment in the difficult clinical situation of tracheomalacia in newborn.

2:00 PM SB06.10.03
NIR Light-Responsive Proteinaceous Ag_2S Nanodots as a Biocompatible Nanotheranosis Platform for Imaging-Guided Photodynamic Anticancer Therapy Mou Seung Kim[1], Yong J. Jeong[2] and Yun Kee Jo[1,1]; [1]Kyungpook National University, Korea (the Republic of); [2]Korea National University of Transportation, Korea (the Republic of)

Light-responsive nanotheranostics are highly desirable for cancer theranostics because they can make it possible to visualize and treat the cancer specifically through precise external modulation of the site *via* a single injection. Quantum dots (QDs) have been extensively considered to construct light-responsive nanotheranostics due to excellent optical properties and rich surface chemistry. However, the clinical application of QDs-based nanotheranositcs is still elusive due to the potential toxicity of contrast agents and the poor retention at the target site. Here, a sticky protein-based nanodots platform that simultaneously allows near-infrared (NIR)-responsive photodynamic therapy (PDT) treatment and real-time tracking in a highly biocompatible, site-specific manner. A suite of proteinic nanoparticles decorated with silver sulfide (Ag_2S) QDs were fabricated through electrospraying and subsequent biomineralization of a bioengineered mussel adhesive protein fused with a silver-binding AgP35 peptide (MAP-AgP35) under mild condition. The light-activatable proteinic Ag_2S nanodots exhibited excellent anticancer therapeutic effects through intensive release of reactive oxygen species (ROS) as well as effective *in vivo* imaging ability under irradiation of NIR light (808 nm), while showing a good biocompatibility towards normal cells. Thus, our mussel protein-based Ag_2S nanodots have a great potential as a externally controllable nanotheranostics to realize imaging-guided therapeutic implications for the complete ablation of cancer.

2:15 PM SB06.10.04
Heterofunctional polYmeric DegRAding Chimeras (HYDRACs)—A Novel Class of Compounds Capable of Targeted Protein Degradation Max M. Wang, Mihai Truica, Brayley Gattis, Sarki Abdulkadir and Nathan C. Gianneschi; Northwestern, United States

ackground
The proto-oncogene Myc is known to play critical roles in tumorigenesis and therapeutic resistance, being dysregulated in >70% of human cancers. Heterodimerization with its binding partner Max is known to be required for oncogenic transformation, yet the development of small molecule inhibitors has been hampered due to the lack of suitable binding pockets. Myc inhibitory peptides derived from the first helix (H1) of the bHLH-LZ region have been generated in efforts to address this limitation. However, poor pharmacokinetic profiles have precluded their clinical translation. Here, we use a novel modular platform technology referred to as the Heterofunctional polYmeric DegRAding Chimera (HYDRAC) for the development of dual-functional Myc inhibitors/degraders.
Methods
HYDRACs were generated using ring-opening metathesis polymerization (ROMP) wherein peptides occupy every side chain, resulting in structures highly resistant to proteolysis. Characterization was done using HPLC, ESI, NMR, and GPC. Taking advantage of the platform's ability to multiplex different payloads in a sequence-controlled manner, heterofunctional constructs were designed incorporating secondary sequences in addition to Myc-targeting H1. Specifically, a degron sequence (RRRG) was incorporated to engage endogenous cellular machinery for targeted protein degradation. For biological

studies, immunofluorescence and confocal microscopy were used to assess cellular penetration; cellular viability assays coupled with use of both cellular (isogenic pairs, Myc-dependent and independent lines) and biochemical (scrambled H1 sequence, homopolymers, monomeric peptides) controls were used to assess tumor antiproliferative effects and Myc-specific responses. Myc target engagement was assessed via immunoprecipitation assays, NMR, circular dichroism, and fluorescence polarization with protein degradation monitored by Western blot. A CRISPR knockdown library screen of all known E3 ligases and mass spec was used to identify pathways responsible for HYDRAC-induced protein degradation.
Results
A library of HYDRACs with narrow polydispersity and predetermined degrees of polymerization were generated. These heterobifunctional compounds were shown to be cell-penetrating with antiproliferative effects at sub-micromolar IC50 values in a formulation- and Myc-dependent manner. HYDRAC treatment resulted in significant decreases in Myc protein levels, which was rescued by proteasomal inhibition with MG132, without changes in mRNA levels. RNAseq showed selective overexpression of Myc pathway genes, suggesting on-target effects. Biophysical analysis showed strong HYDRAC-Myc interactions, which was further supported by the presence of Myc protein following pull-down of biotin-terminated HYDRACs. Selectivity studies revealed that the antiproliferative effects and Myc engagement of HYDRACs require an intact H1 targeting sequence. Identification of E3 ligases implicated in the degradation pathway using a combination of a CRISPR knock down library and mass spectrometry are ongoing. Mice bearing transplanted Myc-CaP tumors, mimicking the clinical course of human castration resistant prostate cancer, showed delayed tumor growth following IP administration of Myc-degrading HYDRACs. Studies exploring the biodistribution and pharmacokinetic profile of the compound, as well as the ability to degrade other proteins of interest using combinations of degron sequences are ongoing.
Conclusion
We present a novel platform technology that addresses the challenges inherent to peptide delivery approaches. The presented work demonstrates the feasibility of HYDRACs for targeted Myc inhibition and degradation, providing rationale for further studies in Myc-driven tumor models. This successful demonstration of a first-in-class compound also opens the door for the development of HYDRACs targeting other proteins of interest and incorporation of different E3 ligase recruiters for tissue or disease-specific activity.

Modeling of Intrinsically Discorded Protein Mimicking Hybrids for Membraneless Organelles Formation Kalindu S. Fernando and Ying Chau; Hong Kong University of Technology, Hong Kong

Dynamic assembly and formation of membraneless organelles (MLOs) via liquid-liquid phase separation (LLPS) is a versatile mechanism for the spatiotemporal regulation of living cells. These MLOs actively regulate biochemical reactions and are enriched in various biomolecules to improve cell functions. Due to these functionalized abilities of MLOs, there has recently been an increasing trend to develop synthetic biomaterials that mimic natural MLOs. We have developed a multi-scale computational framework to predict the LLPS behavior of both Intrinsically Discorded Proteins (IDPs) and IDP mimicking hybrids developed in our lab extracting interactive motifs from FUS, a widely studied model for MLOs.
Our computational model draws essential inspiration from the sticker-spacer representation described in associative polymer theory. The potential stickers are identified using the LARKS (low complexity aromatic rich kinked segments) identifier followed by molecular dynamics (MD) and Monte Carlo (MC) simulations to capture the interaction energies and represent the stochastic nature of MLOs, respectively.
First, we identified 18 LARKS available in FUS protein using LARKSdb as potential stickers, and in-between peptide segments are considered spacers for modeling purposes. Molecular docking, followed by MD simulations for stickers, demonstrated that 13 stickers could form transient beta-sheet-like structures, and others can only form random coils. Further, their suitability for stickers was confirmed by the radius of gyration (6.18 ± 0.6 Å) and solvent-accessible surface area (7.3 to 12.0 nm2). Using the molecular mechanics Poisson−Boltzmann surface area (MMPBSA) method, the estimated pairwise interaction energies between stickers ranged from ~100 kJ/mol. All spacers were enriched in over 70% of disorder-promoting residues and had less than 30% of charged residues at physiological pH conditions by employing the CIDER webserver.
Next, we generated lattice Monte Carlo simulations to describe the stochastic movements of IDPs under physiological conditions incorporating interaction energies found above. IDP chains were configurated as strings of coarse-grained beads and randomly placed in a three-dimensional simple cubic lattice as a canonical ensemble. We performed 106 orders of hypothetical Monte Carlo movements as self-avoiding random walks on the lattice to obtain an equilibrated system using the Metropolis-Hastings algorithm as movement acceptance/rejection criteria. We could qualitatively demonstrate the dynamic assembling and disassembling behavior of the system. We also used the radial distribution function to identify the system's phase boundaries and estimate the degree of LLPS propensity.
FUS-full protein, FUS-prion-like domain, and FUS-RNA binding domain separately found that FUS-full protein has the highest propensity to undergo LLPS and FUS-RBD domain has the lowest propensity to undergo LLPS while FUS-PLD has an in-between propensity. These findings have a good agreement with available experimental observations. Hence the model was validated. Then we applied the computational framework to IDP mimicking hybrid having only two stickers from FUS protein incorporated with dextran as spacers. Our model could successfully track the synthetic hybrid system's dynamic assembly and disassembly behavior. These computational estimations were also verified by turbidity testing and confocal microscopic observations.
In summary, our approach will provide a comprehensive theoretical framework to predict the LLPS behavior of IDPs and IDP-mimicking hybrids. It also provides a fast and economical means to guide the design of such systems to regulate the LLPS process efficiently.

The authors would like to thank the funding support from the Hong Kong Research Grants Council (GRF 16102520). M.K.S.Fernando receives financial support from the Hong Kong Ph.D.Fellowship Scheme.

3:45 PM SB06.11.02
Sequence-Tunable Phase Behavior and Unexpected Fluorescence in Designed, Dynamically Interacting Peptide Networks Deborah Sementa[1], Rachel S. Fisher[2], Dhwanit Dave[1,3], Tong Wang[1], Ye He[1], Shana Elbaum-Garfinkle[1] and Rein Ulijn[1,3]; [1]CUNY Advanced Science Research Center, United States; [2]Columbia University, United States; [3]Hunter College, United States

The liquid-liquid demixing of proteinaceous material is sustained by a network of weakly binding interactions among amino acids’ side chains (e.g.,

electrostatic, cation- and -) and it has been demonstrated that the distribution of such side chains significantly affects their phase separation behavior.
Here, we report *de novo* engineering of peptide analogues for systematically depicting the impact on the phase behavior of the chemical structure of the amino acids' moieties and their nonrandom allocation. Uniformly mixed solution, aggregates, or simple coacervates can be obtained tuning the composition and the patterning of repeats of the motif R/HxxxY, in a pH responsive manner.
Moreover, self-coacervating peptides exhibit a sequence-specific intrinsic fluorescence that is readily observable by confocal microscopy, allowing their specific characterization without any additional dye. Displaying a high cell uptake efficiency, these artificial membraless compartments readily cross the cell membrane and can potentially serve as label-free delivery platform for macromolecular therapeutics.

Peptide-Based Coacervates as Catalytic Microreactors Sara V. Pereira[1], David Reis[1], Ana Priscila Ramos[1], Pedro M. Pereira[1], Leonor Morgado[2,3] and Ana S. Pina[1]; [1]Instituto de Tecnologia Química e Biológica António Xavier Universidade NOVA de Lisboa, Portugal; [2]UCIBIO – Applied Molecular Biosciences Unit, NOVA School of Science and Technology, NOVA University Lisbon, Portugal; [3]Associate Laboratory i4HB – Institute for Health and Bioeconomy, NOVA School of Science and Technology, NOVA University Lisbon, Portugal

Enzymes' machinery has been hypothesized to be evolved from much simpler functional precursors such as peptides (*1*). Peptides are well-implemented as chiral catalysts in organic reactions (*2*). However, their use in aqueous reactions is still limited and remains a challenge in molecular engineering. However, the modest efficiency of peptide catalysts in aqueous media could arise from their heterogeneity in conformation, which is challenging to control (*3*). Different strategies have been used to tackle peptides' conformational heterogeneity, yet their catalytic efficiency is still modest(*4*).
Cells organize their biochemical reactions in membraneless compartments, formed by liquid-liquid phase separation (LLPS) of intrinsically disordered proteins by specific peptide motifs or by their interaction with nucleic acids. Coacervates, also created by LLPS, are associated with the origin of life as primitive models of protocells (*5*) and provide mechanisms for shielding oligomers from bulk solutions and concentrating biomolecules, thus facilitating a variety of processes such as catalytic function(*5*). Therefore, the compartmentalization of catalytic peptides seems an exciting route to evolve catalytic role in often modest peptides and a strategy to constrain their conformational flexibility often observed in bulky solutions(*4*).
In this work, we show for the first time the creation of dynamic micro-sized liquid condensates formed by a catalytic peptide, whose primary sequence (KVYFSIPWRVPM) (*6*) is composed of phase-separating residues (Arg, Lys, Tyr, Phe, Try, and Pro). Simultaneously, the peptide can hydrolyze phosphate ester compounds and bind to phosphotyrosine assemblies with supramolecular selectivity(*6*).

Sequence-structure-function relationship is critical for the formation of these catalytic coacervates. Turbidity measurements and optical microscopy revealed that the peptide could phase separate and form coacervates. However, a delicate balance between peptide concentration and environmental conditions could also lead to peptide aggregates. Circular Dichroism and NMR revealed that the peptide presents a fully-folded β-hairpin structure only in the coacervate phase, and the LLPS driven by cation-π and aromatic interactions. Compared with peptide soluble and aggregated states, the peptide shows a partially folded hairpin-like structure or a lack of structure. The dynamics and sequestration ability of the coacervates towards a range of guest molecules ranging from small molecules to phosphorylated assemblies was exploited. The partitioning of the molecules showed to be controlled by charge interactions. However, the hydrophobicity character of the catalytic peptides seems to play a role in mediating this process, which further influences the microenvironment of the catalytic coacervates.

Ultimately, these catalytic coacervates-based reactors' efficiency was studied and compared to the peptide in bulky solution. This work provides a substantial opportunity to leverage the field of catalytic peptides to regulate catalytic efficiency through the compartmentalization of short peptide catalysts in aqueous media.

A Novel Insect Cuticle Peptide-Based Nano-Capsule Platform Haopeng Li[1], Xuliang Qian[1], Harini Mohanram[1], Tian Liu[2], Huajian Gao[1,3] and Jing Yu[1,1]; [1]Nanyang Technological University, Singapore; [2]Dalian University of Technology, China; [3]A*STAR, Singapore

Nano-capsules can be used to transport a variety of substances into eukaryotic cells. Herein, we develop a novel insect cuticle peptide (ICP)-based nano-capsule platform with the potential for cytosolic drug delivery applications. Originated from insect cuticular proteins, the ICPs can form hollow nano-sized capsules in mixed solvents, via an unusual liquid-liquid phase separation (LLPS) mediated self-assembly process. However, the underlying mechanism of ICP self-assembly remains unclear. By combining molecular dynamics (MD) simulations and biochemical experiments, we present the first study to unravel the mechanics of ICP self-assembly, and to demonstrate the tunability of ICP nano-capsules simply by controlling the peptide sequences. The successful co-delivery of hydrophilic and hydrophobic drugs with synergistic effects is confirmed experimentally. With this work, we aim to exemplify the potential of our ICP-based nano-capsule platform for important biomedical applications, such as drug delivery, cancer therapy and precision medicines.

4:30 PM SB06.11.05
Cell-Like Containers with Inner Organelles Formed by Coacervation of Proteins and Biopolymers Faraz Burni and Srinivasa R. Raghavan; University of Maryland, United States

Eukaryotic cells contain multiple inner compartments (organelles) that enable cells to carry out a variety of biochemical processes. Some of these organelles (such as the nucleolus) lack any external membrane. Recent studies have shown that these membraneless organelles are formed by liquid-liquid phase separation, which is also called coacervation. This coacervation is a dynamic process, and it can be turned 'on' and 'off' as desired; in turn, the nucleolus forms when needed by the cell, and at other times it disappears.

In this study, we mimic cellular architecture by creating biopolymer capsules with a membraneless compartment inside. The inner compartment is created by complex coacervation, which is a liquid-liquid phase separation of a solution containing two oppositely charged polymers. Much like the nucleolus, this compartment can reversibly form and disintegrate by changes in environmental stimuli such as pH, ionic strength, and polymer composition. Different biomolecules and colloidal species can be sequestered by this compartment and in turn, can be released when the compartment disintegrates. Owing to the 'smart' inner compartment, the overall capsules exhibit interesting behaviors and can be used for a variety of applications like drug delivery, biosensing, and reaction engineering. The ability to reversibly assemble such membraneless organelles can also provide insight into important biochemical processes.

4:45 PM SB06.11.06

Biophotovoltaics—Converting Sunlight to Electricity with Photosynthetic Protein Complexes Nahid Torabi[1,2], Xinkai Qiu[3], Andreas Herrmann[2,4] and Ryan Chiechi[1,5]; [1]University of Groningen, Netherlands; [2]Zernike Institute for Advanced Materials, Netherlands; [3]University of Cambridge, United Kingdom; [4]RWTH Aachen University, Germany; [5]North Carolina State University, United States

The incorporation of light-harvesting photosynthetic proteins into device architectures has attracted tremendous attention in the past years. Biophotovoltaic devices utilize the components of natural photosynthetic proteins such as Photosystem I/II (PSI/II) to generate electrical energy under illumination by exploiting light-harvesting pigments as a photosensitizer for light-induced charge separation. Photosynthetic proteins have several desirable characteristics for inclusion into biophotovoltaic devices including rapid charge separation, carbon neutral production, non-toxic, high internal quantum efficiency approaching unity, and highly abundant starting materials. In different works, we have explored several unique strategies to improve interfacial electron transport between PSI proteins and electrodes. In our first work, we demonstrated that self assembled monolayers of simple fullerene derivatives are capable of orienting phtosystem I complexes such that they form a monolayer that injects electrons into the fullerene layer when irradiated. We formed these assemblies on nano structured electrodes embedded in microfluidic channels filled with a redox couple and a liquid metal electrode to complete a dye-sensitized biophotovoltaic device. These proteins guide the photosystem to the electrode such that they are in direct contact, allowing us to compare the efficiency of charge injection with and without the mitigation of the fullerenes. We find that the fullerenes reduce recombination in the complexes, presumably by acting as selective contacts. Moreover, the unique architecture of these devices enables self-regeneration; by circulating fresh photosystem complexes through the device, inactive complexes are replaced by active complexes via self-assembly. Also, self-regeneration is a key feature of these devices because it mimics the replenishment process in biological systems using unmodified, wild-type photosystem I and does not require any encapsulation or other interventions. The performance of devices fabricated using a fullerene, phenyl-C61-butyric acid (PCBA), was superior as determined via the short circuit current, open circuit photovoltage, and power output. The PCBA linkers self-assemble onto the bottom electrodes, simultaneously directing the orientation of PSI and facilitating the collection of photo-generated electrons. In another work, we reported a power conversion efficiency to date of 0.64% in a solid-state biophotovoltaic device by tailoring the transport layers to maximize the extraction of charges from a layer of photosystem I. Specifically, we inserted complexes of gold nanoparticles into reduced graphene oxide to adjust the level alignment without sacrificing carrier mobility. We paired that layer with a polytyrosine-polyaniline hole-extraction layer. The active layer is fabricated by self-assembly, requiring only contact with a solution containing photosystem I. We achieved an overall increase in efficiency by raising the short-circuit current without sacrificing fill-factor or open-circuit voltage. This work establishes a foundation for utilizing the unique properties of graphene-based materials decorated with metal nanoparticles in future biophotovoltaic devices. Furthermore, in other research, solid-state charge transport measurements via PCBA/PSI junctions were carried out at room temperature and down to 150 kelvin. The junctions comprising PCBA/PSI demonstrated excellent stability and reproducibility on different days during around 4 months of measurements over room temperature. The efficient electron transfer through PSI protein complexes opens up possibilities for using such protein complexes as current-carrying elements in solid-state bioelectronic devices.

SESSION SB06.12: Poster Session II: Biomedical Applications of Peptide and Protein-Based Materials
Session Chairs: Daniela Kalafatovic, Jose Carlos Rodriguez Cabello and Jacek Wychowaniec

5:00 PM SB06.12.01

Light and Heat-Responsive Collagen-Based Hybrid Nanoparticles for Controlled Delivery of Functional Proteins Doyun Kim[1], Seungki Lee[1], Sunho Hong[1], Jungwoo Choe[1], Jeong-Min Seo[2] and Inhee Choi[1]; [1]University of Seoul, Korea (the Republic of); [2]NeoRegen Biotech Co., Ltd, Korea (the Republic of)

Stimuli-responsive nanoparticles have been widely studied to improve the stability of bioactive molecules such as proteins and their targeted delivery efficiency. To this end, hydrogel nanoparticles are promising since they can store cargo with high efficiency and minimize the loss of activity. Moreover, the introduction of stimuli-responsive moieties into the hydrogel nanoparticles allows for controllable drug release at the designated sites or times. Here, we present light and heat-responsive collagen nanoparticles (CNPs) for the controlled delivery of functional proteins. Via fast radical polymerization, biocompatible collagen and thermosensitive polymer are simultaneously incorporated into hydrogel nanoparticles and gold-embedded CNPs (Au-CNPs) are simply obtained by adding gold precursor ions to the reaction mixture. Using the Au-CNPs, the functional proteins with different molecular weights, EGF, FGF2, and SOD1, were successfully loaded with high loading efficiency of 68.9%, 65.3%, and 50.3%, respectively. Under light illumination, the photothermal conversion effect from the Au-CNPs leads to the enhanced release kinetics and diffusion of loaded proteins. SOD-encapsulated Au-CNPs are successfully internalized into cells and effectively reduce ROS levels through light-responsive release. Through the wound healing test, we also observe rapid recovery in the case of treatment with EGF-encapsulated Au-CNPs without losing the activities compared with the treatment of EGF only. Furthermore, using three-dimensional cellular spheroids, we demonstrate increased proliferation rates owing to the enhanced penetration of released FGF2. We envision that the proposed light and heat-responsive CNPs will be a promising carrier to improve the physicochemical stability in the protein delivery process and improve intracellular delivery efficiency.

5:00 PM SB06.12.02

Recombinant Keratins Coating for Enhanced Skin-Implant Interface Suyoung Lee[1], Bumjoon Kim[1], Tijana Z. Grove[2], Mark E. Dyke[1,1] and Minkyu Kim[1,1,1]; [1]The University of Arizona, United States; [2]Virginia Tech, United States

Percutaneous osseointegrated prosthetics (POP), composed of metallic implants that penetrate bone and skin, are an alternative to socket-limb connection. Although POP devices have advantages for clinical usage, device failures can occur for long-term usage due to the decrease of epithelial cell attachment, epidermal down growth, inflammation, and avulsion at the skin-implant interface. To enhance the soft tissue-hard implant interface, surface modifications of the device have been conducted using morphological, physicochemical, and biochemical methods. Inspired by the skin-fingernail interface, we have investigated improving the promotion and maintenance of epidermal cell-to-device adhesion by using keratin coatings on the device. Nails, consisting of keratin, form a stable interface with mechanically mismatched skin without mechanical tearing or infection. In addition, keratins extracted from hair, wool, and feather have already been used in various biomaterials, due to its biological and mechanical durability, low immune responses, and cell adhesion properties. In our previous study, we identified that the keratin coating on metallic biomaterials facilitated the attachment of epidermal cells through focal adhesions that promoted a mature phenotype. These in vitro findings translated to an animal model where the results demonstrated reduced epidermal downgrowth. However, the work showed that the keratin coating degraded sooner than desired for the application of interest. This could be caused by various keratin nanostructures from extracted keratins that include various keratin types and contaminants due to a limitation in current keratin extraction techniques. In this study, we biosynthesized recombinant keratin to elucidate their self-assembly behaviors, depending on keratin types and explored the relationship between the self-assembled keratin nanostructures on the surface of metallic biomaterials and epidermal cell adhesion. Throughout the investigation, we examined the possibility to use recombinant keratin materials for enhanced soft tissue-metallic implant interface.

5:00 PM SB06.12.03
Multivalent Vesicles of Stimuli-Responsive Elastin- and Resilin-Based Block Copolypeptides with an Anti-Angiogenic Peptide Shahzaib Shahid, Min Jeong Kang, JaeHee Lee, Jae Sang Lee and Dong Woo Lim; Hanyang University, Korea (the Republic of)

Self-assembled nanostructures of stimuli-responsive block copolypeptides fused with a variety of functional peptides have been of growing interest because they can present multivalent functionalities and show biocompatibility and biodegradability for advanced drug delivery systems, biosensing and bioimaging applications. In this study, we developed multivalent vesicles of stimuli-responsive elastin- and resilin-based diblock copolypeptides (EBP-RBP) with the anti-angiogenic peptide, a vascular endothelial growth factor receptor 1 (VEGFR1, fms-like tyrosine kinase-1, Flt1) antagonist known as anti-Flt1 peptide, to control over migration and tube formation of human umbilical vein endothelial cells (HUVECs) because it competitively binds to the VEGFR1 in the presence of VEGF for anti-angiogenesis. The anti-Flt1-EBP-RBPs were molecularly cloned, over-expressed in *E. coli* and non-chromatographically purified with high yield by inverse transition cycling. The anti-Flt1-EBP-RBPs were self-assembled into vesicles under physiological conditions by thermal trigger due to aggregated RBP block below the UCST (upper critical solution temperature) and soluble EBP block below the LCST (lower critical solution temperature). In contrast to EBP-RBPs, the anti-Flt1-EBP-RBPs showed decrease in LCST and an increase in UCST because of hydrophobicity of the anti-Flt1 peptide (GNQWFI). The vesicles of the anti-Flt1-EBP-RBPs showed concentration and incubation dependent intracellular localization in HUVECs through molecular interactions of multivalent anti-Flt1s against the VEGFR1. Especially, migration and tube formation of HUVECs was largely inhibited in a dose-dependent manner by the vesicles with multivalent anti-Flt1s on the condition of VEGF-triggered angiogenesis signaling. Therefore, the self-assembled block copolypeptide-based vesicles with multivalent VEGFR1 antagonists would be of great potential as targeted drug delivery systems for anti-angiogenesis such as treatment of retinal and choroidal neovascularization.

5:00 PM SB06.12.04
Macro-Scaled M13 Bacteriophage-Based Hierarchical Fiber for Piezoelectricity-Induced Cell Regeneration SangMin Lee, YuJin Lee, CheongWoo Park and Ju Hun Lee; Hanyang University, Korea (the Republic of)

Regenerative medicine is a major domain of medical technology that aims to restore and develop tissue or organs' own functions by replacing or regenerating damaged human cells, tissues, and organs. Of these targets, tissue engineering is a promising method used to identify damage from aging, injury, and degenerative diseases by reestablishing structural and functional properties of tissues, or organs. Previously, scaffolds produced with biocompatible materials have been developed that stimulate tissue regeneration at the cellular or molecular level. However, most of the research regarding scaffolds with biomaterials focused on mechanical support and biofunctionality, which is related to the enhancement of biological interactions with bodily components. These interactions provoke stimulatory actions, although, the effect is insufficient to regenerate the tissue of interest and to make a clinical trial. In this regard, we proposed a system that produces microcurrents, relatively weak currents that mimic the spontaneous generation of currents in the human body, for tissue-specific generation and promotion of cell development/regeneration. These microcurrents induce a therapeutic effect that treats damaged bodily tissues retaining piezoelectric coefficients. The system is composed of an M13 bacteriophage-based material that was hierarchically self-assembled to create a fibrous structure using a bottom-up strategy. A magnetic field was applied to M13 phage solution for unidirectional alignment of the material, followed by fixation. The optical anisotropic property of the aligned macrostructure was qualitatively analyzed using polarized optical microscopy, and quantitatively analyzed using birefringence measurements. When sample was placed between the polarizer and analyzer, there were difference of image appeared between the highly aligned structure and randomly aligned structure. The highly aligned structure presented a higher birefringence value (Δn=|n_e-n_o|) than randomly aligned structure that was not applied magnetic field. Furthermore, Unidirectional alignment of the structure was qualitatively, and quantitatively confirmed through Second Harmonic Generation (SHG) microscopy and its SHG intensity due to the non-linear polarization induced by interactions between photons of incident electromagnetic waves and electrons of molecules constituting non-centrosymmetrical material. The piezoelectric coefficient of the structure can be increased by unidirectionally aligning the bio-piezoelectric M13 phages, which can be adjusted depending on the concentration of the phage and intensity of the applied magnetic field to mimic the piezoelectric coefficient of the target tissue. Specifically, we investigated the piezoelectric response of osteoblasts to bone piezoelectricity-mimetic material. When mechanical force was applied, the phage-based macrostructural material generated a piezoelectric response specific to the bone and promoted proliferation and differentiation of the osteoblasts to osteocytes in vitro. To the best of our knowledge, this is the first case in which biomolecules of a single type are assembled to fabricate a piezoelectric macrostructure that produces a piezoelectric coefficient comparable to signals from bodily tissues. We plan to further develop the system to characterize effects of 3-dimensional scaffolds that made up of M13 phage-based hierarchical materials into various cells or tissues in vitro as well as in vivo.

5:00 PM SB06.12.05
***In Situ* Gelation of Stimuli-Responsive Elastin and Suckerin-Based Tri-Block Copolypeptides with Adhesive Properties** Dong Woo Lim, JaeHee Lee, Jae Sang Lee, Min Jeong Kang and Shahzaib Shahid; Hanyang University, Korea (the Republic of)

Recombinant protein-based bioadhesives have been of great importance for biomedical applications because their amino acid sequences, molecular weights, and physicochemical properties are precisely controlled at gene level while they have biocompatibility and biodegradability. There have been some studies on mussel foot protein-, suckerin- and elastin-based bioadhesives based on the l-3,4-dihydroxylphenylalanine (DOPA)-mediated cross-linking as well as the cross beta sheet. In this work, we rationally designed, bio-synthesized, and non-chromatographically purified a series of ABA type tri-block copolypeptides composed of sticky elastin-based polypeptides (EBPs) and beta sheet-forming suckerin-based polypeptides (SBPs) at different block length ratios for injectable hydrogels with controlled surface adhesion properties. Especially, in order to introduce the adhesive properties of stimuli-responsive EBPs, sticky EBPs with varied ratio of Lys and Tyr residues were prepared for pi-cation interactions and DOPA-mediated surface adhesion by enzymatic hydroxylation. We hypothesized that SBPs would form the stable cross beta sheets while sticky EBPs having DOPA-induced adhesive- and cohesive interactions. The modified ESE (mESE) triblock copolypeptides showed controlled lower critical solution temperature (LCST) behavior depending on the length of SBP under the identical EBP block. Moreover, the mESE triblock copolypeptides under dilute conditions exhibited self-assembled nanostructures mediated via molecular interactions between SBP blocks below LCST. The concentrated mESE triblock copolypeptides with sodium periodate rapidly formed hydrogels via formation of the cross beta sheets of the SBP block and periodate-mediated crosslinking of DOPAs. The physically and chemically cross-linked mESE triblock copolypeptide hydrogels with controlled mechanical properties showed finely tuned adhesive strength in the range of 0.5 – 5.5 MPa depending on the concentration of sodium periodate and SBP block length. In conclusion, the injectable triblock copolypeptide hydrogels with controlled adhesive strength under wet conditions make them ideal candidates for biomedical applications such as sealants after anastomosis and tissue adhesives.

5:00 PM SB06.12.06
Aptamer-Guided Site-Specific Bioconjugation Enables Ultra-Efficient Covalent Coupling of a Nucleic Acid with an Intact Protein Hyesung Jo and Seung Soo Oh; Pohang University of Science and Technology, Korea (the Republic of)

Specific bioconjugation of a nucleic acid to a protein is not only used to identify, manipulate and functionalize the native protein but also provides a programmable linker that can interconnect the active protein with other functional molecules. Currently, most bioconjugation methods apply random modification, thereby disrupting the integrity of the protein structures and functions; otherwise, genetically engineered proteins are required for site-specific modification, significantly increasing its complexity and costs. Site-specific bioconjugation of intact proteins with functional nucleic acids has been an unmet need while fully securing the activity of the conjugated proteins. In this work, we propose the engineered aptamer-guided covalent conjugation of a nucleic acid to an unmodified protein as the guanine analogue, formed by nitrosation of guanine, can mediate activation-free crosslinking with nearby natural proteins. By inventing a synthetic way to prepare the reactive base-containing aptamer, we demonstrate that the newly synthesized aptamers targeting many different proteins can form a covalent linkage to the aimed location of the target proteins with exceptionally high specificity and efficiency.

5:00 PM SB06.12.07
Semi-Permeable Protocells Enable Direct Target Detection in Non-Purified Blood Jinmin Kim and Seung Soo Oh; Pohang National University, Korea (the Republic of)

In controlling the transport of molecules, many different types of size-selective membranes have been used in various applications, including water purification, electrolyte separation of batteries, and biological compartmentalization. In particular, regulation of molecular transport can be beneficial for biosensors; effective exclusion of fouling molecules can be directly linked to sensitive and selective detection of targets, even in complex body fluids. In this work, we explored the potential of semi-permeable protocells for point-of-care testing with no sample purification. Due to the small size, the membrane of the protocells can exclusively allow the entry of analytes with no access to nucleases and charged proteins, which would be an optimal environment for encapsulated DNA sensing probes. To this end, we first introduced the water-in-oil emulsion to construct the semi-permeable microcapsules composed of self-assembled protein-polymer amphiphiles. In the microstructure of the cross-linked membrane, newly designed aptasensors were subsequently enclosed to report the presence of various biomarkers via fluorescent signaling. We demonstrate that the aptasensor-encapsulated protocells achieve multiplexing real-time detection of estradiol, dopamine, and cocaine, even in undiluted blood and serum.

5:00 PM SB06.12.08
TMD Nanosheets with Abiotic Recognition Phases for Pathogen Detection and Inactivation Sin Lee[1], Yoonhee So[1], Chanhee Choi[1], Lee Hyun ji[1], Hongwon Kim[1], Chul-Su Yang[1], Hwankyu Lee[2] and Jong-Ho Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Dankook University, Korea (the Republic of)

Antibodies are representative recognition molecules selectively binding to target antigens, leading to wide applications for sensing and therapy. However, antibodies have some limitations such as low stability, long production time, and high cost. Thereby, there is an increasing demand for the development of alternative recognition molecules in theragnosis. Several biomimetic strategies have been developed to circumvent these limitations, including molecular imprinting, peptoids, and engineering nanointerfaces. Despite these efforts, it is still of great interest to devise an effective strategy to mimic antibodies for simultaneous sensing and therapy. Herein, we report an effective approach for the design of biomimetic nanohybrids capable of the selective recognition and inactivation of pathogenic bacteria. Tripeptides with a nitriloacetate-Cu group were spontaneously assembled on transition metal dichalcogenide (TMD) nanosheets (TMD-TP) to form abiotic recognition phases for target bacteria, producing various types of TMD-TP antibody mimics. The resulting TMD-TP antibody mimics exhibited strong Raman scattering signals for bacterial sensing and photothermal effect under infrared irradiation for bacterial inactivation. The recognition mechanism of TMD-TP antibody mimics against the specific bacteria was thoroughly investigated by experiments and molecular dynamics simulations. Finally, the TMD-TP antibody mimics could sensitively recognize each target bacteria up to a single copy from human serum and urine in a rapid manner. In addition, the $MoSe_2$-CHC antibody mimic was successfully applied for the effective eradication of *S. typhimurium* infecting the wounds of mice under NIR irradiation. These biomimetic nanohybrids can be extended to theragnosis of a variety of biomolecules.

5:00 PM SB06.12.10
The Protein-Like Polymer (PLP)—A Tunable Proteomimetic Nanoplatform for the Development of Rationally Designed Cancer Vaccines with Therapeutic Efficacy in Multiple Tumor Models Max M. Wang[1], Mi Ran Choi[1], Brayley Gattis[1], Baofu Qiao[2], Monica Olvera de la Cruz[1], Bin Zhang[1] and Nathan C. Gianneschi[1]; [1]Northwestern, United States; [2]Baruch College, United States

Background
Utilizing tumor antigens for the development of patient-specific cancer vaccines has been a promising therapeutic strategy. However, significant challenges remain in delivering subunit vaccine components in a manner capable of eliciting antitumor immune responses. To overcome these, we developed rationally designed cancer vaccines using a novel nanoplatform called the Protein-Like Polymer, a reference to its globular structure reminiscent of native proteins, with unique characteristics allowing for sustained targeted delivery of tumor antigens in conjunction with immunomodulatory STING agonists.
Methods
PLPs containing peptide antigens were synthesized via ring-opening metathesis polymerization (ROMP) and characterized using NMR, HPLC, ESI, and SEC-MALS. A library of compounds with different sidechain linkage chemistries, degrees of polymerization (DP, number of side chains per polymer), and inclusion/exclusion of Oligo(ethylene glycol) (OEG) were made. Cell uptake and functional assays using payload-specific T Cells were conducted using polymers with or without fluorescent labels. Immunization in independent tumor models was done to show generalizability. Ability of PLPs to co-deliver adjuvants was tested by electrostatically coupling a small molecule STING agonist, 2’3’ cGAMP, forming stable nanostructures.
Results
Dense brush polymers wherein every side chain extending off a hydrophobic polymer backbone consists of peptide antigens were successfully generated with narrow polydispersity and predetermined DPs. Conjugating peptide antigens to the polymer backbone using a cleavable disulfide linkage, designed to reduce intracellularly in antigen presenting cells (APCs), resulted in increased endosomal localization, higher levels of induced T cell proliferation, cytokine production, and expression of activation markers in CTLs and APCs. Incorporating a diluent amount of OEG side chains reduced enzymatic degradation while increasing immunogenicity and uptake by APCs. Additionally, increasing the DP, and therefore the density of antigen side chains, further improved vaccine efficacy and resistance to proteolysis. Antigen-PLP conjugates enhanced dendritic cell activation and T-cell response only when paired with cells from their cognate system, with no response in immune cells not expressing receptors for the payload, further demonstrating antigen-specificity. Mice bearing established B16F10 melanomas treated with PLPs containing gp100 resulted in significant increases in survival time, reduced tumor burden, and corresponding changes in immune cell profiles. Impressively, mice treated with STING electrostatically complexed to antigen-PLPs showed significantly smaller tumors vs non-complexed combination treatment while allowing for subcutaneous administration of 2’3’ cGAMP, which alone requires intratumoral injection due to rapid diffusion. Studies on MC38, TC-1, and LLC1-OVA tumors, paired with adpgk, HPV-E7, and OVA-bearing PLPs respectively, as well as pools of neoantigens multiplexed onto a single PLP are ongoing.
Conclusion
This work validates the ability of PLPs to overcome major limitations in cancer vaccine development, enabling sustained delivery of antigens and adjuvants. The modularity of the platform allows for complex nano-architectures including systems capable of delivering challenging compounds, ie small

molecule STING agonists, subcutaneously through stable electrostatic coupling. The ability to multiplex multiple different antigenic sequences as mosaic structures further highlights the PLP platform's potential to revolutionize cancer vaccinology.

Theoretical Understanding of Self-Healing Polymer Networks with Dynamic Bonds—from Hydrogels and Elastomers to Thermosets Qiming Wang; University Southern California, United States

Polymer networks crosslinked by dynamic bonds have received intensive attention because of their special crack-healing capability. Diverse DPNs have been synthesized using a number of dynamic bonds, including dynamic covalent bonds, hydrogen bonds, ionic bonds, metal-ligand coordination, hydrophobic interaction, and others. Despite the promising success of polymer synthesis, the theoretical understanding of their self-healing mechanics is still at the very beginning. Here, we present a series of polymer-network-based theoretical models to understand the constitutive and interfacial healing behaviors of these dynamic polymer networks. Our theoretical system can explain various polymer networks in form of hydrogels, elastomers and thermosets, and various dynamic bonds. We expect our model to be a powerful tool for the self-healing community to invent, design, understand, and optimize self-healing polymer networks with various dynamic bonds.

11:00 AM SB07.01.03
Self-healing Cellulose Ionogels—Circularity for Stretchable Electronics Yu Jun Tan; National University of Singapore, Singapore

Cellulose is a bio-based and biodegradable material that can be made self-healing to enhance its durability and lengthen its lifetime. Here we choose carboxymethyl cellulose as the base material for its high chain mobility from the partial substitution of the cellulosic chains. We report a cellulosic ionogel with autonomous self-healing ability and ionic conductivity by adding a non-toxic ionic liquid to carboxymethyl cellulose [1]. The ionogel shows repeatable electro-mechanical self-healing due to the dynamic bonds between the cellulosic hydroxyl groups with the ionic liquid. We also develop an ionically conductive hydrogel by crosslinking the carboxymethyl cellulose network with citric acid and trivalent cation [2]. The hydrogel autonomously self-healing damages thanks to the hydrogen and metal coordination bonds. Due to the presence of free-moving ions in these ionogels, they exhibit high ionic conductivity in the order of 10^{-3} to 10^{-2} S/cm. Along with their high optical transparency, these ionogels show the potential to be employed in a wide range of practical applications, from strain sensing applications to optoelectronics.

11:15 AM *SB07.01.04
Self-Healable Covalently Adaptable Networks (SH-CAN) Marek W. Urban; Clemson University, United States

The effectiveness of van der Waals (vdW) interactions formulated the new path (Science 2018) for the development of acrylic-based copolymers that exhibit self-healing. Taking advantage of the large polarizability of copolymer side groups, non-directional vdW interactions between neighboring macromolecular segments are enhanced, which upon mechanical damage return to their initial conformations. This process can be accelerated by the presence of confined water molecules. Since dipole-dipole, dipole-induced dipole, and induced-dipole induced dipole interactions significantly impact viscoelastic response controlling macroscopic autonomous multicycle self-healing, the presence of ionic liquid units copolymerized into one macromolecular chain also alters vdW forces, thus providing an opportunity for applying electric fields to accelerate self-healing. The last part will focus on the most recent developments of self-healable and reprocessable covalent adaptive networks (CANs).

SESSION SB07.02: Dynamic Polymer Network II—Self-Healing

Tunable and Patterned Biomimetic Networks via Secondary Metal-Ligand Complex Formation Declan Shannon, Josh Moon, Christopher Barney and Craig Hawker; UCSB, United States

Natural systems leverage multiple bonding motifs for reinforcing polymer networks, and as a result biological materials provide an excellent guide for the design of next generation high performance networks. Mixed crosslinking motifs based on covalent and metal-ligand complexes in networks are ubiquitous in nature and have inspired the design of synthetic covalent networks reinforced via metal-ligand bonds. These materials have shown remarkable success in reinforcing mechanical properties of the softer polymeric networks. We report a versatile synthetic procedure for the preparation of modular networks that allows independent tunability of both the covalent and metal-ligand crosslink density. Control over the covalent network is achieved through photopolymerization, followed by post polymerization incorporation of ligand units, allowing different networks to be prepared with a variety ligands. By tuning the ratio of each building block, covalent networks reinforced by metal-ligand bonds exhibit a wide range of properties (elastic moduli up to ~245 MPa), well beyond what can be achieved through purely covalent crosslinking. This facile approach also permits local patterning of metal complexed regions through soft lithography techniques forming distinct hard and soft regions. To showcase the spatiotemporal control of this techniques, biomimetic constructs were fabricated with this modular platform that cannot be achieved through traditional methods, showing promise for applications ranging from composites, to soft robotics, and metamaterials.

1:45 PM SB07.02.02
Valency-Dependent In 3D-Architected Metallo-Polyelectrolyte Complexes Exhibiting Tunable Mechanical Behavior Seola Lee, Seneca Velling, Pierre J. Walker, Cyrus J. Fiori, Zane W. Taylor, Zhen-Gang Wang and Julia R. Greer; California Institute of Technology, United States

Metallo-polyelectrolyte complexes (MPEC) represent a unique class of materials where metal ions embedded into soft organic frameworks undergo reversible electrostatic interactions through the formation and dissociation of dynamic bonds. These molecular-level processes give rise to a wide range of material dynamic responses, for example, stimuli-responsiveness, self-healing, dissolution in solvent, and improved toughness through enhanced energy dissipation. We synthesized a 3D-architected MPEC, with dimensions of a millimeter to a centimeter, fabricated via in-situ polymerization of acrylic acid with divalent and trivalent metal ions such as Ni(II) and Al(III) via stereolithography. Water-solvated metal ions dynamically cross-link with the pendant carboxyl group of polyacrylic acid to form a dense network capable of significant mechanical deformation. From the uniaxial tensile test, the resulting materials with trivalent metal-ions are stiff and tough, with a modulus of ~3MPa and elongation strains upward to ~700% in contrast to the divalent metal-containing gels, whose modulus is about 500kPa to 1MPa with elongation upwards of ~1400%. A large hysteresis in stress-strain response and fracture toughness for trivalent metal-containing gels indicates the significant contribution of dynamic bonds in energy dissipation. The valency of the solvated metal cation critically governs the mechanical and rheological properties of the polymer network. Experiments conducted with a Dynamic Mechanical Analyzer (DMA) demonstrate that the association/dissociation of the metal cation cross-linker induces distinct dynamic properties of the gels: the storage modulus, from ~500kPa to ~5MPa, and a loss factor, tan delta, from less than 0.5 (viscous-solid like) to close to 1 (viscous-liquid like) in the ambient temperature, each varying with the valency and concentration of metal ions. Stress relaxation experiments reveal the gels with trivalent metal ions are ~60 times slower, yet the long-term relaxation process was more apparent than the ones with divalent metal ions. The local lability of the metal ions with the polymer chains serves as the origin of global material properties. To probe the mechanisms of local interaction and their manifestation in global parameters, Molecular Dynamics (MD) simulations have been employed. Using MD simulation, we examine the effects of ion valency on ionic binding within polymer chains of an equilibrated gel, both at equilibrium and under stress. Further, fundamental thermal characterization via Differential Scanning Calorimetry (DSC) and Thermo-Gravimetric Analysis (TGA) – including kinetic analysis and thermodynamics of bonding – has demonstrated the role of solvating water in mediating this valency control and has corroborated the greater enthalpic cost of thermally-activated processes in trivalent compared to divalent metal systems. We utilize valency-dependent material properties to control the nonlinear mechanical instability in 3D-printed multi-material architectures. Uniaxial compression and tension experiments conducted at strain rates of 10^{-4} to 1 s^{-1} demonstrate the strong dependence of instability deformation mode on material compositions and mechanical inputs (applied strain rate or relaxation time). These results demonstrate the synergetic effect of MPEC’s valency-dependent, tunable viscoelastic properties with nonlinear mechanical response of compliant architectures, permitting control of deformation modes in soft mechanical meta-materials.

Novel Click Chemistries for Intrinscically Chiral, Highly Functional and Dynamic Covalent Polymers—Bulk and Single-Polymer Studies Han Zuilhof; Wageningen University, Netherlands

Click chemistry has revolutionized many facets of the molecular sciences, with the realization of reactions that are ‘‘modular, wide in scope, give very high yields, generate only inoffensive byproducts that can be removed by nonchromatographic methods and are stereospecific”.

[i] Yet surprisingly little attention has been given to the development of intrinsically chiral click reactions (potentially enantiospecific rather than ‘only’ enantioselective due to chiral auxiliary groups), while the modularity of many click reactions is best compared to one-dimensional LEGO. Of course, much could be done within the constraints – hence forementioned revolution – but it drove attention towards an extension of available click chemistries.
The talk will focus on the resulting investigations in the field of S(VI) exchange chemistry, with specific emphasis on two fields: a) the development of the first intrinsically enantiospecific click reaction and its use to make synthetic polymers with 100% backbone chirality,[ii] and b) the development of multimodular click chemistry and single-polymer studies by a combination of AFM, TEM, scanning Auger microscopy.[iii]

Autonomic Damage Visualization in Covalent Adaptable Networks Tae Ann Kim and Subin Yoon; Korea Institute of Science and Technology, Korea (the Republic of)

Autonomous polymers that report damages prior to loss of function and simultaneously self-heal are highly relevant for not only preventing catastrophic failures but also extending the lifetime use of the materials, thus ultimately keeping us on the path to sustainability. Particularly, visualizing damages have been achieved by incorporating mechanochromic molecules that change optical properties in response to mechanical stresses into polymeric materials. Spiropyran (SP) is a well-studied mechanochromic molecule that undergoes a force-induced reversible 6p electrocyclic ring opening reaction to a merocyanine (MC) form. Various SP-linked mechanochromic polymers have been developed using polyacrylates, polyurethanes, silicone rubbers, polystyrenes, polyesters, and polycarbonates. But there is no attempt to integrate SP molecules into CANs, especially derived from DA chemistry. Since some DA isomers undergo force-induced retro-DA (rDA) reactions, SP incorporated DA networks would be an interesting subject to study how two different force-sensitive molecules can be mechanically activated in a single polymeric system.
Here we demonstrate self-healing and re-processable thermosets that visualize damages in optical changes by using mechanochromic SPs and thermo-reversible DA chemistry. When the thermoset is mechanically deformed or damaged, affected areas change color and emit fluorescence by SP to MC transition. Upon thermal treatment, colored MC reverts to colorless SP and reversible DA and rDA reactions reorganize polymer networks, resulting in self-healing and reprocessing. Mechanical activation of SPs in DA polymeric networks is investigated both by Ab initio steered molecular dynamics simulation and mechanical testing. We also evaluate self-healing abilities and thermomechanical properties of mechanochromic thermosets after multiple recycling processes.

Mechanics Underpinning Phase Separation of Hydrogels Yu Zhou and Lihua Jin; University of California, Los Angeles, United States

This work reveals the underpinning role of mechanical constraints and dynamic loading on triggering volume phase transitions and phase separation of hydrogels. Using the Flory-Rehner free energy that does not predict phase separation of hydrogels under equilibrium free swelling, we show that mechanical constraints can lead to coexistence of multiple phases. We systematically obtain the states of equilibrium for hydrogels under various mechanical constraints, and unravel how mechanical constraints change the convexity of the free energy and monotonicity of the stress-stretch curves, leading to phase coexistence. Using a phase-field model, we predict the pattern evolution of phase coexistence, and show many features cannot be captured by the homogeneous states of equilibrium due to large mismatch stretch between the coexisting phases. We further reveal that the system size, quenching rate, and loading rate can significantly influence the phase behavior, which provides insights for experimental studies related to morphological patterns of hydrogels.

Hydrogels Crosslinked with Dynamic Thia-Conjugate Bond and Incorporated with Poly(ethylenedioxythiophene) Nanoparticles as Photothermally Responsive Controlled Release System Kushal Thapa[1], Joanna Zepeda[1], McKenzie Siller[1], Edgar Torres[1], Mackenzie Otakpor[1], Thomas FitzSimons[2], Anne Crowell[2], Adrianne M. Rosales[2] and Tania Betancourt[1,1]; [1]Texas State University, United States; [2]The University of Texas at Austin, United States

Introduction: Hydrogels are a class of soft materials formed by crosslinking of hydrophilic polymers. The nature of crosslinks at the molecular level determines the properties of the hydrogels at the macroscopic level. In our research, we utilized a thia-conjugate bond as means of crosslinks in our poly(ethylene glycol) or PEG based hydrogel. This dynamic covalent bond provides a self-healing ability to the hydrogel.[1] Additionally, the equilibrium of the crosslinking reaction can be shifted with thermal, mechanical, or pH stimulus.[2] For the bulk hydrogel, this translates to a controllable transition between gel and sol state by modulating these stimuli. We investigated the thermal response of the hydrogel to develop an on-demand, pulsatile drug delivery system. Further, we incorporated poly(ethylene dioxythiophene) or PEDOT nanoparticles within the hydrogel to facilitate photothermal modulation of the drug release by administering clinically relevant near-infrared (NIR) light.

Materials and Methods: We used Michael addition of thiol-ene pairs from four-arm PEG thiol (PEG-SH) and four-arm PEG benzylcyanoacetamide (PEG-BCA) to form dynamically crosslinked hydrogels. PEDOT nanoparticles were synthesized using an emulsion polymerization process and were entrapped within the hydrogel. The nanoparticles' size, polydispersity index, zeta potential, absorbance spectra, and photothermal profile upon 808 nm laser irradiation were characterized. As for the hydrogel-PEDOT complex, its micromorphology was visualized using scanning electron microscopy (SEM) and its gel-to-sol transition temperature was characterized using rheology. BSA-FITC, a fluorescently labeled protein, was loaded into the hydrogel-PEDOT complex and its release behavior into a buffer upon direct thermal stimulation and photothermal stimulation with an 808 nm laser was investigated. The injectability of the hydrogels was studied using hypodermic needles. The biocompatibility of the hydrogel-PEDOT complex was characterized on the MDA-MB-231 cell line using the MTT assay.

Results and Discussion: PEDOT nanoparticles had an average size of 56.3 nm, a polydispersity index of 0.252, and zeta potential of -77.7 mV. Visible-near infrared (Vis-NIR) spectroscopy showed that the nanoparticles had an absorbance peak at 780 nm. The photothermal stimulation of these nanoparticles with an 808 nm laser (3 W/cm^2) showed a fast increase in temperature plateauing within the first five minutes. The nanoparticles also showed photothermal stability on repeated pulsatile laser stimulation. As for the hydrogel, SEM showed a 3D net-like porous microstructure while rheology showed a gel-sol transition temperature ranging from 33-55 °C depending on the hydrogel weight percent. This transition temperature range being tunable and physiologically relevant lends itself to applications in biomedical engineering. Drug release studies on BSA-FITC loaded hydrogel-PEDOT complex showed zero-order release profiles on continuous thermal and photothermal stimulation. Pulsatile release upon thermal and photothermal stimuli was observed, but the latter method suffered from low reproducibility potentially due to inhomogeneous nanoparticle distribution or uneven hydrogel heating. MTT studies showed that the hydrogel-PEDOT complex is not cytotoxic.

Conclusions: Our dynamically crosslinked hydrogel loaded with PEDOT nanoparticles showed photothermally stimulated drug release in a clinically relevant environment. Future works will investigate the in-vitro performance of this hydrogel-PEDOT system.

Periodic Dynamic Polymers: Engineering Self-assembled Microstructures to Design Artificial Muscles and Underwater Adhesives Christopher B. Cooper and Zhenan Bao; Stanford University, United States

Polymer networks formed through dynamic noncovalent or covalent bonds exhibit robust and tunable mechanical properties (e.g., tough, elastic, self-healable, stimuli-responsive, and reconfigurable). In nature, these networks are often hierarchically-ordered to perform precise functions and assemble via cooperative interactions of many weak bonds as opposed to the independent association of a few strong bonds. Here, we use these principles to design linear polymers with periodically-placed dynamic bonds that collectively assemble into supramolecular nanofibers at equilibrium and under strain. We show that when the overall molecular weight (M_n) is below the polymer's critical entanglement molecular weight (M_c), self-assembly of supramolecular nanofibers occurs, increasing the bulk film modulus by over an order of magnitude and delaying the onset of terminal flow by more than 100°C. We then design a periodic dynamic polymer with record-high shape memory recovery stress (12.8 MPa) and energy density (18.9 MPa) based on the formation of strain-induced supramolecular nanostructures. While initially, polymer chains adopt an amorphous structure ($M_n > M_c$), during strain the polymers form nanostructures that trap the elongated backbones, enabling use as an artificial muscle. Finally, we design periodic dynamic polymers with a controlled nanophase morphology to enable high-strength underwater adhesives that can be reversibly adhered to a variety of substrates and fully recycled after use. These examples show how periodic dynamic polymers are a promising class of materials whose material properties arise from well-defined backbone periodicity.

Role of Stereochemistry in Reconfigurability of Diels-Alder Polymer Networks and Nanocomposites Svetlana A. Sukhishvili[1], Junho Moon[1], Zhen Sang[1] and Frank Gardea[2]; [1]Texas A&M University, United States; [2]Weapons and Materials Research Directorate, DEVCOM Army Research Laboratory South, United States

Diels-Alder polymers (DAP) networks formed by the furan-maleimide "click" reaction demonstrate the unique ability to reconfigure their permanent shapes through the mechanism of network plasticity. We report the important roles of stereochemistry of DA junctions and crosslinking density in the rates of bond reshuffling and reconfigurability of DA networks. Specifically, using a combination of DSC and variable-temperature FTIR techniques, we demonstrate that the rate of bond reshuffling is dependent on the stereochemistry of DA junctions and that this rate is faster for *endo* DA isomers as compared to their *exo* counterparts. We quantify the rates of temperature-dependent conversion of *endo* to *exo* isomers and relate them with changes in Young's moduli, the degree of strain recovery, and stress relaxation in DAP materials. We demonstrate that due to the higher thermal stability of *exo* adducts, the elastic modulus of the DAP networks and strain recovery both improve during temperature annealing. Taking advantage of the facile control of content of *endo* isomers in DAP networks via crosslinking density and flexibility of crosslinks, we introduce a concept of constructing multi-materials with programmable, spatially controlled shape morphing properties. Finally, we show that DAP networks present a powerful platform for constructing conductive nanocomposites with extremely low percolation threshold and re-programmable shape morphing controlled by stereochemistry of DA junctions and driven by electric field.

SESSION SB07.03: Poster Session: Unconventional Polymer Networks

Adaptable Sliding Hydrogels Accelerate Cartilage Regeneration via Enhancing Mechanosensing Julia M. Johannsen, Sarah J. Jones, Xinming Tong, Manish Ayushman and Fan Yang; Stanford University, United States

Introduction: Acute injury to articular cartilage is a leading cause of osteoarthritis, yet effective regenerative therapies remain lacking. Hydrogels have been utilized for cartilage repair due to their injectability and minimally invasive delivery of cells and bioactive molecules. Our lab has previously reported sliding hydrogels (SG) with covalent crosslinks and ligands attached to ring structures, which can slide along linear PEG backbones. This unique design facilitates cellular reorganization of the local niche and accelerates MSC chondrogenesis and cartilage formation compared to non-mobile chemical hydrogels (CG) [1]. Physically-crosslinked alginate hydrogels were recently used to show that viscoelasticity also enhances cartilage deposition by chondrocytes in 3D and correlates with increased cell volume [2]. We hypothesize that introducing viscoelasticity into SG would further enhance chondrocyte-based cartilage formation in 3D. To test this hypothesis, the goals of this study are to develop adaptable sliding hydrogels (ASG) with tunable stress relaxation for enhancing cell-based cartilage formation and to elucidate underlying biophysical mechanisms by characterizing cellular mechanosensing.

Material and Methods: To introduce dynamic crosslink in SG, hydrazine-functionalized polyrotaxane (PR-Hyd) and 8-arm-alkyl- and benz-aldehydes (AA and BA) were used. Three ASG groups were tested, with stress relaxation tuned by varying the ratio AA to BA. To characterize the mechanical properties of hydrogels, unconfined compression and shear-based rheological testing were used. Juvenile bovine chondrocytes were encapsulated at 10M/mL and cultured in chondrogenic medium for 21 days. Cartilage formation was evaluated by biochemical assays for sGAG and collagen, histology, immunostaining, and mechanical testing. Cell proliferation and cell volume change were also quantified. To evaluate the effect of tuning stress relaxation in ASG on cell mechanosensing, IF staining and western were performed to assess expression levels of markers for focal adhesion, cytoskeletal tension and nuclear mechanosensing.

Results and Discussion: By tuning the ratio of AA:BA, ASG with tunable stress relaxation were obtained (slow, intermediate, and fast). Compared to elastic SG, introducing viscoelasticity significantly accelerated sGAG and total collagen production in a dose-dependent manner. The same trend was observed for cell proliferation, interconnectivity of newly deposited cartilage, and type II collagen—a marker for articular cartilage phenotype. Impressively, cell-deposited cartilage matrix led to over 100 fold increase in compressive moduli after 21 days of culture to a range closer to that of native cartilage. Unlike previous alginate hydrogels, ASG-enhanced cartilage formation did not induce changes in cell volume, indicating the involvement of different molecular mechanisms. Increasing stress relaxation also led to enhanced cytoskeletal formation, suggesting ASG-enhanced cartilage formation is mediated through enhanced mechanosensing. Notably, our ASG achieved robust cartilage formation with only 10% of the cell density used in a previous alginate-based study, which is promising in overcoming donor scarcity. Together, these results support our hypothesis and demonstrate that ASG is promising for enhancing cell-based cartilage regeneration with restored mechanical functions.

5:00 PM SB07.03.03
Effects of Silica Nanospheres on the Sol-Gel Transition of Thermo-Responsive Polymers Based on poly(N-vinylcaprolactam) Lucas Ribeiro[1], Renata L. Sala[1,2] and Emerson R. Camargo[1]; [1]Federal University of São Carlos, Brazil; [2]University of Cambridge, United Kingdom

The insertion of nanoparticles in smart polymers allows the addition of new functionalities to the material, as well as the improvement of some of its properties. However, the design of these materials needs to be done with care so that the stimulus-response property is not lost. An example of a responsive polymer is poly(N-vinylcaprolactam) (PNVCL), which suffers a transition when heated above the lower critical solution temperature (LCST). This transition occurs due to a decrease in the mixing entropy that leads to the breaking of hydrogen bonds between the polymer and the water molecules. As a consequence, the polymer self-aggregates through predominant hydrophobic interactions. This polymer is used in biomedical applications, mainly in tissue engineering and drug delivery systems, making its mechanical properties essential to support the daily movements of the human body. One way to enhance this property is through the insertion of nanoparticles of silica that can improve the rheological properties of polymers. Thus, nanocomposites of PNVCL and silica nanospheres were synthesized in situ by radical polymerization. Nanoparticles, of two different sizes (80 and 330 nm) were added at the proportion of 5% and the reaction was carried out for 4h at 70 °C in an inert atmosphere. The LCST and the energies involved during the transition were calculated from the analysis of a polymer aqueous suspension (1% m/v) by UV-vis spectrophotometry. The material changes from a transparent to opaque system when heated, allowing to be studied by its transmittance at different temperatures. All three synthesized polymers showed a LCST close to 34 °C, which results in gel formation in the body temperature. In addition, the pure polymer presented constant transmittance before the transition. On the other hand, the nanocomposites presented a diffuse decay of transmittance with increasing temperature not previously observed for pure polymer, indicating a diffuse transition. This behavior is related to changes in the solvation of PNVCL chains. The presence of nanoparticles disrupts the interactions between water molecules and polymer chains, facilitating phase separation [1]. This phenomenon was confirmed by the dynamic light scattering technique, in which the hydrodynamic diameter of the pure polymer remained constant at 4 nm during heating, while the mean globule size of the nanocomposites increased. The insertion of nanoparticles in the PNVCL can affect not only the transition profile but also its thermodynamics. The calculated enthalpy change during the sol-gel transition for the pure polymer was 9752 kJ/mol. However, the nanocomposites presented lower values, close to 6400 kJ/mol. This decrease was previously reported for crosslinked systems of thermosensitive polymers, indicating that in addition to interfering with the solvation of polymer chains, these nanoparticles also act as crosslinking agents [2]. Furthermore, the size of the nanoparticles did not interfere in the variation of the transition enthalpy. Considering the application of these biocompatible sensitive polymers as injectable systems, the effect of the nanospheres on the rheological properties of PNVCL was analyzed. When the solutions were heated to 37 °C, they still presented the loss modulus higher than the storage modulus, confirming the transition of the materials to the agglomerated state, however with no hydrogel formation. In addition, the nanocomposites presented higher values of G′ and G″ when compared to the pure polymer, confirming that the addition of the nanoparticles can improve the rheological properties after the transition. Thereby, the insertion of silica nanoparticles, despite altering the transition profile of PNVCL, manages to improve rheological properties without affecting their temperature sensitivity.

Two-Way Shape Memory Polymer from a Crosslinked Periodic Dynamic Network Yuran Shi, Christopher B. Cooper, Jiancheng Lai and Zhenan Bao; Stanford University, United States

We recently reported a high-performance one-way shape memory polymer that includes periodic dynamic bonds and exhibits supramolecular nanostructures under stain. The strategy of incorporating periodic dynamic bonds into the polymer greatly enhances shape memory material properties such as energy density and stretchability. The strain-induced supramolecular nanostructures are stable at room temperature and trap the chains in an elongated state. Upon heating, the supramolecular nanostructures become unstable, causing stretched chains to quickly contract. While this material outperforms other one-way shape memory polymers, its practical applications are hindered by the need for the mechanical re-programming after each triggering. Two-way shape memory polymer material is very desirable in many applications especially in the field of biomedical, soft robotics, and actuators. Thus, we incorporate thermal and light initiated crosslinkers into the materials to try and achieve reversible actuation upon change in temperature. Polymer chains will be aligned under strain; at the same time, dynamic bonds will hold the aligned chains in place and crosslinkers will permanently record chain conformation at the stretched state. There were already various realizations of two-way shape memory materials by employing semi-crystalline polymers and liquid crystal networks. We aim to make two-way shape memory polymer from a new approach by using this periodic dynamic network.

5:00 PM SB07.03.05
Shape Fixation of Magnetically Deformed Micropillar Arrays via Dynamic Covalent Bonds Hojun Moon[1], Jae Gyeong Lee[1], Woongbi Cho[1], Jisoo Jeon[2], Jeong Eun Park[3] and Jeong Jae Wie[1]; [1]Hanyang University, Korea (the Republic of); [2]Georgia Institute of Technology, United States; [3]Inha University, Korea (the Republic of)

Polymeric micropillar arrays containing magnetic particles can perform magnetic shape reconfiguration when an external magnetic field is applied. The magnetically actuated shape of micropillar arrays, however, is temporary and recover its original geometry upon removal of magnetic field. Toward the shape-fixation of actuated geometry, in this study, we employed dynamic covalent bonds for the matrix polymer of magnetic composites to provide exchange reactions in chemical networks in response to external stimuli. Magnetic deformation is achieved by the inclusion of hard magnetic particles in the polymer composites at various concentrations. We will discuss the concentration dependent structure-property relationships and optimum concentration of the magnetic particle to maximize the magnetic deformation of micropillars. Finally, we will demonstrate the thermomechanical shape fixation of magnetically actuated micropillars by constructing new chemical networks with adjacent micropillars via dynamic covalent bonds.

5:00 PM SB07.03.06
Understanding Polymer Shear Rates and Their Relation to Molecular Architectures in Micro-Compounders Narcedalia Anaya Barbosa[1,2], Joshua Goetze[2], Christopher J. Ellison[2] and Frank Bates[2]; [1]University of Texas Rio Grande Valley, United States; [2]University of Minnesota, United States

This research provides a better understanding of the rheological behavior of polyethylene at different processing conditions using the DSM Xplore 5 and 15 cc micro-compounders. Polymers used were high density polyethylene (HDPE) with a linear architecture, low density polyethylene (LDPE) showcasing a long chain branched structure, and linear low density polyethylene (LLDPE) exhibiting a short chain branched architecture. Measurements obtained in the micro-compounders were compared to those obtained with an ARES-G2 rheometer for a range of shear rates (50, 100, 150, 200 and 250 RPM), temperatures (150°C, 200°C), fill volumes (80%, 90%, 100%) and polymers. The measurements were used to evaluate the accuracy of the micro-compounders and scalability between the systems. Comparing the rheometer data and micro-compounder predictions can aid in identifying differences related to the polymer architecture and help to understand the impact of simple and extensional shear on the polymer when it is processed.

Liquid Crystalline Thermoplastic Polyurethane with Self-Healing Properties SeYeon Baek and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

Self-healing means autonomously recovering original functions from any physical damage. Self-healing polyurethane(PU) has the common advantages of polyurethane as well as the ability to heal itself without external help. Liquid crystalline polyurethane(LCPU) with such self-healing properties can be widely used in the field of electronic materials, films, and displays. Unlike general liquid-crystalline polyurethane, it can heal itself, so it can be used for a long time by preventing it from being weakened and destroyed over time. In this study, we synthesized the self-healing LCPU through the condensation of a mesogenic diol with a diisocyanate having quadruple hydrogen bonding moieties. To confirm the self-healing properties, a heating test was conducted on damaged PU specimens and they were restored to their original shape after heating. In addition, a polarization microscope and thermal analysis were performed to observe the liquid crystal phase of synthesized LCPU.

5:00 PM SB07.03.09
Biodegradable Nancomposites of Poly(Butylene Succinate) and Cellulose Nanocrystals—Rheological Design of Mechanical and Hydrolytic Properties Hyeonjeong Kim, Youngho Eom and Hyo Jeong Kim; Pukyong National University, Korea (the Republic of)

Petroleum-based plastics are essential commodity in our everyday life because they are light, inexpensive, versatile and easy to process. However, the recent environmental pollution caused by discarded plastic wastes becomes severe owing to the non-degradability of industrial plastics. In order to solve such environmental problem, biodegradable polymers were considered as a practical solution. Both industrially and academically popular biodegradable polymers include poly(lactic acid), poly(butylene succinate) (PBS), and poly(butylene adipate-co-terephthalate). Unfortunately, the poor mechanical performance and relevant low longevity of the biodegradable polymers compared to the petroleum-based plastics have limited their commercialization. The preparation of nanocomposites using reinforcing fillers provides a solution capable of enhancing the performance of the biodegradable matrix. Then, inorganic fillers are unfavorable option because the non-degradability of metals and ceramics makes the sustainability of biodegradable polymers useless. In this regard, biomass-derived natural nanomaterials are indispensable choice for preparing the biodegradable nanocomposites. Using bio-renewable nanofibers such as cellulose nanocrystals(CNCs), cellulose nanofibers, chitin or chitosan, and nanowiskers has emerged as a promising alternative to inorganic fillers. In particular, CNCs have a high aspect ratio, high crystallinity (54-88%) and numerous polar functional groups, making it easy for secondary interaction with the organic polymer matrix.
In this study, PBS/CNC nanocomposites were prepared through solution mixing and precipitation procedures. Owing to the thermally infusible feature of CNCs, the solution blending method using dimethyl sulfoxide (DMSO) as a co-solvent was adopted to fabricate the PBS/CNC nanocomposites. The PBS/CNC mixed solutions in DMSO were precipitated with deionized water as a coagulant. The washed PBS/CNC powder was dried in a vacuum oven at 60 °C for 24 h to obtain the desired nanocomposites. The CNC loading relative to the total polymer content varied from 0 to 3.0 wt%. The PBS/CNC nanocomposites will henceforth be referred to as "CNC*n*" with *n* denoting the CNC loading (wt%).
The ultimate tensile strength (UTS) varies non-steadily with CNC loading, indicating a 1.17-fold increase until 0.8 wt% (33.3 MPa for neat PBS to 39.2 MPa for CNC0.8), followed by a progressive decrease upon further incorporation up to 3 wt% (34.9 MPa for CNC3.0). The increasing extent of Young's modulus (E), UTS, and toughness per unit of CNC loading (1 wt%) [(fold-1) wt%-1] was calculated and shown as a function of the CNC loading in order to assess the effectiveness of CNCs as reinforcing elements in PBS. We identified that at a crucial CNC loading, the reinforcing efficiency shows a noticeable trend change. In relation to E, up to 1.5 wt% CNC loading, reinforcing efficiency increases; after that, it starts to decline. PBS-CNC nanocomposites were hydrolyzed in a chemical condition that contained 0.1 N NaOH. For PBS-CNC nanocomposite films even after the hydrolysis for 6 days (below 0.8 wt%), the films above the critical CNC content (CNC1.0, 2.0, and 3.0) exhibits specific morphology due to an extensive chemical etching by hydroxyl anions in contrast to the less-degraded neat PBS.
By investigating the phase properties and homogeneity, the rheological percolation threshold may be explained. It is rational to assume that the CNCs' percolation behavior in the polymer matrix may be connected with the considerable change in the CNCs' reinforcing efficiency at a certain loading. This study suggests a rheological basis to understand and efficiently control the characteristics of biodegradable nanocomposites of PBS and CNC by adjusting the percolation behavior of the nano-fillers.

Tailored Smart Hydrogels as a Potential Sensing Material for Exhaled Breath Analysis Sitao Wang[1], Gerald Gerlach[1] and Julia Koerner[2]; [1]Technische Universität Dresden, Germany; [2]Leibniz University Hannover, Germany

Smart hydrogels are a very promising sensing material, especially for biomedical applications, due to their stimulus responsiveness, easily achievable biocompatibility and wide range of material compositions. Many different physical or chemical stimuli (e.g. temperature, pH, ionic strength, biomolecules) can cause the volume-phase transition of the polymer which is usually based on the uptake or release of liquid. Hence, in most cases smart hydrogels are employed in aqueous environments [1].
The development of a smart hydrogel material able to maintain the swelling response in gaseous environments would allow to extend the potential for very high selectivity and sensitivity towards analytes in gases such as volatile organic compounds (VOCs).

We have investigated different synthetic smart hydrogel materials with regard to their ability of exhibiting a measurable swelling response in varying relative humidity for the target VOC analytes acetone and isopropanol. The materials include the homopolymers polyacrylamide (PAM), polyacrylic acid

(PAA) and poly(*N*-isopropylacrylamide) (PNIPAAm), and their co-polymer combinations. The swelling response for varying relative humidity from 2% to 100% and different VOC concentrations (up to 100 ppm) was studied by weighing and through piezoresistive pressure sensing. In the latter case, the hydrogels were directly polymerized on a silicon membrane by mask-based UV-polymerization.
We found that PNIPAAm exhibits the most significant swelling response for both target analytes. It furthermore allows to distinguish between the analytes as the weight change for isopropanol is much higher than for acetone.

In a second study we focused on enhancing the stimulus-responsiveness of the material further by increasing porosity through adding of polyethylene-glycol (PEG) into the PNIPAAm pregel solution. After polymerization, PEG is washed out by keeping the sample in deionized water for thirty days, resulting in a porous structure.
However, the pores are not stable and irreversibly collapse when the hydrogel is air-dried for use in a gaseous environment. In order to stabilize the porous matrix and maintain the enhanced swelling response, we determined that the following treatment is necessary after polymerization and washing: (i) freeze-drying of the sample (liquid nitrogen or freezer), and (ii) conditioning in high relative humidity (90 – 100 %). The first step is crucial to preserve the porous network after fabrication. In that state, the polymer chains are stretched and not in equilibrium due to the swelling during washing. In order to allow for relaxation and reordering of the polymer chains, the subsequent conditioning is required where the material shrinks.
Scanning electron microscopy studies confirmed that these steps are essential in preserving the fabricated porous structure. It is furthermore indicated that the addition of PEG is crucial in stabilizing the pores as well. Without PEG, freeze-dried and conditioned samples exhibit the same structural collapse as PEG-modified air-dried and pure air-dried samples [2].

Based on these investigations, we can draw the following conclusions: (i) smart hydrogels can maintain their swelling-response in gaseous environments for a wide range of relative humidity, (ii) PNIPAAm is a promising candidate for acetone and isopropanol detection in gases and (iii) the swelling response can be strongly enhanced by adding of PEG and subsequent freeze-drying and conditioning to stabilize the porous structure.
This study provides a basis for extending the application range of smart hydrogel materials to VOC sensing. Due to the potential for further tunability of the hydrogel material and its favorable mechanical properties, miniaturizable wearable sensor concepts can be envisioned for the future.

Synthesis and Characterization of MXene-Modified PNIPAAm Hydrogel for VOC Gas Sensing Sitao Wang[1], Gerald Gerlach[1] and Julia Koerner[2]; [1]Technische Universität Dresden, Germany; [2]Leibniz University Hannover, Germany

MXene, as a novel two-dimensional (2D) material, has gained tremendous attention due to its unique chemical and physical properties. Especially in gas sensing, the large specific surface area and potential for tailoring by means of surface functionalization are very favorable. To date, most of the sensing devices are based on interdigitated electrodes (IDEs) where the metallic conductivity and p-type sensing behavior of the MXene are harnessed [1]. However, the conventional drop-casting method for material fabrication on IDEs generally creates a compact and dense layer of MXene flakes stacked together which reduces the number of active sites and decelerates gas adsorption and desorption.

In our work, we aim at combining the favorable properties of MXene with smart hydrogels to create fully three-dimensional, highly sensitive and selective composite materials specifically tailored for detection of volatile organic compounds (VOCs). The role of the MXene is twofold: (i) Enhancement of gas sorption and swelling response of the hydrogel and (ii) providing a means for direct transduction of the hydrogel's analyte-dependent swelling-state, constituting a sensing material with integrated transduction.

As a first step, we focused on synthesizing a truly 3D $Ti_3C_2T_x$ bulk MXene by ice-templating and subsequent cation-induced stabilization based on [2]. The gas sorption ability was studied by gravimetric experiments in varying relative humidity from 2% to 100% and different acetone and isopropanol concentrations as test VOCs. In the weighing studies, 3D MXene demonstrated a stable sorption for both analytes without being severely affected by changing humidity. In order to compare the response of our 3D MXene to conventionally drop-cast-fabricated ones, we furthermore synthesized both types on IDEs and tested them in the same gas environments. This revealed a faster response of 3D MXene for both test analytes. Images acquired by scanning electron microscopy (SEM) verified the successful fabrication of a 3D porous MXene. However, the 3D structure oxidized rapidly, leading to material degradation and a significant increase in resistance after few tests.

In a second step, we incorporated the MXene into a smart poly(*N*-isopropylacrylamide) (PNIPAAm) hydrogel. We have recently demonstrated that this type of smart polymer is well suited for VOC detection and which fabrication steps are necessary to achieve a stable 3D porous structure for a fast response [3].
Composite fabrication was achieved by mixing $Ti_3C_2T_x$ MXene suspension with NIPAAm pregel solution containing poly(ethylene glycol) (PEG) as porogen. Leaching of PEG and subsequent freeze-drying of the swollen gel create a porous structure [3]. In order to explore the gas sorption ability of the composite material, gravimetric measurements were carried out in the same manner as described above.
SEM analysis and energy-dispersive X-ray spectroscopy confirmed the formation of a highly porous composite matrix with homogeneous MXene distribution. However, the weighing results did not indicate an improvement of the gas sorption ability (amount of swelling, time constants) of the MXene-enhanced PNIPAAm composite compared to the unmodified PNIPAAm. On the contrary, the achievable delta-weight change was reduced which we ascribe to the fast degradation of the MXene and its, yet unknown, effects on the hydrogel matrix. This will be studied further in fundamental investigations of the interactions between polymer matrix and MXene in order to combine the favorable properties of both for future applications.

Sodium Alginate/Nanochitosan Nanocomposite Films with Enhanced Mechanical Performance for Food Packaging Applications Hyo Jeong Kim, Hyeonjeong Kim and Youngho Eom; Pukyong National University, Korea (the Republic of)

The petroleum-based plastics were regarded as an imperative commodity of our daily life and as a result, the amount of plastic products consumed is increasing exponentially. In addition, the conventional plastic-based disposable materials including plastic cups and straws are not able to be reused and recycled. Consequently, the environmental pollutions caused by the single-use plastics have become severe. To alleviate these issues, biodegradable and sustainable food packaging materials that can replace the traditional polymeric materials and films have attracted significant interests in both academic and industrial fields. Food packaging films are essential component to guarantee the food safety from the external contaminant, damage, and spoilage. Accordingly, as an alternative to the non-degradable plastic-based packaging films, the eco-friendly packaging films should satisfy several properties such as high mechanical strength, water-resistance, and gas barrier.

Natural polysaccharides polymers such as sodium alginate, starch, cellulose, and chitosan have been regarded a promising alternative to the petroleum-driven polymer packaging films. Among them, sodium alginate (SA) extracted from the brown algae is a co-polymer composed of two linked anionic monomers, β-d-mannuronic acid, and α-l-guluronic acid. Especially, owing to the negative charge of SA, this polysaccharide favors ionic interaction with cationic polymers when blended. Considering this feature of SA, we prepared the SA nanocomposite films by incorporating chitosan nanowhiskers (CSWs) with positively charged surface. CSW originates from the chitin biomass, and then was synthesized through two-step process as follows. Chitin was disintegrated using 3 N hydrochloric acid aqueous solution by refluxing for 3 h. The suspensions were centrifuged and washed with deionized (DI) water for several times. The suspensions were neutralized to pH 7 and then dialyzed with DI water for 7 d. The obtained chitin nanowhisker (CNW) suspensions were deacetylated by adding the excess NaOH and then CSW suspensions were eventually obtained. The CSW molecules have positive charge on the surface, in contrast to cellulose nanocrystal (CNC) with negative charge structure, which is another popular bio-derived nano-filler. Thus, it is expected that the interaction between SA and CSW produces the synergistic effect.

The SA/CSW and SA/CNC nanocomposite films were prepared by the solvent casting method. First, CNC powders were dispersed in DI water, whereas CSW aqueous solution with a specific concentration was prepared by diluting CSW suspension with extra DI water. The concentrations of two aqueous solutions were set to 0, 0.5, 1.0, 1.5 w/w% with respect to the SA amount. SA powders were then dissolved in each CNC and CSW aqueous solution at 60 °C for 2 h and then 12.5 g of the respective solutions were poured on petri dish, followed by drying at 40 °C for 20 h. Finally, the structural, mechanical, morphological, water-resistant, and gas-barrier properties of the obtained SA and nanocomposite films were assessed.

In order to identify the network of functional groups and the intermolecular interactions between SA and the natural nano-fillers, the FT-IR characterization was performed. For the neat SA film, the -OH stretching band was observed around 3700-2700 cm^{-1}. On the other hand, the -OH and -NH stretching bands of CSW were observed in SA/CSW nanocomposite films in the identical region. Furthermore, the sharp carbonyl peak of CSW nanocomposites film was shifted to higher wavenumber. This result suggests the intermolecular interactions between anionic SA and cationic CSW. The tensile strength and elongation at break of CSW nanocomposite films were higher than SA films, exhibiting a 1.85, 1.55-fold increase (121 MPa, 9.5% for SA to 223 MPa, 14.7% for CSW 1.5 w/w%) than SA films with increasing CSW contents whereas CNC nanocomposite films were similar to SA films (103 MPa, 5.5% for CNC 1.5 w/w%).

Improvement of Thin-Film Stretchability Through Synthetic Tailoring Diketopyrrolopyrrole Based Polymer for Organic Field-Effect Transistors. Bao-Nguyen T. Nguyen, Xiaozhou Ji, Hao-Wen Cheng, Yilei Wu, Song Zhang and Zhenan Bao; Stanford University, Chemical Engineering Department, United States

Materials with good mechanical and electrical properties are key components for high performance stretchable electronic devices. Well-known for their high charge mobility, diketopyrrolopyrrole- (DPP-) based conjugated polymers are popularly used in many organic devices, such as organic field-effect transistors, solar cells, and sensors. Owing to their high crystallinity, DPP-based polymers often lose their electrical performance under strain. To improve the stretchability and fatigue resistance, both crystalline and amorphous domains of the DPP-based polymers are tuned to accommodate mechanical stretch, such as by introducing long and branched alkyl chains bound to the DPP nitrogen atoms or incorporating flexible units into the aromatic backbones. Here, we report semiconducting polymers synthesised from methyl substituted thiophene DPP (MeTDPP) as an acceptor unit and thienylenevinylene (TVT) as a donor unit. Compared to the analogous TDPP-TVT polymer with no methyl substituted groups, MeTDPP-TVT polymer exhibited higher stretchability with comparable charge mobility. The crystallinity of the polymers was confirmed by GIWAX. The planarity of the polymers was investigated by DFT calculations showing gas-phase torsional angles at the optimised structures. The calculations suggested that the methyl substituted groups disrupted the planarity of the TDPP units, causing the thiophene rings to twist more prominently and thus reducing the crystallinity of the polymer chains. MeTDPP-TVT also showed a shallower HOMO energy level measured by UPS, aligning with its stronger aggregation in thin film state observed in UV-Vis-NIR absorption spectrum.
